## Cooperative Minds: Social Interaction and Group Dynamics

## Proceedings of the $35^{\text {th }}$ Annual Meeting of the Cognitive Science Society

Berlin, Germany, July 31-August 3, 2013

Edited by

Markus Knauff
Giessen University

Natalie Sebanz
Central European University

Michael Pauen<br>Humboldt-Universität zu Berlin

Ipke Wachsmuth
Bielefeld University

Austin, TX: Cognitive Science Society

How to cite a paper in these Proceedings:
APA formatted citation for a 6-page paper:
Author, A. \& Author, B. (2013). This is the title of the paper. In M. Knauff, M. Pauen, N. Sebanz, \& I. Wachsmuth (Eds.), Proceedings of the 35th Annual Conference of the Cognitive Science Society (pp. NUMBERS). Austin, TX: Cognitive Science Society.

APA formatted citation for a published abstract:
Author, A. \& Author, B. (2013). This is the title of the abstract [Abstract]. In M. Knauff, M. Pauen, N. Sebanz, \& I. Wachsmuth (Eds.), Proceedings of the 35th Annual Conference of the Cognitive Science Society (p. NUMBER). Austin, TX: Cognitive Science Society.

APA formatted citation for a talk (or poster) presentation:
Author, A. \& Author, B. (2013, August). This is the title of the talk or poster. Paper (or Poster) presented at the 35 th Annual Conference of the Cognitive Science Society. Berlin, Germany.

## Table of Contents

Introduction ..... 1
Acknowledgements ..... 3
Organizing Committee ..... 4
Program Committee ..... 5
Reviewers List ..... 6
Sponsors ..... 14
Conference Awards ..... 15
Glushko Dissertation Prizes ..... 18
Invited Plenary Presentations ..... 19
Workshops
Diagrammatic Cognition: Discovery and Design ..... 20
William Bechtel
Using Mechanical Turk and PsiTurk for Dynamic Web Experiments ..... 22Anna Coenen, Doug Markant, Jay B. Martin, John McDonnell
Embodied Approaches to Interpersonal Coordination: Infants, Adults, Robots, and Agents ..... 24Rick Dale, Chen Yu, Yukie Nagai, Moreno Coco, Stefan Kopp
Interactive Panel Discussion: Professional advancement through real and virtual international collaboration ..... 26Laurie Beth Feldman, Janet van Hell, Judith Kroll, Suparna Rajaram, Natasha Tokowicz
Workshop Proposal: PRE-CogSci 2013: Bridging the gap between cognitive and computational approaches to reference ..... 28Albert Gatt, Roger van Gompel, Ellen Gurman Bard, Emiel Krahmer, Kees van Deemter
Motivations and Goals in Developing Integrative Models of Human Cognition ..... 30
Glenn Gunzelmann
Deception as a Social Strategy ..... 32Swati Gupta, Tei Laine, Kayo Sakamoto
Mental Model Ascription by Language-Enabled Intelligent Agents ..... 34
Marjorie McShane
When eye see you: Gaze and joint attention in human interaction ..... 35
Maria Staudte, Ulrich Pfeiffer
Tutorials
Using Complex Network Analysis in the Cognitive Sciences ..... 37
Nicole Beckage, Michael Vitevitch, Alexander Mehler, Eliana Colunga
A General Purpose Architecture for Building Spiking Neuron Models of Biological Cognition ..... 39
Chris Eliasmith, Terrence Stewart
Virtual Humans: A New Toolkit for Cognitive Science Research ..... 41
Jonathan Gratch, Arno Hartholt, Morteza Dehghani, Stacy Marsella
Making Robust Classification Decisions: Constructing and Evaluating Fast and Frugal Trees (FFTs) ..... 43
Hansjörg Neth, Uwe Czienskowski, Lael Schooler, Kevin Gluck
Half Day Tutorial on Using Quantum Probability Theory to Model Cognition ..... 45 Emmanuel Pothos, Zheng Wang, Jerome Busemeyer
Types and states: Mixture and hidden Markov modelling for the cognitive sciences ..... 47 Maarten Speekenbrink, Ingmar Visser
Dynamic Field Theory: Conceptual Foundations and Applications in the Cognitive and Developmental Sciences ..... 49
John Spencer, Gregor Schoener, Yulia Sandamirskaya
How to Analyze Verbal Protocols ..... 51
Thora Tenbrink
Computational complexity analysis for cognitive scientists ..... 53
Iris van Rooij, Johan Kwisthout, Mark Blokpoel, Todd Wareham
Invited Symposia
Progress in Joint Action Research ..... 55
Susan E. Brennan, Daniel Richardson, Michael J. Richardson, Andreas Roepstorff, Natalie Sebanz, Günther Knoblich
Language and Gesture Evolution ..... 57
Joseph Call, Susan Goldin-Meadow, Cat Hobaiter, Katja Liebal, Michael Tomasello
New Frameworks of Rationality ..... 59
Nick Chater, Klaus Fiedler, Gerd Gigerenzer, Karl Christoph Klauer, Mike Oaksford, Keith Stenning
Mechanistic Developmental Process: Rumelhart Prize Symposium in Honor of Linda Smith ..... 61
Larissa K. Samuelson, Anthony Morse, Chen Yu, Eliana Colunga, Thomas Hills
Glushko Dissertation Prize Symposium ..... 63
Douglas Knox Bemis, Neil Cohn, George Kachergis, Andrew Lovett, Robert L. Goldstone
Symposia
Communicative Intentions in the Mind/Brain ..... 65Bruno Bara, Nick Chater, Michael Tomasello, Rosemary Varley
Exploring Cognitive Diversity Across Disciplines and Cultures ..... 67
Andrea Bender, Sieghard Beller, Daniel Haun, Cristine Legare, Asifa Majid, Bethany Ojalehto, Douglas Medin
What if? Counterfactual reasoning, pretense, and the role of possible worlds ..... 69
Daphna Buchsbaum, Caren Walker, Alison Gopnik, Nick Chater, David Danks, Christopher Lucas, Charles Kemp, Eva Rafetseder, Josef Perner
Time and Causality: Mutual Constraints; Insights from Event and Time Perception, Motor Control, and Gaming ..... 71
Marc Buehner, David Lagnado, Christos Bechlivanidis, Marc Ernst, Marieke Rohde, Michael Young
Sequential Sampling Models Representing a Unifying Framework of Human Decision Making ..... 73
Jerome Busemeyer, Adele Diederich, Andrew Heathcote, Antonio Rangel, Jörg Rieskamp, Marius Usher
Multiword Sequences as Building Blocks for Language: Insights into First and Second Language Learning ..... 75
Morten H. Christiansen, Inbal Arnon, Elena Lieven, Alison Wray
Distributed remembering in a social context: Effects of communicating a shared past on what is remembered ..... 77
Alin Coman, Gerald Echterhoff, Micah Edelson, William Hirst, Kourken Michaelian, Charles Stone
Beyond Synchrony: Complementarity and Asynchrony in Joint Action ..... 79
Rick Dale, Riccardo Fusaroli, Dorthe Døjbak Håkonsson, Patrick Healey, Dan Mønster, John McGraw, Panagiotis Mitkidis, Kristian Tylén
Computational and Cognitive Aspects of Narrative ..... 81
Mark Finlayson, Bernhard Fisseni, Dedre Gentner, Richard Gerrig, Benedikt Loewe, Jeffrey Loewenstein, Inderjeet Mani, Jan Christoph Meister, R. Michael Young
Structured cognitive representations and complex inference in neural systems ..... 83
Samuel Gershman, Joshua Tenenbaum, Alexandre Pouget, Matthew Botvinick, Peter Dayan
Cognitive Foundations of Cultural Learning ..... 85
Annette Henderson, Ben Kenward, Rachel Watson-Jones, Cristine Legare, Harvey Whitehouse
Constraints on Bayesian Explanation ..... 87
Johan Kwisthout, Iris van Rooij, Matteo Colombo, Carlos Zednik, William A. Phillips
Global Change and Cognition ..... 89
Stephan Lewandowsky, Tania Lombrozo, Gordon Brown, John Cook, Ben Newell, Ullrich Ecker
Is perception cognitively penetrable? A philosophically satisfying and empirically testable reframing ..... 91Gary Lupyan, Dustin Stokes, Fiona Macpherson, Rasha Abdel Rahman, Robert GoldstoneInformavores: Active information foraging and human cognition93Doug Markant, Todd Gureckis, Bjorn Meder, Jonathan Nelson, Peter Pirolli, Chen Yu
Social Cognition, Culture and the Self. An interdisciplinary investigation ..... 95Albert Newen, Gary Bente, Shinobu Kitayama, Shihui Han, Kai Vogeley
Scales of Cognition Evident in Action ..... 97Denis O’Hora, Nicholas D. Duran, Rick Dale, Jonathan B. Freeman, John Tomlinson
Music cognition: Bridging computation and insights from cognitive neuroscience ..... 99
Marcus Pearce, Martin Rohrmeier, Petri Toiviainen, Elvira Brattico, Psyche Loui, Edward Large, Ji Chul Kim
Thinking about norms: Epistemic, rational, and moral norms in human thinking ..... 101
Joëlle Proust, Emmanuel M. Pothos, Jerome R. Busemeyer, Ryan Miller \& Fiery Cushman, Katinka J.P. Quintelier, Shira Elqayam, Valerie A. Thompson, Jonathan St. B.T. Evans, David E. Over, Meredith R. Wilkinson
Implicit Learning Out of the Lab: Language and Music ..... 103
Patrick Rebuschat, Martin Rohrmeier, Morten Christiansen, Zoltan Dienes, Daniele Schoen, Jennifer Misyak, Clement Francois, Xiuyan Guo, Feifei Li, Richard Widdess
The Co-Existence of Naïve and Scientific Concepts in Learning and Development ..... 105
Michael Schneider, Stella Vosniadou, Andrew Shtulman, Kelsey Harrington, Ilonca Hardey, Lindsey J. Powell, Susan Carey, Stellan Ohlsson
Minimal Nativism: How does cognitive development get off the ground? ..... 107Tomer Ullman, Josh Tenenbaum, Noah Goodman, Shimon Ullman, Elizabeth Spelke
Language as a Window into the Brain and its Pathologies ..... 109
Peter Garrard, Peter beim Graben, Brita Elvevåg, Eduardo Mizraji, Juan Valle-Lisboa
The empirical investigation of semantics: Between abstract-symbolic and embodied-simulative models of meaning ..... 111
Markus Werning, Erica Cosentino
Online Education: A Unique Opportunity for Cognitive Scientists to Integrate Research and Practice ..... 113Joseph Jay Williams, Alexander Renkl, Ken Koedinger, John Stamper
Papers
Causal Reasoning with Continuous Outcomes ..... 115
Ahmad Azad Ab Rashid, Marc Buehner
A Metacognitive Stopping Rule for Problem Solving ..... 121
Rakefet Ackerman
An Information-Theoretic Account of Musical Expectation and Memory ..... 127Kat Agres, Samer Abdallah, Marcus Pearce
Effector specific response activation during word processing ..... 133Daniela Ahlberg, Carolin Dudschig, Barbara Kaup
Simulating Overall and Trial-by-Trial Effects in Response Selection with a Biologically-plausibleConnectionist Network139
Blair Armstrong, David Plaut
The dynamics of pragmatic enrichment during metaphor processing: activation vs. suppression ..... 145
John M. Tomlinson, Jr., Stavros Assimakopoulos
Object motion continuity and the flash-lag effect ..... 151Ricky K. C. Au, Katsumi Watanabe
Interface Design and Spatial Cognition: A Case of Virtual Molecule Manipulation ..... 157
Trevor Barrett, Mary Hegarty
Using the words toddlers know now to predict the words they will learn next ..... 163
Nicole Beckage, Eliana Colunga
Simultaneous unsupervised and supervised learning of cognitive functions in biologically plausible spiking neural networks ..... 169
Trevor Bekolay, Carter Kolbeck, Chris Eliasmith
Balancing Fairness and Efficiency in Repeated Societal Interaction ..... 175
Noam Ben-Asher, Christian Lebiere, Alessandro Oltramari, Cleotilde Gonzalez
Beyond Rule versus Rote? Processing of Distinctive Dative and Genitive Case Markers in German ..... 181
Christian Bentz
Social and Environmental Contributors to Infant Word Learning ..... 187
Elika Bergelson, Daniel Swingley
Grid or no grid: Distance distortion in recognizing spatial information from complex cartographic maps ..... 193
Anne-Kathrin Bestgen, Dennis Edler, Frank Dickmann, Lars Kuchinke
Evidence for cognitively controlled saccade targeting in reading ..... 197
Klinton Bicknell, Emily Higgins, Roger Levy, Keith Rayner
Fusiform Face Area in Chess Expertise ..... 203
Merim Bilalic
Analyzing Students' Metacognitive Strategies in Open-Ended Learning Environments ..... 209
Gautam Biswas, John Kinnebrew, James Segedy
"Are we still talking about the same thing?" MEG reveals perspective-taking in response to pragmatic violations, but not in anticipation ..... 215
Sara Bögels, Dale Barr, Simon Garrod, Klaus Kessler
Discovering Processing Stages by combining EEG with Hidden Markov Models ..... 221
Jelmer Borst, John Anderson
Pragmatic priming and the search for alternatives ..... 227
Lewis Bott, Emmanuel Chemla
Space is Special: A domain-specific mapping between time and nontemporal magnitude ..... 233
Roberto Bottini, Daniel Casasanto
Open-Ended Category-Based Induction: The Influence of Associative Strength and Structured Knowledge Representations ..... 239
Aimee Kay Bright, Aidan Feeney
Motor Asymmetries Predict Neural Organization of Emotion ..... 245
Geoffrey Brookshire, Cleve Graver, Daniel Casasanto
The Effect of Discourse Context on Online Sentence Processing ..... 251Juliane Burmester, Isabell Wartenburger, Katharina Spalek
Probabilistic reasoning in the two-envelope problem ..... 257
Bruce Burns
Preschoolers' ability to navigate communicative interactions in guiding their inductive inferences ..... 263
Lucas Butler, Ellen Markman
A Computational Model of General Rule Learning with Unnatural Classes ..... 269
Shira Calamaro
From individual minds to social ones. Cooperation and the structure of animal and human societies. ..... 275
Valentina Cardella, Alessandra Falzone, Antonino Pennisi
Assessing the effectiveness of older adults' spatial descriptions in a fetch task ..... 281
Laura Carlson, Marjorie Skubic, Jared Miller, Zhiyu Huo, Tatiana Alexenko
Hypothesis space checking in intuitive reasoning ..... 287
Christopher Carroll, Charles Kemp
Individuals recapitulate the proposed evolutionary development of spatial lexicons ..... 293
Alexandra Carstensen, Terry Regier
The development of predictive processes in children's discourse understanding ..... 299
Marisa Casillas, Michael Frank
English/Italian Bilinguals Switch Gesture Parameters when they Switch Languages ..... 305
Federica Cavicchio, Sotaro Kita
Modelling Graded Semantic Effects in Lexical Decision ..... 310
Ya-Ning Chang, Matthew Lambon Ralph, Steve Furber, Stephen Welbourne
Eyetracking as an Implicit Measure of Category-Based Induction ..... 316
Stephanie Chen, Brian Ross, Gregory Murphy
General Instruction Following in a Large-Scale Biologically Plausible Brain Model ..... 322
Xuan Choo, Chris Eliasmith
Understanding eye movements in face recognition with hidden Markov model ..... 328
Tim Chuk, Alvin C. W. Ng, Emanuele Coviello, Antoni B. Chan, Janet H. Hsiao
Uniquely human developmental timing may drive cerebral lateralization and interhemispheric coupling ..... 334
Benjamin Cipollini, Garrison Cottrell
Systems from Sequences: an Iterated Learning Account of the Emergence of Systematic Structure in a Non-Linguistic Task ..... 340
Hannah Cornish, Kenny Smith, Simon Kirby
On the Dynamics of Information Accumulation in Recognition ..... 346
Gregory Cox, Nicholas Lewis, Richard Shiffrin
Representing Number Sets: Encoding Statistical Properties ..... 352
Patrick Cravalho, Bradley Morris, Christopher Was, Amy Masnick
Unified Modeling of Proactive Interference and Memorization Effort: A new mathematical perspective with in ACT-R theory ..... 358
Arindam Das, Wolfgang Stuerzlinger
Integrating Cognitive Principles to Redesign a Middle School Math Curriculum ..... 364
Jodi Davenport, Yvonne Kao, Steven Schneider
Achievement Motivation and Strategy Selection during Exploratory Learning ..... 370Daniel DeCaro, Marci DeCaro, Bethany Rittle-Johnson
Cost-Based Pragmatic Inference about Referential Expressions ..... 376
Judith Degen, Michael Franke, Gerhard Jäger
Superficial, rather than true, knowledge interdependence in collaborative learning fosters individual knowledge transfer ..... 382
Anne Deiglmayr, Lennart Schalk
Analogical Reasoning with Rational Numbers: Semantic Alignment Based on Discrete Versus Continuous Quantities ..... 388
Melissa DeWolf, Miriam Bassok, Keith Holyoak
Learning to perceive coherent objects ..... 394
Nimrod Dorfman, Daniel Harari, Shimon Ullman
Removal of Information from Working Memory ..... 400Ullrich Ecker, Stephan Lewandowsky, Klaus Oberauer
Effects of Explanation and Comparison on Category Learning ..... 406
Brian Edwards, Joseph Jay Williams, Tania Lombrozo
Biologically Plausible, Human-scale Knowledge Representation ..... 412
Crawford Eric, Gingerich Matthew, Eliasmith Chris
Cross-Situational Statistical Learning of Phonologically Overlapping Words ..... 418
Paola Escudero, Karen Mulak, Haley Vlach
Intuition versus Reason: Strategies that People Use to Think about Moral Problems ..... 424
Mark Fedyk, Barbara Koslowski
Communicative biases shape structures of newly acquired languages ..... 430
Maryia Fedzechkina, T. Florian Jaeger, Elissa L. Newport
Regularization behavior in a non-linguistic domain ..... 436
Vanessa Ferdinand, Bill Thompson, Simon Kirby, Kenny Smith
Rapid Learning of Morphological Paradigms ..... 442
Sara Finley, Elizabeth Wiemers
Analogical Reinforcement Learning ..... 448James Foster, Matt JonesDevelopmental and postural changes in children's visual access to faces454
Michael Frank, Kaia Simmons, Daniel Yurovsky, Guido Pusiol
The Effect of Incremental Context on Conceptual Processing: Evidence from Visual World and Reading Experiments ..... 460
Diego Frassinelli, Frank Keller, Christoph Scheepers

## Dear Cognitive Scientists:

Welcome to the $35^{\text {th }}$ Annual Conference of the Cognitive Science Society! It is a great pleasure to welcome you at Humboldt-Universität zu Berlin. CogSci 2013's theme is "Cooperative Minds: Social Interaction and Group Dynamics." This theme reflects a rapidly growing interest within the cognitive science community in human sociality that has led to a move from the study of individual cognition to the social realm. The conference offers an exciting program with five plenary talks by distinguished speakers and three invited symposia with highly renowned contributors. But CogSci is also a platform for young scientists and you will likely be impressed by the high quality of research our junior colleagues will present at this conference.

The competition for oral presentations was extremely strong this year since we received more submissions than ever in the history of this conference. After the system was closed we counted 1246 submissions, including 910 full-papers, 269 member abstracts, 34 symposium proposals, 23 proposals for workshops/tutorials, and 10 publication-based talks. The quantity and - even more so - the high quality of the submissions indicate that our discipline is in good shape. After intensive reviewing we accepted 264 (28\%) of the full-paper submissions as oral presentations and $379(40 \%)$ as posters. We also accepted 247 ( $91 \%$ ) member abstracts as posters, 25 ( $73 \%$ ) symposia and 18 (82\%) workshops/tutorials. In a second round, we accepted an additional number of 77 (99 \%) member abstracts as posters. This large amount of presentations was possible only by adding parallel tracks and introducing a new program structure to accommodate more poster presentations. So: Welcome to the largest conference in the history of the Cognitive Science Society.

The outstanding interest in this year's conference might also be related to our venue. Berlin is a city with an eventful history and certainly one of the liveliest metropolises in Europe. It is a city of contrasts with a countless variety of world renowned cultural highlights and attractions that we hope you will enjoy exploring. Humboldt-Universität zu Berlin is one of Berlin's four universities. Until the Reunification of Germany in 1989, Humboldt-Universität was the most important University in East Germany; since then it has established itself as one of Germany’s leading research universities. The University is located in the heart of the city, in walking distance to many historical and contemporary sites of interest. The Brandenburg Gate, for instance, is just a few minutes away from the conference site.

We believe that a university-based conference in the urban center of Berlin will be a unique experience for all of us. Certain things might not be the way they usually are at a hotel-based conference. You may have to walk a bit more; some of the lecture rooms still have a historic aura from
the times when Helmholtz, Hegel, Einstein, and other famous scientists gave their lectures here so the seats may be a bit uncomfortable. And it might happen that not all participants will fit into the main lecture hall (Audimax) during the plenary sessions. The conference co-chairs initially planned to rent a non-university building in the neighborhood but it turned out that this would exceed the budget. So we decided to use the cinema (Kinosaal) right below the main lecture hall as an overflow area where the presentations can be seen on a video screen. The poster sessions will take place in the Maritim Hotel Berlin in the Friedrichstraße, one of the most liveliest streets in Berlin. It's just a ten minutes walk, but you may want to calculate your time to walk there generously since there is a lot to see on your way.

We are in the semester break at Humboldt-Universität but there will still be many students and faculty in the building. So you are invited to enjoy the specific atmosphere of a University that about two hundred years ago, in 1810, implemented Wilhelm von Humboldt's vision of a new type of university. Humboldt-Universität was the first to introduce the unity of research and teaching, to uphold the ideal of research without restrictions, and to provide an all-round education for its students. These principles of Wilhelm von Humboldt became general practice throughout the world. A new era of university and academic research had begun.

We hope you will enjoy this unique historic setting and wish you all an unforgettable conference at Humboldt-Universität as well as a great time in Berlin!

Berlin, Summer 2013
Markus Knauff, Michael Pauen, Natalie Sebanz, and Ipke Wachsmuth

## Acknowledgements

The conference chairs are deeply thankful to many people who helped us to make the conference a reality. First and foremost, we would like to thank the members of the Organizing Committee, the Program Committee, the prize judges, and all the many reviewers for their time and effort. The large number of submissions was a tremendous logistic challenge for all of us. We want to thank all those of you who were involved in the reviewing process for your thoughtful, comprehensive, and helpful reviews. We know many of you were deluged with requests for metareviewing or reviewing and had some trouble to find appropriate reviewers or to handle all requests for reviewing. Thank you for being so cooperative and patient. You can find the names of the program committee members on page 65 and all reviewers are listed in the conference proceedings.

We are also deeply thankful to many other people who helped us with the organization of the conference. Specifically, we want to thank Kai Hamburger for supporting the conference chairs during the submission and reviewing process and Anna Strasser for her unfailing support with all issues related to the local organization. We thank Andy Stull, the CSS conference officer, for his support with all business related issues and all matters having to do with the budget of the conference. We thank Deborah Gruber, the Cognitive Science Society Business Manager, for helping us with the bureaucracy, the Scarritt Group, Inc. for the logistics management, and James Stewart from Precision Conference Solutions for his prompt help to keep the reviewing website running. Finally, our thanks go to Humboldt-Universität and the Berlin School of Mind and Brain for hosting this conference and, last but not least, to our sponsors for giving us the possibility to support students from all over the world to attend the $35^{\text {th }}$ Annual Conference of the Cognitive Science Society.

Brain

## CogSci 2013 Awards

## Marr Prize

The Marr Prize, named in honor of the late David Marr, is awarded to the best student paper at the conference. All student first authors were eligible for the Marr Prize for the best student paper. The Marr Prize includes an honorarium of $\$ 1,000$ and is sponsored by The Cognitive Science Society. The winner of the 2013 Marr Prize for Best Student Paper is:

Nimrod Dorfman, Daniel Harari, and Shimon Ullman: Learning to perceive coherent objects (Thursday, 16:50, Session 31)

## Computational Modeling Prizes

Four prizes worth $\$ 1,000$ each are awarded for the best full paper submissions to CogSci 2013 that involve computational cognitive modeling. The four prizes represent the best modeling work in the areas of perception/action, language, higher-level cognition, and applied cognition. These prizes are all sponsored by The Cognitive Science Society. The winners of the 2013 Computational Modeling Prizes are:

## Perception/Action

Georg Layher, Martin Giese, and Heiko Neumann: Learning representations of animated motion sequences - A neural model (Saturday, 16:30, Session 95)

## Language

Russell Richie, Charles Yang, and Marie Coppola: Modeling the emergence of lexicons in homesign systems (Thursday, 16:50, Session 29)

## Higher-Level Cognition

John V McDonnell, Pedro Tsividis, and Bob Rehder: Reasoning with inconsistent causal beliefs (Thursday, 16:50, Session 32)

## Applied Cognition

Mohammad Khajah, Robert Lindsey, and Michael Mozer: Maximizing students' retention via spaced review: Practical guidance from computational models of memory (Saturday, 15:30, Session 76)

## NSF Funded Conference Grants

In association with the Cognitive Science Society, the US National Science Foundation (NSF) has funded four conference grants to US citizens who are enrolled as students at a US institution to attend the $35^{\text {th }}$ Annual Conference of the Cognitive Science Society (CogSci2013). The awardees were:

Deanne Adams, David Braithwaite, Heather Burte, and Richard Veale

## Student Travel Awards

Travel awards have been provided to students whose submissions were accepted as full papers with the highest reviewer rankings, and who indicated a need for travel funding. A total of 38 students were selected to receive a student travel award.

## Robert J. Glushko and Pamela Samuelson Foundation

The Robert J. Glushko and Pamela Samuelson Foundation generously sponsored $\$ 10,000$ for student travel awards. The 2013 Travel Awards went to:
Ahmad Azad Ab Rashid (Cardiff University, UK)
Daniela Ahlberg (Eberhard Karls Universität Tübingen, Germany)
Shira Calamaro (Yale University, USA)
Benjamin Cipollini (University of California, San Diego, USA)
Roeland Hancock (University of Arizona, USA)
Ryan Hope (Rensselaer Polytechnic Institute, USA)
Chigusa Kurumada (Stanford University, USA)
Marcus Lindskog (Uppsala University, Sweden)
Ross Macdonald (University of Dundee, UK)
MaryLauren Malone (University of Cincinnati, USA)
Tyler Marghetis (University of California, San Diego, USA)
Philip Pärnamets (Lund University, Sweden)
Alexandra Paxton (University of California, Merced, USA)
Eliane Stampfer (Carnegie Mellon University, USA)
Eoin Travers (Queen's University Belfast, UK)
Andrew Whalen (University of California, Berkeley, USA)

## GK - German Society for Cognitive Science

The German Society for Cognitive Science (GK) generously sponsored $3,000 €$ for student travel awards plus a one-year complementary subscription to GK. The 2013 Travel Awards went to:
Eric Arnau (Universitat Autònoma de Barcelona, Spain)
Martin Garcia (Rheinische Friedrich-Wilhems-Universität Bonn, Germany)
Mona Guath (Uppsala University, Sweden)
Christina Meier (University of Exeter, UK)
Falk Lieder (ETH Zurich, Switzerland)
Andrea Ravignani (University of Vienna, Austria)

## EUCog - European Network for the Advancement of Artificial Cognitive Systems, Interaction and Robotics

The European Network for the Advancement of Artificial Cognitive Systems, Interaction and Robotics (EUCog) generously sponsored $4,000 €$ for student travel awards. The 2013 Travel Awards went to:

Ulku Arslan Aydin (Capital Markets Board of Turkey)
Rasmus Bååth (Lund University Cognitive Science, Sweden)
Meadhbh Foster (University College Dublin, Ireland)
Eric Hunsberger (University of Waterloo, Canada)
Matthew J. Kmiecik (Loyola University Chicago, USA)
Yevgen Matusevych (Tilburg University, The Netherlands)
Daniel Rasmussen (University of Waterloo, Canada)
R. Calen Walshe (University of Edinburgh, UK)

## AIJ - Artificial Intelligence Journal

The Artificial Intelligence Journal (AIJ) generously sponsored 4,000 € for student travel awards. The 2013 Travel Awards went to:
Trevor Bekolay (University of Waterloo, Canada)
Chen, Dawn (University of California, Los Angeles, USA)
Choo, Feng-Xuan (University of Waterloo, Canada)
Tim Chuk (University of Hong Kong)
Arindam Das (York University, Toronto, Canada)
Molly Lewis (Stanford University, USA)
Russell Richie (University of Connecticut, USA)
Andrew Saxe (Stanford University, USA)

## Awards Committee

Richard P. Cooper (co-chair), David Peebles (co-chair), Thora Tenbrink (co-chair), Erik Altmann, Berit Brogaard, Jerome R. Busemeyer, Nancy Cooke, Sharon Goldwater, Stefan Kopp, Stephan Lewandowsky, Max M. Louwerse, Brad Love, Padraic Monaghan, Richard Shiffrin, David Uttal, Rineke Verbrugge.

## Robert J. Glushko Dissertation Prizes

The Cognitive Science Society and the Glushko-Samuelson Foundation will award up to five outstanding dissertation prizes in cognitive science each year. The goals of these prizes are to increase the prominence of cognitive science, and encourage students to engage in interdisciplinary efforts to understand minds and intelligent systems. The hope is that the prizes will recognize and honor young researchers conducting ground-breaking research in cognitive science. The eventual goal is to aid in efforts to bridge between the areas of cognitive science and create theories of general interest to the multiple fields concerned with scientifically understanding the nature of minds and intelligent systems. Promoting a unified cognitive science is consistent with the belief that understanding how minds work will require the synthesis of many different empirical methods, formal tools, and analytic theories. 2011 was the inaugural year of this prize, and a new competition is held annually.

## Robert J. Glushko Dissertation Prize Recipients

The 2013 recipients of the Robert J. Glushko Prizes for Outstanding Doctoral Dissertations / theses in Cognitive Science are:

Dr. Douglas Knox Bemis - 2012 PhD thesis "Simple Composition During Language Processing: An MEG Investigation" from New York University

Dr. Neil Cohn - 2012 PhD thesis "Structure, Meaning, and Constituency in Visual Narrative Comprehension" from Tufts University

Dr. George Kachergis - 2012 PhD thesis "Mechanisms for Cross-Situational Learning of WordReferent Mappings: Empirical and Modeling Evidence" from Indiana University

Dr. Andrew Lovett - 2012 PhD thesis "Spatial Routines for Sketches: A Framework for Modeling Spatial Problem Solving" from Northwestern University

Dr. Liad Mudrik - 2011 PhD thesis "Processing Visual Context Violations: The Roles of Attention and Awareness" from Tel Aviv University
http://www.cognitivesciencesociety.org/about awards glushko recipients.html

A special Glushko Dissertation Prize Symposium showcases the PhD research projects of the first four prize recipients listed above (Saturday, 10:30-12:10, Session 68).

## Invited Plenary Presentations

## Heineken Prize Lecture

A Core Brain System in Assembly of Cognitive Episodes
John Duncan, Cambridge (introduced by Michael Tomasello)
Thursday August 1st, 09:00

## Rumelhart Prize Lecture

It's all Connected in Developmental Process: The Body, the Statistics, Visual Object Recognition, and Word Learning
Linda Smith, Indiana University (introduced by Peter Dayan)
Friday August 2nd, 18:00

## Keynote Talks

Cooperative Machines: Coordinating Minds and Bodies Between People and Social Robots Cynthia Breazeal, MIT (introduced by Ipke Wachsmuth)
Thursday August 1st, 18:00
Shared Agency
Michael E. Bratman, Stanford (introduced by Natalie Sebanz)
Friday August 2nd, 09:00
Core Social Cognition
Elizabeth Spelke, Harvard (introduced by Michael Pauen)
Saturday August 3rd, 09:00

# Diagrammatic Cognition: Discovery and Design 

## William Bechtel (bechtel@ucsd.edu)

Department of Philosophy and Interdisciplinary Program in Cognitive Science, University of California, San Diego, La Jolla, CA 92093-0119 USA

Keywords: diagrams, visuospatial representations; external representations; problem solving; diagrammatic reasoning; scientific reasoning; cognitive tools; design

## Introduction

External representations of thought-maps, diagrams, sketches, and the like-are ancient inventions that serve thought and communication in numerous ways. A number of cognitive scientists have investigated roles these representations play in cognition (see, e.g., Donald, 1991; Larkin \& Simon, 1987; Norman, 1993; Schön, 1983). They are created and used by school students, by architects and designers, by mathematicians and scientists, by musicians, dancers, and artists. People design and use diagrams to spatialize thought and make it public, to work through ideas and clarify thinking, to reduce working memory load, to communicate ideas to others, to promote collaborative work by providing an external representation that can be pointed to and animated by gestures and collectively revised. Considerable research has shown that well-designed diagrams promote thought, creativity, discovery, and communication. Diagrams can map abstract thought to space, allowing spatial reasoning to promote abstract reasoning.

Just as many diverse groups create and use diagrams, many diverse groups are actively studying their creation and use. Educators study ways to design effective diagrams and ways to educate students to use them. Psychologists study how diagrams are perceived, comprehended, and created. Both educators and psychologists study ways to promote the spatial thinking skills underlying comprehension and creation of diagrams. Designers study their use in design, artists their use in art. Historians and philosophers of science describe case studies of the insightful development of diagrams by scientists and the insights those diagrams have provided to others. Philosophers analyze formal properties of diagrams. Mathematicians explore the diagrammatic thinking that underlies mathematical thought and discovery. Computer scientists study ways computers can understand and process diagrams. Other computer scientists develop displays that will effectively analyze and convey Big Data. Journalism schools now teach data visualization and diagram narratives, as these are increasingly important in journalism. The proliferation of digital tools have proliferated the use of diagrams.

## Goals and Plan of the Workshop

The goal of the workshop is dual: a) to bring together a diverse set of researchers working on various aspects of diagrammatic reasoning; b) to bring the issues and research to a broader audience in Cognitive Science. To these ends,
the workshop will have presentations from many disciplines: psychology, philosophy, computer science, education, design, and more. There will be two kinds of presentations: i) overview papers ( 30 minutes) by established researchers and ii) blitz talks (5 minutes) presenting specific current research projects. Blitz presentations have been highly successful in previous workshops, and are standard and excellent at large computer science meetings. The blitz presentations will allow broad participation from the cognitive science community and stimulate discussion around specific findings.

## Morning Session: Creating and Coordinating Diagrams

Barbara Tversky, "Creating Diagrams"
Professor Emerita of Psychology at Stanford University and a Professor of Psychology and Education at Teachers College, Columbia University, USA

Patrick Healey, "Coordinating Graphical Languages"
Professor for Human Interaction, School of Electronic Engineering and Computer Science, Queen Mary University of London, UK

David Kirsh, "Thinking with Illustrations"
Professor of Cognitive Science, University of California, San Diego, USA

Blitz Talks: Peter Coppin, University of Toronto; James Corter, Teachers College, Columbia University; Valeria Giardino, Free University Berlin; Azadeh Jamalian, Teachers College, Columbia University; Maithilee Kunda, Georgia Institute of Technology; David Peebles, University of Huddensfield; Anne Schüler, Knowledge Media Research Center; and others

## Afternoon Session: Diagrams in Science

William Bechtel, "Ways Scientists Reason with Diagrams" Professor of Philosophy, University of California, San Diego, USA

Peter Cheng, "Re-discovering diagrams and re-codifying knowledge in science"
Professor of Cognitive Science, Department of Informatics, University of Sussex, UK

Mary Hegarty, "Cognition and Metacognition in Reasoning with Diagrams"
Professor of Psychology, University of California, Santa Barbara, USA

Blitz Talks: Trevor Barrett, Univ. of California-Santa Barbara; Daniel Burnston, Univ. of California-San Diego; Jeff Nickerson, Stevens Institute of Technology; Benjamin Sheredos, Univ. of California-San Diego; Andy Stull, Univ. of California-Santa Barbara; and others

## Research Contributions of the Speakers

The presenters of the overview papers have each made distinctive contributions to cognitive science research on diagrams. The following are selective highlights.

Tversky $(2005,2011)$ has emphasized how people design diagrams by abstracting and schematizing contents, taking advantage of their spatial properties. She emphasizes how diagrams overcome limitations of internal information processing capacities, organize thought, and promote inference and discovery. Turning the focus to the interindividual coordination in the production and comprehension of visuospatial representations Healey (Healey, Swoboda, Umata, \& King, 2007) investigates the parallels between talking and drawing as modes of communication and the factors affecting the evolution of graphical dialects. Kirsh (2010) has identified a variety of ways external representations enhance cognitive power, including by providing a shareable object of thought, reducing the cognitive cost of inference, and coordinating thinking.

The afternoon session turns to uses of diagrams in relation to science. Bechtel has focused on how diagrams function to represent phenomena to be explained (Bechtel \& Abrahamsen, 2012), guide the search for the parts and operations of mechanisms (Sheredos, Burnston, Abrahamsen, \& Bechtel, in press) and direct the recomposition of mechanisms in computational models and synthetic organisms. Hegarty $(2010,2011)$ has employed experimental techniques to identify the cognitive abilities that underlie intelligent use of spatial representations and to address how spatial intelligence facilitates learning by students in the natural sciences. Cheng $(2002,2011)$ has explored how developing appropriate novel diagrammatic formats can enhance student learning about electric circuits and probability.

# Using Mechanical Turk and PsiTurk for Dynamic Web Experiments 

Anna Coenen (anna.coenen@nyu.edu)<br>Doug Markant (doug.markant@nyu.edu)<br>Jay B. Martin (jbmartin@nyu.edu) John McDonnell (john.mcdonnell@ nyu.edu)

Department of Psychology, New York University<br>New York, NY 10003

Keywords: Amazon Mechanical Turk; PsiTurk; Online Experiments; Crowdsourcing

## Objectives

This half-day workshop will demonstrate how to build custom web-based experiments that rely on participants from Amazon Mechanical Turk (AMT). Attendees will learn how to deploy web-based experiments using PsiTurk, a Pythonbased platform that simplifies the process of setting up experiments and interacting with AMT.

Workshops discussing the AMT marketplace have been offered at previous Cognitive Science Society meetings (e.g., Mason \& Suri, 2011). This workshop will complement those by stepping through a working demo that attendees can use to follow along and run on their personal computers. Importantly, the demo will illustrate how AMT can be used with dynamic, externally-hosted experiments, rather than the basic survey templates currently offered on AMT.

The workshop will have two parts. First, we will outline some of the general advantages and principles of using AMT for online behavioral experiments, including a basic introduction to the AMT website and the data collection process more generally. Second, we will show participants how to use the PsiTurk platform to run any web-based experiment on AMT. This portion of the workshop will emphasize "handson" training in AMT and PsiTurk that will teach attendees how to deploy their own web-based experiments.

## Outline of the Workshop

Throughout the workshop we will use both slides and live demonstrations of how to use AMT and PsiTurk for running web experiments.

## Introduction to Mechanical Turk

We will start by introducing the basic structure behind AMT and demonstrate how to run a simple project.

AMT is the largest online service in the US that offers a marketplace for tasks that need to be solved by human rather than machine intelligence. Human Intelligence Tasks (HITs) are submitted by requesters, such as corporations, researchers, organizations, or individuals in need for human participants. They can be completed by workers in exchange for a reimbursement that is set by the requester. Workers can also be awarded bonuses or have their payment rejected based on how they completed a HIT. We will walk attendants
through a simple example of how to post a HIT, oversee the data collection, and reimburse participants on the AMT website.

## Benefits and drawbacks of online experiments

Next, we will cover some of the advantages and pitfalls associated with using AMT for behavioral research.

For cognitive psychologists the appeal of using AMT lies in running computer experiments that would otherwise be completed in the lab, typically by undergraduate students. Online experiments have several advantages:

1. Data from a large number of participants can be collected quickly and at low costs. A few hours are typically sufficient for recruiting a full set of participants in a standard cognition or perception experiment.
2. Since the data collection is anonymous, using AMT minimizes experimenter effects and problems with contaminated subject pools at research departments.
3. For the same reason, experimental results become more replicable. Because subjects do not interact with an experimenter, there is no possibility for experimenter confound. If one researcher runs the code for another's experiment, it is, in principle, a pure replication: there is no source of systematic experimental deviation.
4. In general, web-based experiments are easier to share with other researchers since they are designed to run in standard web browsers and do not require any additional software. This facilitates the re-use of experimental code either for the purposes of direct replication or the design of new experiments.

Potential disadvantages of the method concern the quality of the data, including the possibility that comparatively low reimbursement might lower incentives to engage in a task. To address these questions, several authors have used AMT to replicate classic findings in their field. Paolacci, Chandler, and Ipeirotis (2010), for example, replicated a number of well-known cognitive biases using AMT data. Germine et al. (2012) found no systematic differences in the results of some widely-used perceptual paradigms using laboratory and online data. Rand (2012) also conducted an extensive study into the reliability of AMT workers' demographic data and verified that self-reported demographic information is highly
reliable. At NYU's Cognition and Computation lab we have successfully replicated the main findings of multiple classic studies in the concept learning literature (reported in Crump, McDonnell, \& Gureckis, in press, as Experiments 8-10), but found that it was critical to test participants for comprehension of the experimental instructions. We also manipulated the monetary incentives of one of these tasks and found it had little effect on the performance in the task, but did affect the dropout rate. In addition to these experimental replications, researchers have addressed the objective reliability of AMT data. Our workshop will delve into the findings of the literature so far on what sorts of experiments do and do not work on AMT.

## Running AMT experiments using PsiTurk

Finally, we will demonstrate how researchers can run experiments from their own website using AMT and PsiTurk.

Mechanical Turk offers some basic templates for simple online studies that can be built directly on the website. However, it can also be used to run any web-based experiment programmed directly by the researcher via the External Question type. To facilitate this process, John McDonnell and Todd Gureckis from NYU's Cognition and Computation lab coauthored and continue to maintain a Python-based platform that allows users to create HITs for experiments with minimal effort. It provides a back-end framework, handling interaction with Amazon's servers to credit participants, and logging participants' data and identifying information in a database. This allows researchers to build a user-facing front-end providing their own experimental code without having to write software to handle these logistical issues. The platform is available at http://github.com/NYUCCL/PsiTurk.

Over the course of the workshop, we will introduce the platform and show how attendants can run their own experiments on AMT. We will do so using a demo experiment coded in JavaScript that will be turned into a HIT. The code for this demo will be available for attendants to easily adapt to their own experimental needs.

## Audience

This workshop will appeal to cognitive science researchers who are conducting behavioral experiments in a wide number of areas. For those who are unfamiliar with AMT, the lecture portion of the workshop will explain the mechanics of AMT and review methods for designing and delivering experiments to participants. The interactive portion of the workshop will be particularly informative for scientists who wish to use AMT to run dynamic experiments that go beyond simple surveys, for example involving timing of stimulus presentation, collection of reaction times, or interactions with complex stimuli.

The workshop may also be of use to researchers who are unsure whether online research can accommodate their needs. For example, neuroscientists might be interested in using AMT as a platform for piloting experimental paradigms and online experiments in general for reducing dropout rates for
follow-up tasks, but may be unsure whether their paradigms can be easily translated into online experiments. One important theme of the workshop will be the capabilities and limitations of online experiments in general.

Although AMT is currently only available to requesters in the United States, we believe that researchers from other parts of the world could still benefit from the workshop. They might be able to use AMT through collaborations with laboratories in the United States, for example. Also, PsiTurk offers a general framework for running web experiments which can also be helpful for users of other online services.

## Preparation

We suggest that participants download the PsiTurk platform before attending the workshop and attempt to set it up before attending the workshop. If they do so, they will be able to follow along during the demonstration segment in which we launch an experiment on AMT.

## Presenters

All presenters of the workshop have used AMT and PsiTurk extensively to collect data, and have expertise in writing webbased experiments in JavaScript. John McDonnell is the coauthor and maintainer of the open-source PsiTurk framework for behavioral experiments on AMT. He has also validated AMT as a platform for studying learning using Turkers as participants (Crump et al., in press). The other speakers have several projects in preparation based on AMT data collected using PsiTurk. All of the speakers will be available throughout the workshop to assist attendants in setting up PsiTurk and using the AMT platform.

## Workshop Background and Relevance

Humans interact with other humans. They do so frequently, in a wide variety of circumstances, to accomplish many different goals. This interpersonal interaction, especially in face-to-face circumstances, requires coordination (Clark, 1996). This involves many subtle behaviors, controlled carefully in the context of another person, from eye movements and gestures, to choice of words. The characteristics of the cognitive system that give way to this coordination have been a matter of debate recently in the cognitive sciences. Yet there remain many open questions about how the cognitive system functions in human interactions. How does interpersonal coordination emerge in the dyad? What behaviors are coordinated between persons, and in what manner? How can we model dyads and their interactions?

One challenge to advance our understanding of how human participants utilize social-cognitive cues in everyday communication is that the empirical evidence is based on macro-level behaviors in constrained unnatural contexts and tasks. To truly understand mechanisms of interpersonal coordination, however, we may need to focus on more micro-level behaviors as they unfold in real time, and in free flow interaction, for example, changes in eye gaze and shifts in body position as they are linked to objects, events, and actions of the social partner. Several new directions have pursued this microstructure of interpersonal interaction.

First, with advances in sensing and computing techniques, now we have the capabilities to process visual, audio and other sensory data collected from real-world interactions. This data-intensive approach provides a unique opportunity for new discoveries from various advanced data analysis techniques. These methods have leveraged visualization techniques to mine the temporal relationships between behaviors of two people (Yu et al. , 2009; see Fig. 1). This has shed light on the timing of interpersonal interaction, and how two individuals adapt to each other, both in infant-adult dyads (e.g., Smith et al., 2010; Yu \&
semi-automatic extraction $\longrightarrow$ event alignment and exploration

Figure 1: Visualization software for extracting, aligning and mining large multivariate time series of behaviors to uncover coordination (adapted from Yu et al., 2009).

Smith, 2012; Nagai et al., 2012), and in two adults (Coco et al., 2012; Richardson \& Dale, 2005).

Second, researchers in developmental robotics have investigated mechanisms of interpersonal coordination, to model and implement social systems. In developmental robotics, recent progress has been achieved in developing robots that elicit human scaffolding (Nagai, Nakatani, \& Asada, 2010). This progress has been possible by implementing underlying processes that could be involved in the dynamic control of interpersonal coordination. For example, implementing a model of a mirror neuron system can help basic skills in robots like self-other discrimination, and can support more complex abilities, such as imitation (Nagai et al., 2011; see Fig. 2, left). By grounding highlevel theories into robotic systems, we can address different aspects of how social-cognitive capabilities, such as gaze following and face preference, can be learned through sensorimotor interactions.

Third, research on virtual agents has developed new models of embodied human-agent interaction. This offers new ways to explore processes of interpersonal coordination. This has included, for example, the role of gesture and nonverbal behavior (Sadeghipour \& Kopp, 2011), attentive speaking (Buschmeier \& Kopp, 2011), and feedback (Kopp et al., 2008). Virtual embodied agents provide a foundation for testing theories of adult-adult interaction, and developing exciting social tools to support interpersonal coordination (see Fig. 2, right).

Figure 2. Left: Human-robot interaction; robot equipped with emergent mirror-neuron system (adapted from Nagai et al., 2011). Right: Humanagent interaction to explore models of gesture (adapted from Sadeghipour \& Kopp, 2011).

Together these strands of research offer new insight into human social dynamics, and the means to implement and test theories in robotics and virtual agents. Bringing them together in one workshop is an opportunity to convey these new methods, and find shared interests and synergies among different approaches and different fields, These are the primary goals of the workshop.

## Objective and Overview

The aim of this workshop is to introduce these approaches in an integrative fashion, and offer some basic demonstrations of relevant software, data analysis, and development.
Broad audience. Given the international and interdisciplinary composition of the workshop, we expect to attract broad interest from several domains, from cognitive and language development, to language processing and discourse; from human cognition to artificial intelligent systems; and from human babies, to adult, and to both physical social robots and virtual agents.
Activities. The organizers of the workshop will first offer a series of presentations on relevant research projects (see Schedule). These topics form a coherent collection of new approaches to interpersonal interaction, shown below in Table 1. Talks will include concrete details regarding data collection, system design, and so on; where appropriate, source code or software will be demonstrated and distributed to attendees (e.g., Coco \& Dale's R toolbox for recurrence). The workshop organizers will together lead a discussion with the attendees on limitations, future directions, and so on.

Table 1: Thematic organization of workshop organizers covering domains of interpersonal coordination.

|  | infant | adult |
| :---: | :---: | :---: |
| human | Nagai, Yu | Kopp, Coco, Dale |
| robot / agent | Nagai, Yu | Kopp |

Outcomes. Attendees will gain a basic understanding of human data analysis in the case of large-scale multivariate behavioral data mining (Yu et al., 2009, 2012), and the application of a particular technique referred to as cross recurrence analysis (Dale et al., 2011) which serves as a simple quantification over behavioral channels ( R toolbox
developed by Coco \& Dale, in preparation). Nagai and Kopp will offer details of developing robotics and artificial agents.

## Schedule

| Duration | Topic (Speaker) |
| ---: | :--- |
| $0-5$ minutes | Introduction to the workshop (Dale) |
| 40 minutes | Infant-caregiver coordination through software visualization (Yu) |
| 40 minutes | Adult coordination and cross recurrence analysis (Dale \& Coco) |
| 5 minutes | Break |
| 40 minutes | Social and developmental robotics and interpersonal interaction (Nagai) |
| 40 minutes | Virtual social agents, human-agent interaction, and coordination (Kopp) |
| 20 minutes | Discussion |
| Total: | $\sim 3$ hours |

## Further Materials

The first author of the workshop will maintain a website to distribute publications and software for attendees.

University of Pittsburgh
Pittsburgh, PA 15260-5169 USA

Keywords: cross cultural diversity; networking; participation; professional development; research collaboration.

Women in Cognitive Science (WICS) has a history of conducting panels at yearly meetings of several professional societies. Their goal is to increase attention to the situation of women cognitive scientists, to better understand the reasons for existing problems of under representation in key positions, and to provide a forum for professional development that encourages both junior and senior scientists to consider the ways in which they might work with their own home institutions to effect change. Specific topics have addressed networking and collaboration, best practices for institutional transformation, and issues of family and academic careers. Speakers and panelists have included both women and men who represented senior and junior scientists and topics have focused on the experience of both faculty and administration in negotiating these issues and in developing policies that are likely to support women's success. Its history demonstrates that WICS is in a unique position to address the concerns of junior as well as senior scientists as they pursue their professional careers in the sciences.

The Interactive Panel Discussion: Professional advancement through international collaborations seeks to bring together American and European researchers in Cognitive Science at the 2013 meeting of the Cognitive Science Society in Berlin, Germany. Speakers will discuss national and international collaborations as a tool towards professional advancement and visibility.

Janet van Hell (jgv3@psu.edu)<br>Moore Building<br>Department of Psychology<br>The Pennsylvania State University<br>University Park, PA 16802 USA<br>Suparna Rajaram (srajaram@notes.cc.sunysb.edu)<br>Department of Psychology<br>Stony Brook University<br>Stony Brook, NY 11794-2500 USA

#### Abstract

The central theme will be how to develop new research collaborations outside of one's primary institution, including international collaborations and why this is important to one's career development. All acknowledge that this is not a simple process and often evolves slowly, out of more social networking connections. While such solutions generally occur on an ad hoc basis and vary tremendously across individuals and settings, the aim of the WICS workshop is to enable discussion of this and related activities that enhance productivity and thus visibility. Discussion will include the role of virtual collaborations and virtual research networks in enhancing professional enhancement, even for women with less opportunity/money/time to travel.

At the time of publication, R. Harald Baayen (Eberhard Karls University, Tübingen), Melody Dye (Indiana University, Bloomington), Laurie Feldman (SUNY, Albany \& Haskins Labs), Lael Schooler (Max Planck Institute for Human Development, Berlin), and Anne Warlaumont, (University, of California, Merced) have been invited to describe and contrast varied formats and goals of their international collaborations. These people represent American and European junior and senior researchers, some who have held positions as university administrators and department heads and chairs. Each will share his/her perspective.
The theme of virtual as well as real collaboration will be of relevant not only to those who have funds to attend the meeting in Berlin but to those with more limited travel budgets. Materials from the speakers will be posted on the Women in Cognitive Science website. Because the networking function of our workshop differs from the goal
of most other workshops, it has been scheduled in a special time slot that conflicts only minimally with other workshops.

## Acknowledgments

Women in Cognitive Science (WICS) was founded in 2001 by Judith Kroll (Penn State), Randi Martin (Rice University), and Suparna Rajaram (Stony Brook) with NSF ADVANCE Funds. From 2007 onwards, Laurie Feldman (Albany) and Janet van Hell (Penn State) have assumed a leadership role within the group. In 2012, Natasha Tokowitz joined the group.
Partial funding for this event comes from NSF Award BCS-1049764.

# Workshop Proposal: PRE-CogSci 2013 - Bridging the gap between cognitive and computational approaches to reference 

Albert Gatt

Roger van Gompel
Ellen Gurman Bard
Emiel Krahmer
Kees van Deemter

## Outline

This full-day workshop explores the Production of Referring Expressions (PRE) from different perspectives. It follows two earlier workshops on the same theme, which were associated with two earlier CogSci conferences. The first of these, PRE-CogSci 2009, focussed on the interplay between computational and empirical methods. ${ }^{1}$ The second, PRECogSci 2011, broadened this theme to include work on dialogue and linguistic theory. ${ }^{2}$ Both events were highly successful, with each containing over 20 presentations and an audience of over 60 participants. Following the first workshop, the Topics in Cognitive Science journal published an issue containing 8 peer-reviewed articles selected from 28 full paper submissions (Krahmer et al. 2012). Following the second workshop, we are finalising a Special Issue of the journal Language and Cognitive Processes; accepted papers are expected to appear in 2013-14. A survey of research, by 2 of the organisers, on the generation of referring expressions that came out in the journal Computational Linguistics in March 2012 has since been downloaded over 700 times.

This third PRE workshop is part of CogSci 2013. It will be different from its predecessors in two ways. Firstly, a range of new intellectual themes will be explored that have emerged in recent years. Second, the workshop will be coupled with a satellite event, which will be separately funded, and which will be devoted to the role of reference in practical applications. We expand on these issues below.

## Workshop overview

Interest and significance As the earlier workshops demonstrated, there is abundant scope for cross-disciplinary research on reference. Recent advances (see below) have caused the interest in PRE-CogSci 2013 to increase further.

Importance The boundaries between the different disciplines working on reference are starting to shift, with computational methods (e.g., stochastic and Bayesian methods; ACT-R) permeating theoretical and experimental work. Increased collaboration between computational linguists and psycholinguists is bound to be mutually beneficial: computational work will benefit from a greater awareness of psycholinguistic methods and findings; psycholinguistic models (which often underdetermine the phenomena) have the potential to benefit from precise and explicit algorithmic models. The importance of this cross-disciplinary collaboration has been acknowledged though the award of two recent projects, namely the (Dutch)

[^0]NWO-VICI project Bridging the gap between psycholinguistics and computational linguistics: the case of Referring Expressions (Krahmer, 2009 - 2013), and the (British) EPSRC project REFNET An Interdisciplinary Network Focussing on Reference, (Bard and van Deemter, 2012-2015). Four new themes have recently emerged in this area, which will be explored during the workshop:

- Collaborative reference. Referring expressions are often produced collaboratively, as when one speaker says "The hill just north of us" and the other adds "You mean with the tower on top?" We believe the time has come to address collaborative reference using the combination of computational and empirical methods that have become mainstream in the study of reference. Research that takes off from a view of language as a social and collaborative phenomenon has the potential to shift the goal of production models away from the aim of identifying a referent uniquely towards effective communication.
- Nondeterminism in production. Evidence suggests that a given speaker, confronted with a given situation, will not always produce the same utterance (just like a marksman doesn't always hit the same area of a target). Recent models have started to model algorithmically what variation is found in the production of referring expressions.
- Interaction between comprehension and production. Work on comprehension (i.e., interpretation) and production (i.e., generation) has typically proceeded separately. Recent work on reference, however, has started to study comprehension and production jointly, seeking to exploit their common mechanisms and discover their differences.
- Combinations with research on vision. Recently, researchers in Natural Language Generation and researchers in Computer Vision have joined forces (e.g., EPSRC's Vision \& Language Net in the UK, Belz and Makris 20102013) for example to allow computers to describe a picture and refer to objects in it. This has raised new questions concerning the way in which visual information is represented in the human brain, and how this may be modelled computationally.

Relevance to CogSci 2013 Apart from its relevance to language comprehension and production, the workshop's focus on collaborative reference - in which a sequence of actions by two or more agents achieves an effect that none of them might have achieved on her own - will make it directly relevant to the modelling of social interaction. Our satellite event (see below) will lend further emphasis to social aspects of reference, focussing on real-life situations.

Suitability of organisers Apart from their success in organising the first two PRE-CogSci workshops, the organisers are leading researchers in the field of reference, and their backgrounds range from psycholinguistics to theoretical and applied computing science.
Proposed format and funding For the main event, we envisage a full-day workshop, consisting of two half-sessions, each starting with an address by a keynote speaker. We envisage 8-10 oral presentations and a poster session. Travel expenses of the keynote speakers will be split between the abovementioned projects NWO-VICI and EPSRC-REFNET.

As a satellite, probably on the day before the workshop, we envisage a Cross-pollination meeting in which researchers will interact with practitioners in Human-Computer Interaction, Robotics, and Geographical Information Systems, to discuss challenges involving reference that come from real applications. The satellite event will not be part of the workshop and will be financed by the RefNet project (see above), but we expect the two events to dovetail well, thus adding to the number of people likely to want to come to CogSci.
Likely audience and attendees The workshop will be of interest to a variety of cognitive scientists, including psycholinguists with an interest in computational modelling; computational linguists with an interest in experimental methods; and a limited number of others who will be attracted to the event because of the (satellite) Cross-pollination event; these will probably include a number of representatives from industry. Based on the experience of the first two editions of the workshop, we expect 50-70 participants.
Two keynote speakers have agreed to speak at the workshop: Professor Herb Clark, and Dr Noah Goodman. Professor Clark (Stanford) is a psycholinguist whose longstanding experimental work on reference has been more influential than anyone else's; his work has often stressed collaboration and other social aspects of communication. Dr Goodman (MIT, then Stanford) works in a new area where computer science overlaps with psychology; he has done extensive work in concept learning and has recently turned his attention to the modelling of reference using stochastic algorithms, integrating models of interpretation with models of production. Both speakers' work is highly relevant to the workshop. (See the themes mentioned under the header Importance.) In addition, the following people have agreed to form part of the programme committee:

- Mira Ariel, Tel Aviv University, Israel;
- Jennifer Arnold, University of North Carolina, USA;
- Adrian Bangerter, Univ. of Neuchâtel, Switzerland;
- Dale Barr, University of Glasgow, UK;
- Eva Belke, Ruhr-University Bochum, Germany;
- Holly Branigan, University of Edinburgh, UK;
- Susan Brennan, Stony Brook University, USA;
- Sarah Brown-Schmidt, Univ. Illinois, Urbana-Champaign
- Herb Clark, Stanford University, USA;
- Victor Ferreira, University of California, USA;
- Jeanette Gundel, University of Minnesota, USA;
- Martijn Goudbeek, Tilburg University, The Netherlands;
- Markus Guhe, University of Edinburgh, UK;
- Daphna Heller, University of Toronto, Canada;
- John Kelleher, Dublin Institute of Technology, Ireland;
- Frank Keller, University of Edinburgh, UK;
- Ralf Klabunde, Ruhr University Bochum, Germany;
- Danielle Matthews, University of Sheffield, UK;
- Margaret Mitchell, Johns Hopkins University, USA;
- Paul Piwek, Open University, UK;
- Massimo Poesio, University of Trento, Italy;
- Ehud Reiter, University of Aberdeen, UK;
- Amanda Stent, AT\&T Labs and Stony Brook Univ., USA;
- Matthew Stone, Rutgers University, USA;
- Takenobu Tokunaga, Tokyo Inst. of Technology, Japan;
- Mariët Theune, Twente University, Netherlands.

Publicity and impact A dedicated website, http://pre2013.uvt.nl/, links to the sites of the previous editions of PRE-CogSci, and will (eventually) contain the electronic workshop proceedings, in the form of extended abstracts. The workshop has been advertised on several emailing lists in experimental psychology, computational linguistics and theoretical linguistics. As in the case of the previous two workshops, we envisage a special issue in an appropriate scholarly journal.
List of Requirements The only requirements are a data projector and computer, preferably with internet connection.

# Motivations and Goals in Developing Integrative Models of Human Cognition 

Glenn Gunzelmann (glenn.gunzelmann@us.af.mil)<br>Cognitive Models \& Agents Branch, Air Force Research Laboratory<br>711 HPW/RHAC, 2620 Q St., Building 852<br>Wright Patterson Air Force Base, OH 85212-6061 USA

#### Abstract

There has been tremendous growth recently in theories that attempt to provide more comprehensive accounts of the foundational mechanisms of human cognition. Such theories have taken a variety of forms, and have focused on different levels of analysis. The diversity is important and necessary, but can serve as a barrier to interaction, comparison, and integration, even at venues like the Annual Meeting of the Cognitive Science Society that should foster such dialogue. This workshop is intended to bring together individuals working on integrative models of human cognition, to emphasize shared motivations and goals. Ultimately, building scientific communities that bridge levels of analysis, methodologies, and theoretical approaches to work toward more comprehensive theories will be critical to the addressing the central goal of the Cognitive Science Society understanding the nature of the human mind.

Keywords: Integrated Models; Unified Theories of Cognition; Cognitive Models; Cognitive Architectures; Neural Architectures.

## Introduction

The motivations for integrative models of human cognition have their roots in the origins of cognitive science as a scientific discipline. Even before cognitive psychology emerged, ideas about unifying principles to explain cognition were expressed in the scientific literature (e.g., Newell, Shaw, \& Simon, 1958; Rosenblatt, 1961), including so-called grand psychological theories proposed during the first half of the $20^{\text {th }}$ century. The call for more comprehensive theories was explicitly made by Newell (1973), who expressed concern about the prospect that traditional, phenomenon-driven cognitive psychology would, by itself, lead to the kind of integrative understanding of the human mind that is the goal of cognitive science.

In the decades since, integrative theories of human cognition have become increasingly prevalent in cognitive science. These theories now represent an exciting diversity of theoretical approaches and levels of analysis, better reflecting the diversity of the cognitive science community as a whole. As noted by McClelland (2009), this growth has been tied in important ways to sustained increases in computing power that enable cognitive modeling at a scale and resolution that was unimaginable half a century ago.

The participants in the workshop have been selected to capture much of this theoretical diversity. The current state of the art in this area makes this workshop a timely and important contribution to the Annual Meeting of the Cognitive Science Society and the broader cognitive science community.

## Goals and Scope

The need to bring together this community of researchers was expressed by Newell (1990). Newell explicitly and deliberately referred to Unified Theories of Cognition in the plural, noting that multiple implementations are important for progress in the science. More recently, McClelland (2009) emphasized that "different simplifications are required to explore different issues." (p. 12). Interactions among cognitive scientists from different methodological and theoretical backgrounds are crucial to identifying common foundations and interconnections among levels of analysis and theoretical perspectives.

To reinforce and further develop the identity of this scientific community, this workshop will create an important opportunity for interaction and discussion amongst researchers working toward more integrative theories of cognition. It will not focus on a debate about the merits of developing integrative models of human cognition. The participants share, in general, an appreciation of the value of developing such theories, which provides the unifying theme for the event.

In addition, the workshop will not focus on the claims of particular integrative models. That is an important scientific activity, but the goal here is to build broader appreciation of shared motivations and goals, despite sometimes very different approaches and theories. All of the presenters seek unifying mechanisms that cut through the complexity of human cognition and enhance our understanding. Complementary perspectives and opportunities for integration will be highlighted to emphasize connections. In addition, contemporary challenges in this pursuit will be discussed, which will facilitate future scientific debates regarding particular claims and mechanisms.

## Workshop Organization

The workshop will be organized around a set of presentations and opportunities for discussion. The focus will not be on theoretical overviews. Instead, contributors will comment on the role of integrative models in cognitive science, including understanding the fundamental principles of human cognition broadly, and integrating across components of cognition to perform complex tasks. Presenters will highlight links to alternative approaches and methodologies, and discuss current challenges in developing integrative models of the human mind.

Speakers will be given approximately 25 minutes, with no more than 15 minutes of presentation material. This will allow significant opportunity for questions, comments, and discussion. In addition, the closing session of the workshop will consist of a panel discussion with the goal of
identifying and highlighting common themes and perspectives that have emerged across the day.

## Workshop Organizer

Dr. Glenn Gunzelmann is the Science and Technology Advisor for the United States Air Force Research Laboratory's Cognitive Models and Agents Branch. His research attempts to expand the explanatory breadth of integrative theories, including theories of human spatial competence (e.g., Gunzelmann \& Lyon, 2011) and fatigue (e.g., Gunzelmann, Gross, Gluck, \& Dinges, 2009).

## Target Audience

This workshop targets the central purpose of the Cognitive Science Society - it "brings together researchers from many fields who hold a common goal: understanding the nature of the human mind" (CSS Website). The presenters represent a range of disciplines in cognitive science, who will focus on important challenges associated with creating more comprehensive theories. Because this steps back from the theoretical and technical details of the theories, this workshop should be approachable and of interest to a broad audience at CogSci 2013 , and will make an important contribution to the event.

## Participants

## Presenters

## Joscha Bach

Berlin School of Mind and Brain
Humboldt University

## Jerome Busemeyer

Cognitive Science Program
Department of Psychological and Brain Sciences
Indiana University

## Chris Eliasmith

## Archiving

In conjunction with the workshop, a proposal is being submitted to Topics in Cognitive Science. Presenters at the workshop will be invited to submit brief papers to complement the presentations at the workshop. Discussants will be encouraged to submit commentaries to the Topic on Integrative Models of Human Cognition, based on both the papers and workshop presentations. All workshop attendees, and others in the cognitive science community, will also be invited to contribute to the discussion in the journal.

# Deception as a Social Strategy 

Swati Gupta (guptas@ihpc.a-star.edu.sg), Tei Laine (lainet@ihpc.a-star.edu.sg), Kayo Sakamoto (sakamotok@ihpc.a-star.edu.sg)<br>Programme in Computational Social Cognition, Institute of High Performance Computing, 1 Fusionopolis Way, \#16-16 Connexis North, Singapore 138632

Keywords: deception; lying; social interaction; interpersonal relationships; decision making; goals; computational modeling; risk taking; incentives; motivation; message design

#### Abstract

Deception can be advantageous to a deceiver when the truth conflicts with his or her goals - be they personal or social, selfless or selfish. Thus it is that people regularly use deception to avoid conflict with others, to avoid punishment or embarrassment, to fit into a group, to harm, protect or help others, and for material or non-material benefit to themselves. While there are many ways in which people can deceive, for example, by choosing to fabricate rather than to tell a half-truth, there are always cost-benefit trade-offs, regardless of the strategy a person chooses. Understanding why people deceive in everyday life situations, how they do it, why they choose one strategy over another, and why sometimes they might choose not to deceive at all, even in the absence of any serious anticipated cost, will enable us to build richer models of socially intelligent behavior--models that could be employed in computational systems designed to facilitate enterprises such as elder care, tutoring, and professional training. In this workshop, we aim to address three basic questions: (1) what factors lead people to deceive? (2) what makes them decide to deceive one way rather than another? and (3) how can we model these factors computationally?

## What we aim to achieve

We aim to highlight research on how people use deception as a social strategy, and provide an overview of how issues related to the questions raised above have been addressed by various disciplines. Even though there has been research in several fields including communication studies, philosophy, linguistics, psychology, economics, and neuroscience, on the question of why and how people deceive one another, there is no comprehensive integration of the different views and observations found in the literature. The confirmed speakers represent many of these disciplines, and this workshop would be a good opportunity to explore together similar research questions from different disciplinary perspectives.

## Why is it important

Most of the research on deception has focused on deception detection, rather than generation. We believe there is a need to move in the direction of rectifying this imbalance, for the reasons mentioned in the abstract above. This workshop will provide an opportunity for people interested in deception to focus more on the generation aspect, and will help in making a stronger case of more research in this area.

## Relevance to CogSci 2013

The goals of this workshop, which focuses on an emerging and a cross-disciplinary research topic, are directly linked to the theme of CogSci 2013, which is "Cooperative Minds: Social Interaction and Group Dynamics." We treat deception as a social strategy, which often is used to enhance social interactions and cooperation within groups.

## The Organizers

We are an interdisciplinary team of scientists, with a background in computer science, cognitive science, computational linguistics, and psychology. For the past two years, we have been working on a project on this topic, in which we have brought together literature from diverse fields, and have investigated issues related to verbal deception. We proposed a theory of verbal deception which demonstrated the interaction between a taxonomy of verbal deception types, and the communicative goals of deception. Focusing on the decision making aspect of deception, we also analyzed factors that determine whether a person would deceive or not, and found that these factors differ depending on whether the person is facing potential losses or gains. Following are our most relevant publications.

Gupta, S., Sakamoto, K., \& Ortony, A. (2012).
Telling it like it isn't: a comprehensive approach to analyzing verbal deception. In F. Paglieri, L. Tummolini, R. Falcone \& M. Miceli (Eds.), The goals of cognition: Festschrift for Cristiano Castelfranchi. London, College Publications.

Sakamoto, K., Laine, T., and Farber, I. (in press). Deciding whether to deceive: Determinants of the choice between deceptive and honest communication. Journal of Economic Behavior \& Organization.

## Expected audience

This is a topic of general interest. We expect it to attract audience from a variety of disciplines like psychology, linguistics, philosophy, as well as artificial intelligence, economics, and neuroscience. People working in interpersonal / strategic communication, decision making, unethical behavior, morality, truth, and business ethics, would find it particularly relevant. It would also be of interest to people working on real world domains like law, insurance, tutoring, professional training, and elder care.

Our estimate for the number of people in the audience is approximately 40.

## Confirmed Speakers

We are currently awaiting responses from a few more people, and plan to have around 9-10 speaker slots. Below is the list of confirmed speakers.

## Steve McCornack

## Publicity

Some of the relevant mailing lists that we plan to advertize on are JDM, SPSP, IU's cogsci list, and Cognitive Science Student Society. We will utilize the social networking platform to publicize on the Facebook pages of relevant organizations like the Cognitive Science Society, International Communication Association, Association For Business Communication, and AAAI, to name a few. We also plan to advertise at the Joint Action Meeting, which is collocated with CogSci.

We would also like to document the workshop outcomes in the form of an article or a special issue in the journal of a related discipline.

# Mental Model Ascription by Language-Enabled Intelligent Agents 

Marjorie McShane (marge@umbc.edu)<br>Department of Computer Science and Electrical Engineering<br>University of Maryland Baltimore County<br>Baltimore, MD, 21250, USA

## Topic and Goal

Mental model ascription can be defined as inferring features of another human or artificial agent that cannot be directly observed, such as that agent's beliefs, plans, goals, intentions, personality traits, mental and emotional states, and knowledge about the world. This capability is an essential functionality of intelligent agents if they are to engage in sophisticated collaborations with people. The computational modeling of mental model ascription offers an excellent opportunity to explore the interaction of traditionally separate modules of cognitive architectures, such as language understanding, plan- and goal-oriented reasoning, and memory management.

The study of mental model ascription can benefit from advances in fields as disparate as machine reasoning, social interaction, developmental psychology, robotics, emotion, philosophy and computational linguistics, to name just a few. ${ }^{1}$ The common thread of this workshop will be the computational modeling of unobservable features by intelligent agents using language input as at least one of their modes of perception. Topics of interest include but are not limited to:

1. Developing computational treatments of language phenomena (e.g., indirect speech acts, irony, paraphrase, humor, coercion) that require or give rise to mental model ascription.
2. Applying computational models of other cognitive capabilities (dialog, emotion, agent collaboration/competition and plan- and goaloriented reasoning) to mental model ascription.
3. Modeling agent decisions about what to learn about other agents' unobservable features, considering that attempting to learn everything in every context would incur a heavy cognitive load.
4. Modeling how agents measure their confidence in the results of mental model ascription, which will be affected by their confidence in their understanding of contributing linguistic (or other) percepts as well as their ability to make valid inferences.
5. Modeling dynamic belief modification, including overriding a previous belief and managing memories with respect to modified beliefs.
${ }^{1}$ As a comparison, CogSci 2012 featured a workshop, "Modeling the Perception of Intention" that treated intention recognition with an emphasis on visual perception.

The main goal of the workshop is to foster mutual learning, discussion and future collaboration among researchers pursuing agent-oriented mental model ascription in integrative cognitive architectures.

## Program Committee (confirmed)

Ron Artstein (USC)<br>Jerry Ball (Air Force Research Laboratory)<br>Paul Bello (Office of Naval Research)<br>Graeme Hirst (University of Toronto)<br>Eva Hudlicka (Psychometrix Associates, Inc.)<br>Pat Langley (University of Auckland, NZ and CMU)<br>Marjorie McShane, Chair (UMBC)<br>Sergei Nirenburg (UMBC)<br>Massimo Poesio (University of Essex)<br>Chris Potts (Stanford University)<br>Yorick Wilks (IHMC).

## Organizational

This will be a full day workshop that will include invited talks, talks selected by abstract submission, a round table discussion, and, optionally, a poster session. Talks will be grouped by similarity of theme and approach, and the schedule will allow for extended discussion of each group of presentations, best exploiting the workshop genre.

We expect $30-40$ participants that include students and researchers with broad interests in the computational modeling of cognition and/or psychologically-inspired natural language processing.

The final session of the day will be devoted to planning a special journal issue (for Advances in Cognitive Systems) of papers inspired by the workshop. There are no special requirements for participants in the workshop.

The workshop website is http://ilit.umbc.edu/Workshop/MentalModelCogSci2013.html. The contact email is mentalmodel2013@gmail.com.

The workshop organizer, Marjorie McShane, has been working in the field of AI-NLP for the past fifteen years, with recent work focusing on the development of cognitive simulations of virtual patients to support clinician training. For a brief CV and list of publications, see http://ilit.umbc.edu/PubMcShane.htm.

# When eye see you: Gaze and joint attention in human interaction 

Maria Staudte (masta@coli.uni-sb.de)<br>Department of Computational Linguistics<br>Saarland University

Ulrich Pfeiffer (ulrich.pfeiffer@uk-koeln.com)<br>Department of Psychiatry<br>University Hospital Cologne

Keywords: joint attention; gaze; social interaction; language processing; dialog; grounding.

## Topic and Goals

Gaze behavior provides fundamental mechanisms for sharing mental states such as goals and desires and helps to ground communicative content. In order to establish common ground in verbal and non-verbal interactions, interlocutors often need to acquire knowledge about their interaction partners' focus of visual attention by following their gaze and, in turn, have to direct their partners attention to their own target object or location. Responding to or leading someone's gaze to a location or an object of interest results in a situation of joint attention - a referential triad between two individuals and some entity in the environment. As people often look at what they attend to and where they intend to act, joint attention is considered fundamental to an understanding of other minds and the interaction with other individuals.

Joint attention plays an important role in numerous socialcognitive processes, including Theory-of-Mind (Tomasello, 1995), perspective taking (Moll \& Meltzoff, 2011), and processes relating to learning and memory from early infancy throughout adulthood (Kim \& Mundy, 2012). However, despite extensive research in virtually all areas of cognitive science aiming at an understanding of behavioral functions, cognitive processes, and neural mechanisms of joint attention, there is a plethora of unresolved questions. The interplay of the development of joint attention and language during infancy (Baldwin, 1995) or the relation between joint attention and the perception of other persons (Frischen, Bayliss, \& Tipper, 2007) are among those. Finally, the neural circuits subserving our ability to engage in joint attention have been investigated only recently because appropriate methods to study gaze-based face-to-face interaction in real-time have only recently been made available (Redcay et al., 2010; Schilbach et al., 2010).

In addition to its role in social cognition, seeing and following or directing someone else's gaze is crucial for effective language learning (Morales et al., 2000) and language processing in adults (Clark \& Krych, 2004; Hanna \& Brennan, 2007; Staudte \& Crocker, 2011). Monitoring each other's gaze behavior supports the understanding of what the interlocutor is saying or understanding (Richardson \& Dale, 2005; Hanna \& Brennan, 2007) and fosters the synchronization of interlocutors in discourse (Garrod \& Pickering, 2004). Thus, initiating or establishing joint attention at a chosen point during dialog can be a powerful means to augment and modulate linguistic content.

Finally, severe impairments in multiple aspects of social
cognition and communication are among the core symptoms of autism spectrum disorders (ASD). Due to the broad impact of joint attention on social and communicative skills, its study has become a major focus in the empirical research on ASD. The majority of this research is dedicated to understanding the implications of mutual and triadic gaze for the development of skills related to communication among typically developing individuals and those with ASD (Mundy, Gwaltney, \& Henderson, 2010; Redcay et al., 2012).

Overall, this workshop aims to explore how traditionally separate research areas such as social cognition/neuroscience, psycholinguistics, human-computer interaction and developmental psychology contribute to an understanding of the general phenomenon of gaze-following and joint attention from all these different perspectives - and how these fields can benefit and learn from each other, e.g. by comparing different approaches and methodologies.

## Relevance to the the CogSci Conference

Recently, there has been an increased interest in psycholinguistics and human-computer interaction as well as in social cognition and ASD research to investigate human communication processes in more interactive settings. In particular, scientists have tried to extend their theories and experimental designs by the visual presence and the induced dynamics of an interaction partner in order to accommodate the complex non-verbal behavior that typically accompanies and greatly influences linguistic interaction. The domain of gaze has aroused particular interest as single acts of looking combine perception and action in social encounters. By establishing joint attention, for instance, gaze behavior guides the exchange of goals and desires which are critical motivations for communication. However, experiments incorporating such complex and dynamic yet crucial aspects of human interaction are difficult to implement and a challenge to traditionally very controlled procedures. In this workshop, we would like to gather researchers from related fields and bring them closer together by providing a platform for exchanging theories and approaches as well as methodology that is suited for investigating the use and effect of gaze in human interaction (e.g. Redcay et al., 2010; Saito et al., 2010; Wilms et al., 2010). All related fields are core areas of cognitive science and our research questions are currently of high interest in the field (as partly reflected also by the invited symposium Joint Action).

## Suitability of the Organizers

Dr. Maria Staudte has a background in psycholinguistics and human-agent-interaction and has published in established journals and conferences such as Cognition, HRI, and the An-
nual Conference of the Cognitive Science Society. Her interests have focused on studying how humans use (each other's or an artificial agent's) eye-movements in order to ground references in a shared environment, to infer (referential) intentions, and to predict upcoming action. Ulrich Pfeiffer has a background in linguistics, psychology, and social neuroscience and studies the behavioral functions and neural correlates of gaze behavior in real-time social interactions using a combination of novel and innovative interactive eyetracking and neuro-imaging methods. He has published in established journals such as Frontiers in Psychology, Social Cognitive and Affective Neuroscience, and PLoS One and wrote a book chapter on eye-tracking methodology. He has further co-edited a Research Topic Issue in Frontiers in Neuroscience titled Towards a Neuroscience of Social Interaction.

## Target Audience \& Participants

The target audience of this workshop are researchers from all subfields of cognitive science that have an interest in the study of gaze behavior in interaction and communication. We expect a large audience of approximately 30-40 participants.

## (Invited/Keynote) Speakers

The following high-profile researchers have confirmed to give keynote lectures:

- Dr. Andrew Bayliss, University of East Anglia, on "Gaze cueing: The influence of observing averted gaze on attention and affective evaluations"
- Prof. Susan Brennan, SUNY Stony Brook, tbd
- Prof. Peter Mundy, University of California at Davis, on "The Interaction of Joint Attention and Communication: Cognitive and Neurocognitive Factors"
- Prof. Elizabeth Redcay, University of Maryland, on "Brain systems supporting joint attention behaviors in typical development and autism"

In addition to the keynote lectures, we solicit submissions of abstracts (around 350 words) related to the workshop topic from all areas of the cognitive sciences. We intend this workshop to last a full day of which four $50-\mathrm{min}$ slots would be dedicated to the keynote lectures. Besides an opening session, we expect to have six more $20-\mathrm{min}$ slots to be filled by speakers based on abstract selection.

## Publicizing and Documentation

We aim to make use of our large network of collaborators and colleagues in order to personally publicize this workshop and solicit submissions from specific individuals and labs. Further, we will use social media like Facebook as well as mailing lists such as AMLaP, LINGUIST or ESAN for general advertisement. We have no plans for documentation of the workshop outcome at this point since we truly view this event as a kick-off event that should help to start discussions, form synergies, and initiate new collaborations.

## Contact Information

Maria Staudte, Saarland University / SUNY Stony Brook, 100 Bleecker St, Apt 2f, New York City, 10012 NY. Email: masta@coli.uni-sb.de

# Using Complex Network Analysis in the Cognitive Sciences 

Nicole M. Beckage (Nicole.Beckage@ Colorado.edu)<br>University of Colorado, Boulder<br>Department of Psychology and Neuroscience, 345 UCB<br>Boulder, CO 80309 USA<br>Michael S. Vitevitch (mvitevit@ku.edu)<br>University of Kansas<br>Department of Psychology, 1415 Jayhawk Blvd<br>Lawrence, KS 66045 USA<br>Alexander Mehler (mehler@em.uni-frankfurt.de)<br>Goethe University, Frankfurt<br>Department of Computer Science and Mathematics, Robert-Mayer Straße 10<br>Frankfurt am Main, 60325 Germany<br>Eliana Colunga (Eliana.Colunga@Colorado.edu)<br>University of Colorado, Boulder<br>Department of Psychology and Neuroscience, 345 UCB<br>Boulder, CO 80309 USA

Keywords: Network analysis, graph theory, complex systems, network descriptives, R , language

## Objectives and Scope of the Tutorial

- Provide an elementary introduction to network analysis as a tool within cognitive science, using examples from the domain of language.
- Demonstrate how to import, manipulate, and analyze network data using the R programming language.
- Participants who complete the tutorial will be able to perform basic network analyses, and use this powerful suite of analyses to examine relational data in their own domains of research.

## Tutorial Delivery

The general format of the tutorial will be a half-day introduction to research in the field of complex network analysis followed by a more detailed study of a specific research project on language acquisition. In the course of the more detailed study participants will have an opportunity to perform some statistical and hypothesis testing on networks while learning interpretations and meaning of network analysis techniques.

We will begin by introducing a few research findings that are specific to network analysis. These include results showing that there are structural network differences that can be quantified and compared between groups as well as examples of conclusions that readily emerge from a networking framework that would otherwise be difficult to capture. These require a fundamental understanding of a variety of network descriptives that will be defined and applied to the research questions at hand. For example, in capturing and explaining structural network differences, we introduce the idea of clustering coefficients and geodesic distance. These network descriptives have become specifically relevant to the field, as they have given rise to
the idea of small-world structure, which has been shown to allow for efficient processing and navigation of information. From there we introduce the idea that network statistics change with the size and density of a graph. That brings up concepts of randomization and statistical tests. While these will be handled initially as definitions and concepts, the second part of the tutorial will include working through the analyses that were conducted to yield the research results. We will conclude the tutorial by allowing participants to design their own hypothesis tests and help with refining individualized research goals in light of network theory. If time and interest permits we will also consider process models of networks, inference on missing data and missing link information as well as network-based algorithms.

We will teach participants how to do basic network calculations with built-in functions of R as well as help develop an intuitive understanding of network models. At the end of the session we will also introduce the idea of network process models specifically looking at preferential attachment and page rank algorithms.

## Instructor experience with Network Analysis

Nicole Beckage is a graduate student majoring jointly in Cognitive Science and Computer Science at University of Colorado Boulder. Nicole has spent most of her course work and research focusing on network analysis and language acquisition. She has helped run network tutorials at the Institute of Social Network Analysis's annual conference and has taken many classes in a variety of disciplines with network theory as a main topic. Her research has utilized and designed novel network approaches and she has been invited to give network related talks at many workshops and conferences. The focus of the methodological tutorial will be motivated by the techniques of her paper entitled 'Small worlds and semantic network growth in typical and late talkers' published in PLOS One in 2011.

Michael Vitevitch is an Associate Professor in the Department of Psychology at the University of Kansas. Prof. Vitevitch combines the analytic tools of Network Science with conventional psycholinguistic tasks to better understand the processes and representations involved in spoken word recognition. His work in this area has appeared in several mainstream Psychology journals (e.g., Cognitive Science, Journal of Memory \& Language, Journal of Experimental Psychology: Human Perception \& Performance) as well as in journals that focus on the topics of chaotic, complex, and nonlinear systems (e.g., Entropy, and International Journal of Bifurcation and Chaos). In addition to organizing a satellite conference on the topic of "Language and Network Science" at the 2012 NetSci conference in Chicago, he has been invited to present his network research at a number of international workshops and conferences.
Alexander Mehler is professor for Computational Humanities at the Goethe University Frankfurt am Main, Germany, where he heads the Text technology Lab as part of the Department of Computer Science and Mathematics. He is a member of the executive committee of the LOEWE Priority Program "Digital Humanities" at Frankfurt University. His research interests include empirical analysis and simulative synthesis of discourse units in spoken and written communication. He aims at a quantitative theory of networking in linguistic systems to enable multi-agent simulations of life cycles. He integrates models of semantic spaces with simulation models of language evolution and topological models of network theory to capture the complexity of linguistic systems. He heads several research projects on the analysis of linguistic networks. His work has appeared in several journals in the area of computational linguistics, cognitive science and complex systems (Neural Networks, Journal of Quantitative Linguistics, Computer Speech and Language, Entropy, Applied Artificial Intelligence). In 2012, he organized a conference on Modeling Linguistic Networks based on which he will coedit the first (Springer) volume on linguistic networks in cognitive science and related disciplines.
Eliana Colunga is an Associate Professor in the Departments of Psychology and Neuroscience and Computer Science and a Fellow of the Institute of Cognitive Science at the University of Colorado Boulder. Prof. Colunga studies interactions between language and cognition using crosslinguistic, developmental and computational modeling methods. Her work on computational models of language development has been published in journals such as Psychological Review, Cognition, Developmental Science, and has been funded by the John Merck Fund and the Eunice Kennedy Shriver National Institute of Child Health \& Human Development of the National Institute of Health. She received her PhD in Computer Science and Cognitive Science from Indiana University and her MS in Artificial Intelligence and BS in Computer Science from the Instituto Tecnologico y de Estudios Superiores de Monterrey, Mexico.

## Why Network Analysis at Cognitive Science?

Over the last few decades the work on network analysis has been revived and expanded with new analytical, numerical and theoretical approaches. It has become a fundamental force within a variety of fields from physics, computer science and psychology to sociology and political science. The types of questions many cognitive scientists ask, such as studying the structure of language, studying group dynamics or neuronal dynamics, can be framed within a network perspective and we hope by building a team of researchers who work with network analysis as their main framework we can excite others in the field to utilize these techniques. Further, utilizing a tutorial structure will allow for us not only to explain our research findings but also give others the tools they need in order to begin answering their own questions within this framework. With this in mind, we expect the audience of this tutorial to be interested in learning about network analysis for any purpose.

## Likely Audience for the Tutorial

Because our expertise is mostly tied to language many participants may be interested specifically in language, but the application of this method extends beyond language. This tutorial is specifically useful for types of relational data. Though the material covered in this workshop will be relatively basic, we hope to give participants a flavor for the strength and power of network analysis techniques.

## Special Requirements for the Tutorial

The participants will be asked to bring laptops to the meeting as well as have R and a few select libraries (statnet, sna package and network package) installed. A .zip file will be available with other necessary files for the completion of the tutorial material. By working through past research findings, participants will receive an overview of basic network functions in R and have the opportunity to perform cognitively meaningful network data manipulation. We will also introduce visualization techniques of network data. We perform statistical tests to understand the structure present in the observed network compared to what might happen under different conditions. This requires calculations of network descriptives (e.g., centrality scores, graph-level indices); and use of classical network analytic techniques and network specific statistical tests.

No prior experience with R is necessary and attendees do not need to have a familiarity with the basic concepts of descriptive network analysis.

## Acknowledgments

This tutorial was made possible with generous help from Carter Butts at University of California, Irvine, Ryan Acton at University of Massachusetts Amherst and Lorien Jasney at the University of California, Davis who contributed previous tutorial materials for adaption.

# A General Purpose Architecture for Building Spiking Neuron Models of Biological Cognition 

Chris Eliasmith (celiasmith@uwaterloo.ca)<br>Terrence C. Stewart (tcstewar@uwaterloo.ca)<br>Center for Theoretical Neuroscience, University of Waterloo 200 University Ave West, Waterloo, ON, N2L 3G1, Canada

Keywords: SPAUN, cognitive modeling; neural engineering; representation; decision making; working memory; cognitive architecture; cognitive control; semantic pointers

## Tutorial Objectives

We have recently created the world's largest biologically realistic brain model that is capable of performing tasks (Eliasmith et al., 2012). This model uses 2.5 million spiking neurons, takes visual input from a $28 \times 28$ pixel visual field, and controls a physically modelled arm. By presenting different visual inputs, the model can perform eight different tasks, including memorizing and writing a list of numbers, single-digit addition via counting, and flexible pattern completion in the Raven's Matrices task. This tutorial is meant to introduce the software toolkit and theoretical background that would allow other researchers to build their own models using the same architecture, allowing them to explore other tasks and brain functions. This tool supports a novel cognitive architecture (SPA; the Semantic Pointer Architecture) that directly connects neuroscience with cognitive science.
Our previous tutorials have focused on the underlying theory of the Neural Engineering Framework (NEF; Eliasmith and Anderson, 2003), a general method for implementing high-level cognitive theories using biologically realistic spiking neurons. In this tutorial, our emphasis will be on building large-scale models with our open-source toolkit Nengo ([http://nengo.ca](http://nengo.ca)). The tutorial will be the first presentation of our Semantic Pointer Architecture, a Python module for Nengo which takes a high-level description of the desired cognitive system, including (basic) visual processing, motor control, working memory, associative memory, and cognitive control. The software takes this specification and creates a biologically realistic neural model, including various cortical areas, the basal ganglia, and the thalamus.

An example model using the SPA is shown in Figure 1. It is able to follow basic commands such as "WRITE TWO" and "REMEMBER THREE <long pause> WRITE NUMBER". When run in Nengo, this creates a model with 48,000 spiking neurons and produces predictions of spike patterns, firing rates, fMRI time-courses, accuracy, and reaction times. Complete details can be found in the book How to Build a Brain (Eliasmith, 2013).
Participants will leave the tutorial having interactively used a method for constructing cognitive models with spiking neurons, and experience using that method in an intuitive software environment.

```
class Rules:
    def read_action(category='ACTION'):
        set(action=vision*2)
    def read_object(category='OBJECT'):
        set(object=vision*2)
    def do_write(vision='DONE',
            phrase='ACTION*WRITE', scale=0.5):
        set(motor=phrase*'~OBJECT')
    def do_write_remembered(vision='DONE'
            phrase='ACTION*WRITE+OBJECT*NUMBER' ) :
        set(motor=memory)
    def do_remember(vision='DONE',
            phrase='ACTION*REMEMBER', scale=0.5):
        set(memory=phrase*'~OBJECT')
    class Parser(SPA):
    vision = Vision()
    category = Buffer(feedback=0)
    action = Buffer(feedback=0)
    object = Buffer(feedback=0)
    actionC = Cleanup(mutual_inhibit=0.5)
    objectC = Cleanup(mutual_inhibit=0.5)
    phrase = Buffer(feedback=0)
    motor = Motor()
    memory = Buffer(pstc_feedback=0.1)
    flow = Flow("""
        action->actionC
        object->objectC
        actionC*1.1->action
        objectc*1.1->object
        action*ACTION->phrase
        object*OBJECT->phrase
        vision.WRITE->category.ACTION
        vision.REMEMBER->category.ACTION
        vision.ONE->category.OBJECT
        vision.TWO->category.OBJECT
        vision.THREE->category.OBJECT
        vision.NUMBER->category.OBJECT
        """)
    BG=BasalGanglia(Rules())
    thal=Thalamus(BG)
```

## Tutorial Structure

This full-day tutorial starts with a quick overview of the theory behind the Neural Engineering Framework, showing how we can specify models by solving for the synaptic connection weights between groups of neurons that cause particular computations to be approximated. By specifying what each neural group represents and what computations should be computed between neural groups, large-scale neural models can be created. This is paired with many hands-on example of applying these concepts using the Nengo software. Neural groups and connections can be created using a drag-and-drop interface, or using the Python scripting interface. Participants are expected to bring a laptop to follow along with these tutorials (Windows, OS X, and Linux are all supported, and software is provided).

The first half of the tutorial covers the basic principles of the NEF and using Nengo. The second half introduces the concept of semantic pointers (vectors that combine the benefits of semantic similarity measures with the compositionality of symbol structures). We show how this method provides a unified approach to many types of cognitive models, including perceptual processing, symbolic reasoning, and motor control models. In particular, we show how these representations can be used to bind and manipulate symbol-like structures.

In this second half of the tutorial, we introduce our semantic pointer architecture and its implementation within Nengo. This provides a scripting language for building cognitive models, allowing researchers to create models of different brain areas and connect them together via the cognitive control of a cortex-basal ganglia-thalamus loop. This system is a general-purpose, biologically constrained, and neurally plausible cognitive architecture implemented using spiking neurons, and is the core foundation of our large-scale brain simulation.

Variants of this tutorial without the SPA cognitive architecture were presented at ICCM 2009, CogSci 2010, Telluride 2011, CogSci 2011, and CogSci 2012.

## Tutorial Justification

The Neural Engineering Framework provides a method to bridge the gap between cognitive and neural theories. It has been used to build special-case models of serial-order recall (Choo \& Eliasmith, 2010), action selection in the basal ganglia (Stewart, Choo, \& Eliasmith, 2010), the Wason card task (Eliasmith, 2005), the Tower of Hanoi task (Stewart \& Eliasmith, 2011), and inductive rule generation (Rasmussen \& Eliasmith, 2010).

By combining these models with a general method for cognitive control (the cortex-basal ganglia-thalamus loop), we have created the beginnings of a novel biologically realistic cognitive architecture. Our tools allow researchers to quickly create large-scale brain models that combine novel models of particular brain areas with existing models of many other areas. We believe this is a powerful new tool for understanding cognition.

Given that understanding the SPA cognitive architecture requires a basic understanding of the Neural Engineering Framework, we feel that a full-day tutorial is required. The NEF provides an exciting new tool for cognitive science, as it provides a technique for producing direct neural predictions from cognitive theory. It is also general enough that the same framework can be used for category learning, memory research, linguistic processing, vision, and motor control research. Furthermore, components from existing cognitive architectures (such as ACT-R) can be directly interfaced to these neural models.

## Audience

Participants are not expected to have any previous experience with neural modeling. All participants are encouraged to bring a laptop for installing Nengo (Linux, OS X, and Windows versions are provided), allowing for hands-on interactions with the models discussed.

## Presenters

Chris Eliasmith holds a Canada Research Chair in Theoretical Neuroscience, and is director of the Centre for Theoretical Neuroscience at the University of Waterloo. His recent book, How to Build a Brain, and his earlier book, Neural Engineering, form the basis for this tutorial.

Terry Stewart is a research associate in the Centre for Theoretical Neuroscience. He developed the SPA module and has used it to create a variety of cognitive models.

# Virtual Humans: A New Toolkit for Cognitive Science Research 

Jonathan Gratch (gratch@ict.usc.edu), Arno Hartholt (hartholt@ict.usc.edu), Morteza Dehghani (morteza@ict.usc.edu), Stacy Marsella (marsella@ict.usc.edu)<br>Institute for Creative Technologies, University of Southern California<br>12015 Waterfront Drive, Playa Vista, CA 90094, USA

Keywords: Virtual humans, embodied cognition, social cognition, virtual confederates

## Tutorial Objectives

Virtual humans (VHs) are digital anthropomorphic characters that exist within virtual worlds but are designed to perceive, understand and interact with real-world humans. Although typically conceived as practical tools to assist in a range of application (e.g., HCI, training and entertainment), the technology is gaining interest as a methodological tool for studying human cognition. VHs not only simulate the cognitive abilities of people, but also many of the embodied and social aspects of human behavior more traditionally studied in fields outside of cognitive science. By integrating multiple cognitive capabilities (e.g., language, gesture, emotion, and the control problems associated with navigating and interacting with a simulated virtual world) and requiring these processes to support real-time interactions with people, VHs create a unique and challenging environment within which to develop and validate cognitive theories. In this tutorial, we will review recent advances in VH technologies, demonstrate examples of use of VHs in cognitive science research and provide hands on training using our Virtual Human Toolkit (http://vhtoolkit.ict.usc.edu/).

## Virtual Humans and Cognitive Science

In helping to define the field of cognitive science, Herb Simon emphasized the importance of "understanding by simulating" (Simon 1969, 17-22). From the perspective of cognitive science, VHs provide the opportunity to understand the mind by simulating the body. Although still limited in their capabilities, VHs combine a rich set of capabilities for exploring how cognitive processes manage interactions with the physical and social world. In this sense, they complement recent interest in robotics as a tool for cognitive science, and address many of the limitations of physical robots.

Embodied Cognition: Embodied theories argue that the brain and body are tightly linked: the configuration and state of one's body profoundly influence cognitive processes and vice versa. For example, posture can impact how easily we are persuaded (Petty, et al. 1983); gestures and language are closely coupled, often grounded in shared metaphors (McNeill 2005); and facial expressions can influence our emotions (Niedenthal, et al., 2010). VH technology is increasingly used to unpack this relationship between mind and body (e.g., Sprague, et al., 2007) and in the tutorial we will review research in this growing area.

Social Cognition: People interact socially through their bodies and VHs allow researchers to systematically examine and model the cognitions underlying social interaction. VHs can act as "virtual confederates" (Blascovich et al., 2002), allowing systematic manipulation of visual appearance, speech type, and contextual graphical environments. This makes VHs a convenient platform to isolate unique sociocultural characteristics and realize them through simulation. Along with enhanced experimental control, ease of manipulations, consistency and controlled measurements, these features make VHs useful and reliable tools for studying social cognitions. In the tutorial, we will review several examples, including how expressions of emotion by VHs can influence decision making in negotiations tasks and social dilemmas (e.g. de Melo et al., 2012; Dehghani et al., 2012); the role of accent in cultural cognition (Dehghani et al., 2012) and the role of rapport and gender in enhancing participants' performance (Karacora et al., 2012).

## The Virtual Human Toolkit

The University of Southern California's Institute for Creative Technologies (ICT) is recognized as a leader in the development of VH technology (Gratch et al., 2002) and in applying this research to application domains including "virtual role players" for interpersonal-skills training (e.g., Campbell et al. 2011), informal science education (e.g. Swartout et al., 2010), intelligent tutoring, (e.g. Lane et al., 2011), and as "virtual confederates" to study cognitive and social processes (e.g. de Melo et al., 2012; Dehghani et al., 2012). One goal of the institute is to foster research in VH by making this technology freely available for research purposes through the Virtual Human Toolkit.

The research underlying the toolkit draws heavily on cognitive science research. For example, VH "brains" are inspired by psychological theories of human cognition (e.g. Swartout, Gratch et al., 2006), language (e.g. Traum, 2008) and emotion (Gratch \& Marsella, 2005), VH bodies are informed by knowledge of physiological and biomechanical processes (e.g. Honglun, et al. 2007; Thiebaux et al., 2008) and the relation between the VH's brain and body is informed by social psychology research (Lee \& Marsella, 2006, Wang et al, 2013). Translating these theories and findings into working software requires the integration of advanced capabilities from a number of domains of computer science research including machine perception, artificial intelligence, cognitive modeling, graphics and animation.

The complexity of creating a VH can appear daunting. Fortunately, considerable research has focused on the de-
velopment of modular, sharable software architectures to facilitate application development. The Virtual Human Toolkit is a general-purpose collection of integrated VH capabilities, including speech recognition, natural language processing, perception, and nonverbal behavior generation \& execution. The goal of the Virtual Human Toolkit is to make creating VHs easier and more accessible, and thus expand the realm of VH research as well as other research areas, including cognitive science.

In this tutorial, participants will have the opportunity to get hands-on experience with the Toolkit, with the intent to create a basic virtual confederate. In particular, participants will be able to select a character from a library; place the character in a scene; author a set of lines for the confederate to speak; manipulate its gestures and facial expression; and create a set of experimental stimuli that they can take home.

At the conclusion of the workshop participants should have gained a basic understanding of VHs and their capabilities, of how VHs can be of value in the field of cognitive science in the form of virtual confederates, and of how to utilize several aspects of the Virtual Human Toolkit.

## Audience

The likely audience for this tutorial consists of researchers looking to incorporate VHs in their work. This includes researchers in the fields of human computer interaction, education, social cognition, embodied cognition, language and dialogue among others. All participants are encouraged to bring a laptop for installing the Virtual Human Toolkit for hands-on interactions to build a virtual human.

## Presenters

The presenters combine over 40 years of experience researching virtual human technologies, developing virtual human applications for health and training, as well as using the technology as a methodological tool in the study of human behavior.

# Making Robust Classification Decisions: Constructing and Evaluating Fast and Frugal Trees (FFTs) 

Hansjörg Neth, Uwe Czienskowski, Lael J. Schooler<br>\{neth, sciencec, schooler\}@mpib-berlin.mpg.de<br>Center for Adaptive Behavior and Cognition<br>Max Planck Institute for Human Development, Berlin, Germany

Kevin Gluck<br>kevin.gluck@us.af.mil<br>Air Force Research Laboratory<br>Wright-Patterson AFB, OH, USA

#### Abstract

Fast and Frugal Trees (FFTs) are a quintessential family of simple heuristics that allow effective and efficient binary classification decisions and often perform remarkably well when compared to more complex methods. This half-day tutorial will familiarize participants with examples of FFTs and elucidate the theoretical link between FFTs and signal detection theory (SDT). A range of presentations, practical exercises and interactive tools will enable participants to construct and evaluate FFTs for different data sets.

Keywords: Fast and frugal trees; binary classifications; simple heuristics; signal detection theory; validity; robustness

## Motivation

Many real-world problems call for binary classification decisions. We may want to predict whether a partnership is promising, whether an investment is profitable, or whether a patient is in peril. Such classifications have important consequences, yet are typically made under time-pressure and uncertainty. Predictions of experts and laypeople in the real world require robust decision strategies that work swiftly and reliably on the basis of limited information.

Fast and Frugal Trees (FFTs) allow efficient and effective binary classification decisions by sequentially attending to a list of diagnostic cues (Martignon, Vitouch, Takezawa, \& Forster, 2003; Martignon, Katsikopoulos, \& Woike, 2008). FFTs are a special case of simple heuristics - simple decision processes that often perform remarkably well in comparison to more complex methods (Gigerenzer, Todd, \& the ABC research group, 1999; Gigerenzer, Hertwig, \& Pachur, 2011) - and have been linked with the theoretical framework for diagnostic classification decisions provided by signal detection theory (SDT, Luan, Schooler, \& Gigerenzer, 2011).

Figure 1 illustrates an example of a FFT that predicts whether an antibiotic prescription is indicated for some patients, particularly children. By checking only one or two cues physicians can identify patients at risk of being infected with a specific type of bacteria and prescribe an appropriate antibiotic treatment (Fischer et al., 2002). Beyond being both effective and efficient FFTs are useful by virtue of being robust (by being insensitive to perturbations due to noisy data and by providing reliable out-of-sample predictions) and communicable (e.g., they can easily be understood, learned

Figure 1: Example of a FFT that allows clinicians to prescribe treatment with macrolides (see Fischer et al., 2002).
and taught). FFTs have successfully been developed in a variety of applied domains, including medical, legal, and financial decision making (see Luan et al., 2011, for examples).

## Content, Structure, and Activities

This half-day tutorial builds upon the lectures and materials used in previous tutorials (e.g., at the International Conference on Cognitive Modeling, ICCM 2012) and workshops (e.g., at the Max Planck Research School on Adapting Behavior in a Fundamentally Uncertain World, 2012, and the ABC Summer Institute on Bounded Rationality, 2013). Through a combination of presentations and practical exercises participants will become familiar with the theoretical framework behind FFTs, contrast them with alternative classification algorithms, and learn to construct and evaluate FFTs for realworld data sets.

The half-day tutorial interleaves lecture-style presentations with practical exercises and will be structured as follows:

Theoretical background [45 min]: We briefly introduce the basic ideas behind the simple heuristics framework to explain when and why biased minds can make successful inferences. This illustrates how strategies with limited information search can yield robust classification decisions relative to computationally more complex models (Katsikopoulos,

Schooler, \& Hertwig, 2010). Theoretical notions reviewed in this part include the predictive validity of cues, speedaccuracy tradeoffs, the bias-variance dilemma, assessing classification outcomes via contingency tables (hits and correct rejections vs. false alarms and misses), as well as fundamental concepts of SDT (e.g., criterion shifts, bias $c$, the sensitivity index $d^{\prime}$, and the interpretation of ROC curves, Luan et al., 2011). The question How can we make effective and efficient classification decisions on the basis of limited and noisy data? will set the stage for the practical exercises.

Hands-on sessions [2 $\times 45 \mathrm{~min}]$ : Two practical parts will explore the consequences of specific cue and criterion choices. By using interactive software tools participants will acquire hands-on experience in constructing FFTs.

1. Spreadsheet-based FFTs: In a first practical part, participants will be guided through a series of exercises using a pre-designed MS Excel ${ }^{\mathrm{TM}}$ sheet. To facilitate the transfer from theoretical notions to applicable expertise we will examine the consequences of different cue choices, bias values, and criterion shifts on various measures of classification performance. After assessing a selection of minimal FFTs (with only one predictive cue) participants will re-construct a FFT that has been designed to help emergency-room doctors to rapidly decide whether to send a patient with severe chest pain to the coronary care unit (Green \& Mehr, 1997). Finally, particpants will explore alternative multi-cue FFTs and evaluate their performance on a variety of outcome measures.
2. Interactive software tool (FFT-builder): A second practical session will introduce a new version of FFT-builder an interactive software tool that allows rapid-prototyping, explorative learning and the visual inspection of outcome measures in the context of FFTs (see Figure 2). FFT-builder provides a range of features to create and manage environments, data sets, and corresponding FFTs. Numeric and visual analysis tools allow to quantify and compare the performance of different solutions to the same data or explore and inspect the consequences of applying FFTs to different data sets.

Validity and robustness [45 min]: In a final session we will cover two topics central to the theory and practical application of FFTs: their validity and their robustness. The point here is not to merely declare FFTs to be valid and robust, but rather to examine the evidence base and methodological options for addressing these important concerns. Results from cross-validation analyses and a formal quantification and methodological operationalization of robustness will supplement the conceptual discussion.

## Objectives

The goal of this tutorial is to provide participants with intellectual and software tools to tackle real-world classification problems. Upon completing the tutorial, participants will be familiar with theoretical criteria and practical skills for designing efficient, effective, and robust classification algorithms. By building and evaluating a variety of FFTs in an in-

Figure 2: Screenshot of the FFT-builder software tool.
teractive fashion, participants will be enabled and encouraged to apply FFTs to data sets in their own domain of expertise.

Psychological and Brain Sciences, Indiana University, Bloomington 47468 Indiana, USA.

Keywords: probability theory, Bayesian probability, quantum theory, decision making, probabilistic models.

## General Purpose

This tutorial introduces why and how to build cognitive models using quantum probability (QP) theory. In the tutorial, we will show that QP is inherently consistent with deeply rooted psychological conceptions and intuitions. It offers a fresh conceptual framework for explaining some puzzling empirical findings of cognition, and provides a rich new source of alternative formal tools, compared to classical probability ( CP ) theory, for cognitive modeling.
CP models, including Bayesian models, have had an enormous influence in cognitive science (e.g., Griffiths et al., 2010). Such formal models are appealing for many reasons. First, CP theory provides an integrated, coherent, self-consistent set of principles, which can be flexibly applied in any inductive inference situation. Second, such approaches are more falsifiable. Core principles of CP theory are inter-dependent, and identifying an empirical violation of one principle in a setting could invalidate the applicability of CP theory as a whole in that setting. Third, CP principles are intuitive. In the words of Laplace (1816, cited in Perfors et al., 2011), "probability theory is nothing but common sense reduced to calculation."
However, human cognition often goes against the description and prescription from CP theory. In one of the most influential empirical traditions in cognitive psychology, Kahneman, Tversky, and colleagues have reported persistent, clear violations of CP principles in decision making (e.g., Tversky \& Kahneman, 1974). For example, consider the famous conjunction fallacy. Participants are told of a person, Linda, looking very much like a feminist and unlike a bank teller. Then, they are asked to judge probabilities of some events. Violating CP rules, people think the probability that Linda is a bank teller and a feminist is higher than the probability that she is just a bank teller. According to CP theory, it is a fallacy to think $\mathrm{P}(\mathrm{A}$ and $B)>P(A)$. Importantly, even when we become aware of our "fallacy," we cannot shake off the impression that Linda is indeed more likely to be a bank teller and a feminist, than to be just a bank teller.
Important findings like this have led to intense and extensive controversy about the mechanisms which guide human cognition and decision making. The inspiration for
exploring QP theory in cognitive modeling partly arises as a way to resolve this controversy.

The physical theory of quantum mechanics is a marriage between a framework for how to assign probabilities to events and assumptions regarding the nature of the physical world. We can call the former QP theory (or just quantum theory). Can it be applied outside of physics? The motivation for doing so is twofold. First, QP theory is a highly rigorous framework for probabilistic inference. It has been developed over several decades by some of the most brilliant scientists of all time (e.g., Bohr, Dirac, von Neumann, Planck) and has been intensely scrutinized ever since. Thus, the application of QP theory in cognitive modeling has exactly the same formal advantages as that of CP theory. Second, quantum theory allows us to consider the possible relevance in cognitive modeling of several novel concepts. For example, in quantum theory, a cognitive system can be in a superposition state. This means that relative to a question or measurement, the system is in an indefinite state, with all definite states having potential to be expressed. This provides an intrinsic formal representation of the conflict, ambiguity, or uncertainty that people experience in cognitive processes. For another example: states can be entangled, which means a change in one part of the system inexorably and instantaneously affects another part. Entanglement is a form of extreme association, which can be helpful for formalizing important cognitive processes, such as holism, cognitive dissonance, and social projection.

Fundamental quantum conceptions, such as superposition, entanglement, interference, and complementarity, have no formal counterparts in cognitive theory. We are part of a growing group of researchers who have been intensely exploring their applicability in understanding human cognition. Quantum theory reveals alternative intuitions in probabilistic models of cognition. The quantum cognition research program aims to explore whether these alternative intuitions can explain paradoxical findings in decision, memory, and other areas of cognitive processing.

The tutorial introduce the basic principles of quantum theory, in the context of well-known empirical findings in psychological literature. The basic elements of QP theory will require only some knowledge of linear algebra. No background in physics or quantum theory is assumed. The tutorial will be self-contained. It will show how probability
computations can be carried out in quantum theory, how one can build quantum cognitive models, and what the nature of probabilistic intuition is in such models. The tutorial will be useful to all researchers interested in modeling cognition.

## Previous Tutorials and Symposia

Similar tutorials have been presented regularly at the CogSci meetings in Nashville (2007), Washington DC (2008), Amsterdam (2009), and Sapporo (2012), and the Society of Mathematical Psychology meeting (2012). Around $30-50$ participants attended each of the tutorials, with an increasing number of attendees over the years. We have been invited to present short workshops at various universities, such as University of Osnabruck, university of Cincinnati, and Cornell University. At the 2011 CogSci meeting, we co-organized a symposium covering recent progress in the quantum cognition research program. Other tutorials were organized for the annual meetings of Quantum Interaction (since 2009; about 40 participants).

## Presenters

The main presenters, Pothos and Wang, have both contributed extensively to the quantum cognition research program. They both have multiple publications on quantum cognitive models in psychological journals targeting a broad audience. Their presentation will be rigorous, clear, relevant, and accessible. Notably, Pothos has recently coauthored a Behavioral \& Brain Sciences target article, summarizing progress with the quantum cognition research program. Wang has co-edited a special issue of Topics in Cognitive Science that synthesizes current research on quantum cognitive models. Also, both Pothos and Wang have good experience with traditional cognitive models and are currently associate editors for the Frontiers in Cognitive Science journal. Finally, Busemeyer is one of the pioneers of the quantum cognition research programme and has extensive relevant publication and editorial experience.

## Material to be covered

The tutorial will be organized in two parts: (1) an introduction to the key concepts and mathematical modeling tools in QP theory; and (2) an overview of successful cognitive applications, with concrete examples of cognitive models and corresponding MATLAB codes.
In the first part, we will provide a working definition of QP theory. What is it? Why should it be relevant to a cognitive scientist? What are its main characteristics in comparison to CP theory? We will then introduce the basic elements of QP theory (state vector, Hilbert spaces, how to compute simple and conjunctive probabilities) using simple illustrative models of well-known decision and judgment fallacies. We will explain the differences in how probability is computed in the classical vs. quantum way and how these differences give rise to QP theory's unique properties (superposition, incompatibility, interference).

An important question we will address is: is it possible to achieve some sort of isomorphism between (limited cases of) QP and CP models and, if yes, at what price?

We will then introduce structured representations and the idea of entanglement, another unique feature in QP. Time evolution in quantum models will be compared with time evolution in classical models and we will discuss how interference effects can arise in the former, but not the latter, correspondingly leading to violations of the law of total probability, or not.

In second part, we will review successful applications of QP to explain puzzling empirical results in human cognition and decision. We will present some simple MATLAB code illustrating the implementation of QP models in example situations. Perhaps contrary to the common impression of being mysterious and difficult, quantum cognitive models are intuitive. They can be very simple as well, based mostly on linear algebra. We will focus on recent quantum cognition work on probabilistic judgment, measurement order effects, memory, and conceptual combination. What these areas have in common is that they all led to empirical insights which have been hard to reconcile with a CP perspective. Yet, as we will discuss, the unique properties of QP have enabled natural, compelling, and falsifiable accounts of these empirical results. Finally, the tutorial will outline directions for future research.

# Types and states: Mixture and hidden Markov modelling for the cognitive sciences 

Maarten Speekenbrink (m.speekenbrink @ucl.ac.uk)<br>Cognitive, Perceptual and Brain Sciences, University College London<br>Gower Street, London WC1E 6BT, United Kingdom<br>Ingmar Visser (i.visser@uva.nl)<br>Department of Developmental Psychology, University of Amsterdam<br>Weesperplein 4, 1018 XA Amsterdam, The Netherlands

Keywords: Mixture model, hidden Markov model, latent class analysis, categories, types, states, state transitions

## Objectives and scope

There are many situations in which one may encounter distinct types of entities, such as different animal species, and different states in which these entities may exist, for example motivational states like hunger. Cognition is sometimes also best understood in terms of discrete types and states. For example, aspects of cognitive development can be characterised as the acquisition of increasingly complex rules constituting different types of reasoning (Jansen, Raijmakers, \& Visser, 2007). And rather than a gradually shifting trade-off, people may switch rapidly between distinct decision-making modes favouring either speed or accuracy (Dutilh, Wagenmakers, Visser, \& van der Maas, 2011). The idea that cognitive processes are guided by qualitatively different strategies underlies a wide range of theories of word recognition, cognitive development, categorization, and decision making, to name but a few topics (for an overview, see e.g. Scheibehenne, Rieskamp, \& Wagenmakers, 2013).

As the identity of cognitive types and states is generally not directly observable, appropriate statistical techniques are required to identify them. This tutorial will focus on mixture models (MMs) and hidden Markov models (HMMs), which are the foundation of such techniques. In MMs, a type or state (e.g., a cognitive strategy) is formalized as a probability distribution over observables. Because a dataset may contain different types, the overall distribution is a mixture of such individual component distributions. As the component distributions need not be of the same parametric family (e.g., Gaussian distributions can be mixed with other distributions), MMs allow for considerable flexibility in the definition of types and states. HMMs are a natural extension of MMs, allowing switches between states over time, making them particularly useful when people can switch between cognitive strategies during a task. In addition to identifying the different states, HMMs allow one to also focus on the process underlying state transitions.

While MMs and HMMs are widely used in fields such as computational biology (e.g., for DNA sequence analysis) and machine learning (e.g., for speech recognition and text classification), their use in the analysis of cognition and behaviour is relatively rare. This is unfortunate, as MMs and HMMs are ideally suited to test and explore important theoretical ideas in
cognitive science. The objective of this tutorial is to provide researchers in cognitive science with an accessible introduction to MMs and HMMs and provide them with the necessary skills to apply them in their own research.

## Outline of the tutorial

The tutorial is divided into two parts. The first part introduces the theory behind MMs and HMMs. The second part will be more practical, using a number of examples to show (a) how to apply MMs and HMMs with user-friendly and freely available software, (b) how to interpret these models, and (c) how the models can reveal aspects in the data which remain hidden with more traditional analyses. The first part of the tutorial will be delivered as a classroom style lecture. The second part will use a more hands-on approach with practical computer-based examples and exercises. The audience is encouraged to bring a laptop; all necessary software and material will be made available in advance.

## Part I: Theory

Introduction to mixture models. This part will introduce the basic structure of MMs and the use of graphical and other techniques to determine whether MMs might be applicable.

Estimation. This part will provide an intuitive treatment of maximum likelihood estimation and introduce numerical optimization and Expectation-Maximization (EM), the two main methods for this type of estimation of MMs and HMMs. Practical issues such as starting values and local maxima will also be discussed.

Inference. This part will discuss methods for model selection and how to determine the number of components (i.e., types, or latent classes). We will also discuss methods to test parameters for significance and the use of posterior probabilities to determine the component to which a data point belongs.

Hidden Markov models. This part will introduce hidden Markov models as a direct extension of mixture models. We will then discuss how to generalize the previously discussed methods of estimation and inference to these models.

## Part II: Practice

Introduction to depmixS4 This part will introduce depmixS4 (Visser \& Speekenbrink, 2010), a flexible package
to estimate MMs and HMMs in the R environment for statistical computing ( R Development Core Team, 2010). The examples in the remainder of the tutorial will mainly use this package.

Examples of mixture models Examples will include the use of MMs to detect developmental stages in the liquid conservation task and the use of MMs to detect multiple learning strategies in a category learning task.

Examples of hidden Markov models Examples will include the use of HHMs to analyse speed-accuracy trade-offs and the use of HMMs to model response strategies in multiple cue learning.

Extensions This part will briefly discuss some extensions to basic MMs and HMMs, including the use of covariates to predict the identity of mixture components and states. We will also briefly discuss the use of Bayesian methods to estimate MMs and HMMs.

## About the organizers

The organizers are the developers of depmixS4 (Visser, Jansen, \& Speekenbrink, 2010), a popular R package to estimate mixture and hidden Markov models. They are also the authors of an upcoming book on this topic (commissioned by Springer for their "UseR" series) and a recent tutorial on hidden Markov models (Visser, 2011). The organizers have extensive experience in the application of MMs and HMMs to research in developmental and cognitive science (e.g., Speekenbrink, Lagnado, Wilkinson, Jahanshahi, \& Shanks, 2010; Visser et al., 2010). They can draw upon this experience to provide the audience with real examples and practical advice relevant to a cognitive science audience.

## Justification

Theories which propose the existence of distinct types and states are widespread in the cognitive sciences. Traditional statistical analysis, such as t-tests and ANOVAs, or not applicable to test such ideas. MMs have been successfully used to test "toolbox models" of cognition (e.g., Scheibehenne et al., 2013) and HMMs to test discrete strategy switches (e.g. Speekenbrink et al., 2010; Jansen et al., 2007). This tutorial will provide cognitive scientists with the intuitive understanding and practical knowledge of these models necessary to apply them to their own research.

## Intended audience

This tutorial will be mainly introductory and no specific prior background knowledge is required. While basic knowledge of probability and statistics will be helpful, treatment of the theoretical concepts will largely be conceptual. Familiarity with the $R$ environment will be helpful in general, but by making the commands and code available, previous experience is no requirement to follow and replicate the results of the practical examples.

## Requirements

Participants would ideally bring a laptop to the tutorial. The required software ( R and depmixS4) is open source and freely and easily obtainable. $R$ is available for all major platforms and can be downloaded from http://www.r-project.org. The depmixs4 package can be downloaded from http://cran.r-project.org/web/packages/depmixS4/ or installed from within $R$ through the command install.packages('depmixS4').

# Dynamic Field Theory: Conceptual Foundations and Applications in the Cognitive and Developmental Sciences 

John P. Spencer (john-spencer@uiowa.edu)<br>Department of Psychology and Delta Center, University of Iowa, Iowa City, IA USA<br>Gregor Schöner (gregor.schoener@rub.de) and Yulia Sandamirskaya (sandayci@rub.de) Institut für Neuroinformatik, Ruhr-Universität Bochum, Germany

## Objectives and scope

Dynamical Systems thinking has been influential in the way psychologists, cognitive scientists, and neuroscientists think about sensori-motor behavior and its development. The initial emphasis on motor behavior was expanded when the concept of dynamic activation fields provided access to embodied cognition. Dynamical Field Theory (DFT) offers a framework for thinking about representation-in-the-moment that is firmly grounded in both Dynamical Systems thinking and neurophysiology. Dynamic Neural Fields are formalizations of how neural populations represent the continuous dimensions that characterize perceptual features, movements, and cognitive decisions. Neural fields evolve dynamically under the influence of inputs as well as strong neuronal interaction, generating elementary forms of cognition through dynamical instabilities. The concepts of DFT establish links between brain and behavior, helping to define experimental paradigms in which behavioral signatures of specific neural mechanisms can be observed. These paradigms can be modeled with Dynamic Neural Fields, deriving testable predictions and providing quantitative accounts of behavior.

One obstacle for researchers wishing to use DFT has been that the mathematical and technical skills required to make these concepts operational are not part of the standard repertoire of cognitive scientists. The goal of this tutorial is, therefore, to provide the training and tools to overcome this obstacle.

We will provide a systematic introduction to the central concepts of DFT and their grounding in both Dynamical Systems concepts and neurophysiology. We will discuss the concrete mathematical implementation of these concepts in Dynamic Neural Field models, giving all needed background and providing participants with some hands-on experience using interactive simulators in MATLAB. We will review robotic implementations to make the ideas concrete. Finally, we will take participants through a number of selected, exemplary case studies in which the concepts and associated models have been used to ask questions about elementary forms of embodied cognition and their development.

The interactive simulators will be available at the tutorial. We will take participants through the process of building and simulating models. We will use online tools available now

## Target audience

No specific prior knowledge of the mathematics of dynamical systems models or neural networks is required as the mathematical and conceptual foundations will be provided during the tutorial. An interest in formal approaches to cognition is an advantage.

## Material covered in the course

1. Conceptual foundations of Dynamical Systems Thinking and Dynamical Field Theory (DFT): Embodied and situated cognition; Stability as a necessary property of embod-
ied cognitive processes; Distributions of population representation as the basis of spatially and temporally continuous neural representations;
2. Dynamical Systems and Dynamic Field Theory Tutorial: Concept of dynamical system; Attractors and stability; Input tracking; Detection, selection, and memory instabilities in discrete neuronal dynamics; Dynamical Fields and the basic instabilities: detection, selection, memory, boost-driven detection; Learning dynamics; Categorial vs. graded mode of operation; Practical implementation of DFT in simulators; Interactive simulation; Illustration of the ideas through robotic implementations;
3. Case study using DFT to understand embodied cognition and its development: visual and spatial working memory in children and adults; spatial precision hypothesis as a developmental mechanism in spatial recall, position discrimination, and change detection; mapping of DFT to functional neuroimaging with children.
4. Case study using DFT to understand brain-behavior relations in humans with functional neuroimaging: mapping of neural activation patterns in dynamic neural fields to the hemodynamic response measured with fMRI and fNIRS; case study on the neural processes that underlie visual working memory in children and adults.
5. Case study using DFT to understand how flexible action sequences can be generated: Dynamics of serial order and behavior organization; Coupling to real sensor and motor systems; Stability and flexible timing of actions in a sequence; Autonomy and executive control in neural and robotic systems.

## Lecturers

John P. Spencer is a Professor of Psychology at The University of Iowa and the founding Director of the Delta Center (Development and Learning from Theory to Application). He received a Sc.B. with Honors from Brown University in 1991 and a Ph.D. in Experimental Psychology from Indiana University in 1998. He is the recipient of the Irving J. Saltzman and the J.R. Kantor Graduate Awards from Indiana University. In 2003, he received the Early Research Contributions Award from the Society for Research in Child Development, and in 2006, he received the Robert L. Fantz Memorial Award from the American Psychological Foundation. His research examines the development of visuo-spatial cognition, spatial language, working memory, and attention, with an emphasis on dynamical systems and neural network models of cognition and action. He has had continuous funding from the National Institutes of Health and the National Science Foundation since 2001 and has been a fellow of the American Psychological Association since 2007. He will teach the tutorials on development and functional neuroimaging (numbers 3,4 below).

Gregor Schöner holds the Chair for Theory of Cognitive Systems and is the Director of the Institut für Neuroinformatik, Ruhr-Universität Bochum, Germany. Following his PhD in 1985 in theoretical physics at the University of Stuttgart, he held positions at the Center for Complex Systems of Florida Atlantic University, the Institut für Neuroinformatik, and the Center for Cognitive Neuroscience of the CNRS in Marseilles, France before returning to Bochum, Germany in 2001 to assume his current position. Dr. Schöner has received funding from different agencies in the US, Germany, France, and the European Union. He has published over to 200 scientific articles and chapters. Dr. Schöner is considered one of the world's experts on dynamic systems theory within the fields of Psychology and Cognitive Science, and is also a pioneer in the application of Dynamic Neural Fields to autonomous robotics. He will teach the conceptual and mathematical tutorials (numbers 1, 2 below).

Yulia Sandamirskaya is a Post-Doctoral researcher at the Institut für Neuroinformatik, Ruhr-Universität Bochum, Germany. She obtained her PhD (Dr.rer.nat.) in Physics for her work on embodied sequence generation within DFT. In her research, Dr. Sandamirskaya develops DNF models and robotic implementations of DNF architectures for sequence generation, behavior organization, and spatial language. Her work has been published in three journal articles, several conference proceedings, and a book chapter. Dr. Sandamirskaya will lecture on autonomy and sequence generation in DFT and present robotic implementations that demonstrate how concepts of DFT can lead to autonomous behavior in real environments (number 5 below).

## Schedule

1. Conceptual foundations of Dynamical Systems Thinking and Dynamical Field Theory (DFT): 30 minutes
2. Dynamical Systems and Dynamic Field Theory Tutorial: 90 minutes
3. Case studies using DFT to understand embodied cognition and its development: 60 minutes before and 60 minutes after the lunch break
4. Case study using DFT to understand brain-behavior relations 60 minutes
5. Case study using DFT to understand flexible action sequences 60 minutes

## Computer use

Participants who bring lab-tops with Matlab installed (student version is sufficient) will be able to follow demonstrations by actively working with the simulator during the lectures.

## Online resources

Publications, lecture material, and interactive simulators can be found at our DFT Summer School websites http://www.robotics-school.org and http://www.uiowa.edu/delta-center/research/dft

# How to Analyze Verbal Protocols 

Thora Tenbrink (t.tenbrink@bangor.ac.uk)<br>School of Linguistics and English Language<br>Room 331, 3rd floor New Arts, Bangor University, College Road, Bangor, Gwynedd<br>LL57 2DG, UK<br>Fon: +44 1248382263 ; Fax: +44 1248383267

Keywords: Think-aloud protocols; verbal data; cognitive processes; cognitive discourse analysis; linguistic structure; problem solving; complex cognition.

## Objectives and Scope

Cognitive science researchers are interested in a subject that is not directly accessible to observation: processes in the mind and brain, thoughts and thought processes. One way of addressing higher-level cognitive processes is to analyze verbal protocols produced along with cognitively complex tasks (Ericsson \& Simon, 1993), such as problem solving or decision making. Linguistic data of this kind can be seen as an external representation of some aspects of what is going on in the mind. In particular, think-aloud protocols and retrospective reports provide procedural information that complements other data, such as decision outcomes and behavioral performance results.

This tutorial explores the scope and limitations of verbal protocol analysis, and offers practical support for systematic analysis procedures. Language data can be analyzed with respect to content as well as structure. Conventionally, the focus of verbal protocol analysis lies on the content of verbal data, addressing those aspects (e.g., particular thought processes or strategies) that the speakers are themselves aware of (or 'heed', Ericsson \& Simon, 1993). The content-based inspection of verbal reports, particularly if carried out by experts in the problem domain and set against a substantial theoretical background (Krippendorff, 2004), often leads to well-founded specific hypotheses about the cognitive processes involved.

A detailed linguistic analysis can substantially support such content-based insights, but it can also offer further insights (e.g., Hölscher et al., 2011; Tenbrink et al., 2011; Tenbrink \& Seifert, 2011; Tenbrink \& Wiener, 2009). Research in cognitive linguistics, psychology, discourse analysis, and psycholinguistics indicates that patterns in language are systematically related to patterns of thought (e.g., Chafe, 1998). Drawing on these insights, one focus of the tutorial is to identify types of linguistic structure that point to specific cognitive processes. This is the main idea in the method of Cognitive Discourse Analysis (CODA) (Tenbrink, 2008; Tenbrink \& Gralla, 2009; Tenbrink, 2010).

Some aspects of language use reflect cognitive aspects that go beyond conscious reflection by individual speakers, and that are not necessarily directly observable in linguistic content. Speakers are typically unaware of the cognitive structures that are reflected in particular ways of framing a representation linguistically. Furthermore, they are not
consciously aware of the network of options (Tenbrink \& Freksa, 2009) that allows for a range of linguistic choices beside their own, which emerges more clearly by considering a larger data set collected under controlled circumstances. According to previous research in cognitive linguistics and discourse analysis (e.g., van Dijk, 2008), linguistic features such as the verbal representation of semantic domains reflected in ideational networks, specific choices of prepositions, lexical omissions and elaboration, conceptual perspectives revealed by language, presuppositions, hesitation and discourse markers, and many other linguistic features indicate certain conceptual circumstances; these are related to the current cognitive representations in ways that distinguish them from other options available in the network. In particular, the chosen linguistic options reflect what speakers perceive as sufficiently relevant to be verbalized, as well as the information status assigned to the diverse parts of the verbalization.

Besides building on established insights about the significance of particular linguistic choices, validating evidence for the relationship between patterns of language use and the associated cognitive processes can be gained by triangulation, i.e., the combination of linguistic analysis with other types of evidence such as memory or behavioral performance data, reaction times, eye movements, decision outcomes, or any other relevant data that can be collected in cognitively complex tasks.

## Format and organization

This tutorial is designed to cover a half day (three hours) and will be highly interactive. The tutorial will take the participants' current or intended projects as a starting point. It will be organized so as to cover the complete process of language data analysis (from initial ideas to evaluation of analysis results), including short presentations, discussion, and practical exercises where feasible. In particular, the following issues will be addressed:

Motivation: How (and to what extent) can language data serve as empirical resources to address research questions in cognitive science?

Data collection: What kinds of issues need to be considered in the light of actual research purposes?

CODA based analysis (main part): Systematic data annotation and interpretation informed by linguistic insights.

Triangulation: How can other types of empirical data complement the insights gained from language?

Participants who have already collected natural language data are encouraged to bring examples as handouts or on their computers. Furthermore they are encouraged to contribute a $10-\mathrm{min}$ talk related to one step of this process, and also to raise questions or issues to discuss for other steps. It is envisioned to prepare either a collection of papers or a collective paper, with authors interactively developing content based on combinations of their talks and the discussed issues.

## Target audience information

There is no prerequisite for taking this tutorial. It is open for researchers in cognitive science at any point in their career, ranging from graduate students to established experts.

Participants interested in a future publication are encouraged to submit a 300 -word abstract to propose a $10-$ minute presentation as part of the tutorial, and / or a critical issue to discuss.

## Tutor Information

Thora Tenbrink is a Lecturer in Cognitive Linguistics at Bangor University (Wales, UK), and a principal investigator in two projects in the Collaborative Research Center SFB/TR 8 Spatial Cognition (Bremen/Freiburg, Germany). Her main interest concerns complex cognitive processes and their representation in language. She is the author of "Space, Time, and the Use of Language" (Mouton de Gruyter, 2007), and co-editor of "Spatial Language and Dialogue" (Oxford University Press, 2009) and "Representing space in cognition: Interrelations of behavior, language, and formal models" (Oxford University Press, in press). Current research addresses cognitive strategies in various problem solving tasks, spatial communication in complex built environments, cognitive transformation processes, and inferences derived by problem solvers from situational clues, experience, and verbal and graphical information. See $\mathrm{http}: / / k n i r b . n e t$ for further information.

## Previous instantiations

This tutorial has previously been offered in various versions as listed below (see Tenbrink et al., 2012, for a report). The current version will focus on complex problem solving processes across all areas of cognitive science, tailored to the needs of its participants by establishing email contact in advance as far as possible.
"Understanding spatial thought through language use". Half-day tutorial at Spatial Cognition, August 31 September 03, 2012, Abbey Kloster Seeon, Germany.
"Understanding cognitive processes through language use". Half-day tutorial at ICCM 11th International Conference on Cognitive Modeling, April 12-15, 2012, Berlin, Germany.

Workshop "Language analysis in cognitive science". Cognitive Science Institute, University of Osnabrück (Germany), May 7-8, 2011.

Course "Language analysis in cognitive science" at the Cognitive Science Institute, University of Freiburg (Germany), summer semester 2009.

# Computational complexity analysis for cognitive scientists 

Iris van Rooij [contact person], Johan Kwisthout, Mark Blokpoel<br>Radboud University Nijmegen, Donders Institute for Brain, Cognition and Behaviour<br>Montessorilaan 3, 6525 HR Nijmegen, The Netherlands,<br>i.vanrooij@donders.ru.nl

Todd Wareham<br>Department of Computer Science, Memorial University of Newfoundland, St. John's, NL, Canada

Keywords: computational complexity theory, computational modeling, intractability, NP-hard, scalability, algorithms, fixedparameter tractability, approximation.

## Aims and Motivation

Many computational- or rational-level models of cognition postulate computations that appear to be computationally intractable (e.g., NP-hard or worse). Formally, this means that the postulated computations consume an exponential amount of time. Informally, this means that the postulated computations do not scale in any obvious way to explain how the modeled cognitive capacities can operate in the real world outside the lab. This problem of intractability is quite common in cognitive science. It is observed in practically all domains of cognition, including, for instance, perception, language, reasoning, categorization, decision-making, and motor planning. It is also not specific to any particular class of models, as it can arise for symbolic, connectionist, probabilistic (e.g. Bayesian), dynamical, logic-based, and even heuristic models of cognition.

How can cognitive scientists effectively deal with the intractability of their models? Several sophisticated and well-established concepts and techniques for computational complexity analysis have been developed in theoretical computer science over the last decades that can be directly utilized by cognitive scientists. Using these techniques cognitive scientists not only can assess whether or not a particular model is intractable, but also identify parameters of the model that are responsible for that intractability. As a result, these techniques can be used to generate hypotheses about how the models can be revised so as to make them computationally tractable, thereby improving the computational plausibility and scalability of the models. With this tutorial we aim to make these techniques for computational complexity analysis available for interested cognitive scientists.

[^2]computational complexity analysis, and (c) learn about the philosophical foundations of, and debate surrounding, the use of computational complexity theory for analyzing computational-level theories of cognition.

The tutorial will assume a basic level knowledge of cognitive psychology and an affinity with computational considerations.

## Morning session

In the morning session, participants will learn about the conceptual and mathematical foundations of computational complexity analysis in the context of cognitive modeling. The session will include a conceptual primer on several complexity-theoretic concepts (e.g., NP-hard, fixedparameter tractability) and techniques (e.g., polynomialtime and parameterized reduction). All these notions and techniques are also explained in: van Rooij, I. (2008). The tractable cognition thesis. Cognitive Science, 32, 939-984. Participants are kindly requested to read this paper prior to attending the tutorial. During the morning session, participants will have the opportunity to practice the described techniques via hands-on exercises (these can be done using paper and pencil). The lecturers will use an interactive style of instruction to help participants work through the exercises.

## Afternoon session

In the afternoon session, we will illustrate the broad applicability of the methodology. Wareham will guide participants through a detailed analysis of a model of analogy derivation based on Structure-Mapping Theory (van Rooij, Evans, Müller, Gedge, \& Wareham, 2008). Blokpoel will do the same for a Bayesian model of action understanding (Blokpoel, Kwisthout, van der Weide, \& van Rooij, 2010). Through interactive exercises, participants can see why both models are NP-hard and which parameters cause this intractability.

We then consider the important topic of approximation as an approach to dealing with intractability, with a focus on approximating Bayesian inferences. Kwisthout will present various notions of approximation and illustrate novel results on how constraining particular parameters of probability distributions may make approximation Bayesian strategies (like sampling or local search) successful. Our intent here is
to demonstrate that approximation is neither panacea nor a placebo when it comes to intractability (see also Kwisthout, Wareham, \& van Rooij, 2011; Kwisthout \& van Rooij, 2013).

We will close the tutorial with an interactive discussion session about questions, issues, objections and philosophical controversies regarding the demonstrated methodology (e.g., such as also covered by van Rooij, 2008; van Rooij, Wright, \& Wareham, 2012). Participants will be encouraged to bring in their own questions and points of discussion.

## Website and Materials

For more information about this tutorial, full details of the schedule and extra materials, please refer to our website: $\underline{\text { http://tcs.dcc.ru.nl/cogsci2013/. At the start of the tutorial, }}$ print-outs of the lecture notes will be made available to all participants in a tutorial booklet.

## A Current Trend in Cognitive Science

Joint action is an increasingly popular topic in Cognitive Science. This popularity reflects a recent theoretical trend of postulating, in one way or another, that human perception, action, and cognition are geared to enable successful coordination and communication with others. The speakers in the symposium will provide an overview of current progress in joint action research. Their contributions will address a wide range of phenomena ranging from tight temporal coordination to shared planning and discourse processes. Together, the contributions will illustrate that social constraints affect cognitive processing in a deeper sense than the more traditional notion of specific modules for social perception and social reasoning would suggest.

## Joint Action Shapes Processing in Dialogue Susan E. Brennan

Language processing is typically studied as comprehension or production, in solitary contexts. Studies of language use, on the other hand, often have pairs of people performing tasks together that require them to communicate, in which they fill the roles of speaker and addressee in rapid alternation or even simultaneously. Data from such studies have tended to take the form of transcribed dialogues from
which linguistic forms are coded. But a transcript is only an artifact of the processes that generated it. What are the effects of joint action on language processing, moment-bymoment, in dialogue? I will discuss several studies that illustrate how both global and local information have the potential to affect processing, and at what grains they do so. Global information may involve some degree of mentalizing about a partner and the partner's needs or intentions; this information is available at the start of the interaction (whether in detailed or quite rudimentary form) and may or may not be updated as the dialog unfolds. Local information includes verbal and nonverbal cues that emerge during the course of the interaction and that can be construed as evidence about the state of the task or the partner; such cues may be provided intentionally or instrumentally (as a byproduct of doing the task). Such cues can shape language processing in dialogue, whether implicitly (outside of awareness) or explicitly.

## The Reciprocity of Attention and Joint Action Daniel Richardson

Attention is shaped by joint action, and joint action is shaped by attention. When two participants have a discussion over an intercom, their gaze coordination is modulated by what they each believe the other can see and what they believe the other knows. But conversation is not required for coordination. We found that individuals looked
at photographs differently if they simply believed that another person sat elsewhere was looking at the same images. Joint activity does not always produces joint looking, however. Incorporating results from other labs, we can see that joint action can cause attention to converge or diverge depending on subtle aspects of the task, the rewards and the relationships between co-actors. So far, I have used visual attention as marker of perceptual and cognitive processing. But gaze, perhaps uniquely, has another function. The eyes take in information, but also interact with the social world. I will conclude with new experiments showing that gaze patterns are changed by looker's belief that they are being looked at. Gaze is not just a window onto the cognitive processes of joint action, but a tool used in its construction.

## Joint Action Coordination Michael Richardson

A fundamental feature of social behavior is face-to-face or co-present physical interaction. The success of such jointaction, whether measured in terms of social connection, goal achievement, or the ability of individuals to understand and predict the meaningful intentions and behaviors of others, is not only dependent on numerous neural-cognitive processes, but also on the physical and informational processes of perceptual-motor coordination. Understanding and modeling the dynamics of these coordination processes, including how they emerge and are maintained over time, as well as how differing stable states of coordination are activated, dissolved, and transformed is therefore imperative. Here I review research aimed at uncovering the dynamics of the perceptual-motor coordination that can emerge across a range of joint-action tasks and describe a dynamical modeling strategy for capturing such coordination. I further argue that as the enactment of a shared intention or task goal, the behavioral dynamics of perceptual-motor coordination not only lawfully express the physical, informational, and neural-cognitive relations that underlie successful joint-action, but also operate to control the behavioral intentions and action strategies adopted by social situated co-acting individuals.

## Coordination as Predictive and as Productive: Bootstraping from Low-Level Automaticity to Top-Top Interaction Andreas Roepstorff

An emerging body of research demonstrates how people, in direct interaction, become coupled along a number of dimensions: e.g., physiology, behavior, and semantics. However, once these methods are applied to more complex, goal-oriented settings, it seems that the patterns of coordination are not only synchrony and mimicry, but also more complex forms of complementarity such as in division of labor. This raises the issue of whether the same mechanisms may explain the simple and the more complex forms of coordination? I will explore the hypothesis that in a
predictive framework, the unfolding of more basic forms of coupling may support bootstraping into higher order coordination as shared perceptions, joint action and division of labor.

## Planning joint actions Natalie Sebanz

It has commonly been thought that to perform joint actions, individuals need to plan their actions around others'. However, recent evidence suggests that individuals not only plan actions around each other, but instead plan each others' actions. I will review studies showing that co-actors 1) form representations of and keep track of each other's tasks, 2) engage in motor simulation to predict the timing of each others' actions, and 3) form action plans that specify relations between their actions, thus enabling group-level action planning. These findings not only tell us about the cognitive mechanisms of joint action, but also challenge us to rethink the role of shared intentions in joint action.

Keywords: gesture, language evolution, children, nonhuman primates, homesigner, sign language

## Introduction

In humans, gestural communication is closely intertwined with language: adults perform a variety of manual gestures, head movements and body postures while they are talking, children use gestures before they start to speak, and highly conventionalized sign systems can even replace spoken language. Because of this role of gestures for human communication, theories of language evolution often propose a gestural origin of language. In searching for the evolutionary roots of language, a comparative approach is often used to investigate whether any precursors to human language are also present in our closest relatives, the great apes, because of our shared phylogenetic history. Therefore, the aim of this symposium is to present recent progress in the field of language evolution from both a developmental and comparative perspective and to discuss the question if and to what extent a comparison with nonhuman primates is suitable to shed light on possible scenarios of language evolution.

## Gestural Communication in Wild Chimpanzees (Cat Hobaiter)

The gestural communication of great apes has provoked considerable interest by demonstrating striking evidence for the flexible and intentional use of a large communicative repertoire, key aspects of human language. We have recently expanded the extensive work in captivity, with the
first systematic study of gesture in a wild ape. In this presentation I will describe the gesturing of free-ranging chimpanzees in the Budongo forest, Uganda. Here we find that chimpanzee gestures are used in intentional communication by individuals of all ages, across a wide range of contexts, including evolutionarily urgent ones. I will discuss possible explanations for the combination of gestures into sequences, including: a) persistence following failed communications, and b) the idea that young chimpanzees may employ sequences as a fail-safe strategy to explore and fine-tune a very large repertoire of available forms, down to a more specific repertoire in regular use. I will examine flexibility in gestural communication, considering: a) whether or not gestures have specific meaning, b) if this is consistent across signalers, and c) whether or not the extent of flexibility in gestural repertoire varies with factors such as social context.

## What Can Gestures of Nonhuman Primates Tell us About Language Evolution? (Katja Liebal) ${ }^{1}$

Theories of language evolution usually argue for a unimodal origin of language, either gestural or vocal. Many of them draw on comparative evidence of the communicative

[^3]abilities of our closest relatives, the nonhuman primates. In this presentation, we will summarize the results of a systematic review of the literature on gestural communication in nonhuman primates covering the past 40 years and compare it with the main findings of studies on facial and vocal communication. We demonstrate that research into vocal, gestural and facial behaviors has very different theoretical and methodological approaches and as a result, comparisons of communicative patterns across modalities are problematic. We suggest that a multimodal approach to primate communication is essential to understand the complexity of nonhuman primates' communicative systems and to identify phylogenetic precursors to human language as part of a multi-modal system.

## From Homesign to Sign Language: Creating Language in the Manual Modality (Susan Goldin-Meadow)

Imagine a child who has never seen or heard any language at all. Would such a child be able to invent a language on her own? Despite what one might guess, the answer to this question is "yes". I describe congenitally deaf children who cannot learn the spoken language that surrounds them, and have not yet been exposed to sign language, either by their hearing parents or their oral schools. Nevertheless the children use their hands to communicate-they gesture-and those gestures, called homesigns, take on many of the forms and functions of language. I first describe the properties of language that we find in homesign. I next consider properties of language that homesigners can and cannot develop by comparing their linguistic systems to those developed by deaf individuals in Nicaragua. Thirty years ago large numbers of homesigners were brought together for the first time and Nicaraguan Sign Language (NSL) was born; NSL continues to develop as new waves of children enter the community and learn to sign from older peers. I end by taking an experimental approach to when gesture does and does not take on linguistic properties. I examine hearing individuals asked not to speak and instead communicate using only their hands. Although these silent gesturers can create some properties of language on the spot, they do not create all of the properties that homesigners develop over time.

Keywords: rationality; bounded rationality; reasoning; probabilistic reasoning; deductive reasoning; decision making; heuristics

## Introduction

The nature and extent of human rationality is an issue of ongoing debate. In the last two decades, this debate has been enlivened by the development and application of new theoretical frameworks. These include Bayesian notions of adjusting and using uncertain beliefs in an inductive manner as well as deductive probability-based logics as normative guidelines against which to weigh human judgments and decisions; the notion of ecological rationality based on lean and frugal heuristics well adapted to the structure of the environment; the notion of meta-cognitive myopia according to which people are accurate and sensitive in the processing the information in a given sample of observations, but are blind and naive to the history and validity of the sampled data; and game theory.

## Virtual Agreement: A Rational Framework for Joint Action and Communication (Nick Chater)

Game theory typically models interactions between agents in terms of players that are rational at the level of the individual. But when people need to coordinate their behaviour, which arises in joint action and communication, a vicious circle arises. What is rational for each player depends on what the other does; but figuring out what the other will do is no easier than figure out what one should do oneself. I will describe an
approach which assumes that players can resolve this problem by a process of "virtual agreement" - that is, the players figure out what they would agree to do, if they could discuss or bargain. Where the answer is well-defined, the agreement can be reached "virtually", i.e., without any information being exchanged. Virtual agreement requires common aims and knowledge - and can fail when players mis-estimate this common ground. Interesting, the process of reaching agreement can, in some cases, be modeled by conventional game theory.

## Cognitive Myopia (Klaus Fiedler)

What I have come to call "meta-cognitive myopia" (MM), using a term once suggested by Robyn Dawes, is the phenomenon that people are pretty accurate in utilizing even large amounts of stimulus information, whereas they are naive and almost blind regarding the history and validity of the stimulus data. This uncritical reliance on the information given is the most conspicuous when the task context makes it crystal-clear that the stimulus data should not be trusted. In the introduction, MM is located within a broader framework of meta-cognition research, and several examples are provided to illustrate the phenomenon. The central message is laid out that MM offers an alternative account of many biases in judgment and decision making, which have been traditionally explained in terms of capacity constraints, limited reasoning ability, motivational forces, or severely biased environmental input. The explanatory power of the MM construct, and its theoretical potential to predict new findings, is
then demonstrated in a major review section with reference to five paradigms: inability to discard irrelevant information; utilization of selectively sampled information; conditional inference biases; sample-size neglect; and myopia for the impact of aggregation levels. The final discussion is concerned with the learning origins of MM and the question of why evolution did not equip Homo sapiens with more effective metacognitive tools. An analysis of the costs and benefits will reveal that MM may serve important adaptive functions, and that eliminating MM may have maladaptive effects. Nevertheless, in the context of many real decision problems, the costs and irrational consequences of MM cannot be denied. The final discussion therefore focuses on possible ways to avoid and alleviate MM and its irrational consequences.

## Less Is More: Simple Solutions for Complex Problems (Gerd Gigerenzer)

In worlds of known risks, probability theory can provide the optimal course of action. In uncertain worlds, however, simple heuristics can result in smart solutions by focusing only on a few cues and ignoring the rest. The heuristics in the "adaptive toolbox" are anchored in the mind and the environment. They are embodied in the sense that they can exploit capacities of the human mind (such as recognition memory), which allow judgments to be quick. They are anchored in the environment in the sense that they can exploit statistical or social structures (such as signal-to-noise ratio). The study of the ecological rationality of heuristics and the bias-variance dilemma provides a general account to understand why and when less can be more.

## New Paradigms and Old Insights: Integrated Theories of Reasoning and Dynamic Inference (Mike Oaksford)

The new paradigm in reasoning, based on the probability conditional and dual process theory, offers new insights into human rationality. However, as with any psychological theory, there are a range of algorithmic issues concerning representations and processes that the new paradigm must address. We argue that doing so may require integrating these new insights with old insights from previous theoretical frameworks. In particular, the cognitive system needs to build small-scale models of the world which elaborate on information given in the premises and which are interrogated in reasoning. The nature of these processes has consequences for the new paradigm. For example, elaborative processes mean that conditional reasoning is most often dynamic and nonmonotonic involving changes in the probability distributions over which inference is defined. We draw out these consequences and sketch an integrative theory for conditional inference.

## What Linda Did Next: Relations Between an Interpretative Approach to Reasoning and the Judgment and Decision Literature (Keith Stenning and Michiel van Lambalgen) ${ }^{1}$

Stenning and van Lambalgen (2008) proposed that multiple logics are necessary to model human cognition, prominently a nonmonotonic logic known as Logic Programming (LP), which provides a cognitive model of fast frugal automatic reasoning from large human knowledgebases, to interpretations of current input. Much of the data from supposedly classical logical reasoning tasks (e.g. conditional reasoning, syllogisms, Wason's Selection Task) is derived from mixtures of subjects many of whom have nonmonotonic understandings and goals. This talk will position this program of research with regard to the judgment and decision literature on heuristic reasoning as exemplified by the Heuristics and Biases (H\&B) program of Kahneman and Tversky and the ecological fast and frugal heuristics of Gigerenzer and the ABC Research Group (ABC).

A multiple logics approach shares concerns with the ecological heuristic reasoning of the ABC group: with multiple methods of reasoning; with "automatic" rather than reflective reasoning; and with contextualisation. We illustrate with the well known Linda problem. The problem gives a personality description of Linda appropriate to the beginning of a story, but then asks a question ("Which is more likely? That Linda is a bank teller, or Linda is a bank teller and an active feminist?") from probability theory. Although there have been disagreements between $\mathrm{H} \& \mathrm{~B}$ and ABC , they share the assumption that this task is interpreted as calling for extensional reasoning. Of course there is no doubt it is intended as such an exercise, or that it is educationally important that students learn to recognise it as such. But we suggest that most subjects initially regard this task as an intensional reasoning problem, as readily developed within LP. This proposal points to the neglect of theories of the rationality of intensional reasoning. We sketch how such a program might look, and draw out some consequences for theories of reasoning, judgment and decision, and for theories of rationality more generally.

Keywords: cognitive development; word learning; computational models; robotics; dynamic systems.

## Motivation

Traditional views of cognition, cognitive development, and word learning have viewed knowledge as divorced from processes of perceiving and acting. Linda Smith has championed a dynamic, mechanistic, and processoriented view of cognition and focused on questions of development. She has shown how knowledge is embedded in, distributed across, and inseparable from the processes of perceiving and acting in the world. In so doing, she has enabled a new understanding of the nature of cognition and of how new ways of thinking come to be. This Rumelhart symposium in her honor illustrates how this focus on developmental process changes the questions asked and our resulting understanding of cognition. The five speakers will examine the developmental process of word learning from different vantage points ranging from perceptual to social to cognitive, and spanning multiple periods from the first words to rapid vocabulary growth to the building of semantic networks.

## Smart Behaviors from Simple Processes

## Author: Larissa Samuelson

Abstract: The period between16-months and 3-years of age is one of rapid vocabulary growth and diversification. Children this age are often referred to as "amazing word
learners" as they seem to know the whole category to which a new word applies after hearing one exemplar named one time. This perspective leads to theories of development couched in terms of innate knowledge structures and complex hypothesis testing. In contrast, this paper will present a view of development as the accumulation of small moments of knowing based on the specifics of the here-andnow that accumulate over longer timescales via simple associative processes. Data will illustrate how children use multiple sources of information such as the statistics of their vocabulary, associations in language structure, consistent space, and the relative novelty or familiarity of stimuli to solve language problems in a moment. Dynamic Neural Field and Hebbian Recurrent Network models will then be used to show that although children's behaviors look amazing, the processes that underlie them are not.

## A Unified View of Early Word Learning: Linking social interaction to sensory-motor Dynamics in Child-Parent Interaction

## Author: Chen Yu with Daniel Yurovsky

Abstract: Many theories of early word learning begin with the uncertainty inherent to learning a word from its cooccurrence with a visual scene. However, the relevant visual scene for infant word learning is neither from the adult theorist's view nor the mature partner's view, but is rather from the learner's personal view. To understand the mechanistic nature of early word learning, this talk focuses on micro-level behaviors as they unfold in real time in the dynamically complex interactions of child-parent interactions. We found that when infants interacted with
objects in play with their parents, they created moments in which a single object was visually dominant. If parents named the object during these moments of bottom-up selectivity, later forced-choice tests showed that infants learned the name. The sensory-motor behaviors of infants and parents were analyzed to determine how their actions on the objects may have created these optimal visual moments for learning. By studying the quality of parent-child social interactions at the sensory-motor level, the research provides a mechanistic understanding of the developmental dependencies between sensory-motor processes, social behavior, and language learning.

## Body Posture and Constraints on Word Learning in Robots and Children

Author: Anthony Morse with Viridiana Benitez

Abstract: The starting point for many theories of word learning is the co-occurrence of the visual object being attended, and the spoken word, but in reality such crosssituational learning has many problems and is unreliable in ways that simply don't match the human data. For example, in a series of recent experiments Smith, Samuelson \& colleagues demonstrate that children around 2 years old can learn object names in their absence so long as they are typically observed in consistent locations. We hypothesize that body posture is orchestrating this learning. In ongoing work with Linda Smith, we took this hypothesis literally placing the body centrally and binding ongoing multimodal experience via the body posture as a way to control the humanoid robot iCub , not only to replicate this data but to further generate predictions subsequently confirmed in further child experiments. With iCub we go beyond isolated cognitive modeling, embodying our system in real sensory and motor data, in a real interaction mirroring closely the setup of the psychology experiments. Based in spreading activation and self-organization our model tests and explores the role that the body plays in embodied cognition leading to a wider set of experiments in language learning. Finally we explore the role of competing systems (body and language), and simple learned skills in producing an explosion of word learning in an artificial robot.

## Time Considered as a Helix of Precious Words: Modeling the Emergence and Interactions of Word Learning Biases

## Author: Eliana Colunga

Abstract: Early word learning may be supported by a developmental feedback loop: the kind of words a child learns early on support the generalization of attentional biases, which in turn guides subsequent word learning. In a series of neural network simulations and a longitudinal behavioral study with toddlers in the lab, we explore the interactions between words learned and word learning biases, and argue that it is this interaction that builds the individual developmental trajectories children follow. First, we look at the development of the shape bias for solids and how its emergence is accompanied by an attentional shift in novel noun generalizations for other solidities, in both networks and toddlers. Second, we look at how the
emergence of a shape bias for solids is related to a shift in rate of learning for different kinds of words - shape-based or material-based - in networks and toddlers. Third, we look at how these interactions follow different developmental patterns in typically developing children at risk for language disorders, so-called "late talkers". Finally, we discuss the implications of this approach in increasing our understanding of language disorders, as well as our ability to improve early diagnosis and the design of individualized intervention plans.

## Growing Semantic Networks in a Sea of Words

Authors: Thomas Hills with Nicole Beckage
Abstract: Children learn language from exposure to a sea of words. The structure of this sea can be quantified using semantic space models applied to corpora of child-directed speech, which identify potentially meaningful statistical signatures from the company that words keep-including contextual diversity and associative structure (à la Saussure). At the same time, the words children learn can be characterized using computational models of growing networks of semantic information, with the edges between words based on semantic information embedded in the corpora. Our research has aimed at developing a quantitative theoretical account of early word learning based on the structure of the learning environment and the words children know-which we call the associative structure of child-directed language-and using this to predict the structure and growth of children's semantic networks over time. We have used this approach to predict the order of early word learning, to detect differences in typical and late talkers, and to predict differences in child versus adultdirected speech.

## Motivation

The Annual Glushko Dissertation Prize in Cognitive Science was established in 2011 as a way to promote future growth in cognitive science, and encourage students to engage in interdisciplinary efforts to understand minds. The prize is jointly sponsored by the Cognitive Science Society and the Robert J. Glushko and Pamela Samuelson Foundation, and honors young researchers conducting ground breaking research in cognitive science. The immediate goal is to recognize outstanding efforts to bridge between the areas that impinge on cognitive science and create theories of general interest to the multiple fields concerned with scientifically understanding the nature of minds and intelligent systems. Encouraging junior researchers to engage in these enterprises is one of the best ways to assure a robust future for cognitive science. The overarching goal is to promote a unified cognitive science, consistent with the belief that understanding how minds work will require the synthesis of many different empirical methods, formal tools, and analytic theories.

This symposium showcases the PhD research projects of the 2013 winners of the Glushko Dissertation Prizes. 2013 marks the first year that a symposium has been formed to assemble and showcase Glushko Prize winners' research. The prize-winning projects involve research on linguistic compositionality, understanding pictorial narratives, learning object-to-name mappings from complex environments, spatial problem solving, and visual awareness. The recruited research methods include neuroimaging, computational modeling, formal linguistic modeling, corpus analysis, psychological experiments, and theoretical analysis. Taken as a whole, the research projects strongly reinforces the view that contemporary cognitive science research is highly diverse, rigorous, creative, and fertile.

## Simple Composition During Language Processing: An MEG Investigation

Douglas Knox Bemis - 2012 PhD from New York University
Keywords: language; minimal phrases; magnetoencephalography.
Abstract: Language derives its expressive power from the ability to combine simple elements into complex ideas. To date, however, the vast majority of neurolinguistic investigations into combinatorial language processing have focused not on this transition from simple to complex, but rather on manipulations of complexity itself or measuring neural activity related to expectation violation. In this talk, I will present a novel neurolinguistic paradigm designed to isolate brain activity related to simple compositional mechanisms by combining the fine spatio-temporal resolution of MEG with the processing of minimal adjective-noun phrases (e.g. "red boat"). First I will demonstrate the ability of this paradigm to identify neural correlates of basic combinatorial processes that underlie the comprehension of such phrases. Then, I will present several experiments that probe the scope of these core processes both within language - comparing comprehension to production - and beyond - investigating combinatorial processing within both the pictorial and mathematical domain.

## Structure, Meaning, and Constituency in Visual Narrative Comprehension

Neil Cohn - 2012 PhD from Tufts University Keywords: narrative; grammar; comics.
Abstract: Narrative has been formally studied for at least two millennia, dating back to the writings of Aristotle. Contemporary research on the structure and comprehension of narratives has examined the discourse of spoken language. However, visual narratives in the form of
sequential images have also been pervasive throughout history, from cave paintings to contemporary comic books and strips. Yet, compared with the study of discourse in verbal language, the study of sequential image comprehension has been relatively impoverished. Just what are the structures motivating visual narratives and how are they processed?

I will explore this question using experiments guided by an overall theory that sequential images at the narrative level are structured and processed analogously to sequences of words at the sentence level. The main idea is that a narrative "grammar" organizes the structure of sequential images in the visual language used in comics, similar to the way that syntax organizes words into coherent sentences. We focus here on two salient parts of this analogy. First, I will explore the idea that visual narrative comprehension involves a system of narrative structure and a system of semantic coherence that contribute to comprehension. This correspondence is akin to the interaction between syntax and semantics at the sentence level. Second, I explore the idea that narrative structure is a hierarchic system that organizes images into constituents, analogous to the phrase structures of syntax in sentences. I will conclude by discussing the overall implications for the analogy between narrative structure in sequential images and syntax in sentence.

## More Naturalistic Cross-situational Word Learning

George Kachergis - 2012 PhD from Indiana University Keywords: statistical learning; cross-situational learning; language acquisition.
Abstract: Language acquisition is a ubiquitous, challenging problem involving fundamental cognitive abilities of attention, learning, and memory. Previous research has found that people can use word-object co-occurrences from ambiguous situations to learn word meanings. A recent associative model can account for a wide variety of wordlearning results using competing biases for familiar pairings and for stimuli with uncertain associates (Kachergis, PhD thesis). However, most studies of cross-situational learning present an equal number of words and objects in each learning situation, which is likely unrealistic. Moreover, displaying an equal number of words and objects may encourage learners to use assumptions such as each word going with one object, which may simplify the problem. This paper (Kachergis \& Yu, 2013) presents several conditions in which the number of words and objects do not match: either additional objects appear at random, or objects appear sometimes without their intended words. These manipulations do generally hurt learning in comparison to balanced conditions, but people still learn a significant proportion of word-object pairings. The results are explored in terms of statistics of the training trials-including contextual diversity and context familiarity-and with the uncertainty- and familiarity-biased associative model. Parametric differences between conditions hint at hidden cognitive constructs.

## Spatial Routines: A Framework for Modeling Visual Problem-Solving

Andrew Lovett - 2012 PhD from Northwestern University
Keywords: cognitive modeling; qualitative representation; visual problem-solving.
Abstract: Visual problem-solving tasks are an effective tool for evaluating cognitive abilities and predicting future performance. For example, Raven's Progressive Matrices is an intelligence test in which participants compare sequences of images to solve for a missing image. To better understand these tasks and the abilities they evaluate, I developed Spatial Routines, a general computational framework for modeling visual problem-solving. The framework is based on three psychological claims: 1) When possible, people reason about space using qualitative representations (e.g., identifying that one object is right of another), rather than absolute quantitative values. 2) Spatial representations are hierarchical. A given image might be represented as object groups, individual objects, or the parts within each object. 3) Qualitative spatial representations can be compared via structure-mapping: aligning their relational structure to find the corresponding elements.

The models generate symbolic representations from sketched input. They manipulate and compare these representations to determine an answer. They are useful for evaluating theories of perception, comparing problemsolving strategies, and identifying sources of difficulty for test-takers. Because the models must construct their own representations, they can highlight difficulties in representation-building and abstraction not identified by other computational models.

Three task models were constructed: Raven's Progressive Matrices, geometric analogy, and the visual oddity task. All three models perform as well as human adults, and problems that are difficult for the models are also difficult for people. Furthermore, by ablating a model's ability to perform certain operations and examining the resulting error pattern, one can generate new hypotheses about human reasoning.

# Symposium <br> Communicative Intentions in the Mind/Brain 

Bruno G. Bara (bruno.bara@unito.it)<br>Center for Cognitive Science<br>University of Turin, Italy

Nick Chater ( Nick.Chater@wbs.ac.uk)<br>Warwick Business School, University of Warwick, UK

Michael Tomasello (tomasello@eva.mpg.de)<br>Max Planck Institute for Evolutionary Anthropology Leipzig, Germany

Rosemary Varley (rosemary.varley@ucl.ac.uk)<br>Division of Psychology and Language Sciences<br>University College London<br>London, UK

Keywords: communication; evolutionary psychology; neuropsychology; neuroscience.

The nature of intentions is a perpetual locus of interest for investigators of the human mind. Both occidental and oriental philosophical traditions treat intentions as the root of behavior; and many possible classifications have been offered in order to try to systematize the different types of intention. Moreover, recognition of intentions in others appears to be central to child development, and necessary for becoming a competent member of the society (Tomasello, 2008).

Recent work in the social neurosciences has focused, in particular, on social intentions, which may underpin the human predisposition toward joint, collaborative behavior. Communicative intentions are particularly central, yet have a puzzling recursive form (Bara, 2010). That is, given an actor's intention to convey a particular informational content, $C$, the actor must choose an act $A$, so that the partner will infer the actor's intention to communicate $C$. Yet the partner's inference itself depends on reconstructing that the actor would have chosen $A$, in order that the partner to infer the actor's intention to convey C (Grice, 1975).

The symposium on communicative intentions offers an analysis from a wide range of perspectives on these issues: evolution and development (Tomasello: Max Planck Institute for Evolutionary Anthropology in Leipzig, Germany), psychology and game theory (Chater: Warwick Business School, United Kingdom), neuropsychology (Varley: Division of Psychology and Language Science, University College London, United Kingdom), cognitive neuroscience (Bara: Center for Cognitive Science, Turin, Italy).

## Michael Tomasello: Communicating without Conventions

The evolutionary and developmental approach will provide a comparison between the gestural communication of human children and their nearest primate relatives, the great apes. This comparison reveals some of the cognitive and social-cognitive skills necessary for the human way of communicating that are present developmentally, and were probably present evolutionarily, before the emergence of conventional linguistic communication.

## Nick Chater: Virtual Bargaining as a Micro-Foundation for Communication and Joint Action

The psychological and game-theoretic approach outlines how a new theory of strategic social interaction, which extends the standard game theory of economics, can provide a rational theory of joint action; and how communication can be viewed as a special case of joint action, where both actor and partner must jointly infer the same content, $C$, given a mutually observed communicative act, $A$.

## Rosemary Varley: Communication without a Functioning Language System

Insights from neuropsychology and in particular, the relationship between language and communicative intentions, will be explored by examining the impact of severe aphasic language impairment on signaling communicative intentions and decoding the intentions of others. The evidence from acquired aphasia indicates considerable autonomy between language and communicative intentions in the established cognitive system (Willems, Benn, Hagoort, Toni \& Varley, 2011).

## Bruno Bara: The Intentionality Neural Network

The neuroscientific approach will describe a model of a dynamic intentionality network consisting of four brain regions, i.e. the right and left temporo-parietal junctions, the precuneus, and the anterior paracingulate cortex (Ciaramidaro et al., 2007). This model is based on a novel theoretical distinction among varieties of intention, which differ by the nature of an individual's pursued goal (private or social) and by the social interaction's temporal dimension (present or future). The intentionality network, which is independent from modality of expression, either linguistic or gestural (Enrici, Adenzato, Cappa, Bara \& Tettamanti, 2011), shows different activation patterns in relation to the nature of the intentions. The theoretical model of intention proposed contributes to enlarge our knowledge on the neurobiological bases of intention processing, in both healthy people and in people with impairments to the neurocognitive system that underlies intention recognition (Bara, Ciaramidaro, Walter \& Adenzato, 2011).

Bethany Ojalehto (bethany.ojalehto@gmail.com)<br>Douglas L. Medin (medin@northwestern.edu)<br>Department of Psychology, Northwestern University, USA

Since the cognitive revolution, a widely held assumption has been that-whereas content may vary across cultures-cognitive processes would be universal, especially those on the more basic levels. Even if scholars do not fully subscribe to this assumption, they often conceptualize, or tend to investigate, cognition as if it were universal (Henrich, Heine, \& Norenzayan, 2010). The insight that universality must not be presupposed but scrutinized is now gaining ground, and cognitive diversity has become one of the hot (and controversial) topics in the field (Norenzayan \& Heine, 2005). We argue that, for scrutinizing the cultural dimension of cognition, taking an anthropological perspective is invaluable, not only for the task itself, but for attenuating the home-field disadvantages that are inescapably linked to cross-cultural research (Medin, Bennis, \& Chandler, 2010).

In a recent debate on the role of anthropology in and for cognitive science, obstacles that may hamper rapprochement were discussed in detail (Bender, Beller, \& Medin, 2012). In this symposium, we intend to move a step forward and showcase efforts to overcome these obstacles. The contributions to this symposium pursue a problem-driven approach to tackle specific questions of shared interest. The symposium brings together scholars from different disciplinary backgrounds (including cognitive and evolutionary anthropology, psycholinguistics, and cognitive, developmental, and comparative psychology), who are among the leading scientists in their fields. Each of them has contributed considerably to our expanding knowledge on how culture and cognition interact (e.g., Beller \& Bender, 2008; Haun et al., 2011; Legare \& Souza, 2012; Majid, Boster, \& Bowerman, 2008; Medin \& Atran, 2004). They present current research on different domains, ranging from causal cognition on the physical world through semantic categorization of olfaction and mental state understanding to processes of cultural transmission and moral reasoning in the biological domain, thus shedding new light on a field in cognitive science, in which recent years have seen an upsurge of interest and controversial debates.

## Olfactory language and cognition

> Asifa Majid

It has long been claimed "humans are astonishingly bad at odor identification and naming" (Yeshurun \& Sobel, 2010). However, recent evidence suggests exquisite elaboration of
olfactory lexicons in Aslian languages spoken in the Malay Peninsula (Burenhult \& Majid, 2011; Wnuk \& Majid, 2012). I present new data from speakers of Jahai, showing that Aslian language speakers show more agreement and shorter reaction times when free naming odors than their Western (Dutch) counterparts. This data further demonstrates that some speakers can be astonishingly good at odor naming. Furthermore, the Jahai data challenges current accounts of olfactory language and cognition, which in turn has implications for the larger language-thought debate.

# Weighing up physical causes in Germany and Tonga: A cross-cultural study on causal cognition 

Sieghard Beller, Annelie Rothe, Gregory Kuhnmünch, \& Andrea Bender

When people determine which of the entities involved in a physical interaction is responsible for its outcome, they weigh the entities differently even if the interaction is symmetric. This effect depends on various factors and also varies cross-culturally (Bender \& Beller, 2011). However, our results differ from previous research. In a replication study with participants from Germany and Tonga we investigate whether this is due to differences in the presentation of stimuli (visual vs. verbal) or to differences in answer mode (explanations vs. ratings of responsibility), and we test hypotheses on which cultural and/or linguistic factors may account for the cultural differences.

## Mental perspective taking across species and cultures

Daniel Haun, Katja Liebal \& Juliane Kaminski

Any trait claimed to define a species, needs not only be derived in that species, i.e. unique amongst its close phylogenetic kin, but also widespread across that species. Hence only concerted comparisons across related species and human cultures wield the power to identify the skills that define the human species (e.g., Haun et al., 2006). In the last years, psychologists have claimed such definitive traits in the area of social cognitive abilities such as the ability to understand others' knowledge, desires and beliefs. Here we compare individuals' abilities to understand others' mental states at dif-
ferent levels of complexity across a selected set of human cultures as well as across all non-human great ape species. In a non-verbal competitive game, participants were challenged to predict a competitor's moves, based on his/her knowledge, beliefs and desires. While children of all three cultures predicted with similar proficiency what their competitor chose, the non-human apes succeeded only in interpreting their competitor knowledge state, but showed no evidence of interpreting beliefs and desires. This data is consistent with the claim that reasoning about others' beliefs and desires is cross-culturally common and derived in humans.

## Communities of values: Moral reasoning about human-plant interactions among Indigenous Ngöbe of Panama

Bethany Ojalehto \& Douglas L. Medin

Research on sacred values often asks participants to make tradeoffs between a sacred good (e.g. acres of forest) and an instrumental incentive. As the external decision-maker, the participant decides the outcome for an insentient entity. But how might the decision-making process change if the entity is thought to be mindful? In previous research, we found that Indigenous Ngöbe adults of Panama are sensitive to signs of plant and animal sentience and may consider them agents with moral standing. Drawing on research suggesting that mind perception is key to moral reasoning (Gray, Gray, \& Wegner, 2007), the current study investigated Ngöbe reasoning about human-plant sacred value conflicts (e.g., right to life for plants versus humans). We find that Ngöbe treat plants as moral subjects whose interests must be considered. However, Ngöbe reframed tradeoffs from cases of competing interests to cases of cooperative relationships, reasoning in terms of the need for balanced reciprocity. We propose that Ngöbe treat sacred values not as absolute, objective goods which are pitted against each other, but as relational goods seen from multiple points of view (both human and nonhuman) which ultimately converge in systems-level perspective. We discuss implications for research on sacred values and morality.

## Imitative Foundations of Cultural Learning

## Cristine H. Legare

Imitation is multifunctional; it is crucial not only for the transmission of instrumental skills but also for learning social conventions such as rituals and facilitating social interaction. Thus, although children are indeed instrumental imitators (Gergely, Bekkering, \& Király, 2002), high-fidelity imitation has recently been linked to quintessentially social concerns, including the acquisition of normative behavior and affiliative motivations (Kenward, Karlsson, \& Persson, 2011; Over \& Carpenter, 2012). Despite the fact that imitation is a pervasive feature of children's behavior, there does not yet exist an integrated theoretical account of how children use imitation flexibly as a tool for cultural learning. Little is known about the kinds of information children use to determine when an event provides an opportunity for learning instrumental skills versus cultural conventions. I propose
that the cognitive systems supporting instrumental and conventional learning are facilitated by the differential activation of an instrumental stance (i.e., rationale based on physical causation) and a ritual stance (i.e., rationale based on cultural convention). I will present data demonstrating that (a) conventional framing increases imitative fidelity and the detection of differences between the performances of two actors and (b) witnessing multiple actors perform an action sequence increases imitative fidelity. The ritual stance increases imitative fidelity, a process essential for understanding cultural learning.

Keywords: counterfactuals; pretense; causal reasoning

Symposium Moderator: Daphna Buchsbaum

## Motivation

Counterfactual thinking, where one envisions alternative possible events and their outcomes, is hypothesized to be one of the primary ways in which we reason about causal relationships (e.g., Pearl, 2000; Woodward, 2003). Recent computational and experimental work suggests that both adults and children may reason about causality in a manner consistent with probabilistic graphical models - coherent, complex representations of causal structure that allow distinctive kinds of inferences (e.g., Gopnik et al., 2004; Griffiths \& Tenenbaum, 2009). In particular, the causal models approach supports and distinguishes two types of inferences, predictions, on the one hand, and interventions, including counterfactual interventions, on the other. In predictions, we take what we think is true now as a premise and then use the model to calculate what else will be true. In counterfactuals, we take some value of the model that we currently think is not true as a premise, and calculate what would follow if it were.

Intuitively, childhood pretense bears a striking resemblance to counterfactual inference, but this relationship has not been widely explored. In general, pretend play seems paradoxical. Why should children spend so much time thinking about unreal worlds? Moreover, why would counterfactual inference itself be useful, since it is also about things that are not real? In this symposium we will explore the ways in which pretense and counterfactual thinking might be related (Buchsbaum, Walker \& Gopnik; Rafetseder \& Perner), the types of computations that might underly both kinds of thought (Lucas \& Kemp; Chater) and the ways in which both
might contribute to our causal understanding of the world, even without exposing us to new data (Chater; Danks).
Children's complex causal reasoning in pretend play
Authors: Daphna Buchsbaum, Caren M. Walker \& Alison Gopnik In causal counterfactuals and in causal interventions we take some value of a causal model that we currently think is not true as a premise, and calculate what would follow if it were. We propose that these crucially important abilities - creating possible causal interventions and testing alternative causal hypotheses - depend on the same cognitive machinery that children use when they pretend: adopting a premise that is currently not true, creating an event sequence that follows from that premise, and quarantining the result of this process from reality.

Empirical results with preschool children support these ideas. Buchsbaum, Bridgers, Weisberg, and Gopnik (2012) found a significant and specific relationship between counterfactual inference and pretense in a causal task. In a new study, we gave children a complex causal structure involving four different variables (e.g. the sun comes up, which makes the rooster crow and the birds chirp, and the rooster crowing wakes up the farmer). Children's counterfactual inferences about this complex structure paralleled their inferences about pretense and both were significantly accurate. Interestingly, children were more likely to make "backtracking" counterfactual inferences when explicitly asked to reason counterfactually. In contrast, they were significantly more likely to treat the "fixed" variable as an intervention ("non-backtracking") when asked to pretend its value.

## Representations, counterfactuals, and pretense

Author: Nick Chater Cognitive science views thought as computation. Computations are often conceived of as functions between input and output. But it may be more produc-
tive to explore the standard mantra from computer science, that a computer program consists of an algorithm operating over a data structure (see Chater \& Oaksford, in press; and related work by Pearl, 2000). The behaviour of the algorithm is well-defined even if there are interventions into the contents of the data structure, during the computation (if, for example, the contents of the Turing machine tape, or a register in a pocket calculator, are modified, the algorithm will react in a well-defined way). Thus, a computer program can be viewed as defining a rich set of counterfactuals over possible modifications to the data structure, as the computation unfolds.

It turns out that this point of view provides a natural analysis of what it means for information to be represented: that which is represented can be modified by an intervention on the data structure. From this perspective, human counterfactual thinking and pretend play may have a common basis: they may be different sources of evidence concerning the flexibility with which the cognitive system is able to modify its own data structures, to reason about how the world might have been (e.g., modifying the representation of the past and tracing the consequences), or how it might differently be conceived (in children's play acting, modifying a representation of a banana to be a representation of phone).

## Counterfactuals, causal learning, simulation, and pretense

Author: David Danks Causal structures provide information not just about what actually did occur, but about what would have occurred in various alternative scenarios. Counterfactuals are thus a key - in fact, necessary - guide for learning causal structures. Any method for learning about causal structures in the world must employ counterfactuals, whether explicitly or implicitly. The standard ways to judge counterfactuals for causal learning are through the use of interventions, or by focusing on "similar" (in relevant ways) cases. In many situations, however, these methods are too risky, too expensive, or infeasible for any number of other reasons. We must instead find other ways to judge counterfactuals.

Simulations based on one's present, uncertain causal beliefs provide a natural method for discovering surprising implications and incoherence in one's causal beliefs. We can use what we currently think about some causal structure to consider alternative possibilities, and thereby learn about our own (implicit) expectations and beliefs. Entirely mental simulation of causal relations is a challenging task, however, even for adults who have received training in it. One way to simplify the task is to ground the simulations in external, physical events that are analogous (in appropriate ways) to the underlying causal structure. That is, pretense and pretend play can help us learn about causal structures in the real world.

## A unified theory of counterfactual reasoning

Authors: Christopher G. Lucas \& Charles Kemp Bayesian networks have been used to account for many aspects of causal reasoning, including inferences about coun-
terfactual scenarios. We present a Bayes net model of counterfactual reasoning that generalizes and extends the work of Pearl (2000). The model distinguishes between counterfactual observations and counterfactual interventions, and can reason about both backtracking and non-backtracking counterfactuals. Several experiments demonstrate that our model accounts better for human inferences than Pearl's original proposal and a more recent Bayes net account developed by Rips (2009).

## Counterfactual reasoning vs reasoning counter-to-fact

Authors: Eva Rafetseder \& Josef Perner Pretense has some affinity with counterfactual reasoning. It typically contains a counterfactual supposition that something (a prop) is something other than what it really is, and like reasoning, it proceeds to further suppositions in a constrained, nonarbitrary way. Rafetseder, Cristi-Vargas, and Perner (2010) have distinguished counterfactual reasoning from hypothetical reasoning counter to fact. Reasoning counter to fact makes suppositions that may contradict known facts and then uses known regularities to draw further inferences. Counterfactual reasoning is more constrained; it has to adhere to the nearest possible world constraint, i.e., the reasoning from the counterfactual assumption has to stay as close as possible to what actually happened. Conformity to this constraint develops rather late around 6 to 12 years. In hypothetical reasoning typical regularities (e.g., If [whenever] somebody takes shoes off floors tend to be clean) are applied to counterfactual questions (e.g., If Carol had taken her shoes off, would the floor be dirty or clean?) without regard to what actually happened (e.g., that Max had also been walking across the floor with dirty shoes). The importance of this distinction for pretense is that the affinity of pretense to counterfactuality is limited to reasoning with premises counter to fact.

## General Background

The problem of how humans and other intelligent systems construct causal representations from non-causal perceptual evidence has occupied scholars in cognitive science since many decades. Most contemporary approaches agree with David Hume that patterns of covariation between two events of interest are the critical input to the causal induction engine, irrespective of whether this induction is believed to be grounded in the formation of associations (Shanks \& Dickinson, 1987), rule-based evaluation (White, 2003), appraisal of causal powers (Cheng, 1997), or construction of Bayesian Causal Networks (Pearl, 2000). Recent research, however, has repeatedly demonstrated that an exclusive focus on covariation while neglecting contiguity (another of Hume's cues) results in ecologically invalid models of causal inference. Temporal spacing, order, variability, predictability, and patterning all have profound influence on the type of causal representation that is constructed (Greville \& Buehner, 2010; Young \& Cole, 2012).

The influence of time upon causal representations could be seen as a bottom-up constraint (though current bottom-up models cannot account for the full spectrum of effects). However, causal representations in turn also constrain the perception of time: Put simply, two causally related events appear closer in subjective time than two (equidistant) unrelated events. This reversal of Hume's conjecture, referred to as Causal Binding (Buehner, 2012) is a top-down constraint, and suggests that our representations of time and causality are mutually influencing one another. At present, the theoretical implications of this phenomenon are not yet fully understood. Some accounts (e.g. Haggard, Clark, \& Kalogeras, 2002) link it exclusively to human motor planning (appealing to mechanisms of cross-modal temporal
adaptation, or forward learning models of motor control), while others adopt a broader perspective in line with models of Bayesian Evidence Integration (e.g. Buehner, 2012).

Causal beliefs influence not only time perception, but also judgments of temporal order, event segmentation, and phenomena related to multi-sensory integration. This symposium brings together researchers from various disciplines and backgrounds who all explore the interrelations between time, causality and perception, and do so applying learning theory, Bayesian approaches, physiological considerations, and high-level theories of cognition.

## Participant Abstracts

## Temporal Binding: Causality, Intentionality, or Both? (Buehner)

Since the first demonstration of temporal binding between actions and their consequences (Haggard et al., 2002) more than ten years ago, various theories have been put forward to account for it, ranging from modifications of an internal clock to sensory-specific re-adaptation. The common denominator across all demonstrations of the effect appears to be causality: binding in time and space occurs when there is a causal relation linking an action and its effect. I will discuss evidence of temporal binding in the complete absence of motor action. These results are at variance with theories based on sensuo-motor realignment and thus rule out intentionality as the basis for the effect. Instead, they can be accommodated by a Bayesian Framework of event perception. Intentionality could be included in this framework as an additional predictor.

## Constructing Time and Cause (Lagnado \& Bechlivanidis)

The notions of time and causality are intimately linked. Previous research shows that temporal information provides critical cues for causal inference (Greville \& Buehner, 2010; Lagnado \& Sloman, 2006) and that causal beliefs modulate judgments of temporal duration (Buehner, 2012). Using a novel experimental paradigm, where participants actively engage with a software-based 'physics world', we show both that temporal order guides causal judgments, and that causal judgments can themselves determine perceptions of temporal order. These findings highlight the constructive nature of causal and temporal perceptions.

## Asymmetries in Processing and Recalibration of Visuo-Motor Time Perception (Ernst \& Rohde)

If a voluntary movement event (e.g., a button press) and a sensory event (e.g., a visual flash) belong together, the button press has to happen before the flash, as a cause always comes before its effect. We investigated in a series of experiments whether this causal asymmetry also leads to a perceptual asymmetry in the perceived timing of visual and motor events. Participants had to judge the temporal order and the temporal interval of a visual flash and a button press after being trained to vision-lead and movement-lead temporal discrepancies. To be able to present visual stimuli both before and after motor events, we tracked participants' finger movement in real time and predicted the moment of a button press to time a visual flash with respect to this estimate. While the perception of temporal order is recalibrated symmetrically around the point of actual simultaneity, there are strong asymmetries in the recalibration of interval perception, which is mostly confined to the movement-lead side of the range of discrepancies. In a second study, participants had to rate simultaneity and action authorship, where again asymmetries around the point of actual simultaneity were observed. The temporal order of cause and effect thus has profound influences on human time perception of visual and voluntary motor events.

## Causal choice in the face of environmental complexity (Young)

Prior research on causal judgment and choice has focused on situations in which the events either lack temporal extent, only one candidate cause and effect are being judged, or events are presented as a series of discrete trials. All of these approaches help to manage the complexity of the interaction being judged, and evidence suggests that people engage in forward inference under these simplified conditions. I will discuss evidence from Video-game based research that suggests that greater environmental complexity appears to produce backward, rather than forward, inference.

Keywords: Decision Making, Sequential Sampling Models, Evidence Accumulation, Attention Shifts, Cognitive Modeling

Sequential sampling models have been applied for describing the cognitive processes underlying various psychological processes such as memory, perception, or value-based decision making. They share the common assuming that people accumulate information stochastically over time and once the accumulated information passes a decision boundary a response is made. Depending on the cognitive domain the models differ in the specific nature of the accumulation process. In particular, they differ in their assumption about what type of information is processed, how the information is represented, and how the boundary is defined.
In this symposium we will illustrate how sequential sampling models successfully explain human behavior for various cognitive domains. For the decision making domain we show how people construct their preferences by accumulating options' attributes values over time once a decision threshold is reached. For the perceptual domain we show how gradual accumulation of sensory evidence over time explains people's perceptual decisions. Furthermore, we illustrate that sequential sampling models do not only predict the final outcome of a cognitive process but also present a description of the cognitive process itself. As such the symposium will illustrate how the analyses of response time distributions provide evidence for the dynamic accumulation process. Furthermore, the neurological basis of the dynamic accumulation process has recently also been explored. In sum, the symposium will illustrate the strength of sequential sampling model as a unifying framework for explain human cognition and behavior across many domains.

## Accumulation of Information with Attention Shifting Across Attributes Adele Diederich* \& Jerome Busemeyer*

Most applications of sequential sampling (diffusion) models to decision making assume that information is sampled from a constant or stationary, albeit noisy, source of information during the accumulation period leading up to a decision. Formally, these models usually employ a constant mean drift rate throughout the accumulation process leading up to a decision. However, many cognitive and decision tasks provide conflicting attributes that could compete for selective attention to guide the accumulation process while making a decision. For example, when choosing a consumer product, a person needs to shift attention between quality and cost; when a security agent scans a bag, the person needs to shift attention to different objects in the bag; when making a social choice, a person can attend to either implicit attitude feelings or explicit rational arguments.

Diederich (1997) developed a multiple stage diffusion model that represents this attention shifting as a Markov process that changes the drift rate across stages of the decision. This work describes the multiple stage model and reviews five major applications which compared the multiple stage model to stationary models with respect to their ability to account for perceptual decisions involving conflicting attributes. This includes behavioral studies modeling choice and response time as well as electrophysiological studies that used the model to account for the trajectory of neural activation during evidence accumulation. Based on this body of evidence, we conclude that there is substantial empirical support for an attention shifting process during multi-attribute decision making.

## A Two-Phase Theory of Choice Conflict Tasks

## Andrew Heathcote* \& Kirsty Hannah

We propose a theory of how decision processes are affected by response conflict. The theory is developed to account for the fine-grained time course of both response speed and accuracy as quantified by delta functions and conditional accuracy functions. The theory, Two-Phase Evidence Accumulation (TPEA), extends Brown and Heathcote’s (2008) Linear Ballistic Accumulator (LBA) model to provide a unified account of three tasks that have been central to the study of cognitive interference the Stroop, Simon and Flanker tasks. The theory is explicated by demonstrating that it provides a coherent parametric account of Stroop and Simon effect delta functions shown by Pratte, Rouder, Morey and Feng (2010) to be incompatible with existing theories. We then show that, without modification, TPEA is also able to account for White, Ratcliff and Starns' (2011) flanker data.

## The Attentional Drift-Diffusion-Model: Eye-tracking and Neurobiological Evidence

## Antonio Rangel*

We propose a computational model of value-based binary choice in which fixations guide the comparison process. The model is an extension of the classic Drift-Diffusion-Model to an environment in which attention matters. We provide eye-tracking evidence showing that the model can quantitatively explain complex relationships between fixation patterns and choices, as well as several fixationdriven decision biases. We also provide fMRI evidence showing that key elements of the model are consistent with the operations of the decision-making circuitry at the time of choice.

## Decision Making With Non-stationary Evidence, Adaptation and Decision-Confidence

## Marius Usher*

The integration of evidence supporting different choice options is a fundamental process underlying all of our decisions, ranging from the simplest perceptual decisions (e.g., detect the presence of an enemy-rocket signal embedded in a noisy radar stream) to complex economic ones (e.g., which apartment to buy). A limitation of most studies that examined evidence-integration, however, is that they focussed on situations in which the evidence is stationary. I will present recent computational and experimental studies that examines decision-making under non-stationary evidence, characterized by temporal uncertainty: Observers detected visual luminance "signals" embedded within longer streams of "noise" with signals varying in duration and occurring at different onset latencies. Using a computational model, we showed that optimizing performance under such conditions, requires a leaky ("forgetful") integration process, the time-scale of
which is matched to the expected signal duration. In subsequent psychophysical experiments, we tested whether human observers can indeed control their integration-time scale, such as to flexibly adapt it to the characteristic signal duration. The results provide strong support for this idea. Finally, I will discuss how the evidence-integration framework can account for data that requires the observers to report their decision-confidence.

## Comparing Perceptual and Preferential Decision Making

Gilles Dutilh \& Jörg Rieskamp*
What are the differences between perceptual and preferential decisions? In a perceptual decision the decision maker aims for a correct decision and there is an outside criterion that determines which decision is correct. In contrast, in a preferential task the decision maker's goals are subjective, so that no correct option exists. Despite these differences sequential sampling models have successfully been applied to both types of decisions. In our study we explore the overlap and the differences between perceptual and preferential decision making. To do so, we developed an experimental task that can be presented as either a perceptual or a preferential task. We show that the classic speed-accuracy trade-off and effects of stimulus difficulty are elicited in the perceptual version of this task. In the preferential version of the task, the stimulus array reflects a gamble that the participant can choose to play or not. In this gamble, the black and white dots represent potential gains or losses. We show that people behave risk and ambiguity averse in this task. The diffusion model is applied to both versions of the task for identifying the essential differences between the two types of decision making. We conclude that similar evidence accumulation processes could underlie rather different decision making processes, but that the model parameters have to be interpreted differently.

## Acknowledgments

We like to acknowledge the Australian research council professorial fellowship awarded to Andrew Heathcote and the SNSF research grant (SNSF100014_143854/1) awarded to Gilles Dutilh and Jörg Rieskamp.

# Multiword Sequences as Building Blocks for Language: Insights into First and Second Language Learning 

Moderator: Morten H. Christiansen (christiansen@cornell.edu) Department of Psychology, Cornell University, USA<br>Moderator: Inbal Arnon (inbal.arnon@gmail.com)<br>Department of Psychology, University of Haifa, Israel<br>Elena Lieven (elena.lieven@manchester.ac.uk)<br>School of Psychological Sciences, University of Manchester, UK

Alison Wray (wraya@cardiff.ac.uk)<br>School of English, Communication \& Philosophy, Cardiff University, UK

Keywords: formulaic language, language acquisition, language processing, second language learning, usage-based learning

## Introduction

Many grammatical frameworks view words and rules as the basic building blocks of language, with multiword sequences being treated as peripheral exceptions in the form of idioms, etc. (e.g., Pinker, 1999). The new millennium, however, has seen a shift toward construing multiword sequences not as linguistic rarities but as important building blocks for language acquisition and processing. Based on a growing bulk of evidence of sensitivity to multiword sequences in language learning and use (see Ellis, 2012, for a review), multiword sequences have come to figure prominently in many current approaches to language, including item-based learning (Lieven, 2010), formulaic language (Wray, 2008), usage-based language processing (Arnon \& Snider, 2010), and chunk-based learning (McCauley \& Christiansen, in preparation). This symposium brings together experts from these different approaches to language to explore the idea that first (L1) and second (L2) language learners differ with respect to their ability to use multiword building blocks to learn and process language, and that this difference affects learning strategies and outcomes.

Unlike young children, adult learners rarely reach native proficiency in pronunciation, morphological and syntactic processing, or the use of formulaic language and idioms (see Ellis, 2012, for a review). Yet adults do not have problems with all aspects of novel language learning: they seem to learn certain aspects of language (e.g., words) better than others (e.g., grammatical relations, formulaic expressions). Existing accounts of the differences between L1 and L2 language learning have tended to focus on biological, cognitive, and neural differences between children and adults. These accounts predict the general difference in proficiency between the two populations, but struggle to explain the specific patterns of language learning observed in children and adults.

Understanding the different paths and outcomes of L1 and L2 learning has wide-reaching implications for cognitive science in terms of what it means to know a language, how much of such knowledge is 'built-in', and how learning changes as a function of prior knowledge and experience. Crucially, while L1 acquisition, adult psycholinguistics, and L2 learning are often studied separately, we bring together insights from developmental psychology (Lieven), psycholinguistics (Arnon), computational investigations of language structure (Christiansen), and applied psycholinguistics (Wray) to present a diverse and rich perspective on multiword building blocks in language learning and use.

The symposium participants have all worked extensively on language acquisition and use. Lieven has been at the forefront of developing the usage-based approach to language learning and has conducted numerous studies on the nature of children's early language use and representation. Arnon has been studying both the processing of multiword sequences by adult native speakers and the way chunk-based learning can impact adult performance in artificial languages. Christiansen has conducted extensive psycholinguistic and computational work exploring the units of language learning and the way such units affect learning. Wray has worked broadly on formulaic expressions in both native and non-native speakers as well as more recently in the language of Alzheimer's patients. Together, the participants have published more than 70 papers relating to the role of multiword sequences in language.

## Lieven: Multiword Sequences in L1 Acquisition

Theoretical and empirical reasons suggest that children build their language not only out of individual words but also out of multiword strings. These are the basis for the development of schemas containing slots. The slots are putative categories which build in abstraction while the schemas eventually connect to other schemas in terms of both meaning and form. Evidence comes from the nature of
the input (Cameron-Faulkner et al., 2003); the ways in which children construct novel utterances (Lieven et al., 2009); and the computational modeling of children's grammars (Bannard et al., 2009). However, nearly all this research is on English which is unusual in its rigid word order and impoverished inflectional morphology. There has also been much less research on the development of the 'meaning pole' in the form-meaning mappings of schemas. I will address both these issues using our recent studies in English, German, Polish and Chintang.

## Arnon: Multiword Sequences in Adult Language Learning and Use

Prior studies have shown that native speakers are sensitive to the distributional properties of multiword sequences when processing language (see Ellis, 2012, for a review). Results are presented suggesting that this sensitivity also extends to language production and is not modulated by syntactic constituency: higher frequency phrases are phonetically reduced within and across syntactic boundaries indicating the prominence of sequence based information. A second study investigated whether such sensitivity to multiword sequences might be harnessed to improve L2 learning. Adult learners showed better learning of an artificial language incorporating a grammatical gender system when first exposed to larger chunks (sentences) and only then individual words (noun-labels). This result suggests that L2 learning of grammatical gender languages may be improved by initially exposing learners to multiword sequences instead of isolated words, thus mirroring the sensitivity to multiword sequences in L1 acquisition and use.

## Christiansen: Computational Investigations of Multiword Chunks in Language Learning

Computational modeling provides further means to investigate the use of multiword chunks by different types of language learners. The Chunk-Based Learner (CBL; McCauley \& Christiansen, in preparation) gradually builds an inventory of chunks-consisting of one or more wordsused for both language comprehension and production. The model learns incrementally from corpora of child-directed speech using simple distributional information and accommodating a range of developmental findings. Results are presented indicating that multiword chunks provide a useful basis for capturing children's productions across a number of different languages independent of their word order. When applied to L2 learner corpora, CBL reveals that the productions of such speakers rely less on multiword chunks compared to speech of both L1 learners and adult native speakers. Thus, these modeling results corroborate our hypothesis about the differential use of multiword building blocks by L1 and L2 learners.

## Wray: Formulaic Expressions: Further Issues

Why have we not progressed further than we have, in understanding the role of formulaic sequences in L2
learning? This presentation will consider how certain assumptions underpinning the existing body of knowledge could constrain the research questions we ask. For instance, how safe is the assertion that non-native speakers rarely achieve nativelikeness (typically attributed to not mastering formulaic sequences)? How appropriate is it to gauge the formulaic language knowledge of adult L2 learners by comparing it to what, for native speakers, is anchored in the social and cognitive experiences of childhood? To what extent can we assert that (all) L1 speakers know the same things about how words fit together? How do recent proposals by Hanks (2013), Port (2007) and Sinclair (Cheng et al., 2009) that the word is not a reliable unit of form or meaning impact on the growing evidence that multiword strings might be?

## Symposium Format

The symposium starts with a 5-minute introduction, followed by four 20 -minute presentations (including time for questions), and concludes with a 15 -minute general discussion.

Keywords: Distributed cognition, memory, conversations, agent-based modeling, collective memory

## Challenging Issue

Remembering frequently involves collaboration among two or more individuals, often taking the form of a conversation. In some conversations, one person conveys new information to another, as when a daughter announces to her mother that she is engaged. In other conversations, two people talk to each other about a shared past, as when a couple reminisce about the evening on which they became engaged. When the conversation is about a mutually experienced event or a shared body of knowledge, it has the potential to shape both what emerges in the discussion, as, for instance, when one participant scaffolds the remembering of the other. It also has the potential to reshape how participants might subsequently remember the material, with the possibility that the memories of the participants will be more similar after the conversation than before it. In other words, what people remember is, in part, the result of how they jointly recount the past with others. Yet, despite the critical contribution of joint conversational remembering to memory, detailed study of this phenomenon is only beginning to be undertaken. The objective of this symposium is to bring together several strands of research that explores conversational, or, more generally, communicative influences on memory. The speakers
offer a range of different approaches. Dr. Stone explores how public speeches can induce forgetting as well as reinforce memories across a large population and thereby promote a mnemonic convergence through a single social interaction. Dr. Echterhoff considers the role of motivation in moderating conversational influences. Dr. Coman investigates whether these conversational influences propagate across large networks of individuals and can thereby promote a mnemonic convergence. Dr. Edelson examines the neuroscience underlying memory conformity. And Dr. Michaelian engages the philosophical underpinning of the concept of collective memory. In a short summation, Dr. Hirst places these papers in the larger context of social aspects of memory and moderates further discussion.

## Charles B. Stone

A conversation can not only reinforce already existing memories and implant misleading ones, but also induce forgetting for unmentioned, but related memoriesaterial. Dr. Stone discusses how this selective remembering can induce forgetting not only in speakers, but also in listeners. In his talk, he extends the laboratory finding on induced forgetting to the effects of political speeches on public memories, showing that listening to a recent speech by the King of Belgium induced forgetting for unmentioned, but related political material, but not unmentioned, unrelated material for French-speaking

Belgians. Similar induced forgetting was not observed in French-speaking Belgians who did not listen to the speech or Dutch-speaking Belgians more generally. The finding underscores the importance of communicative influences on everyday memories.

## Gerald Echterhoff

After tuning their message to their audience's attitude during an initial retelling, communicators' subsequent memory for the topic often reflects the audience-tuned view expressed in the message. Dr. Echterhoff presents research investigating the motivational underpinnings of such audience-congruent memory alignment, specifically, speakers' motives to create a "shared reality" with their audience. Shared-reality creation, in turn, satisfies epistemic needs, that is, needs for a valid and confidently held understanding of the world. When speakers are epistemically uncertain, they should be more likely to incorporate the audience-tuned view into their mnemonic representation. Dr. Echterhoff discusses recent work that demonstrates the importance of epistemic motives in creating a "shared reality" and explores the implications for the social sharing of memories.

## Alin Coman

Do the conversational influence observed by Drs. Stone and Echterhoff, among others, propagate across a network of individuals? Are there limits to the extent of this propagation? How do these limits shape the formation of collective memories within the network? Dr. Coman addresses these questions using agent-based modeling techniques in order to investigate how macro-level social phenomena, such as mnemonic convergence, can emerge out of psychologically informed micro-level local dynamics. The findings show that communicative influences at the dyadic level, as well as network factors (network size, network topology, number of conversations) interact to drive mnemonic convergence in communities.

## Micah Edelson

The underlying brain mechanisms through which the social environment influences human memory are unknown. Dr. Edelson reports on studies of memory in individuals exposed to contradictory recollections of others. Using fMRI, the research finds that social milieu influences memory through evolutionary conserved medial temporal circuits, whereas the ability to overcome social influence is mediated by newer prefrontal circuits. The interplay between these systems determines the balance of personal memory versus conformity to the group.

## Kourken Michaelian

Much of the psychological work on communication and memory evokes the concept of collective memory, in that conversations are considered one critical means for forming a collective memory. Dr. Michaelian explores the philosophical underpinnings of the concept of collective memory. Although some scholars treat the concept as more than a metaphor that likens collective memory to individual memory, Dr. Michaelian argues that, when the process of consolidation is considered, critical differences exist between individual and collective memory that suggests that the concept of collective memory is metaphorical at best.

## William Hirst

Building on his extensive work on conversational remembering and the formation of collective memory, Hirst relates these different approaches to the study of communication and memory and articulates how they provide a foundation for understanding how conversations can influence individual and collective memory.

## Acknowledgements

Dr. Echterhoff would like to acknowledge the contributions of Drs. Olivier Klein (Free University of Brussels) and René Kopietz (University of Münster), and Sabrina Pierucci (Free University of Brussels); Dr. Stone would like to acknowledges, the contributions of Drs. Olivier Luminet, (Université catholique de LouvainCatholic University of Louvain), Olivier Klein (Free University of Brussels) and Laurent Licata (Free University of Brussels).

Keywords: Joint action; distributed cognition; social cognition; interpersonal coordination.

## Summary of Topic

Recent advances in social cognition and joint action reveal the social and the mutual, rather than the individual and the dichotomous aspects of cognition (Hasson, Ghazanfar, Galantucci, Garrod, \& Keysers, 2012). A widespread and powerful model of socially interactive behavior is 'synchrony' (Jirsa \& Kelso, 2004): Numerous studies have thus recently indicated how individuals through social interaction become increasingly entrained on multiple levels from physiology to syntax: through interaction people synchronize their heart rates, their subtle postural sways, their gestures and gaze behaviors, align their lexicon and their syntax (Fusaroli \& Tylén, 2012; Louwerse, Dale, Bard, \& Jeuniaux, 2012; Pickering \& Garrod, 2004). However, emerging scholarship is increasingly attending to many instances in which patterns of complementary and asynchronous actions rather than synchronous ones seem to predict high levels of interpersonal coordination and joint performance. While some activities such as expertly timed
rowing may afford interacting agents to synchronize their individual behaviours to reach high levels of joint performance, other types of joint activity - like playing a game of baseball - rather afford complementary actions: i.e. tightly coupled, reciprocal activity derived from different behaviours performed across an extended temporal sequence. Shared construction tasks as well as task-oriented dialogues, for instance, have been shown to require smooth turn-taking, and the development of interactional routines which might involve complementary roles (Dale, Fusaroli, Duran, \& Richardson, in press; Fusaroli, RaczaszekLeonardi, \& Tylén, accepted). Cultural practices dwell upon and stabilize complementary distribution of work, to make challenging task as the sailing of a warship or the construction of huge buildings possible (Hutchins, 1995; Perry, 2010).

The session will address the implications and respective roles of synchrony, complementarity and asynchrony as components of coordination. Different methods and perspectives for quantifying and assessing coordinative dynamics in language, behaviour and physiology will be presented conceptually and in their empirical application.

## Speakers

Rick Dale (moderator) is a cognitive scientist at UC Merced. He has worked and published extensively on language and social interaction developing and applying a range of novel non-linear statistical methods to assess dynamical properties of multimodal social coordination (Dale, et al., in press; Dale \& Spivey, 2006; Louwerse, et al., 2012; Tollefsen \& Dale, 2012).

Patrick Healey is a professor of human interaction and head of the Interaction Media and Communication research group at University of London. His research concerns experimental work on technology-mediated dialogical communication and - in particular - miscommunication (Healey, Howes, \& Purver, 2010; Healey \& Mills, 2006; Mills \& Healey, 2008).

John J. McGraw, cognitive anthropologist (TESIS, a Marie Curie Initial Training Network), and Panagiotis Mitkidis, cognitive psychologist (Interacting Minds Centre at Aarhus University and Center for Advanced Hindsight at Duke University) investigate the role of objects and material structures in the coordination of behavior, cognition, and the enhancement of cooperation (Xygalatas et al., accepted).

Dorthe Døjbak Håkonsson is an associate professor at the Aarhus School of Business. As an organization scientist, her research focuses on how team shared emotions influence organizational decision-making (Håkonsson, Burton, Obel, \& Laurdisen, 2012). Dan Mønster is a physicist and assistant professor in the Department of Economics and Business at Aarhus University. His current research interest is investigating interactions among team members and the effects of these interactions on team decisions and team performance.

Kristian Tylén and Riccardo Fusaroli are both post doctoral fellows at the Center for Semiotics and the Interacting Minds Center, Aarhus University, with a background in semiotics and cognitive science. They have published on experimental and dynamical systems approaches to social coordination - in particular taskoriented dialogue (Fusaroli et al., 2012; Fusaroli, et al., accepted; Fusaroli \& Tylén, 2012).

## Acknowledgments

Research was supported by NSF BCS-0826825 (RD), EPSRC (PH), TESIS, a Marie Curie Initial Training Network (JJM, PM), MINDLab, Danish Ministry of Science, Technology and Innovation (DDH, DM), EuroUnderstanding (Eurocore) and the Danish council for Independent Research (RF, KT).

#### Abstract

Narrative, a distinctly cognitive phenomenon, has long been of interest to the disciplines that comprise cognitive science. The past decade has seen a resurgence of work using computational methods to understand, manipulate, generate, and leverage narratives. This symposium, which is held in association with the Fourth International Workshop on Computational Models of Narrative (CMN'13), a satellite event of CogSci 2013, will focus on aspects of the scientific and computational understanding of narrative that intersect with cognitive science. The speakers and moderators are drawn from diverse fields including cognitive psychology, artificial intelligence, cognitive science, computational linguistics, and the humanities, and they will focus on a variety of topics including: narrative and its role in analogy, education, and persuasion; challenges in the representation of syntax, discourse, and semantics of narrative; psychological and neuropsychological aspects of narrative; and the growing integration of computational models of narrative in humanities research.

Keywords: Computational Models of Narrative
Narratives are ubiquitous in human experience. We use them to communicate, convince, explain, and entertain. As far as we know, every society in the world has narratives, which suggests they are rooted in our psychology and serve an important cognitive function. It is becoming increasingly clear that, to truly understand and explain human intelligence, beliefs, and behaviors, we will have to understand why narrative is universal and explain the function it serves.

Cognitive science has long recognized the importance of narrative as an activity that engages diverse and important cognitive facilities, as well as a phenomenon that is worthy of study in its own right. After a long period of dormancy, the past decade has seen a resurgence of interest in the formal understanding and computational modeling of of narrative, as well as a more recent boom in cognitive, psychological, and neuroscientific studies relating to narrative. This symposium is an attempt to catalyze the interaction between the research community working on computation-compatible approaches to narrative with cognitive science community proper.

## The Computational Models of Narrative Workshop Series

The research community in question aims to advance the scientific understanding of narrative through progress across a
wide range of fields including cognitive science, psychology, computer science, artificial intelligence, sociology, anthropology, linguistics, logic, and philosophy. To foster and encourage this community, the Computational Models of Narrative ${ }^{1}(\mathrm{CMN})$ workshop series was founded in 2009 . The series was so titled because we believe that a true science of narrative must adhere to the principle espoused by Herbert Simon in his book The Sciences of the Artificial: that without computational modeling the science of a complex human phenomenon such as narrative will never be successful, and that computational models are the proper lingua franca of such a diverse, inter-disciplinary community.

Because the workshop series is relatively new, and the research community is still growing and developing, it was decided to embed the early workshops in the conferences of different intersecting communities, in order to promote cross-fertilization and a more diverse membership. In 2010, the second workshop was hosted by the Association for the Advancement of Artificial Intelligence (AAAI) as one of its Fall Symposia. In 2012, the third workshop was hosted by the Language Resources and Evaluation Conference (LREC), which is a part of the computational linguistics community.

In 2013, the Fourth Workshop on Computational Models of Narrative will be held in Hamburg, Germany, directly after CogSci 2013 as a satellite event. The symposium described here is the on-site event associated with the workshop, and is intended to highlight the intersection between cognitive science and the topics covered in the workshop.

## Speakers

The symposium will be moderated jointly by the workshop co-chairs, Mark Finlayson and Benedikt Löwe. Our speakers and moderators span multiple fields, highlighting the inter-disciplinarity of this symposium. The moderators bring expertise in artificial intelligence, computer science, philosophy, and mathematical logic. Among the speakers, Jeffrey Loewenstein and Dedre Gentner represent cognitive science proper, and they will discuss applying work on analogy to advance our understanding of business practice and psychol-

[^5]ogy, a field where narratives (cases) are of great importance. Richard Gerrig is a cognitive psychologist who has written extensively on human subject experiments regarding people's experiences on reading narrative. Inderjeet Mani is a computational linguist by training, and an expert in corpus annotation and linguistic representations for capturing narratives. Jan Christoph Meister is a humanist who seeks to apply the many advances in computational modeling of narrative to scholarly advances of relevance to his field. Michael Young is a computer scientist who pursues the scientific understanding of narrative to advance the state of the art in digital games.

Each subsection that follows outlines the topic which will be discussed by each speaker. The symposium is structured to leave time for a general discussion that includes the moderators and the audience.

## Loewenstein \& Gentner: Narrative Knowledge and "Repetition-Break" Plot Structures

Narratives convey causal, temporal, and other kinds of relational knowledge, the sort of knowledge that comprises expertise. Comparing narratives is one of the quickest and most powerful ways to develop expert knowledge, as indicated by the analogy literature. Analogy provides a means for identifying commonalities, and in particular, structural commonalities, and so provides a basis for revealing narrative structure. A further insight is the pairing of repetition with contrast to form a plot structure that serves as a recipe for surprise. Folktales (e.g., the three billy goats gruff), jokes (e.g., three guys walk into a bar. . . ), advertisements (e.g., MasterCard's priceless campaign), and other types of narratives frequently make use of these "repetition-break" plots. The repetition in the narrative structure leads audiences to draw comparisons, perhaps learning something, and forming expectations that more similar items will follow. The break or contrast in the narrative structure surprises audiences by deviating from their expectations. Narratives with repetition-break plots are prevalent, often well-liked, often socially-selected both by popular attention and expert judges, and capable of influencing audiences towards adopting the narrative's views. This is just one example of the potential for narrative structure to yield significant returns.

## Gerrig: Readers' Participation in Narrative Experiences

Gerrig will outline a participatory perspective on readers' experiences of narratives. He proposes that readers encode types of mental contents (called participatory responses) that fall beyond the ordinary scope of computational models of narrative. Readers, for example, encode responses toward characters actions and preferences for particular outcomes. Those participatory responses vary from reader to reader and structure their individual experiences toward narratives.

## Mani: Naturalness and Computability in Computational Narrative Representations

Humans have an astonishing ability to infer different facets of narrative structure from a description of events. These facets include the representation of the temporal order of events as well as the motivation behind the actions and reactions of agents based on their goals and beliefs. Computational representations of narrative time and plot can be assessed in terms of their naturalness for humans to infer as well as their computability. Such an assessment suggests a number of psychological investigations that could help provide constraints on formal aspects of these representations.

## Meister: Statistical vs. Intelligent Modelling of Human Narrative Processing

The former Google CEO's Eric Schmidt's dictum "In God we trust-all others bring data" epitomizes the neo-positivist underpinning of 'big data' approaches to complex phenomena. Search engine algorithms aim at representing such phenomena in terms of mathematical and statistical phenomena which by-pass human intelligence. Meister's talk will aim to reinterpret what looks like a purely methodological decision as an ethically problematic choice that is based on a reductionist concept of intelligent behavior. Meister will use examples from narrative to illustrate and emphasize his points.

## Young: Cognition as the Decider: Comprehension and the Next Steps to Plan-Based Narrative Generation

A range of methods for the automatic construction of narratives have been developed in the last 10 years, many of them based on automatic planning methods drawn from AI. While these techniques have benefited from extensions to the standard knowledge representations that target interesting aspects of narrative structure, they often leave out the role of narrative at the discourse level. These models speak to only part of the functional properties of narrative as a result. In this talk, Young will point to these limitations in his own work and describe new models being developed that focus on narrative as a means to prompt comprehension on the part of the reader/viewer/player. These new models attempt to produce narrative story and discourse in text, video and video games that create experiences for their users rather than focus solely on the creation of appropriate narrative structural elements.

## Acknowledgments

This symposium is supported by the John Templeton Foundation (JTF) via the project What makes stories similar? (Grant No. 20565).

#### Abstract

Summary The dream of cognitive neuroscience has always been a seamless integration of cognitive representations with neural machinery, but-despite decades of work-fundamental gaps remain. Part of the problem is that many contemporary theories of cognition are formulated in terms of representations and computations that are quite different from those used in computational neuroscience. Bridging this gap requires more than simply a translation between theoretical concepts in the two fields; what is needed is a more radical updating of neuroscience's theoretical vocabulary.

What should this vocabulary look like? Some important features of representations and computations used in contemporary cognitive theories are:

- Compositional, recursive and relational representations (Fodor, 1975; Smolensky, 1990; Hummel \& Holyoak, 2003; Stewart et al., 2011).
- Flexible use of different structural forms (e.g., taxonomic vs. causal knowledge; Kemp \& Tenenbaum, 2009).
- Multiple levels of abstraction (Tenenbaum et al., 2011).
- Knowledge partitioning / clustering (Lewandowsky \& Kirsner, 2000).
- Complex intuitive theories (e.g., naive physics, theory of mind; Carey, 2009).
- Algorithms that operate on these representations (e.g., dynamic programming, Monte Carlo methods; Griffiths et al., 2012).

These representations and computations are "structured" in the sense that they incorporate rich domain knowledge and strong constraints (Tenenbaum et al., 2011).

This symposium addresses the question: how do neural circuits acquire and compute with structured representations? This question is examined from a number of angles. Gershman introduces the basic issues and discusses attempts to articulate a neurally plausible theory of structured cognition. Pouget describes recent work on implementing complex probabilistic computations in neural circuits. Botvinick shows how neural circuits can be used to discover hierarchical task structure in the environment. Finally, Dayan discusses work on wedding richly structured models of semantics with representations of individual episodes. Each talk will be 20 minutes long, followed by a 20 minute panel discussion with speakers moderated by Tenenbaum.

## Gershman: from knowledge to neurons

How can neurons express the structured knowledge representations central to intelligence? This problem has been attacked many times from various angles. I discuss the history of these attempts and situate our current understanding of the problem. I then outline a new approach based on the idea of compressing structured knowledge using neurons in a way that supports probabilistic inference. I illustrate this approach using examples from motion perception and value-based decision making.

## Pouget: modeling the neural basis of complex intractable inference

It is becoming increasingly clear that neural computation can be formalized as a form of probabilistic inference. Several hypotheses have emerged regarding the neural basis of these inferences, including one based on a type of code known as probabilistic population codes or PPCs (Ma et al., 2006). PPCs have been used to model simple forms for multisensory integration, attentional search, perceptual decision making or causal inference, for which human subjects have been shown to be nearly optimal. However, most inferences performed by the brain are too complex be solved optimally in a reasonable
amount of time and must therefore involve approximate solutions. We have started to explore how neural circuits could implement a particular form of approximation, called variational Bayes, with PPCs (Beck et al., 2012). Remarkably, this approximation requires a nonlinearity known as divisive normalization which has already been found in most neural circuits. This approach can be applied to a wide range of complex inferences, such as the ones involved in olfactory processing, image processing in the primary visual cortex and other related problems.

## Botvinick: discovering hierarchical task structure

Naturalistic action displays a hierarchical structure: Simple actions cohere into subtask sequences or component skills, which in turn combine to realize overall goals. Computational models from cognitive psychology, artificial intelligence, and most recently neuroscience, have sought to characterize the representations and mechanisms underlying hierarchical action control (Botvinick, 2008). However, such models tend to neglect a fundamental question: How do hierarchical representations of action or task structure initially arise? We approach this as a learning problem, asking how useful component skills can be inferred from experience. Behavioral evidence suggests that such learning arises from a structural analysis of encountered problems, one that maximizes representational efficiency and, as a direct result, decomposes task into subtasks by 'carving' them at their natural 'joints.' A key question is how this analysis and optimization process might be implemented neurally. Recent data suggests an intriguing answer: Detection of hierarchical task structure might arise as a natural consequence of predictive representation. I'll present computational work fleshing out this possibility, along with behavioral and fMRI data that lend it considerable initial support.

## Dayan: unsupervised learning and the representation of episodic structure

The representation of hierarchically structured knowledge in systems using distributed patterns of activity is an abiding concern for the connectionist solution of cognitively rich problems. One particularly important unresolved issue concerns episodic versus semantic structure-how rich generative models of the semantics of domains can be used in the representation of particular, structured, entities. I will unpack this problem and suggest some routes to solutions.

Harvey Whitehouse (harvey.whitehouse@anthro.ox.ac.uk)<br>School of Anthropology and Museum Ethnography, University of Oxford<br>51 Banbury Road, Oxford OX2 6PE, England

Keywords: Ritual; imitation; collaboration; affiliation; cultural learning; normativity; convention

## Cognitive Foundations of Cultural Learning

The ability to learn from others is integral to sustaining and transmitting human culture. What are the cognitive processes that support imitative and collaborative cultural learning? How does cultural learning contribute to group dynamics, such as cohesion and conflict? Recent research has focused on how children acquire instrumental skills through causal inference (Call, Carpenter, \& Tomasello, 2005; Whiten, McGuigan, Marshall-Pescini, \& Hopper, 2009). However, children also need to acquire the norms and conventions of their culture, as well as an understanding of cooperative behavior, to become full-fledged members of their community. This acquisition begins early in ontogeny and is likely reliant on a unique mix of causal reasoning and affiliative goals, triggered by the nature of the action sequence itself and a variety of social cues. In this symposium, we consider the emerging experimental literature on the development of imitation and collaboration with the goal of applying this work to broader issues of group dynamics and the transmission of culture. Henderson will consider the understanding of collaborative goals in infancy. Kenward will consider the normative basis of young children's over-imitation. Watson-Jones will examine affiliative motivations underlying children's imitation. Whitehouse will consider how ritualized, normative behavior and cognition impacts group dynamics of coordination and social cohesion.

## Henderson: Infants' Understanding of Cooperative Action

Cooperative activities in which two (or more) individuals coordinate their independent actions to attain a common
goal are critical for human survival. Food, shelter, reproduction, protection from threats and knowledge transfer require cooperation (Barkow, Cosmides, \& Tooby, 1992; Tomasello, 2009). The ability to cooperate with others emerges early in development (for a review see Brownell, 2011) and plays a critical role in facilitating children's socio-cognitive development (Rogoff, 1990; Sommerville \& Hammond, 2007). Despite the growing body of evidence documenting the development of cooperative behaviour across the first few years of life, very little is known about infants' understanding of cooperation. In her talk, Annette Henderson will present new findings from a series of studies investigating the age at which infants understand that the actions of cooperating partners are directed towards the attainment of a common goal using an innovative visual habituation paradigm. Identifying when and how infants come to understand cooperation provides valuable information about the age at which infants possess the mental capacity to make sense out of the vast array of cooperative actions that they witness in their everyday lives.

Annette Henderson is a Senior Lecturer in Developmental Psychology and Director of the Early Learning Laboratory at the University of Auckland, New Zealand. Her research interests include the development of children's understanding of activities involving shared intentions, which include linguistic and non-linguistic cooperative activities.

## Kenward: The Mechanisms Behind Imitation of "Unnecessary" Actions

Why do children imitate actions with unclear functions? Copying behavior without understanding the function of the behavior is often beneficial - you don't need to know about the crocodile to benefit from copying avoidance of the river. This argument does not explain the mechanism of such blind copying, however. Various proposals have been put
forward, such as an automatic assumption of causal effect (Lyons, Young, \& Keil, 2007), and a motive to socially affiliate (Over \& Carpenter, 2012). Evidence will be presented demonstrating that when imitating a simple action sequence with a clear goal but including irrelevant actions, children do not believe that the irrelevant actions are causally necessary for achieving the goal. This evidence speaks against the hypothesis of causal assumption. Secondly, evidence will be presented demonstrating that children have a sufficiently strong belief that such irrelevant actions should be performed that they protest when a third party does not perform them. This shows that children have a normative belief that it is correct to copy actions performed by adults, even when their purpose is unclear. Kenward argues that children's ability to encode actions as normative without any information about what domain determines the normativity implies that children are capable of holding normative beliefs that are not anchored in a specific domain, such as convention, morality, or instrumental rationality.

Ben Kenward is a Researcher in Psychology at Uppsala University, Sweden. He focuses on development but has professional ADHD, having published recently on unconsciously motivated action, moral development, social learning, the development of decision making, and animal tool use.

## Watson-Jones \& Legare: Affiliative Motivations and the Development of Imitation

Imitation is used to acquire both instrumental skills (Call, et al. 2005; Lyons et al., 2007; Whiten et al., 2009) as well as cultural conventions, such as ritual. Legare, Whitehouse, Herrmann, and Wen (under review) have proposed that the causal opacity associated with cultural conventions results in high fidelity copying and low levels of innovation. The motivation to engage in imitation may be fundamentally related to implicit affiliation goals (Over \& Carpenter, 2012). We propose that affiliative motivations play an important role in the transmission and learning of cultural knowledge. Rachel Watson-Jones will present new research in collaboration with Cristine Legare and Harvey Whitehouse, demonstrating that affiliation goals may differentially affect the imitation of instrumental actions versus actions related to cultural conventions. Using ostracism as a conceptual lens, the findings of this research provide evidence of the affiliative basis of imitation.

Rachel Watson-Jones is a Postdoctoral Fellow at the University of Texas at Austin within the Cognition, Culture, and Development Laboratory. Her interests include the development of social cognition, cultural transmission, and the cognitive science of religion.

## Whitehouse: Ritual, Community, and Conflict

Some of the greatest atrocities have been caused by groups defending or advancing their political aspirations and sacred values. In order to comprehend and address the wanton violence of war, terrorism and genocide, it is necessary to
understand the forces that bind and drive human groups. Here I describe a five-year program of research investigating one of the most powerful mechanisms by which groups may be formed, inspired, and coordinated: ritual. The project examines the role of ritual in child development, in social behavior, and in the evolution of political systems. Studying how children learn the rituals of their communities is shedding light on the various ways in which rituals promote social cohesion within the group and distrust of groups with different ritual traditions. Qualitative field research, surveys, and controlled psychological experiments are being conducted in a number of troubled regions (including the Middle East and North Africa) to investigate the role of ritual in group bonding and intergroup competition. New databases are being constructed to explore the relationship between ritual, resource extraction patterns, and group structure and scale over the millennia.

Harvey Whitehouse is professor of social anthropology, director of the Institute of Cognitive and Evolutionary Anthropology, and a fellow of Magdalen College at the University of Oxford. His interests include recurrence and variation in religious thinking and behavior, and he has published many books and articles on this topic.

## Introduction

The hypothesis that human cognition may be well characterized as a set of Bayesian computations has been the topic of considerable debate over the last two decades. Recently, critics have argued that this hypothesis is either unlikely to be true or otherwise too unconstrained to be particularly useful for explaining cognition (e.g., Bowers \& Davis, 2012), whereas proponents have defended their position by stating that the Bayesian perspective has been misunderstood, is not necessarily in conflict with other perspectives on cognition, and can still be explanatorily useful as a framework for cognitive science even if underconstrained in many ways (e.g., Griffiths, Chater, Norris, \& Pouget, 2012). Our position in this debate is that both sides of this debate may be right as well as wrong: Proponents may be right that the Bayesian perspective has something uniquely useful to bring to cognitive science (and then the critics are wrong in their denial of this); yet, the critics may be right that cognitive theories are explanatorily useful only if properly constrained (and then proponents are wrong in their denial of this).

With this perspective in mind, we wish to move the debate forward in a constructive way by bringing in new perspectives and proposing novel constraints that can be exploited for purposes of improving the explanatory values and virtues of Bayesian explanations of cognition. Specifically, with this symposium we aim to focus on how constraints on Bayesian explanations can be exploited in ways that are yet underrepresented and underexplored.

The symposium brings together researchers from various disciplines, contributing a variety of perspectives on how Bayesian explanations can be fruitfully constrained, drawing on theories, analyses, and results from philosophy of
science, cognitive neuroscience, information theory, machine learning, and theoretical computer science.

## A complexity-theoretic perspective on the preconditions for Bayesian tractability

## Johan Kwisthout (joint work with Iris van Rooij)

Many Bayesian computations have been proven to be computationally intractable (NP-hard) for unconstrained input domains, even if only an approximate solution is sought. Informally, this means that computations postulated by Bayesian models can take astronomical amounts of time for their completion even for realistic sized inputs. This property seems to be in strong contrast with the ease and speed with which humans can typically make the inferences that are modeled by Bayesian models. Some critics of the Bayesian approach have taken this property of Bayesian models as a reason to reject the entire approach (e.g., Gigerenzer, 2008). In contrast, I propose that it means that tractability forms a useful constraint on Bayesian explanations of cognition. In this talk, I will elucidate the use of complexity-theoretic concepts and techniques for making Bayesian models meet the tractability constraint, building on known results from theoretical computer science (e.g., Kwisthout, 2011). I will furthermore report on recent complexity results that have lead to novel hypotheses about the conditions under which Bayesian inferences can be tractably approximated (Kwisthout \& van Rooij, 2013).

## Bayesian cognitive science, unification, and explanation

Matteo Colombo (joint work with Stephan Hartmann)
A recurrent claim is that the greatest value of studying cognitive phenomena such as perception, action, categorization, and decision-making, within the Bayesian framework consists in its unifying power. Several Bayesian
cognitive scientists, however, implicitly assume that unification is obviously linked to explanatory power. But this link is not obvious (e.g., Morrison, 2000).

A crucial feature of adequate explanations in the cognitive sciences is that they reveal aspects of the causal structure of the mechanism that produces the phenomenon to be explained. The kind of unification afforded by the Bayesian framework to cognitive science does not necessarily reveal the causal structure of a mechanism (cf. Colombo \& Seriès, 2012). Bayesian unification is the product of the mathematics rather than of a causal hypothesis concerning how different cognitive phenomena are brought about by a single type of mechanism. Nonetheless, Bayesian unification can place fruitful constraints on causal mechanical explanation, which will be elucidated in this talk.

## Bayesian modeling and heuristic strategies for model-development

## Carlos Zednik (joint work with Frank Jäkel)

It is generally agreed that Bayesian models in cognitive science operate at Marr's computational level of analysis (Marr, 1982). Unfortunately, it remains unclear exactly how the computational, algorithmic, and implementation levels are related.

This talk explicates inter-level relationships in terms of heuristic strategies for model-development (Zednik, in press). Specifically, Bayesian computational-level models play the heuristic role of suggesting possible algorithms to compute a particular function, and of suggesting particular ways of delineating and interpreting the components of a physical mechanism. In turn, algorithmic and mechanistic models specify memory, time, and resource limitations that constrain the cognitive tasks described by Bayesian models. In contrast to the view that Bayesian computational-level modeling is independent of low-level considerations, on this view the development of Bayesian models is constrained by, and at the same time itself constrains, the development of models at lower levels of analysis.

## Neuronal inference from the perspective of Jaynes's probability theory and the coherent infomax objective

William A. Phillips

In support of the 'Bayesian' perspective on cognition, I will agree that the adaptively organized complexity of life, and particularly mental life, depends on inductive inference. I will put five major caveats on this support, however. First, this perspective should be based not on Bayes theorem alone but on the logic of probability theory as developed most rigorously and extensively by the statistical physicist Edwin T. Jaynes (1998/2003). Interpreting probabilities as quantifying uncertainty he showed that optimal inference rests on a few requirements, or 'desiderata', and he developed maximum entropy methods for justifiably allocating prior
probabilities given only what is known. Second, Jaynes's desiderata can only be met in simple cases. Third, contextual modulation operates via likelihoods, not priors (Kay \& Phillips, 2010). Fourth, inferences are the common currency of feed-forward transmission, not prediction errors. Fifth, modulatory interactions within hierarchical levels are at least as crucial as those between levels.
I will also note that, in addition to the constraints imposed by Jaynes's desiderata, the use of prior event frequency is constrained by the curse-of-dimensionality. It becomes rapidly less useful as dimensionality of the event space increases because the number of possible locations within it then increases exponentially.
Finally, I will briefly outline the possibility that functional specializations combined with various cellular and localcircuit mechanisms for context-sensitive gain-control have evolved within mammalian cortex to restrict the problems to be solved by neuronal inference to what is feasible within the above constraints, as formulated using information theoretic concepts in the theory of coherent infomax (Phillips, 2012).

# Symposium: Global Change and Cognition 

Moderator: Stephan Lewandowsky (stephan.lewandowsky@bristol.ac.uk)<br>Department of Experimental Psychology, University of Bristol,<br>12a Priory Road, Bristol BS8 1TU, and<br>School of Psychology, University of Western Australia, Crawley, WA 6009

Contributors<br>Tania Lombrozo (University of California, Berkeley)<br>John Cook (University of Queensland)<br>Gordon D. A. Brown (University of Warwick)<br>Ben R. Newell (University of New South Wales)<br>Ullrich K. H. Ecker (University of Western Australia)

#### Abstract

We are living in a period of considerable global change. From climate change to peak oil we are facing multiple challenging problems that need to be managed carefully and wisely. Cognitive science has much to say about how people are likely to view those problems and how they will respond to them. This symposium will shed some light on those cognitive processes and how they can help-or indeed hinder-the problems we are facing.

Keywords: Global change; cognition of climate change; public acceptance of science; complex reasoning

## Summary of Symposium

There can be little doubt that human societies are facing numerous serious problems, ranging from food insecurity to resource depletion and, perhaps most serious of all, climate change. Although technological solutions to those problems arguably exist, to date there has been little enthusiasm among politicians and the public to tackle those problems. At least in part, this inaction has resulted from political factors. However, the inaction may also reflect factors related to the limitations of human cognition: People's reasoning is known to be subject to numerous biases and limitations, and our cognitive apparatus may be ill-matched to the magnitude of current global problems.

Nowhere is this mismatch more apparent than with respect to climate change, which challenges numerous cognitive and psychological processes. At a basic cognitive level, people have difficulty understanding that emissions are cumulative and that greenhouse gases remain in the atmosphere even if emissions are reduced (Sterman \& Sweeney, 2007). At a more abstract level, the public in some countries-in particular the U.S. but also in Australia-has become increasingly polarized in their attitudes towards science. Since the 1970's, Conservatives-unlike Liberals or Moderates-have become increasingly skeptical and distrustful of science (Gauchat, 2012), and people who embrace a laissez-faire vision of the free market are less likely to accept that anthropogenic greenhouse gas emissions are warming the planet than people
with an egalitarian-communitarian outlook (Dunlap \& McCright, 2008; Hamilton, 2011; Heath \& Gifford, 2006; Kahan, Jenkins-Smith, \& Braman, 2011; McCright \& Dunlap, 2011).

In light of the fundamental importance of science to the solution of global problems, the rejection of well-established scientific facts by large segments of the population must be of concern. How can this rejection be overcome? Even putting aside ideological barriers, how can people's reasoning about the future become better calibrated with the actual risks from global change?

This symposium surveys a broad range of research that addresses these questions and related issues. Tania Lombrozo will highlight the fragile relationship between understanding particular scientific claims and accepting them as true; John Cook will analyze the multi-faceted role of perceived scientific consensus (i.e., what the public believes scientists are thinking) and how that impacts attitudes; Gordon Brown will be presenting an agent-based simulation that is built around consensus-detection and will show how that explains attitude polarization; Ben Newell will report on how people judge temporal distances when considering future gains and losses; and Ullrich Ecker will explain how best to deal with the dissemination of misinformation that characterizes much contemporary public debate.

## Contributions

## Understanding science vs. accepting it

Tania Lombrozo (University of California, Berkeley)
Addressing many contemporary challenges-such as climate change and increasing resistance to antibiotics-will require more than scientific and technological advances; it will also require changes in people's attitudes and behaviors. To what extent are people's attitudes towards science and particular scientific claims shaped by their understanding of the science? There is a relatively fragile relationship between understanding particular scientific claims and accepting them as true. Nonetheless, there does seem to be a relationship between people's understanding of the nature of science in general, on the one hand, and their acceptance of specific scientific claims, on the other. Tania Lombrozo will present data for the case of evolution and consider implications for education, science communication, and policy.

[^6]It is well established that political ideology has a strong influence on public opinion about climate change, and on how people update their beliefs in the light of new climate information. Specifically, people who endorse an extreme view of free-market economics tend to reject findings from climate science. Providing people with information about the scientific consensus has been shown to partially neutralise this ideological bias (Lewandowsky, Gignac, \& Vaughan, 2012). Paradoxically, this is despite the fact that those most sceptical about climate change are also most distrustful of the scientific community. Data from several experiments are presented that explore the psychological mechanisms underlying the effectiveness of consensus information. The results are modeled within a Bayesian belief network.

## Social norms and polarization of attitudes

## Gordon D. A. Brown (University of Warwick)

Gordon Brown will describe an agent-based model of social norm effects and polarisation. The model will be applied to understanding attitudes towards climate change. The model assumes that agents located within a social network observe the behavior of neighbours and infer from that behavior the social distribution of particular attitudes (e.g. towards climate change). Agents are assumed to dislike behaviours that are extreme within their neighbourhood (social extremeness aversion), and hence have a tendency to conform. However, agents are also assumed to prefer choices that are consistent with their own true beliefs (authenticity preference). Behavioural choice-and expression of attitudes towards climate change-reflects a compromise between these opposing principles. The model sheds light on the role of perceived rather than actual scientific consensus, and "balanced" media coverage, on attitudes to climate change.

## How to weigh your options with the passage of time: Subjective and objective time preferences

## Ben R. Newell (University of New South Wales)

Many global challenges are difficult precisely because they involve trade-offs between immediate certain costs-e.g., increase in electricity prices to reduce carbon emissions-and uncertain future benefits-e.g., avoiding the worst and costliest effects of climate change. It has long been known that people discount the future very steeply; that is, they consider present monetary amounts to be more salient and valuable than when they are delayed into the future, even if those future amounts are objectively far greater. The functional form of people's discounting, however, is not well understood. This talk presents work on inter-temporal choice that sheds light on how people deal with trade-offs that involve a future cost. A particular focus is the difference between subjective and objective time estimates (cf. Malkoc \& Zauberman, 2006; Zauberman, Kim, Makoc, \& Bettman, 2009) and their implications for hyperbolic and exponential discount functions.

## Misinformation, disinformation, and the need for debiasing

Ullrich K. H. Ecker (University of Western Australia)

The dissemination of misleading information presents an obstacle for the success of science communication, public education, and evidence-based policy. Of particular concern is the resilience of misinformation: Even in the presence of clear corrections, misinformation often continues to influence people's memory and reasoning. Misinformation is particularly difficult to correct when it supports existing attitudes and when corrections counter those attitudes. Refutations of incorrect beliefs hence need to be well-designed to be efficient. Ullrich Ecker will discuss the effects of attitudes on the processing of misinformation and retractions, and highlight the important factors in the design of refutations.

Keywords: perception; top-down effects; perceptual learning; philosophy of cognitive science

## Introduction

The question of whether perception can be penetrated by cognition is in the limelight again. The reason this question keeps coming up is that there is so much at stake: Is it possible to have theory-neutral observation? Is it possible to study perception without recourse to expectations, context, and beliefs? What are the boundaries between perception, memory, and inference (and do they even exist)? Are findings from neuroscience that paint a picture of perception as an inherently bidirectional and interactive process relevant for understanding the relationship between cognition and perception?

We have assembled a group of philosophers and psychologists who have been considering the thesis of cognitive (im)penetrability in light of these questions (Abdel Rahman \& Sommer, 2008; Goldstone, Landy, \& Brunel, 2011; Lupyan, Thompson-Schill, \& Swingley, 2010; Macpherson, 2012; Stokes, 2011). Rather than rehashing previous arguments which appear, in retrospect, to have been somewhat ill-posed (Pylyshyn, 1999), this symposium will present a thesis of cognitive (im)penetrability that is at once philosophically satisfying, empirically testable, and relevant to the questions that cognitive scientists find most interesting.

## Dustin Stokes <br> Towards a consequentialist understanding of cognitive penetration

Philosophers of mind and cognitive scientists have recently taken renewed interest in in the cognitive penetration of perceptual experience. The question is whether cognitive states like belief influence perceptual experience in some important way. Since the possible phenomenon is an empirical one, the strategy for analysis has, predictably, proceed-
ed as follows: define the phenomenon and then, definition in hand, interpret various psychological data. However, different theorists offer different and apparently inconsistent definitions. And so in addition to the usual problems (e.g., definitions being challenged by counterexample), an important result is that different theorists apply their definitions and accordingly get conflicting answers to the question "Is this a genuine case of cognitive penetration?" This hurdle to philosophical and scientific progress can be remedied, I argue, by returning attention to the alleged consequences of the possible phenomenon. There are three: theory-ladenness of perception in contexts of scientific theory choice, a threat to the general epistemic role of perception, and implications for mental architecture. Any attempt to characterize or define, and then empirically test for, cognitive penetration should be constrained by these consequences. This is a method for interpreting and acquiring experimental data in a way that is agreeable to both sides of the cognitive penetration debate. Put crudely, the question shifts to "Is this a cognitive-perceptual relation that results in (or constitutes) one or more of the relevant consequences?" In answering this question it may turn out that there is no single unified phenomenon of cognitive penetration. But this should not matter, since it is the consequences that are of central importance to philosophers and cognitive scientists alike.

## Fiona Macpherson <br> Adjudicating between cognitive penetration and perceptual learning

Do we have good evidence that cognitive penetration occurs? There is a history of disagreement between those who think that perceptual experiences can be cognitively penetrated and those who think that they cannot. The argument has often proceeded on a case-by-case basis. Those who think that experiences can be penetrated present alleged examples. Most of these examples are cases in which it is
claimed that there are two different experiences, and that the best explanation for this difference is that one of the experiences was penetrated and the other was not or that the two experiences were penetrated by different cognitive states. Those who think that cognitive penetration does not occur try to offer alternative explanations. One kind of alternative explanation is that the experiences differ due to a non-cognitive difference-such as a difference in perceptual attention or in eye movement. In this paper, I discuss one variant of this strategy that tries to explain away a case of different colour experiences by claiming that the difference is due to perceptual learning, untainted by cognition. I discuss what evidence we would need to have to show that this case was one of penetration, rather than perceptual learning. I claim that we have actual evidence which is tantalizingly close to being the sort of evidence we require to show cognitive penetration, rather than perceptual learning, is occurring, and that a modicum of further easy-to-gather evidence would probably settle this case in favour of the existence of cognitive penetration.

## Rasha Abdel Rahman

## The influence of semantic knowledge on visual perception

The perception of complex visual stimuli such as objects and faces is determined not only by physical properties but may be affected by various sources of top-down influences such stored verbal categories or attention. I will present a series of experiments examining the influence of different types of semantic knowledge on perception, using the finegrained temporal resolution of event-related brain potentials (ERPs) to localize semantic effects on high and low-level components of visual analysis. The different types of knowledge include functional information that directly relates to the visual appearance of objects and their specific properties, thus explaining object shapes and features. Alternatively, the information may be unrelated to visual properties. This typically holds for biographical information about persons that can neither be derived from vision nor account for the visual appearance of a person's face. Likewise, affective biographical knowledge cannot directly be related to features or emotional expressions of faces. Furthermore, semantic information is also a major determinant of the meaningfulness of verbal categories, and semantic contents or the depth of information associated with verbal labels may play a critical role in explaining categorical perception. The results show that different types of semantic information that may or may not be directly related to visual stimulus properties shape the perception of objects and faces, including emotional facial expressions. These effects suggest an influence of semantic knowledge on sensory processing in the visual cortex that may be mediated by knowledge-induced attentional modulations and may reflect embodied cognition or reentrant activation form higherlevel semantic to sensory cortical areas.

## Robert Goldstone Hacking Our Own Perceptual Systems so that Cognition Improves

Training allows our perceptual processes to deliver outputs that would have otherwise required abstract or formal reasoning. Even without people having any privileged access to the internal operations of perceptual modules, these modules can be reliably altered over time so as to better subserve our high-level cognition needs. Strategic changes need not be implicated when perceptual systems adapt. However, there is also a continuum of intentional specificity, and with varying degrees of precision we are also able to intentionally alter our perceptual systems for our own purposes. We "hack" our perceptual systems by A) physically changing our perceptual equipment, B) strategically employing our existing perceptual equipment in new ways, $C$ ) making explicit efforts to accelerate our own perceptual adaptation process, D) creating new perceptual objects to emphasize task-relevant properties, and E) creating new physical tools to help us perceive better. Certainly not all of these adaptations should count as cases of cognitive penetration on perception, but there are striking parallels between these five classes. Strategic mechanisms of adaptation demonstrably present in some of the classes can be inferred to be at work in other classes. The semi-strategic nature of perceptual adaptation is well illustrated by the hybrid process of educating experts. The training of experts in medicine, sports, engineering, design, and food science has converged on a combination of frequent perceptual exposure to cases, explanation of causal mechanisms, and verbal descriptions that lead to selective attention to previously extracted features as well as organization into new perceptual features.

# Informavores: Active information foraging and human cognition 

Doug Markant (Moderator) and Todd Gureckis<br>Dept. of Psychology, New York University<br>Björn Meder and Jonathan D. Nelson Center for Adaptive Behavior and Cognition, Max Planck Institute for Human Development<br>Peter Pirolli<br>Palo Alto Research Center<br>Chen Yu<br>Dept. of Psychological and Brain Sciences, Indiana University

Keywords: active learning, self-directed learning, information search, sensemaking

Just as the body survives by ingesting negative entropy, so the mind survives by ingesting information. In a very general sense, all higher organisms are informavores. Miller (1983)

Unlike a passive sponge floating in a sea of information, humans are active information foragers - informavores - who gather and consume new knowledge. From controlling the movement of our eyes to determining which sources of news to consult, judging the quality of alternative sources of information is a critical part of our behavior. The goal of this symposium is to bring together researchers who are working to understand the cognitive processes underlying active information foraging and how they interact with more general aspects of cognition.

The study of active information search is in the midst of a renaissance. Psychological research from diverse areas ranging from developmental psychology (Schulz \& Bonawitz, 2007), to higher level cognition (Nelson, 2005) to visual perception (Najemnik \& Geisler, 2005) have begun to understand information gathering strategies in terms of a common set of computational principles. Simultaneous developments in machine learning on "active vision" and "active learning" (Settles, 2009) have resulted in new algorithms that optimize their own learning by focusing on useful training data. Similarly, models from optimal foraging theory from biology are being brought to bear on cognitive search processes both within and outside the mind (Pirolli, 2007; Todd, Hills, \& Robbins, 2012).

This symposium aims to bring together leading experts in this area to discuss how active information foraging can be understood from a diverse set of perspectives within cognitive science. Key themes include how prior knowledge influences search (Markant \& Gureckis), how information and reward interact to determine choice (Meder \& Nelson), developmental patterns in information seeking behavior (Nelson et al.), information foraging in complex sensemaking tasks (Pirolli), and the allocation of attention during statistical word learning (Yu). While each represents a distinct area of research, all discussants in the symposium share a core approach of applying computational models to understand information search
in humans. The symposium should appeal to a broad set of attendees including educators, developmental psychologists, cognitive modelers, and computer scientists.
The influence of priors on sequential search decisions Doug Markant and Todd Gureckis

Normative models of information acquisition predict that people's search decisions should be strongly influenced by their prior beliefs, which capture the set of alternative hypotheses they are considering. In the present experiments we tested whether people adjusted their information search behavior in response to sequential changes in the prior. Participants played a search game in which they had to identify the shape and location of multiple hidden targets in a display (similar to the board game Battleship). During the task they were told that the set of possible shapes had changed, and the key question was whether they would adjust their search decisions according to the predictions of a normative model. Manipulations of the prior included changes in the frequency of certain classes of targets as well as the introduction of higherorder constraints (e.g., that all targets would have the same shape). The results showed that an individual's prior could be recovered from their sequences of search decisions, but that there were notable differences in their ability to adjust to certain changes in the hypothesis space, an effect that is not predicted by the normative model. We discuss the implications of these findings for how people generate and represent hypotheses during the course of information foraging.
Is people's information search behavior sensitive to different reward structures? - Björn Meder and Jonathan Nelson

In situations where humans actively acquire information for classification, information search preferentially maximizes accuracy (Nelson et al., 2010). However, the goal of obtaining information to improve classification accuracy can strongly conflict with the goal of obtaining information for improving utility when there are asymmetries in costs and benefits for classification decisions (e.g., in many medical diagnosis situations). Is people's information search behavior sensitive to such asymmetries? We addressed this experimentally via multiple-cue probabilistic category-learning and information-search experiments, where the payoffs corresponded either to accuracy, with equal rewards associated with the two categories, or to an asymmetric payoff function with different rewards associated with each cate-
gory. We found that people have difficulties identifying the reward-maximizing (rather than accuracy-maximizing) feature in search, following a neutral category learning task. Conversely, when trained to classify under asymmetric payoffs, they had difficulties conducting accuracy-maximizing queries when searching under symmetric rewards, where the accuracy-maximizing feature maximizes reward.

Finally, if words and numbers are used to convey environmental probabilities, neither reward nor accuracy consistently predicts search. These findings emphasize the necessity of taking into account peoples goals and search-and-decision processes during learning, thereby challenging current models of information search.
Sequential information search: Theoretical, developmental and psychological issues - Jonathan Nelson, Björn Meder, Bojana Divjak, Gudny Gudmundsdottir, Matt Jones, and Laura Martignon

We theoretically and empirically examine sequential search games in which the task is to identify an unknown target object by asking yes-no questions about its features. Globally optimal decision trees were identified using exhaustive search, in two task environments. This provided a benchmark for evaluating the efficiency of heuristic and stepwise optimal experimental design (OED) approaches for selecting questions. Some, but not all, OED approaches are useful for selecting queries. A heuristic strategy, the split-half heuristic, is mathematically equivalent to information gain, a stepwiseoptimal OED method. We investigated 4th-grade childrens search strategies on this task. Results show that children have good intuitions regarding questions' usefulness and search adaptively, relative to the statistical structure of the task environment. Search was especially efficient in a task environment that was representative of real-world experiences. This suggests that children can use their knowledge of real-world environmental statistics to guide their search behavior.

One issue for future work is to characterize the circumstances under which people identify efficient search strategies, especially in environments in which no stepwise strategy is optimal. A related issue is whether directed play can foment generalizable insights or intuitions.

## Some models of human information foraging and sensemaking - Peter Pirolli

Information Foraging Theory aims to explain and predict how people shape their information seeking behaviors to their information environments (e.g., the Web, Twitter, social tagging systems, etc.). Typically, the key steps in developing a model of information foraging involve: (a) a rational analysis of the task and information environment (often drawing on optimal foraging theory from biology) and (b) an ACTR computational cognitive model. I will present work on individual information seeking (e.g., on the Web), and then discuss how this work has been expanded to an ACT-R simulation of a complex sensemaking task involving geospatial intelligence analysis. This map-based task requires seeking (choosing) various types of available intelligence informa-
tion, and using that information to revise probability estimates about which insurgent groups might commit a future bombing attack. The model exhibits information-seeking patterns that are comparable to humans studied on this task and both model and people deviate from a rational model based on greedy maximization of expected information gain. The model also exhibits observed human biases in seeking and using information.
Active learning and selective attention in statistical word learning - Chen Yu

There are various kinds of statistical regularities in a realworld learning environment. Therefore, statistical learners have to be selective and actively gather just-in-time information required by internal learning processes and then update their internal learning states which will consequently influence their attention and selection in the next learning moment. The present study provides evidence for the operation of selective attention in the course of cross-situational learning with two main goals. The first was to show that selective attention is critical for the underlying mechanisms that support successful statistical learning. The second one was to test whether an associative mechanism with selective attention is sufficient to explain momentary gaze data in human learning.

Toward these goals, we collected eye movement data from participants engaged in a cross-situational statistical wordlearning task. Various gaze patterns were extracted, analyzed and compared between strong learners who acquired more word-referent pairs through training, and average and weak learners who learned fewer pairs. Fine-grained behavioural patterns from gaze data reveal how learners actively control their attention to gather statistical information after hearing a word, how they attend to individual objects which compete for attention within a learning trial, and how statistical evidence is selected and accumulated moment by moment, and integrated across words, across objects, and across wordobject mappings. Taken together, these findings provide new evidence on the real-time active learning mechanisms operating in the human cognitive system.

# Social Cognition, Culture and the Self 

Albert Newen (albert.newen@rub.de)<br>Ruhr-Universität Bochum, Institut für Philosophie II<br>Gary Bente (bente@uni-koeln.de)<br>Universität Köln, Dept. of Psychology<br>Shinobu Kitayama<br>University of Michigan, Dept. of Psychology<br>Shihui Han<br>Peking University, Dept. of Psychology<br>Kai Vogeley<br>Clinic of Psychiatry, Universität Köln

#### Abstract

The processing of social information belongs to the most complex cognitive capacities of humans, enabling us to live together in social communities. The symposium will focus on the everyday competence to form social impressions and understand others. This capability includes 1 . the understanding of oneself on the basis of an explicit selfconstrual, 2 . the understanding of others by processing their mental and bodily characteristics and states 3 . the understanding of social encounters by adequately interpreting actions, communicative signals and social roles. Human communication is essentially embedded in cultural contexts and is shaped by it; at the same time it constitutes the cultural background shared by the interactants. The main goal of this symposium is to investigate the role of cognitive and cultural factors influencing self-construal, person perception and understanding of others. Thus we deal with the following leading questions: How do we understand other human beings, what are the best theoretical perspectives, what can we learn from cognitive psychology and neurosciences and what is the role of culture in the process of understanding oneself and others? In the recent development of social cognition it has become clear that we not only have to account for the observational stance towards other people but that we also have to systematically consider situations of online interaction with other human beings ( $2^{\text {nd }}$ person perspective). The main aim of the symposium is to present the state of the art of some key topics of social and cultural cognition from the perspectives of philosophy of mind, cross-cultural psychology and social-cognitive neuroscience as well as to outline some paradigmatic lines for future research.

## Albert Newen: The Place of Culture and Self in Theories of Social Understanding

How do we make sense of the behaviour of other people? Theory-Theory and Simulation Theory both only account for an observational understanding of others. This motivated the development of the interaction theory (S. Gallagher/D. Hutto). I will shortly outline a main deficit of the latter
before I develop an alternative approach: the Person Model Theory. Person models are the basis for our ability to register and evaluate behaviour. I argue that there are two kinds of person models we rely on, nonconceptual person schemata and conceptual person images (and both kinds are developed for groups and for individuals). This theoretical approach accounts for two levels of understanding: intuitive and inferential understanding. Furthermore, it has the advantage to account for the difference of understanding very familiar persons (relying on person models of individuals), on the one hand, and complete strangers (reyling on person model for groups and thus understanding a person by his social role as a student), on the other. The person model theory accounts for modelling myself by presupposing self-models in addition to models of others. The theory allows to spell out the interaction of relying on modelling oneself and others and finally it explicitly accounts for the role of culture as shaping the mind. (s. Newen/Schlicht 2009; de Bruin/Newen 2011).

## Gary Bente \& T. Dratsch: The Role of Tacit Cues and Social Order in Observing Others. Analyzing Nonverbal Behaviour and Impression Formation across Cultures

There is ample evidence that visual cues including physical appearance and nonverbal behaviour play a crucial role in person perception and impression formation. A short look at a face can lead to attributions of trustworthiness, a body posture or movement can be perceived as dominant and a smile can lead to warm feelings of connectedness. Humans are highly sensitive to nonverbal signals and our responses are fast and mostly beyond awareness and conscious control. There is also evidence supporting the notion that culture plays a prominent role in molding our nonverbal behaviors. In a series of studies we investigated the role of culture in the processing of nonverbal cues in conflict laden interactions, collaborative tasks as well as economic games focusing on the dimensions of liking, power/control and trust. The studies involving German, American, Chinese and Arab participants clearly point to cultural specificities indicating that distinct cultural values
as described for Westerners and Easterners are also implemented on the micro-level of social interactions.(see Bente et al. 2008, 2010; Goergescu et al. in press)

## Shinobu Kitayama: Error-Related Brain Activity Reveals Self-Centric Motivation

To secure the interest of the personal self (versus social others) is considered a fundamental human motive, but the nature of the motivation to secure self-interest is not well understood. To address this issue, we assessed electrocortical responses of European Americans and Asians as they performed a flanker task while instructed to earn as many reward points as possible either for the self or for their same-sex friend. For European Americans, error-related negativity (ERN) -an event-related-potential component contingent on error responses-was significantly greater in the self condition than in the friend condition. Moreover, post-error slowing-an index of cognitive control to reduce errors-was observed in the self condition but not in the friend condition. Neither of these self-centric effects was observed among Asians, consistent with prior cross-cultural behavioral evidence. Interdependent self-construal mediated the effect of culture on the ERN self-centric effect. Our findings provide the first evidence for a neural correlate of self-centric motivation, which becomes more salient outside of interdependent social relations (see Markus \& Kitayama 1991; Kitayama et al. 2011).

## Shihui Han: What constitutes the self? Cultural neuroscience studies of neurocognitive representation of the self

The self is a mixture of both biological and social construction. How is the self represented in the human brain? I'll present psychological and brain imaging studies of self-face recognition and self-concept published by our group during the last years. These studies investigated how neurocognitive processing of the self undergo cultural and biological influences. Our findings have implications for our understanding of the biosocial nature of the human brain and mental health. (see Han et al. 2008; Ma et al. in press).

## Kai Vogeley: Person perception and culture. The perspective of neuroscience

Psychology and neuroscience have recently started to reintroduce culture as an independent factor into the experimental designs of empirical studies focusing on cognitive processes and neural mechanisms. On a conceptual level culture cannot be treated as a rigid body of generalized features of different cultural backgrounds as defined by nationality or language, but has to be conceptualized more adequately as a dialectic exchange between individual members and their collectives with
respect to habits, practices and belief systems. However, experimental studies require operationalized approaches. We have recently used Asian-looking and European-looking virtual characters that expressed anger and happiness while gazing at the participant or another third invisible person in a Chinese and a German population. Overall, expressions are perceived more pronounced if the participant was looked at. Direct gaze emphasized the perceived emotion of ethnic out-group members, but not of ethnic in-group members. These results suggest that social interaction supervenes or is at least as influential as culture related differences in the perception of emotions. (see Vogeley et al. 2009; Han et al. 2013).

#### Abstract

When cognitive processes occur alongside observable actions, it is possible for characteristics of these processes to influence the ongoing performance of those actions. This satisfies everyday intuitions. For example, negotiators and poker players claim to be attuned to 'tells,' these early behavioral indicators of eventual decisions. Going beyond intuitions, however, several researchers have exploited this fine-grained source of behavior to highlight online cognitive processing. Using even a simple measure such as computer-mouse tracking can reveal a wide range of cognitive processing. Four participants in this symposium report on applications of the analysis of the action dynamics of cognition across multiple scales: (i) basic decisions, (ii) language processing, (iii) false responding, and (iv) social processes. The similarities and differences in expression of these processes in action highlight important continuities and discontinuities across cognitive and neural processes.

Keywords: action dynamics; social cognition; learning; decision making; language

## Cognition and Action

A perhaps still prevailing notion of the relationship between cognition and action is that motor movement takes place mostly near the end of a cognitive process or decision. Implicit in this notion is that the systems are relatively independent, potentially modular and encapsulated. An outcome of this attitude is that action has, to some extent, been neglected in many quarters of the cognitive sciences (for review on this issue, see Rosenbaum, 2005). In contrast, recent work suggests that action and cognition facilitate one another to such a degree that one can understand action as "part and parcel" of cognition (Freeman, Dale, \& Farmer, 2011). In this work, researchers extract the computer-mouse cursor movements of participants who carry out a cognitive task. By analyzing dynamic properties of the cursor, such as motion latencies, velocities, complexity of movement, and so on, new insights into cognitive processing are possible.

A tighter relationship between cognition and action has inspired explorations of cognition using densely-sampled be-
havioural data. Put simply, it may now be possible to investigate ongoing action for evidence of purported cognitive processes. The dynamic characteristics of ongoing behaviour provide a testbed for the comparison of models in various areas of cognitive science. The papers in this symposium will report on applications of the analysis of the action dynamics of cognition at four very different scales. The first talk will address the dynamics of basic choice processes by studying the dynamics of movement while those choices are made. The second talk addresses sentence process and pragmatic inferences. The third showcases the dynamics of false responding as a model of cognitive processes involved in deception. Finally, the fourth talk discusses the application of these dynamic techniques to social cognition. The symposium will end with 20-minute interactive discussion of the relationship between action and cognition, the impact of these measures on theoretical issues across scales, and the inevitable differences in how measures behave at these levels and their different tasks.

## (i) Mechanics of Choice and Decision-Making

Our everyday language about choice and decision making is, in English at least, replete with dynamic physical metaphors. We are 'pulled' or 'drawn' towards choices that we sometimes 'cannot resist'. When we make a decision, we might be asked, 'How did you come to this conclusion?' and we might feel were 'pushed' towards it or that we 'fell into it'. These metaphors highlight certain characteristics of decisionmaking. First, decision making takes time; our preferences gradually develop from less stable to more stable as we choose. Second, how we make our decisions tells us much about the quality of the decision, whether it was easy or difficult, fearful or hopeful, and so on. Indeed, the dominant models of preferential decision-making within cognitive science include the dynamic evolution of choice in that repeatedly sampling information biases the unfolding decision.

Within a short discrimination learning task, Denis O’Hora and colleagues manipulated the strength of attraction to available choices by changing the points available for making these choices. He will describe how they used this method to investigate choice trajectories under a range of conditions of choice conflict.

## (ii) Interplay between Pragmatic and non-Pragmatic Inference

Unlike most linguistic phenomena, the derivation of pragmatic inferences is optional. For example if a speaker is asked, "Are Todd and Sam coming to the party," and she responds, "Todds coming," the listener could interpret the utterance as 1) the speaker only knows that Todd is coming but doesnt know about Sam or 2) derive the inference that only Todd is coming and Sam is definitely not. In both cases, listeners at least know that Todds coming. Because pragmatic inferences are highly context dependent, research on the comprehension of inferences needs to tease part the likelihood of making an inference from the process of deriving on one (Bott, Bailey, \& Grodner, 2012).

John Tomlinson will present work on how action dynamics cannot only capture this important distinction, but also how action dynamics provide clearer insight into how pragmatic inferences are derived. In several of studies, listeners motor movements show strong initial preference for nonpragmatically enriched interpretations for scalar implicatures before correcting towards pragmatic interpretations. Studies will be presented on how intonation, context, and speaker information can streamline these inferences. Critical for this symposium is how action dynamics, specifically time normalized mouse movements, can provide new insights into how such factors above and beyond that of real time data analyses such as reaction times and eye-movements.

## (iii) Action Dynamics Reveal False Responses

Human beings are surprisingly adept at responding to questions with information that is in opposition to what is known to be true. There remain, however, many open questions about how deception is possible. Do we hold in mind what is known to be true, and actively inhibit it to respond falsely? Does it matter whether that information is biographically relevant, or is simply a statement that can be readily falsified in our own semantic memory? Does answering falsely get easier if our cognitive system can prepare for it?

Questions such as these pertain to the underlying cognitive processes that contribute to deception. Yet it is extremely difficult to create experimental situations that permit direct access into such mechanisms. In this presentation Dale and Duran survey a variety of experiments that utilize the mousetracking methodology to explore the dynamics of false responses. For example, in one experiment, participants were prompted to respond falsely about their personal experiences and biography (Duran, Dale, \& McNamara, 2010). In another, participants were prompted to lie to an imagined part-
ner in a game of 20-questions, thus confusing them about a target objects of the game (Duran \& Dale, 2012).

## (iv) Cognitive Processes in Social Categorization

Mere exposure to a social target has long been known to trigger spontaneous categorization along multiple dimensions (e.g., sex, race, age). Such categorizations are extremely rapid and efficient, yet also reflect the complex integration of a variety of bottom-up (e.g., facial and vocal cues) and topdown (e.g., stereotypic expectations, motivation) information sources. Jonathan Freeman will discuss recent work exploiting the tight link between cognitive and action dynamics to understand the underlying social categorization process.

In one series of studies, for example, participants were presented with sex-typical and sex-atypical faces and asked to categorize the targets sex by clicking on a male or female response on the screen (Freeman, Ambady, Rule, \& Johnson, 2008). During categorization of sex-atypical faces, hand trajectories were continuously attracted to the opposite sexcategory before settling into the correct response. These findings and others support an account of social categorization in which dynamic competition is central; perceived facial, vocal, and bodily cues (among other constraints) simultaneously weigh in on multiple partially-active category representations that dynamically evolve over time into stable categorical perceptions (Freeman \& Ambady, 2011).

## Goals and Scope

In recent years, computational models have become an increasingly important part both of cognitive science and cognitive neuroscience. In tandem with these developments neuroscientific and cognitive investigations of musical experience and behaviour have been gathering pace. In this context, music cognition constitutes a rich and challenging area of cognitive science in which the processing of complex, multi-dimensional temporal sequences can be studied without interference of meaning or semantics (see Pearce \& Rohrmeier, 2012, for a review). Because of its complexity and well-defined problem-space, computational modelling of music witnessed a rapid growth of successful higher-order modelling approaches. This workshop investigates computational modelling as a bridge between cognition and the brain, with a focus on understanding the psychological mechanisms involved in perceiving and producing music.

Many approaches have been taken to modelling the large variety of different cognitive processes involved in music perception and creation involving various modules of basic structural processing, statistical learning, memory, as well as motor, emotional and social cognitive processes. Recent computational models range from hierarchical, rule-based systems for representing harmonic movement inspired by probabilistic grammars for language, through oscillator based network models for modelling metrical and tonal perception, to probabilistic methods derived from machine learning for modelling dynamic learning and predictive processing of style-specific musical structure. Turning to cognitive neuroscience, recent years have seen increasing interest in advanced computational modelling of EEG and fMRI data used to distinguish brain regions responsible for the processing of different aspects of music (e.g., rhythm, pitch, timbre, harmony) and the functional connectivity between them. The purpose of this symposium is to bring together and display current research trends towards a synthesis of these two research areas linking the parameters and subcomponents of cognitive models of musical processing to functional and anatomical properties of the brain.

## Petri Toiviainen and Elvira Brattico Decoding the musical brain during naturalistic listening

Encoding, or prediction of neural activation from stimulus, is a common modeling approach in neuroscience. In our recent neuroimaging study, we applied encoding to predict brain activity during listening to different pieces of music from an extensive set of musical features computationally extracted from the pieces, and found widespread brain activation, including auditory, limbic, and motor areas (Alluri et al., Neuroimage, under review). With such complex and distributed neural activation, evaluation of different encoding models is not straightforward, because the goodness of prediction is difficult to assess. Decoding, or prediction of physical or perceived stimulus features from the observed neural activation, has the potential benefit of a more straightforward model evaluation because of easier performance characterization in terms of, for instance, correct classification rate.

In a series of experiments, our participants were measured with functional magnetic resonance imaging (fMRI) while they were listening to three different musical pieces. Subsequently, musical features were computationally extracted from the pieces, and continuous emotion ratings were collected from the participants. For decoding, the fMRI data were subjected to dimensionality reduction via voxel selection and spatial subspace projection, and the obtained projections were subsequently regressed against the musical features or the emotion ratings. To avoid overfitting, cross-validation was utilized. Different voxel selection criteria and subspace projection dimensionalities were used to find optimal prediction accuracy. The decoding results and the challenges of the approach will be discussed at the symposium.

## Psyche Loui <br> Behavioral and DTI Studies on Normal and Impaired Learning of Musical Structure

One of the central questions of cognitive science concerns how humans acquire knowledge from exposure to stimuli in the environment. In the context of music, knowledge
includes the structure of harmony and melody that govern how musical pitches are combined. While people of all cultures and ages show some knowledge of the structure of their music, people with tone-deafness (also known as congenital amusia) show a lack of behavioral sensitivity to harmony and melody. Here we combine behavioral evidence from subjective ratings, neuroimaging evidence from Diffusion Tensor Imaging, and neuropsychological evidence from tone-deaf individuals, to support the thesis that much of what we know and love about music is acquired via statistical sensitivity to the frequency and probability of occurrence of events in the auditory environment. This statistical learning mechanism relies on intact white matter connectivity between temporal and frontal lobe regions, and may subserve multiple auditory-motor functions including language as well as music.

## Edward Large and Ji Chul Kim A Universal 'Grammar' for Music

Since antiquity, science has asked whether mathematical relationships among acoustic frequencies govern the perception of musical relationships. Modern psychophysicists rejected this approach, citing evidence that the auditory system performs a linear analysis of sound. Cognitive psychologists have since relied primarily on statistical learning to explain music cognition, despite continued demonstrations of the importance of frequency relationships. Today evidence is rapidly mounting that the auditory system is highly nonlinear, inviting reevaluation of the role of frequency in constraining in the perception of music. Here, we present a dynamical systems analysis of auditory nonlinearities that predicts substantive universals in music perception and cognition. This approach explains perceptual ratings of Hindustani raga not only by encultured listeners, but also by listeners who were completely unfamiliar with the music of North India. This evidence suggests that universal properties of neural oscillation explain cross-cultural invariants in the perception of tonal music, implying neurodynamic constraints on the acquisition of musical languages.

## Martin Rohrmeier Computational Models of Musical Syntax

In order to create the variety of our rich musical experience, Western music employs a complex combination of interwoven features of pitch, rhythm, metrical structure, harmony and melody. Various computational models of music processing are based on local (event-to-event) processing of musical features (cf. Rohrmeier \& Koelsch, 2012). On the other hand, a number of theoretical approaches suggest that music involves recursive, hierarchical structures organized in ways similar to linguistic syntax. Further recent neurocognitive research provides evidence indicating that musicians as well as nonmusicians are sensitive to subtle long-distance violations resulting from the underlying syntactic structure. These insights suggest that musical processing is more complex than previously assumed and involves rich mechanisms of
structural parsing and implicit learning to deal with these syntactic features. This talk presents the picture emerging from converging evidence of theoretical approaches, recent experimental work and computational modeling. Probabilistic models of musical syntactic processing based on Hidden Markov Models and probabilistic context-free grammars underpin that the inference of complex nonlocal dependencies from mere exposure is plausible. They further predict experimental data of musical tension and expectancy showing that a variety of features of musical experience can be modeled by such approaches.

## Marcus Pearce <br> Expectation and Emotion in Music Perception: Computational Modeling of Dynamic Cognitive and Neural Processes

The idea that aesthetic experience of music is dependent on the confirmation and violation of expectation dates back at least to Hanslick. Meyer (1957) further proposed that such expectations depend on probabilistic models of musical structure, acquired through exposure. However, until recently such theories remained largely untested. Here we present evidence corroborating these proposals and filling in some of the details in terms of cognitive and neural processing. First, we show that musical expectations elicited in a range of musical styles result reflect probabilities acquired through a process of statistical learning. Subjective expectedness and uncertainty can be modeled dynamically through time using the information-theoretic concepts of information content and Shannon entropy respectively. Second, we identify time-locked electrophysiological brain responses to events differing in information content. Third, we show that variations in information content lead to distinct psychological and physiological emotional responses elicited in a live concert of music for solo flute. The results also indicate that expectations and emotion are influenced by factors other than the musical structure such as visual aspects of the performance. In summary this research suggests that musical expectations rely on dynamic probabilistic cognitive processing of musical structure, supported by corresponding neural processes, and generates characteristic physiological and psychological emotional responses.

Keywords: action; epistemic norms; is-ought problem; moral norms; normative inference; rational norms

## Thinking about norms

Humans are uniquely good at inventing norms, thinking about norms, complying with norms and defeating norms. It is small wonder, then, that norms are a focus of much interest as well as debate across the cognitive sciences, encompassing such diverse issues as rationality, morality and action. The aim of the present symposium is to bring together a range of psychological and philosophical contributions to this pertinent debate. Contributors come from diverse backgrounds, including epistemology, metaethics, moral judgment, decision making, and reasoning. We will examine foundational issues in normative thinking, such as: What is the relation between norms and descriptions? What are the psychological mechanisms underlying normative thinking? How do epistemic and moral norms guide action? What, if any, are the appropriate norms for knowledge, rationality, and moral behaviour, and how can they be determined?

## Proust: The norms of acceptance

An area in the theory of action that has received little attention is how mental agency and world-directed agency interact. The purpose of the present contribution is to clarify the rational conditions of such interaction, through an analysis of the central case of acceptance. There are several problems with the literature about acceptance. First, it remains unclear how a context of acceptance is to be construed. Second, the possibility of conjoining, in acceptance, an epistemic component, which is essentially mind-to-world, and a utility component, which requires a
world-to-mind direction of fit, is merely posited rather than derived from the rational structure of acceptance. Finally, the norm of acceptances is generally seen as related to truth, which turns out to be inapplicable in a number of cases.

We will argue, first, that the specific context-dependence of acceptances is derived from their being mental actions, each embedded in a complex hierarchy of acceptances composing, together, a planning sequence. Second, that acceptances come in several varieties, corresponding to the specific epistemic norm(s) that constitute them. The selection of a particular norm for accepting answers to considerations of utility - to the association of an epistemic goal with an encompassing world-directed action. Once a type of acceptance is selected, however, the epistemic norm constitutive for that acceptance strictly applies. Third, we argue that context-dependence superimposes a decision criterion on the output of the initial epistemic acceptance. Strategic acceptance is regulated by instrumental norms of expected utility, which may rationally lead an agent to screen off her initial epistemic acceptance.

## Pothos \& Busemeyer: Implications for the rationality debate from the quantum cognition research programme

Bayesian theory has enabled an influential perspective on human rationality, partly based on such arguments as long term convergence and the Dutch book theorem. Moreover, behavioral predictions in decision making from Bayesian theory are typically supported by strong intuition. Yet, this intuition often goes against empirical findings. For example, Kahneman, Shafir, Tversky and collaborators have provided many compelling demonstrations of violations of the law of total probability or the conjunction principle. Recently,
researchers have shown that many of these violations can be naturally accounted for within quantum probability theory, a framework for formal probabilistic modeling alternative to Bayesian theory. If one accepts that quantum theory provides a more accurate framework for modeling human behavior, at least in some cases, then what are the implications regarding (or not) the debate on human rationality? After all, probabilistic inference in quantum theory can be strongly context and perspective dependent, perhaps going against an intuition that probabilistic inference is rational to the extent that it is objective (in some sense). Equally, we note that probabilistic inference in Bayesian models presupposes adherence to the, perhaps cognitively unrealistic, principle of unicity, the requirement that there is a complete joint probability distribution for all relevant possibilities. Consideration of the above issues provides us with two broad themes. First, is the Bayesian notion of normative rationality cognitively feasible, even if appropriate from an abstract perspective? Second, can a perspective about normative rationality arise from quantum cognitive models?

## Miller \& Cushman: Action, outcome and value

How can we characterize the underlying cognitive mechanisms that give rise to moral judgment? A popular approach has been to contrast "emotion" with "cognition", but this is widely regarded as a problematic distinction--even by its chief proponents. We advocate for an alternative approach motivated by the distinction between model-based and model-free reinforcement learning. A model-based system chooses actions with the greatest expected value based on a detailed causal model of their likely outcomes. A model-free system associates positive or negative feelings with particular actions intrinsically. We will present a series of studies suggesting that this distinction between outcome-based and action-based decision-making matches the dualsystem structure of moral judgment, with many benefits over the traditional distinction of emotion vs. reason. Dual system approaches in the moral domain have been used widely, although controversially, to distinguish normatively warranted and unwarranted moral judgments. The application of reinforcement learning theories to the moral domain has the potential to inform debates over the normative status of moral judgments. It allows us to state precisely the relationship between value, experience and choice. Leveraging this formal precision, we join others in arguing that psychological facts have implications for the normative status of moral judgments.

## Quintelier: The real is-ought problem in ethics

Numerous scholars have pointed out that 'is' and 'ought' should be kept separated. While valuable, this pursuit distracts from an equally important issue: In order for
empirical findings to be relevant for ethics, we need an account of how 'is' and 'ought' can be properly linked.

I illustrate this by means of the moral universalism versus relativism debate: Scholars have advocated that we should think of moral rules as universal because, among other reasons, lay people intuitively think of morality as universal. Recent studies however show a diversity of moral reasoning, including relativist moral reasoning, in the folk. Nevertheless, it is now debated how these data are relevant for ethics because, arguably, 'is' and 'ought' should be kept separated. In the moral universalism versus relativism debate though, illegitimate inferences from 'is' to 'ought' are not the problem. While it is true that previous arguments in favor of moral universalism relied on a specific relation between 'is' and 'ought', this relation is refuted by presentday scholars. However, no alternative is put in place. Moreover, at the same time, the rationale for doing empirical research on this topic is to further a normative debate. Thus, either existing empirical research is irrelevant, or researchers have to defend a link between 'is' and 'ought'.

## Elqayam, Thompson, Evans, Over, \& Wilkinson: When do we infer ought from is?

The debate on norms in cognitive science goes back at least as far as Hume's critique of what has come to be known as the is-ought problem: when, if ever, is it valid to infer normative conclusions from descriptive premises? Whereas philosophers are interested in the validity of such inference, we ask about the psychological mechanisms underlying it.

We present a new processing model of inference from 'is' to 'ought'. The relevant logic is deontic, the logic of rules and regulations. We propose that such inference is pragmatic, in the sense that it is socially rich, contextualised, probabilistic, and defeasible. Agents infer deontic, normative conclusions from descriptive premises under a set of conditions: (1) an agent; (2) a goal, or a valued outcome (3) an action causally linked to the goal. We present a set of findings to show that the direction of the deontic conclusion that people endorse matches the psychological value of the goal; that the strength of the conclusion is a function of the strength of the causal link between action and outcome; and that the inference is suppressed when additional premises present conflicting goals, triggering a utilitarian conflict; or conflicting norms, triggering a deontological conflict. We suggest that this normative inference underlies much of human epistemological and moral judgement and action.

Keywords: Implicit learning; statistical learning; explicit learning; music cognition; language acquisition.

## Goals and Scope

Implicit learning, essentially the ability to acquire unconscious (implicit) knowledge, is a fundamental aspect of human cognition. This symposium focuses on the acquisition of two cognitive systems that are widely regarded as prime examples of implicit learning "in the real world", namely language and music (see e.g. Rebuschat et al., 2011; Rohrmeier \& Rebuschat, 2012). This symposium brings together leading researchers from across the cognitive sciences (psychology, linguistics, cognitive neuroscience, computer science, and musicology) in order to discuss current trends in implicit learning research, to identify the progress made in recent years, and to outline future directions to take, both in terms of topics and novel methodologies.
The symposium will consist of five talks, followed by a brief general discussion. Each talk approaches the symposium topic from a highly innovative and interdisciplinary angle. Christiansen and Misyak focus on individual differences in implicit language learning, while Rebuschat concentrates on the role of implicit and explicit learning in second language (L2) acquisition. François and Schön's work demonstrates the impressive effect of musical practice on the implicit learning of linguistic structure, while the last two talks, by Dienes and colleagues and by Rohrmeier and Widdess, focus on the implicit learning of Chinese tonal poetry and of syntactic features of North Indian music, respectively. These last two studies reflect a particularly important trend in implicit learning research

towards the use of more ecologically-valid stimuli. In addition to introducing novel and exciting subject areas, the research discussed in this symposium also reflects the strong tendency, within cognitive science, for methodological diversification. The talks will discuss data from behavioral and neurophysiological experiments as well as results of computational modeling.

## Morten H. Christiansen and Jennifer B. Misyak Individual differences in implicit statistical learning and language

Over the past decade, implicit learning under the guise of statistical learning has emerged as an important experimental paradigm with which to study mechanisms involved in language acquisition. Although few empirical studies have directly linked variation across statistical learning and language, it is generally assumed that greater sensitivity to statistical structure leads to better language performance. Here, we report the results of studies investigating the relationship of individual differences in statistical learning of adjacent and nonadjacent dependencies to variations in the processing of local and nonlocal dependencies in natural language. Together, the results indicate that individual differences in statistical learning are positively related to variations in language processing. However, the complexity of the pattern of interrelations suggests that future developmental and adult work on implicit statistical learning must incorporate careful attention to a diversity of natural dependency-structures to establish the proper relationship between adjacent and nonadjacent manifestations of statistical learning and the
extent to which they map onto similar structures in language.

## Patrick Rebuschat Implicit and explicit learning of $\mathbf{L} 2$ syntax

First language acquisition is generally characterized as a process where most learning proceeds implicitly, i.e. incidentally and in absence of awareness of what was learned. At the same time, however, there is considerable debate as to whether implicit learning plays a similarly important role in the case of adult second language (L2) acquisition. In this talk, I will review a series of experiments that investigated the implicit and explicit learning of L2 syntax by means of an artificial language paradigm. This research addressed questions such as the following: Is there implicit learning in the case of L2 acquisition? If so, how is implicit knowledge of language represented in the mind (rules, patterns, chunks...)? How do task instructions affect the acquisition of implicit and explicit knowledge? Is there an implicit-explicit interface? And what is the role of individual differences (e.g. working memory capacity), in the implicit and explicit learning of languages?

## Zoltan Dienes, Xiuyan Guo, Shan Jiang, and Feifei Li <br> Implicit learning of symmetries in tonal language

Implicit learning research has identified a number of structures that people can unconsciously learn, including chunks and fixed patterns of repetition. Language and music appear to involve structures more complex, indeed higher than finite state, for example symmetry structures that are simply generated by recursive rules (e.g. centre embedded, cross-serial dependency structures). The implicit learning of such structures presents an interesting challenge to existing models of implicit learning, such as the Simple Recurrent Network (SRN). We build on our earlier work in music and movement, by looking at symmetries in the tonal structure of Chinese poetry. We show that people can acquire unconscious knowledge of both cross-serial dependencies and centre embeddings in tonal poetry, with the former being easier than the latter. We also show that people can generalise their unconscious knowledge from being trained on strings of a certain length to test strings of a different length, indicating apparent learning of the symmetry itself rather than chunks or fixed length associations. We also show the SRN can model many of the details of this learning, exploring whether the SRN is more than a graded finite state machine.

## Clément François and Daniele Schön Implicit learning of linguistic structures and the effect of musical practice

Both speech and music involve sequences of sounds ordered in time according to complex rules. The acquisition of both
language and music require learners to engage several cognitive functions and notably the ability to sequence sound patterns. There is increasing evidence showing that the statistical regularities found in the input can play a important role in the implicit acquisition of several linguistic and musical structures. We previously showed that combining music and language into song can facilitate speech segmentation in implicit learning paradigms (Schön et al., 2008). Moreover, we recently conducted a set of experiments with adults and children showing that musical practice directly affects sensitivity to statistical regularities in speech both at the neural and behavioral levels (François \& Schön, 2011; François et al., 2012). Interestingly, our results seem to show that musical training and expertise have effects on brain plasticity that may go beyond primary auditory regions. These results also confirm that neurophysiological measures are more robust and sensitive than behavior to study implicit statistical learning processes.

## Martin Rohrmeier and Richard Widdess Implicit learning of musical grammar: The acquisition of North Indian music

Recent years have witnessed an increasing interest in the implicit and statistical learning of music (see Rohrmeier \& Rebuschat, 2012, for a review). Despite this interest, only few studies employed stimuli that resemble actual musical systems more closely, and only little research has been carried out on the acquisition of non-Western music. In this paper, we present the findings of a study that addressed this gap. The study focused on the implicit learning of modal melodic features in traditional North Indian music by Western learners who were unfamiliar with this musical system. Participants were trained on the ālāp (introduction) section of either the rāga Toṛī and Multānī and tested on novel excerpts from (later) jor sections of both rāgas featuring five distinct melodic features. Three of the five features were melodically distinctive of either rāga, whereas two were only distinctive based on other than mere pitch sequence features (for instance, emphasis). Findings indicated that Western participants unfamilar with Indian music learned to distinguish features of either rāga without intending to and after a very short exposure period. These results confirm that implicit learning constitutes a powerful mechanism that plays a fundamental role in the acquisition of highly complex, ecologically-valid musical stimuli.

# The Co-Existence of Naïve and Scientific Concepts in Learning and Development 

Moderator: Michael Schneider (University of Trier, Germany, m.schneider@uni-trier.de) Discussant: Stella Vosniadou (University of Athens, Greece) Participants:<br>Andrew Shtulman \& Kelsey Harrington (Occidental College, USA) Michael Schneider (University of Trier, Germany) \& Ilonca Hardy (University of Frankfurt, Germany)<br>Lindsey J. Powell \& Susan Carey (Harvard University, USA)<br>Stellan Ohlsson (University of Illinois at Chicago, USA)

Keywords: Conceptual change; conceptual development; naïve concepts; misconceptions; knowledge fragmentation.

## Motivation

Conceptual learning is sometimes described as replacement of incorrect knowledge by correct knowledge. However, a number of recent studies show that the storage of correct concepts in memory does not automatically erase related incorrect concepts from memory. As a result, naïve and scientific concepts in the same domain can coexist in a learner. The symposium aims at discussing these findings and their implications for definitions, models and empirical studies of conceptual learning and development.

From an empirical point of view, the coexistence of naïve and scientific concepts in learners raise the questions how common this phenomenon is, whether it differs between content domains and whether it changes in response to educational interventions, over the course of conceptual change, or over the life span. Intervention studies, crosssectional studies, and longitudinal studies are needed to investigate these aspects.

If learners simultaneously agree with naïve concepts and scientific concepts with various degrees, new operationalizations of conceptual knowledge are needed that adequately reflect this multidimensionality of knowledge. Researchers need to know when and how one-dimensional assessments of conceptual knowledge can bias empirical findings and what alternative methods yield more valid and reliable results.

Formal logic shows that from a contradiction one can derive any conclusion (ex falso quodlibet). According to coherence theories of truth, logical coherence is the defining characteristic of scientific theories. Thus, the coexistence of correct and incorrect conceptual knowledge in learners raises the questions whether a learners' conceptual knowledge in a domain can still be characterized as a theory, how incoherent knowledge influences learners' reasoning, and how learners evaluate the adequacy of their concepts.

The contributions to this symposium approach these problems from different theoretical and empirical angles. They use newly developed assessment tasks along with theoretical analyses, reaction time analyses and latent variable modeling. The studies compare age groups ranging
from 5-year olds over adults to the elderly and investigate scientific concepts as well we learners' theories of mind.

## Assessing the Resilience of Naïve Theories Across the Lifespan

Andrew Shtulman \& Kelsey Harrington

Three decades of research in cognitive development and science education have shown that students enter the science classroom with rich theories of everyday phenomena that often interfere with learning. Science educators are thus charged with two tasks: not only must they help students learn the correct, scientific theory at hand, but they must also help students unlearn their earlier, less accurate theories. This process has typically been characterized as a kind of radical restructuring, with scientific knowledge coming to overwrite earlier intuitions, but recent research suggests that those intuitions may never be fully overwritten. In this talk, I will present a method for assessing the resilience of early intuitions in potentially any domain of knowledge. This method entails asking participants to verify two types of statements as quickly as possible: "consistent" statements, whose truth value is consistent across both naïve and scientific theories of a particular domain (e.g., "The moon revolves around the Earth," which is true on both naïve and scientific theories of astronomy), and "inconsistent" statements, which involve the same conceptual relations but whose truth value differs across those theories (e.g., "The Earth revolves around the sun," which is true on a scientific theory but not a naïve theory).

If naïve theories continue to be represented in some form, then the latter should cause greater cognitive conflict than the former. Consistent with this hypothesis, adults have been shown to verify inconsistent statements more slowly and less accurately than consistent ones, and this effect has been documented in domains as diverse as astronomy, evolution, fractions, genetics, and mechanics. Naïve theories thus seem to survive the acquisition of a mutually incompatible scientific theory, coexisting with that theory for many years to follow. Indeed, preliminary research with an elderly population suggest that pre-scientific intuitions may persist across the lifespan.

# A Latent Transition Model of Naïve and Scientific Knowledge in Conceptual Change 

Michael Schneider \& Ilonca Hardy

Conceptual change requires learners to restructure parts of their knowledge base. Prior research has raised the questions to what extent misconceptions, everyday conceptions, and scientific concepts can co-exist during the course of conceptual change, whether this extent is stable over time, and how it changes in response to educational interventions. To address these questions we assessed 161 third-graders’ knowledge about floating and sinking of objects in liquids at three measurement points by means of multiple-choice tests. The tests assessed how strongly the children agreed with commonly found but mutually incompatible misconceptions, everyday conceptions, and scientific concepts about floating and sinking.

A latent profile transition analysis of the test scores revealed five profiles, some of which indicated the coexistence of inconsistent pieces of knowledge in learners. The majority of students (63\%) were on one of seven developmental pathways between these profiles. Children's knowledge profiles at a point in time were useful predictors of their further knowledge development. The extent of co-existence of misconceptions, everyday conceptions, and scientific concepts decreased on some individual developmental paths, increased on others, and remained stable on still others. The study demonstrates the usefulness of explicit quantitative models of conceptual change. The results support a constructivist perspective on conceptual development, in which developmental changes of a learner's knowledge base result from idiosyncratic, yet systematic knowledge construction processes.

## Using Executive Function Depletion to Assess Conflict between Advanced and Naïve Theories

Lindsey J. Powell \& Susan Carey

Demonstrations that children's executive function abilities (EF) correlate with conceptual development in diverse domains, including theory of mind, math, biology, and physical reasoning, have lead researchers to propose that EF plays a role in acquiring new concepts and theories. However, it may also be the case that this relationship partly reflects a critical role for EF in deploying new knowledge after its acquisition, especially if people persist in representing naïve theories that compete with their more sophisticated or scientific understanding of a given domain. We will discuss research that develops and deploys a methodological tool that can help disentangle questions of acquisition and expression by asking whether EF resources are necessary for children to use newer theories in place of older, naïve ones.

Adult research on executive function (or "ego") depletion has shown that deploying EF resources in one context decreases the ability to draw upon further EF resources immediately thereafter. An initial experiment demonstrated that the same is true for 5-year-old children. Subsequently,
we asked whether EF depletion would impair 5-year-olds' performance on a standard false belief task. While the performance of a control group suggested that children at this age have successfully acquired an explicit understanding of how beliefs impact actions, the EF depletion manipulation significantly impaired children's ability to use this understanding to guide their predictions of others' actions. A follow-up study asking children to explain rather than predict actions based on false beliefs suggests the role of EF in belief reasoning is not limited to suppressing an egocentric point of view. Even when presented with an outcome only consistent with their mature understanding of beliefs, children subjected to EF depletion were impaired in their ability to use that knowledge to generate an explanation of others' actions. Although applied here to theory of mind development, I will also discuss how this EF depletion method could be used to look at the role that EF plays in adjudicating between coexisting naïve and scientific theories in other domains.

## Cognitive Utility as the Arbiter Among CoExisting Knowledge Structures

## Stellan Ohlsson

There is little doubt that several different views of a topic can co-exist in a person's memory. For example, a science historian might be able to reason about a chemical reaction both from the perspective of the phlogiston theory and the perspective of the oxygen theory of combustion. Laboratory data from a re-categorization study in support of coexistence will be summarized briefly. If the individual components of knowledge structures are conceived as beliefs that are true or false, co-existence becomes problematic: What does the person 'really' believe? The belief-centered view also requires a theory of how people evaluate the relative strength of the evidence for alternative beliefs, a notoriously difficult problem.

Neither the history of science, nor social psychology, nor cognitive psychology has produced a widely accepted theory of how people decide on the strength of the evidence for or against a particular belief. For example, in both philosophical and political discourse, adherents of opposing views sometimes exchange arguments and other types of evidence for decades, even centuries, without resolving their disagreements, casting doubt on the idea that the evaluation of evidence is a real cognitive process. In this talk, I will develop the alternative idea that the quantity that people estimate is not the strength of evidence but the cognitive utility of a knowledge structure. The utility-based view dissolves some of the difficulties generated by the beliefcentered view, while raising some question of its own. An explanation will be offered why it seems as if (some) people are engaged in the evaluation of evidence. The utility-based view supports the notion of hands-on science instruction, but also explains why such instruction might fail under certain circumstances. The utility-centered view was anticipated by William James, Charles Sanders Peirce, and other pragmatist philosophers.

# Minimal Nativism: How does cognitive development get off the ground? 

Tomer D. Ullman and Joshua B. Tenenbaum<br>Department of Brain and Cognitive Sciences, MIT<br>Cambridge, MA USA 02139<br>Noah D. Goodman<br>Department of Psychology, Stanford University<br>Stanford, CA USA 94350<br>Shimon Ullman<br>Department of Computer Science and Applied Mathematics, Weizmann Institute of Science<br>Rehovot 76100 Israel<br>Elizabeth Spelke<br>Department of Psychology, Harvard University<br>Cambridge, MA USA 02138

Keywords: Cognitive development; Core knowledge; Learning; Computational modeling

When constructing a mind, what are the basic materials, structures and blueprints a young child has to work with? Are most of the structures already in place, with children merely working to embellish them? Do children begin with several buildings already in place (the Physics Building, the Social Building, the Number building, etc.), and only decorate a bit as they get older, perhaps building bridges between them using language? Such a view might describe a strong innate core hypothesis (Spelke et al., 1994). Or does the child begin with more of an empty plain, and an ability to construct whatever is necessary out of whatever materials are at hand at the time? Such a view might be more along the lines of classic empiricism (Quine, 1964).

Many other views are possible, lying somewhere between the extremes of positing that the child starts with everything, and positing that the child starts with nothing. For example, perhaps the child begins with a powerful general-purpose learning mechanism and a general blueprint for how to organize the world's entities into core domains, but no detailed, specific understanding of how these domains operate. Or perhaps the child begins with a powerful learning mechanism and a general blueprint for cognitive architecture, but no abstract concepts - only raw sensory experience. Yet if her sensory experience can be structured by a few crucial 'proto-concepts' - low-level input analyzers that tug her learning apparatus in certain appropriate directions - that minimal scaffolding could be sufficient.

Of course metaphors for cognitive development will only take us so far. In the last few years, a number of stimulating proposals for how cognitive development might get off the ground have been framed by computational modeling researchers, and these models offer to bring greater precision, clarity and subtlety to classic "nature versus
nurture" debates. At the same time, recent empirical work with young children offers striking new data that both motivates and challenges these computational accounts. Our symposium brings together some of the researchers who have contributed to these developments from both computational and empirical perspectives (Goodman, Ullman, \& Tenenbaum, 2011; Spelke \& Kinzler, 2006; Tenenbaum, Kemp, Griffiths, \& Goodman, 2011; Ullman, Harari, \& Dorfman, 2012; Ullman, Goodman \& Tenenbaum, 2010; Xu \& Kushnir, 2012). Our goals are to survey the landscape of developmental possibilities across multiple domains of physics, psychology, number, geometry, and language; to bring recent models and empirical work into closer contact; and to confront, honestly and clearly, the deep challenges that remain unaddressed.

Our plan is to have four 15 -minute talks, followed by a 30-40 minute discussion. T. Ullman will speak first, sketching out the space of potential approaches to a "minimal scaffolding" for cognitive development, and touching briefly on his own work modeling the development of intuitive physics, intuitive psychology, and the interface between these domains. N. Goodman will then present the "probabilistic language of thought" view - that an innate, abstract, domain-general, language-like ability for composing and manipulating conceptual representations is the minimal structure necessary for learning, potentially supplemented with specific 'named-functions' or inputanalyzers for certain domains. S. Ullman will then expand on the notion of innate perceptual input analyzers, illustrating with a case study drawn from his recent work on computer vision systems that learn to identify and reason about agents and actions in real-world video. E. Spelke will approach these issues from the standpoint of her recent work on the development of space, number and other mathematical concepts. She will also provide a more general critical perspective on the various computational perspectives presented earlier. This will set the stage for our
discussion, to be facilitated by Tenenbaum and Spelke, with the active involvement of audience participants as well as all our speakers.

## Tomer Ullman: The theoretical landscape, and a case study in the origins of physical and psychological knowledge

Cognition can be viewed as a program, albeit an incredibly complex one. Cognitive development then is the process by which the mind moves from one program to another. I will introduce a range of approaches to modeling cognitive development as different takes on the problem of "program induction" or "program synthesis". I will argue for the value of beginning with abstract templates that can capture deep patterns common to the explanatory structure of theories in many domains. I will show how this approach provides insight into the development of children's first physical and psychological concepts, such as force and utility, as well as the interface between these domains. I will briefly speculate on how these templates might arise or grow over the course of development or evolution.

## Noah Goodman: Minimal nativism and the language of thought

How much must be built into the language of thought? Universal formal languages can be built with a very small number of primitive operations, yet adult humans have a large number of conceptual operations ready-to-go for new situations. Indeed, developmental psychologists have argued that a significant and rich subset of these are innate primitives. I will argue that a universal language of thought together with a powerful learning mechanism is able to construct many of the needed concepts very quickly. However, I will find that some basic concepts can be learned more easily when supported by low-level modules that transform the perceptual input -- input analyzers. This combination cuts a middle road between strongly nativist and strongly empiricist view -- a minimal nativism.

## Shimon Ullman: Bootstrapping from domainspecific 'proto-concepts'

Already in their first months of life, infants rapidly learn to recognize complex objects and events in their visual input. Two striking examples are the detection of agents' hands and their direction of gaze, properties which play an important part in understanding actions and goals (Woodward 1998, Flom et al. 2007). In computational schemes, these problems are notoriously difficult. In contrast, detecting hands and gaze direction, and using them to make inferences and predictions, are natural for humans, and appear early in development. I will briefly describe how these problems can be solved using a learning scheme guided by an empirically motivated innate mechanism - the detection of 'mover' events in dynamic images, which are the events of a moving image region causing a stationary region to move or change after contact. The implications go
beyond the specific tasks, by showing how domain-specific 'proto concepts' can guide the system to acquire meaningful concepts, which are significant to the observer, but statistically inconspicuous in the sensory input.

Such proto-concepts may exist in other domains, forming a bridge between the notion of innate conceptual knowledge and that of learning mostly from sensory experience.

## Elizabeth Spelke: The origins of spatial and numerical thinking

When children begin to learn arithmetic, measurement, and geometric symbols such as maps, what cognitive systems support this learning process? I propose that this process is supported by four domain-specific cognitive systems: two core systems of number and two core systems of geometry. These systems are present and functional at the time that a child or animal first encounters the entities on which they operate: in this strong sense, they are innate. The systems also remain functional throughout life and support mathematical reasoning in adults as well as children: in this sense, they are foundations of mature mathematical reasoning. But the systems are far less general or powerful than the formal mathematical systems that children come to acquire, including the systems of natural number and Euclidean geometry. Powerful, domaingeneral systems for representing the information delivered by core systems, and for forming new concepts from this information, therefore constitute a fifth foundation for mathematics.

This may be the general scheme for much of later conceptual knowledge: combining core domains that have isolated innate concepts using later maturing domaingeneral systems.

## Introduction

Traditionally, psycholinguistics and neuropsychology have been informed by conspicuous pathologies such as aphasia, which revealed the localization of some of the processes involved in language comprehension and production, in particular of those related to lexical access and morphological and syntactic processing. One of the main objectives of this symposium is to explore whether psychiatric pathologies are informative of the processes involved in meaning construction and comprehension, in the same way that aphasia research has contributed to our knowledge of the neurobiology of other aspects of language (Elvevåg, Helsen, De Hert, Sweers, \& Storms, 2011).

The kind and type of language disturbances displayed by patients can shed some light on the underlying pathologies, hopefully suggesting tractable lines for further research. Conversely, an improved understanding of the mechanism of psychiatric diseases can promote the understanding of some intricate aspects of non-pathological language production. In this Symposium we bring together different perspectives to the study of language in pathology and as a manifestation of the underlying neural networks' workings. The symposium is thus centered around language, both from an empirical perspective and a modeler's point of view. We describe this two aspects in the following sections.

## Language analysis in pathology

The last decades have seen a tremendous increase in the development of techniques to study the physiological and pathological processes in the brain. Among them, the study of language production and comprehension has been recognized as a central research topic. The disturbances in language vary between different brain pathologies. For instance Garrard and coworkers (Garrard, Maloney, Hodges \& Patterson, 2005) have shown that Alzheimer's disease can
notoriously affect the way lexical items are selected and used by a writer, even before the symptoms of the disease are apparent. Several measures of language comprehension and production have been used to assess the presence and course of schizophrenia and mania. Classically, for patient state evaluation, there is a variety of fine-grained rating scales of the coherence of speech and communication, such as the Scale for the Assessment of Thought, Language and Communication (Andreasen \& Grove, 1986). The use of these scales requires extensive training and the results remain open to variance across raters. Several recent approaches attempt to devise automatic or semiautomatic methods aimed at diagnosis or with the purpose of understanding the cognitive deficits involved (Cabana,Valle-Lisboa, Elvevåg, \& Mizraji, 2011). The description of the underlying causes of these alterations is specially relevant when these methods are combined with imaging and modeling data. We turn next to models.

## From data to models

The complex patterns of linguistic productions, with the associated generation of measurable neurobiological responses, can only be interpreted in light of models and theories. The other aspect of the symposium is the use of neural models and theories in order to interpret the data, to propose new experiments and to suggest new therapeutic avenues for research. The models of choice are based on connectionist approaches. There is an increasing tendency to develop connectionist models of psychiatric pathologies (e.g. Hoffman, Grasemann, Gueorguieva, Quinlan, Lane, \& Miikkulainen, R., 2011). At the symposium two types of models will be discussed. One type is that of coarse-grained models that when deteriorated can lead to alterations of language processing and production that mimic some of the properties displayed by language produced by patients (Valle-Lisboa, Pomi, Cabana, Elvevåg \& Mizraji, 2013 ). This type of model is aimed at the level of brain networks as
derived from fMRI. The other type of model is concerned with the syntactic level of description and its expression through brain potentials as measured through EEG (beim Graben \& Potthast, 2012). Interestingly, both type of models can be related through their basic assumptions (i. e. multiplicative synaptic interactions).

The symposium will consist of a 10 minute introduction by the chairman followed by 20 minute talks by each speaker and followed by a round of discussion.

## Speakers

## Dr. Peter Garrard (pgarrard@sgul.ac.uk)

Dr Garrard is a Neurologist with vast experience in the study of semantic dementia and Alzheimer's disease, in particular the linguistic manifestations of those pathologies. He has developed several diagnostic procedures and is currently exploring the symptoms and neuroimaging manifestations of patients suffering atypical dementias. He is Reader in Neurology at St George's, University of London and Honorary Consultant Neurologist, St George's Stroke and Dementia Research Centre, UK.

Dr. Peter beim Graben (peter.beim.graben@hu-berlin.de).
Dr beim Braben is a Physicist who works in Cognitive Neurodynamics, Computational Psycholinguistics and Computational Neuroscience. His recent work is related both to the processing of sentences by neural networks and the electrical potential measurements of neural activity. He is DFG Heisenberg Fellow for Cognitive Neurodynamics, at the Institut für deutsche Sprache und Linguistik, HumboldtUniversität zu Berlin, Germany.

## Dr. Brita Elvevåg (brita@elvevaag.net).

Dr Elvevåg is a research psychologist interested in cognitive neuropsychiatry, cognitive neuroscience, and the cognitive, neural and genetic basis of language in healthy individuals and those with clinical conditions that affect the brain, especially psychosis and dementia. She is Professor of Psychiatry in the Department of Clinical Medicine at the University of Tromsø, and also at the Norwegian Centre for Integrated Care and Telemedicine at the University Hospital of North Norway Tromsø, Norway.

## Dr. Eduardo Mizraji (mizraj@ffien.edu.uy)

Dr. Mizraji is a Biophysicist who studies neural network theory and the implementation of high level cognitive activities through the use of neural models. The part of his recent works more related to the symposium are concerned with discourse generating neural models, and the emergence of symbolic activities in a neural network. He is Professor
of Biophysics in the School of Sciences, Universidad de la República, Uruguay.

## Chairman and Organizer

## Dr. Juan Valle Lisboa (juancvl@fcien.edu.uy)

Dr Valle Lisboa is a Biophysicist and Neurobiologist interested in theoretical neuroscience and the neural basis of high level cognition. His latest works include the development of language production models and their deterioration in pathologies as well as neural models of lexical representation. Dr Valle Lisboa is at the School of Sciences and the School of Psychology at the Universidad de la República, Uruguay.

# The empirical investigation of semantics: Between abstract-symbolic and embodied-simulative models of meaning 

Markus Werning (markus.werning@rub.de)<br>Department of Philosophy, Ruhr University Bochum 44780 Bochum, Germany<br>Erica Cosentino (ericacosentino@libero.it)<br>Department of Philosophy, University of Calabria 87036 Rende (CS), Italy

Keywords: embodiment; abstract symbol theories, EEG, emulative semantics

## Introduction

Classical theories of meaning in the field of linguistics and psycholinguistics assume that meaning arises from the combination of symbols for which a substring or other partwhole relation is defined. According to this perspective, symbols are abstract, amodal (i.e., neither perceptual, nor motoric) and only contingently related to entities in the external world.

For a long time, a convincing case for classical models has been the absence of alternatives. However, more recently, several theories subsumed under the notions of "embodied" or "grounded" theories have challenged the fundamental assumptions of classical models (e.g., Barsalou, 1999; Glenberg, 2010; Pecher \& Zwaan, 2005). From the point of view of embodied theories, cognition is grounded in modal representations which simulate actual objects, properties and situations. Such a claim carries theoretical, empirical and methodological repercussions that also change the way linguistic processes are conceived of (Ferretti et al., 2013; Zwaan \& Radvansky, 1998). The goal of the symposium is to explore which repercussions these issues have on the nature of linguistic meaning and its neural and cognitive realization or representation.

A main motivation for the symposium is that, in spite of the relevance of the issue, to this day the relationship between classical and embodied models of meaning is still not clear. More to the point, it is not clear whether classical and embodied models describe different aspects of meaning (and are then compatible) or whether they are mutually exclusive explanations of the same phenomena. As the nature and representation of meaning is a topic of increasing cross-disciplinary interest, the symposium aims to encourage an in-depth discussion among scholars interested in the problem, providing a cross-disciplinary forum of dialogue.

A further motivation for the symposium is that researchers in many specialized fields of cognitive sciences have been providing results which seem to support at least
some form of embodiment (Meteyard et al., 2012; Vigliocco et al., 2011). However, due to the specialization of competences, the circulation of these results among scholars in different arenas has not always been easy. This symposium will provide an opportunity to bring together philosophers, linguists, psychologists and neuroscientists joined by a common interest in the application of experimental methods to the analysis of the nature of meaning.

Given the interdisciplinary nature of the symposium, we would like to stress that the speakers are not only specialized in the field of semantics, but that they are also able to work at the crossroad between several disciplines. The symposium organizers share a background in philosophy with an active interest in neurolinguistics, at both a theoretical and an experimental level (Ferretti et al., 2013; Werning, 2012).

## Speakers and abstracts

## Erica Cosentino

Classical theories of meaning are two-step models, according to which contextual information is considered only after establishing phrase or sentence local meaning. In this perspective, local semantics cannot initially be overruled by the wider context. In this study we tested this prediction analyzing the effect of discourse context on affordances. Two-steps models predict that a verb-object violation, as in "She uses the funnel to hang her coat" will always be considered inappropriate, regardless of the wider discourse. In the current study we found that when this anomalous combination is embedded in a neutral context it elicits a typical N400, indicating that the subject is experiencing interpretative problems. However, when preceded by a supportive context, the very same sentence becomes perfectly acceptable, as reflected by the absence of an N400 effect. This finding challenges the classical approach to meaning suggesting that affordances are immediately integrated in the construction of meaning and that contextual information is immediately taken into account.

## Lars Kuchinke

The embodied-simulative view proposes that linguistic meaning is grounded in memory traces in modality-specific brain regions as distributed neural representations of previously experienced internal and external states. This view also subsumes emotional information linked to words, and recent empirical evidence from emotional word recognition supports this assumption. Electrocortical findings point to a very early locus of these emotional effects preceding or at least altering the onset of lexical access. These effects are modulated by emotional valence, leading back to the 'semantic cohesiveness' hypothesis that proposes differences in the amount of semantic associations of valenced words. We recently proposed an associative read-out model based on co-occurence statistics that
correctly predicts higher recognition rates for words with a greater amount of associations to other stimuli. Based on this model, we show that effects of positive words can be explained by their semantic cohesion, whereas negative words explain variance beyond their associations.

## Gabriella Vigliocco

Theories of semantic representation ought to account for how we use this information, how we learn it and how it breaks down after brain damage. I will set the stage locating existing theories along a continuum from disembodied to fully embodied and presenting evidence from behavioural, imaging and patients' studies that limit the viable theories to those that incorporate some degree of embodiment but also include information from other sources such as language. I will then give a bird eyes overview of one such theories that we have developed in the past few years in which all concepts (concrete and abstract) are grounded in our sensory motor and affective experience but also statistical information from language contributes to the learning and representing meaning.

## Markus Werning

In the first part of the talk, the central tenets of Emulative Semantics will be outlined. In the second part an EEG-based case study on the understanding of linguistic emotion contexts will be presented. (1) Emulative Semantics (Werning, 2012) is a naturalist theory of meaning. It claims that linguistic meaning consists in patterns of neuroemulations. Unlike rival naturalist theories of meaning, Emulative Semantics is a non-symbolic, but still compositional theory of meaning. Neuro-emulations are abstractly described dynamical states of the brain's sensorymotor regions that are partially isomorphic to modeltheoretical structures. Emulative Semantics thus inherits many formal features of model-theoretical semantics, which has been very successful as a formal account of meaning. (2) One prediction of Emulative Semantics is that the understanding of linguistic contexts about emotional scenarios should involve the emulation of emotions. Since the emulation of emotions is also thought to be a basis for the human capacity of empathy, Emulative Semantics predicts a correlation between empathy with emotions and the comprehension of linguistic emotion contexts. In a recent ERP study we could in fact show that, in linguistic emotion contexts, the N400 effect, which indicates violations of semantic expectations, depends on empathy as measured by the Multifaceted Empathy Test.

## Rolf A. Zwaan

Language comprehension involves the construction of mental representations. This seems an uncontroversial statement in most of cognitive science. Much research has focused on the nature of these representations: are they textbased or situational (or both) are they abstract or grounded in perception and action? My goal here is to propose and
describe an integrative view. I will do this by discussing recent research from my lab.

# Online Education: A Unique Opportunity for Cognitive Scientists to Integrate Research and Practice 

Joseph Jay Williams (joseph_williams@berkeley.edu)<br>Department of Psychology, University of California at Berkeley

Ken Koedinger (koedinger@cmu.edu)<br>Human Computer Interaction Institute, Carnegie Mellon University

Alexander Renkl (renkl@psychologie.uni-freiburg.de)<br>Psychological Institute, University of Freiberg<br>John Stamper (jstamper@cs.cmu.edu)<br>Human Computer Interaction Institute, Carnegie Mellon University

#### Abstract

That there is a rapid expansion of online education is much better understood than what its consequences will be. This symposium considers that one key feature of "real-world" education that takes place on the Internet is that it provides a high level of experimental control and automatic data collection \& analysis, which can support cognitive science research that was previously only possible in laboratory settings and small-scale educational environments. The presenters discuss the unprecedented opportunities online learning provides for conducting research in ecologically valid contexts: linking existing laboratory experiments to relevant online contexts, personalizing adaptive instruction, embedding in vivo research studies of education, and using the vast amount of high quality data available. The product of such work is not only theories and empirical discoveries that better characterize learning, but also the opportunity to directly translate these into practical benefits to students through concrete improvements to educational resources.

Keywords: learning; education; technology; online education; online learning; e-learning; intelligent tutors; educational data mining;

Laboratory experiments and classrooms rarely overlap in the physical world, much to the chagrin of educational psychologists. But researchers increasingly use computers and the Internet to run experiments, and the recent explosion of online education now brings student learning into the very same digital medium. Hundreds of thousands of students take Massive Open Online Courses (MOOCs from Coursera, Udacity, EdX) at the university level, use websites like www.mathtutor.cmu.edu, www.khanacademy.org or www.mathalicious.com that are populated with K-12 videos \& interactive exercises, not to mention a host of supplementary online educational resources that can be delivered over devices as ubiquitous as smartphones.

These web-based resources offer the potential for extensive novel research on learning (Anderson, 2008; Ally, 2004; Linn et al, 2004; Pea, 2003). One distinctive feature is the possibility of embedding in vivo randomized experimental comparisons (Koedinger et al, 2012) into these (now) ecologically valid online educational environments. Furthermore, unlike educational environments in bricks-and-mortar education, in a digital medium there can be precise control over materials and instructions, and systematic collection of data from large samples (Stamper et al, 2012). In addition to investigating learning processes in authentic educational contexts, studying online learning
provides an unprecedented opportunity to simultaneously carry out basic and applied research. When experimental manipulations correspond to comparisons of instructional effectiveness, stimuli are educational materials, and dependent measures are students' learning outcomes, experimental methodology from cognitive science can be used to iteratively improve the pedagogical principles incorporated into online educational resources. Rather than years of laboratory research that "suggest" instructional principles or are eventually followed by a laborious classroom study, the steps from basic to translational research are greatly simplified.

Moreover, the product of research programs that investigate online learning is not only new scientific knowledge, but specific products that concretely instantiate theories and learning principles. These proven and iteratively improved resources can be provided directly to students for use as they exhibit such great fidelity to research context. And using the Internet, they can be disseminated to hundreds of thousands of students over an extended period of time, all across the world - a clear contribution of cognitive scientists to public education.

## Mapping laboratory studies to online educational settings

In the context of his research on the role of explanation in learning, Joseph Jay Williams presents a perspective from basic experimental psychology on finding fruitful connections between lab experiments and experimental manipulations embedded in authentic online educational resources. He discusses the interplay and transitions between typical lab experiments (research on explaining membership in artificial categories, Williams \& Lombrozo, 2010), to online studies using convenience samples from Amazon Mechanical Turk (in which explaining promotes learning of mathematics, Williams et al, 2012), and experiments implemented using identical mathematics exercises on Khan Academy's educational platform, but with real students who visit the site for genuine help with authentic schoolwork.

This approach blends rigorous experimentation in contexts with different levels of control, rapid iterative improvement, and the development of an ecologically valid educational resource. Such web resources serve a basic research goal, as (for example) the structure and dynamics of an interactive video or exercise reflects a concrete and empirically supported instantiation of theoretical principles
and empirical discoveries that would otherwise be verbally communicated - reminiscent of the benefits of computational models. They also serve a clear practical goal, as the products of research are empirically evaluated and multiply revised resources that have been shown to work in learning online. They can therefore be disseminated using the massive scale of the internet, to improve education for thousands of students over an extended period of time.

## Using Eye-Tracking and Rapid Assessment to Detect and Address Knowledge Gaps During Learning

Alexander Renkl has conducted extensive research in computer environments, such as investigating how learning from worked examples can be enhanced by the use of scaffolding, fading and other instructional design features. He reports a project that bears on the ability of online environments to personalize instruction.

The project develops and researches an adaptive approach to closing gaps in students' knowledge that remain after initially studying the learning materials. Rapid assessment tasks are interspersed in the learning environment to identify the knowledge deficits in individual students, which can then be targeted by prompting learners to engage in remedial activities. In the first experiment, university students $(\mathrm{N}=71)$ learned about mitosis in a multimedia learning environment. When rapid assessment tasks indicated gaps in students' knowledge, the experimental manipulation was to randomly assign them to one of three different types of prompts, hypothesized to be optimal for the particular deficit. However, we found that each type of prompt was equally effective in closing the knowledge gaps identified by rapid assessment.

In the second experiment we obtained further results as to the effects of different prompts - finding that ostensibly "enriched" prompts even led to sub-optimal effects. Comparing our results to the final test of learning outcomes, we identified our rapid assessment tasks as failing to detect important knowledge gaps. Rather than risk disturbing learning by increasing the number of rapid assessment tasks, we now integrate eye-tracking data to improve our assessment. We use this data to select rapid assessments to verify the presence of a knowledge gap. Pilot data suggests such a combined approach is more effective for learning.

## In-vivo experiments with cognitive tutors

As director of the Pittsburgh Science of Learning Center and one of the pioneers in the development of intelligent tutoring systems, Ken Koedinger has helped set the standards of rigorous research in realistic educational contexts. He discusses how cognitive tutors can be used to conduct in vivo experiments in classroom environments, collecting sophisticated learning measures and giving personalized feedback to learners. He considers how cognitive tutors and in vivo experiments can be integrated with online education platforms to take advantage of
complementary strengths and disseminate these benefits on a large scale.

## Automated improvement of instructional systems using educational data mining

John Stamper runs Datashop, the largest openly available repository of detailed student learning data, with learning and instructional events logged as often as every 10 seconds, scored, and tagged based on models of student learning. He will discuss how educational data mining and statistical models of students' learning can be used to infer improvements to instructional systems, automatically develop intelligent tutoring systems, and shed light on many of the problems that typically are solvable only through extensive human investment.

#### Abstract

We describe an attempt to understand causal reasoning in situations where a binary cause produces a change on a continuous magnitude dimension. We consider established theories of binary probabilistic causal inference $-\Delta P$ and Power PC - and adapt them to continuous non-probabilistic outcomes. While $\Delta \mathrm{P}$ describes causal strength as the difference of effect occurrence between the presence and absence of the cause, Power PC normalizes this difference with the effect base-rate to obtain a proportional measure of causal power, relative to the maximum possible strength. Two experiments compared the applicability of each approach by creating scenarios where binary probabilistic scenarios were directly mapped onto inference problems involving continuous magnitude dimensions. Results from counterfactual judgments tentatively indicate that people reason about causal relations with continuous outcomes by adopting a proportional approach when evaluation preventive causal powers, and a difference approach in generative scenarios.

Keywords: causal learning; continuous outcomes; reasoning; counterfactual.

## Background

The capacity to learn about and represent causal knowledge is a fundamental aspect of cognition without which humans lose the ability to not only make predictions and decisions, but also to forecast, prepare and direct their behaviours towards achieving goals and fulfilling desires. Current research mostly focuses on causal relations involving binary events. Outside the lab, however, people do not only encounter binary events. In fact, we are more likely to be dealing with continuous variables: How much faster could I run if I lose 20 pounds of weight? How much weight would I gain if I ate cheeseburger everyday? How much sugar do I need to add to avoid over sweetening? These questions are daily examples of people's involvement with causal relations entailing continuous variables.

Binary causal relations involve a state change of a binary event (cause present/absent) to produce a change in another binary event (effect present/absent), but such simplicity is not the case for continuous variables. In a continuous causal scenario, a magnitude change of a continuous variable is produced by a magnitude change of another continuous variable. For example, in a binary relation, a state change of a cause could be flicking a switch from off to on which changes the status of a bulb from off to on. On the other
hand, a continuous relation involves a change of a dial position to cause a change of luminosity from dimmer to brighter. Despite many daily-life examples of continuous variables, very few studies have been investigating causal judgment involving continuous variables (White, 2001). Here we are trying to find out how people acquire causal knowledge involving continuous variables?

## Learning Framework: Difference or Proportion

Most theories of binary causal learning are rooted in Hume's empiricism (1739/1888): Causal knowledge is not explicitly available via sensory modalities but instead is inferred using the input received via them. One of Hume's cues to causation is contingency - i.e. the frequency of an effect and a cause co-occurring.

A longstanding model formalising contingency as an indicator of causal belief is $\Delta \mathrm{P}$, which calculates the difference of the probabilities of the effect in the presence vs. the absence of the cause (Jenkins \& Ward, 1969):

$$
\Delta P=P(e \mid c)-P(e \mid \neg c)
$$

Consider these hypothetical scenarios involving the study of skin rash as a side effect of a new group of medicines on a group of forty patients. In scenario 1 , none of them had a rash before taking medicine A , but 20 of them had rash after taking the medicine. In scenario 2 , also none of them had rash before taking the medicine, but only 10 of them reported rash after taking medicine B . $\Delta \mathrm{P}$ computes causal strength by considering the difference in relative frequencies of patients before and after taking the medicines, giving $\Delta P$ values of 0.50 and 0.25 respectively; hence concluding that medicine A has higher causal strength than medicine $B$ to cause skin rash.

Consider another scenario 3 in which 20 of 40 patients already had skin rash even before taking medicine C , but the number of patients suffering with rash increased to 30 after taking the medicine. Applying $\Delta \mathrm{P}$ in scenario 3 results in medicine C having a causal strength index of 0.25 , which is similar to medicine B. However, studies have shown that despite having the same $\Delta \mathrm{P}$ values, people tend to conclude that medicine C is more effective than medicine B in causing the rash (Cheng, 1997; Buehner, Cheng, \& Clifford, 2003). This discrepancy is captured by another influential theory on causal learning: Power PC (Cheng, 1997).

Power PC argues that in addition to the difference causal strength is also influenced by the base-rate, $\mathrm{P}(\mathrm{e} \mid \neg \mathrm{c})$. Power

PC normalizes the difference with the base rate to obtain a proportional measure of causal power.

$$
p_{g e n}=\frac{\Delta P}{1-P(E \mid \neg C)} \quad p_{\text {pre }}=\frac{-\Delta P}{P(E \mid \neg C)}
$$

Power PC has also been used to parameterise Bayesian models of causal learning (Griffiths \& Tenenbaum, 2005) and is generally recognized as a rational account of causal strength.

Applying Power PC onto scenarios 2 and 3 results in having causal strength indexes of 0.25 and 0.50 for medicine B and C respectively. Unlike $\Delta \mathrm{P}$, this model therefore captures people's ability to provide normative responses. The key difference between $\Delta \mathrm{P}$ and Power PC is that the former considers the absolute difference the cause makes to the occurrence of the effect, while the latter calculates the difference relative to the maximum causal change possible, and thus provides a proportional index of causal strength.

In the earlier scenarios, medicine B had the opportunity to cause skin rash in all 40 patients, and did so in 10 of them; in contrast, in the scenario involving medicine C , the medicine only had the opportunity to cause skin rash in 20 patients because the other 20 already had rash even before taking the medicine. From these 20 unaffected patients, medicine C managed to affect 10 of them to have skin rash. Therefore, Power PC suggests that for medicine B, the causal strength index is 0.25 because 10 out of 40 patients had rashes whereas for medicine C it is 0.50 because it caused rashes in 10 out of 20 (i.e. the initially unaffected) patients.

Moreover, the Power PC theory also tackles ceiling and floor effects. In another scenario where all 40 of the patients already had skin rash before taking medicine D , and all 40 still had skin rash after taking the medicine, $\Delta \mathrm{P}$ for this scenario would be zero, suggesting that medicine D makes no difference to the occurrence of rash. A rational judgment, however, would be that the experiment is inconclusive with respect to generative causal power because medicine D had no opportunity to demonstrate its potential effectiveness, and thus the causal status of D is unknown. Wu and Cheng (1999) showed that reasoners indeed follow this logic, and withhold judgment in cases where causal power is unknowable. If Power PC is applied to this scenario, the equation is undefined (due to division by 0 ), which is consistent with both rational assessment and empirical results.

We highlighted the contrast between the difference and proportional perspectives of both theories because they will be relevant when considering approaches to continuous causation. Proportions can only be computed with respect to a reference limit. In binary probabilistic causation, the relevant limits are $\mathrm{P}(e)=0$ (the effect never happens) and $\mathrm{P}(e)=1$ (the effect always happens). These probabilities provide the upper limit of maximal causal effectiveness for preventive and generative causation, respectively, in a binary probabilistic framework: The maximum impact a preventor could have would be to reduce the probability of
the effect to 0 , while the maximum impact of a generator would be to raise it to 1 . When considering causal changes to continuous outcome magnitudes, such natural limits are not necessarily present. While the maximum impact a preventor could have would still be to reduce the quantity of the effect to 0 magnitude, the maximum impact a generator could have might be unknown because it could keep on increasing the magnitude unless there is a known upper limit.

## Study Scope

The central idea of this study was to investigate whether people reason about causal relations involving nonprobabilistic continuous outcomes within a difference or proportional framework. Because of the wealth of prior works assessing the suitability of these approaches with respect to binary probabilistic causation, we wanted to create scenarios that afford a similar comparison between the two accounts. To this end, and as a first step on our quest, we only considered situations where a binary cause can produce a (deterministic) magnitude change on a continuous variable. This allowed us to set up situations that are one-to-one mappings of binary probabilistic causation to scenarios involving continuous outcomes. More specifically, in both cases the cause is still either present or absent, but instead of it resulting in a change of probability of the outcome, it now affects the magnitude of the outcome.
In probabilistic causation the (binary) cause results in a binary state-change across a group of entities; aggregating these state-changes across a sample results in an assessment of the change of probability of the effect brought about by the presence of the cause, which is of course a continuous variable bound between 0 and 1 . In contrast, we considered changes of a continuous outcome magnitude in a single entity. This allowed us to preserve exactly the same structure as in probabilistic causal inference tasks. For example, a probability condition of $\mathrm{P}(\mathrm{e} \mid \mathrm{c})=0.75$, which indicates that skin rash is present in 75 out of 100 patients given that all of them took the medicine, was mapped onto a quantity condition of $\mathrm{Q}(\mathrm{e} \mid \mathrm{c})=7.5 \mathrm{~cm}^{2}$, indicating that 7.5 $\mathrm{cm}^{2}$ of skin from an area of $10 \mathrm{~cm}^{2}$ where the ointment was applied broke out with a rash.

In order to maximize comparability to binary probabilistic causation and preserve structural identity, our studies employed an artificial upper limit on a continuous scenario to serve as a reference for maximum causal effectiveness (see Method). Imposing such a limit allowed us to derive predictions not only for a difference based, but also for a proportional approach. Moreover, it afforded the opportunity for a more stringent test of the two approaches, by using different counterfactual scenarios to elicit causal judgments. More specifically, we asked one counterfactual question where the upper limit of causal effectiveness corresponded to the artificial limit in the learning phase, while another made reference to a higher limit, not previously experienced in the learning phase. If reasoners
approach causal inference problems involving continuous outcome magnitudes with a difference-based approach, changing the reference limit should have no impact on their predictions for causally induced magnitude change: All that would matter is the difference the cause made in the learning phase, regardless of the upper limit of causal effectiveness. In contrast, according to a proportional approach, reasoners would relate that difference to the maximum possible difference, and scale their predictions accordingly in the presence of a different limit.

Imagine that a government wants to test the efficacy of a 20 mph speed limit on traffic fatalities in residential areas. Community A serves as a pilot and fatalities are reduced from 20 per year before the trial to 10 per year after the trial. What would we predict if community $B$, which is larger, has more roads, and suffers from 50 fatalities a year, were to adopt the same program? According to a difference-based approach, we would predict that the program results in the same absolute reduction by 10 , to result in 40 fatalities per year. The proportional approach would consider the maximum change possible in A (20) and would recognize that 10 corresponds to half of that. Consequently, it would predict a reduction from 50 to 25 . We used a similar logic to compare difference to proportion based approaches.

## Experiments

## Participants

Thirty different undergraduates from Cardiff University's School of Psychology participated in each preventive and generative experiment in exchange for course credit.

## Design and Procedure

Each participant worked on 15 conditions directly adapted from the binary probabilistic design of Experiment 1 in Buehner et. al. (2003). Each condition consisted of a pair of quantities of an effect in the presence vs. absence of the cause (see Table 1).

The generative experiment used a cover story that asked participants to imagine they were pharmaceutical consultants researching the side effects (skin rash) of synthetic substances in cosmetic creams. Fifteen different fictitious cosmetic creams corresponded to the 15 causal conditions in Table 1.

The cover story also described that the size of skin rash was measured before and after the application of the cream, and that some patients may develop skin rash even in the absence of any cosmetic products. Instructions stressed that each cream was applied to cover $10 \mathrm{~cm}^{2}$ of a patient's back and that the base rate (rash before cream application) was also expressed with reference to this $10 \mathrm{~cm}^{2}$ area. This served to impose an artificial limit of maximum causal efficacy - the cream could only create rash so as to cover the entire $10 \mathrm{~cm}^{2}$ area.

A similar cover story was used for the preventive experiment, this time introducing ointments that relieve skin rash. Again, adopting the same 15 conditions, the story
described a proper motivation on how allergic reaction would cause the skin rash to occur up to $10 \mathrm{~cm}^{2}$ without any preventive measure, and on how the ointment would reduce the skin rash.

Table 1: Fifteen causal conditions for both experiments

| $\mathrm{Q}(\mathrm{e} \mid \mathrm{c})$ | $\mathrm{Q}(\mathrm{e} \mid \neg \mathrm{c})$ | $\|\Delta \mathrm{Q}\|$ | Causal Power |  |

| ${ }^{1}$ Values of $\mathrm{Q}(\mathrm{e} \mid \mathrm{c})$ and $\mathrm{Q}(\mathrm{e} \mid \neg \mathrm{c})$ are switched in preventive |  |  |  |  |

After going through the cover story, participants were presented with 15 visual stimuli to correspond to the 15 conditions in a random order (see Figure 1). They then had to judge how strong the cause generates/prevents the effect by answering two counterfactual questions - one at a time. The two counterfactual questions were presented to correspond to two limits - a limit that was consistent with the cover story, and a higher limit.

Figure 1: Sample Stimuli from the generative component

$|\Delta Q|: \bullet: 0.00$ ■: $0.25 \star: 0.50 *: 0.75 *: 1.00$ Difference:- Proportion:---

Figure 2: Power PC and $\Delta \mathrm{P}$ Predictions of Causal Ratings.
The counterfactual question for the generative experiment was: Now imagine a new patient who does not have any skin rash. If we applied this cream on the back of this patient to cover an area of $10 \mathrm{~cm}^{2}$, how big would the area of skin rash be on this patient? The exact same sentence was used for the second question except that the area (i.e. the limit) was changed to $50 \mathrm{~cm}^{2}$.

The counterfactual question for the preventive experiment was: Now imagine a new allergy patient suffering from a rash of $10 \mathrm{~cm}^{2}$. If we apply the ointment, how large would the area of rash be? Similarly, the second question was exactly the same except for substituting the area with 50 $\mathrm{cm}^{2}$. Participants provided numerical responses using the keyboard.

## Predictions

Figure 2 shows causal strength prediction plots for the 15 conditions, derived from difference based $(\Delta \mathrm{P})$ and proportional (Power PC) approaches (solid and dashed lines respectively). Causal conditions that have identical $\Delta \mathrm{Q}$ values are linked together and plotted against the base-rate.

To allow comparisons both with previous literature, and across the two limit scenarios, these predictions were plotted with respect to the value of the limits tested. Since the maximum area of skin rash is $10 \mathrm{~cm}^{2}$ in the consistent-limit scenario, the maximum power in the prediction has been set to 10 as well. In contrast, in the scaled-up limit scenario, the maximum power in the prediction has been set to be at 50 to match up with the maximum rash area of $50 \mathrm{~cm}^{2}$.

Participants' judgments were analogously converted: For instance, an area judgment of $10 \mathrm{~cm}^{2}$ in the consistent-limit scenario was converted into a causal rating of 10 in the generative, and a causal rating of 0 in the preventive experiment.

$|\Delta Q|: \bullet: 0.00$ ■: 0.25 *:0.50 *:0.75 *: 1.00

Figure 3: Medians of Counterfactual Responses.
More specifically, we subtracted the counterfactual response given by the participant from the relevant upper limit. This conversion was made on the judgments to reflect that an increase of affected skin area would indicate an increase of causal power when considering generative causes, while larger predicted skin areas would indicate weaker causal powers when considering preventive relations.

The absolute difference approach predicts that causal strength is unaffected by increments of base-rate, and that causal ratings vary only as a function of $\Delta \mathrm{P}$. Furthermore, a strict interpretation of difference approach would suggest that the same difference is then applied to a different context, involving a higher upper limit. Consequently, prediction plots for the difference approach remain within the range of 0 to 10 , across both the consistent-limit and scaled-up limit scenarios.

The proportional approach, on the other hand, predicts a consistent influence of base-rate onto causal ratings in both limit cases, which varies depending on whether generative or preventive powers are assessed. Despite having the same non-zero difference values (i.e. $\Delta \mathrm{P}$ ), in the generative scenario causal ratings should increase as the base rate increases. The reverse pattern is predicted in preventive scenarios. These influences of base rate, however, are not predicted for when the difference value is zero, and causal ratings should remain at zero for both generative and preventive cases. In addition, the proportional approach also dictates that counterfactual causal ratings are scaled up in line with a higher limit.

## Results

Kolmogorov-Smirnov test showed that judgments were nonnormally distributed. Consequently, Figure 3 plots median
judgments, and statistical analysis was based on nonparametric tests.

A qualitative inspection of the generative results in Figure 3 suggests that judgments correspond more to difference than proportional approach predictions. In the consistentlimit scenario, apart from the conditions involving $\Delta \mathrm{Q}=$ 0.25 , the judgments for other $\Delta \mathrm{Q}$ values are relatively flat at the predicted difference values, suggesting a minimal influence of base-rate.

This minimal influence of base-rate is also evident on causal judgments in the scaled-up limit scenario. In this scenario, judgements from conditions involving identical values of $\Delta \mathrm{Q}$ are also relatively consistent at the difference values, even though a small indication of a positive trend is observed in the $\Delta \mathrm{Q}=0.25$ case. Even though the minimal influence of base-rate influence is in line with a difference account, generative judgments violate its other significant property: They vary from 0 up to 50 , instead of 10 . We will discuss this in the next section.

Qualitatively inspecting the preventive results in Figure 3 suggests they fit well with proportional approach. In both limit scenarios, the contingent cases indicate the influence of the base-rates. Instead of remaining constant at the difference values, the judgments decrease as the base-rate increases. Moreover, for the non-contingent cases, judgments also follow proportional predictions, in that they stay at zero despite a change of the base-rate. Even though there is an indication of a non-normative trend in the consistent-limit scenario when $\Delta \mathrm{Q}=0.25$, in general, the preventive judgments seem to have followed proportional predictions, both with a consistent and inconsistent limit.

Statistical Analysis (Generative) Nonparametric Friedman's ANOVA was used to determine the main effect of the base-rate for every $\Delta \mathrm{Q}$ value.

Analysis of ratings from the consistent-limit case found a significant effect of base-rate when $\Delta \mathrm{Q}=0, X_{\mathrm{F}}^{2}(14)=$ $14.750, p<.05$ and $\Delta \mathrm{Q}=0.25, X_{\mathrm{F}}^{2}(14)=10.545, p<.05$. The analysis does not show any significant effect of baserate when $\Delta \mathrm{Q}=0.50, X_{\mathrm{F}}^{2}(14)=0.347, p>.05$ and $\Delta \mathrm{Q}=$ $0.75, X_{\mathrm{F}}^{2}(14)=1.190, p>.05$.

Unlike in the consistent-limit case, analysis of the scaledup limit scenario shows a significant effect of base-rate only when $\Delta \mathrm{Q}=0.25, X_{\mathrm{F}}^{2}(14)=7.978, p<.05$. No significant effects of base-rate are found when $\Delta \mathrm{Q}=0, X_{\mathrm{F}}^{2}$ (14) $=$ $6.681, p>.005 ; \Delta \mathrm{Q}=0.50, X_{\mathrm{F}}^{2}(14)=1.357, p>.005$; and $\Delta \mathrm{Q}=0.75, X_{\mathrm{F}}^{2}(14)=1.087, p>.005$.

Surprisingly, the statistical test indicates an effect of the base rate in the non-contingent case of consistent-limit scenario, despite an observation of a flat line in Figure 3. Inspection of the data distribution in these conditions (Figure 4) reveals three noteworthy points: i) the modal response is 0 in all cases, ii) a minority of participants give a non-normative non-zero response, iii) this minority of participants appears to exhibit an outcome density bias (Buehner, Cheng, \& Clifford, 2003). Because the Friedman

Test ignores ties, the significant result in $\Delta \mathrm{Q}=0$ condition is thus driven by this minority of participants.

Statistical Analysis (Preventive) In the consistent-limit scenario, no significant effect of base-rate was found when $\Delta \mathrm{Q}=0, X_{\mathrm{F}}{ }^{2}(14)=4.500, p>.05$. However, significant effects of base-rate were obtained when $\Delta \mathrm{Q}=0.25, X_{\mathrm{F}}{ }^{2}$ (14) $=57.854, p<.05 ; \Delta \mathrm{Q}=0.50, X_{\mathrm{F}}^{2}(14)=15.892, p<.05$; and $\Delta \mathrm{Q}=0.75$ as well, $X_{\mathrm{F}}^{2}(14)=9.783, p<.05$.

Similar trends were observed in the scaled-up limit scenario. The analysis shows no significant effect of baserate when $\Delta \mathrm{Q}=0, X_{\mathrm{F}}^{2}(14)=1.222, p>.05$. Again, significant base-rate effects are found when $\Delta \mathrm{Q}=0.25, X_{\mathrm{F}}^{2}$ $(14)=27.931, p<.05 ; \Delta \mathrm{Q}=0.50, X_{\mathrm{F}}^{2}(14)=12.302, p<$ $.05 ; \Delta \mathrm{Q}=0.75, X_{\mathrm{F}}^{2}(14)=3.846, p<.05$.

As with the generative scenario, non-contingent conditions uniformly elicited a median and modal response of zero. While there was also a minority of participants who deviated from this normative assessment, judgments from these participants did not display any systematic patterns. More specifically, unlike in the generative scenario, there was no evidence of an outcome density bias, even in the minority of non-normative judgments.

Figure 4: Judgment Distributions of non-contingent Conditions $(\Delta \mathrm{Q}=0)$ in the consistent-limit scenario

## Discussion

Overall, our results seem to suggest that when people reason about continuous outcomes, they do so within a proportional framework, if the context is one of preventive causation, i.e. the goal is to reduce the outcome magnitude. However, if the context involves increasing the outcome magnitude (generative causation), people seem to focus on the difference the cause makes, without normalizing this difference to an upper limit, even when the task clearly implies such a limit. Interestingly, people then do not adhere to the absolute difference a cause makes in a given context, but instead scale up this difference, where appropriate, in different scenarios.

For instance, in the condition when $\mathrm{Q}(\mathrm{e} \mid \mathrm{c})=1.00$ and $\mathrm{Q}(\mathrm{e} \mid \neg \mathrm{c})=0.25$, participants learned that a skin area of 2.5 $\mathrm{cm}^{2}$ was covered with of rash before the application of the cream, and that applying the cream to an area of $10 \mathrm{~cm}^{2}$ resulted in that entire area breaking out with rash. They considered the difference the cream made, and concluded that its application increases the area of rash by $7.5 \mathrm{~cm}^{2}$ when applied to $10 \mathrm{~cm}^{2}$ of skin of a patient who does not yet suffer from rash. Had they taken the proportional approach, they would have concluded that this cream is maximally
effective in producing rash, and applying it to an area of $10 \mathrm{~cm}^{2}$ of healthy skin would lead it all of it to break out with rash. When they were asked to transfer their knowledge to a different scenario, where the cream was applied to $50 \mathrm{~cm}^{2}$ of healthy skin, they took the difference ( $7.5 \mathrm{~cm}^{2}$ ) and scaled it up to this new area, concluding that $33 \mathrm{~cm}^{2}$ (i.e. nearly $37.5 \mathrm{~cm}^{2}$ ) of the $50 \mathrm{~cm}^{2}$ will break out with rash.

Inspection of Figure 3 shows that participants were relatively consistent in scaling up their counterfactual judgments across all the generative conditions: a factor of approximately 5 emerges. This suggests that participants indeed scaled up their judgments from one context to the other, rather than merely considering the difference, as suggested by a strict interpretation of a difference-based approach. It appears then that people were aware of the upper limit we imposed on our scenarios, and scaled their judgments up accordingly in both preventive and generative situations. However, the judgments they formed were based on proportions only for preventive contexts, and on differences in generative contexts.

One tempting conclusion might be that perhaps our generative cover story might simply have failed to instill a clear sense of an upper limit in the learning phase, despite our best efforts to do so. After all, even when cream is applied to only to $10 \mathrm{~cm}^{2}$, it is still feasible for a rash to occur in a larger area than that. In contrast, the preventive scenarios were not hampered this way - the natural upper limit of preventive causation is always 0 : No treatment could reduce rash to less than an area of $0 \mathrm{~cm}^{2}$. However, we have conducted studies with other generative contexts, involving continuous outcome magnitudes that definitely do have clear and unambiguous upper limits (such as relative humidity in the atmosphere), and the results mirror those reported here: People largely adopt a difference-based approach when evaluating generative causal influence.

## Conclusions

The work reported here represents the beginning of a quest to chart the waters of continuous causal inference. We have taken a cautious approach and created situations that are structurally identical to conventional binary probabilistic causal inference. We knew that doing so would limit the ecological validity of our results. After all, most causes are continuous variables themselves, influencing continuous outcome magnitudes. However, our goal here was a proof of concept: We wanted to measure people's inferences about causal change to continuous outcomes under ideal conditions and with clear explicit upper limits (which are not always present in the world). If under these conditions, inferences followed patterns similar to those observed in probabilistic causal inference, this might suggests that a fruitful avenue to pursue might be to try and adapt theories and models from binary probabilistic causal inference to inference about continuous causation.

Tentatively, we would conclude that people's inference patterns do correspond to what we know about probabilistic causal inference. Deviations from normative models are found frequently also in probabilistic causal inference (e.g. Lober \& Shanks, 2000), although sometimes such deviations seem to reflect ambiguities in the task demands. And indeed perhaps the non-normative results of our generative experiment may be due to such ambiguities. We are currently addressing this with follow-up studies. For example, we have not considered the reliability of the information on which participants base their judgments. Bayesian models of causal inference (e.g. Griffiths \& Tenenbaum, 2005) consider both the strength of a causal relation (as indexed by power PC), as well as the reliability of the information (as indexed by the sample size, or the effective sample size). For simplicity, and to ensure the one-to-one mapping to probabilistic causation, our study involved only single entities (i.e. one patient per treatment).

In future work, we hope to consider not only multiple instances of continuous outcome change from the same cause, but also to begin working with causes that are in themselves continuous variables.

## Acknowledgments

# A Metacognitive Stopping Rule for Problem Solving 

Rakefet Ackerman (Ackerman@ie.technion.ac.il)<br>Faculty of Industrial Engineering and Management, Technion - Israel Institute of Technology<br>Technion City, Haifa, 3200003 Israel

#### Abstract

Although people expect to improve by investing effort in solving a problem, several studies have found negative timeconfidence correlations in various problem-solving tasks. The present study employed the metacognitive approach to illuminate why, despite lengthy thinking, people provide solutions in which they have only low confidence. According to the proposed Diminishing Criterion Model (DCM), as people invest longer in a problem, their confidence in their solution increases in a goal-driven manner, in accordance with the common belief. Nevertheless, the process ends up with a negative time-confidence correlation, because people tend to find lower confidence levels as satisfactory as they invest longer in solving a problem, reflecting a compromise in their stopping criterion. The hypotheses derived from the DCM were supported with two problem types. Even when the participants were allowed to submit a "don't know" response, they still provided low confidence solutions after lengthy thinking, suggesting that they found these low confidence solutions to be satisfactory. The study offers reconciliation between beliefs and empirical findings and explains why people end up offering solutions with low confidence rather than continuing attempts to improve or admitting failure (via the "don't know" option).

Keywords: Metacognition; problem solving; dual-process theory; stopping rule; time allocation.

## Introduction

Solving a problem requires representations of the relevant components, rules (or constraints), and goal, followed by a sequence of inferences or calculations. However, beyond the cognitive process per se, solving a problem also involves regulation of the cognitive effort. Regulation of effort is at the heart of metacognitive theories. According to this approach, to achieve a cognitive goal, people constantly judge, or monitor, the state of their performance relative to the goal they pursue and decide whether to continue to invest further effort or cease (Koriat, Ma'ayan, \& Nussinson, 2006; Nelson \& Narens, 1990). The metacognitive approach is commonly used for learning research, mainly memorizing, but as yet is rarely employed for problem solving. Although metacognitive considerations have been mentioned in some discussions (e.g., Payne \& Duggan, 2011), establishing metacognitive monitoring as a causal link in regulating problem solving has only started to emerge, in particular with regard to dual-process theories.

According to the dual-process theories (Kahneman, 2003), System 1 or Type 1 processes (T1) are responsible for suggesting a quick solution that comes to mind based on default procedures. System 2 or Type 2 processes (T2)
execute more deliberate and lengthy analytic reasoning. However, Evans (2009) identified a third type of processes (T3). These T3 processes are responsible for (a) identifying the need for T 2 intervention, and (b) examining whether a given model is satisfactory (see also the reflective mind suggested by Stanovich, 2009a). Thompson (2009) proposed that metacognitive processes underlie identifying the need for T2 intervention. Indeed, Thompson and her colleagues (Thompson, Prowse Turner, \& Pennycook, 2011; Thompson et al., in press) asked participants to provide an initial answer and their Feeling of Rightness (FOR) about it. Subsequently, they were allowed to reconsider their answer. As expected, lower FORs were associated with more reconsideration time and with a higher likelihood of providing an alternative for the initial answer. These findings support the role of metacognitive monitoring as bridging T1 and T2 processes. This relates to the first aspect mentioned by Evans (2009). The present paper deals with the second aspect he mentioned; namely, examining whether a given model is satisfactory for deciding whether to stop investing effort in a particular problem.

## Metacognitive Stopping Rules

In the experimental examinations of metacognitive regulation of memorizing, the fact that people invest more time in studying the more difficult items has led to the development of the discrepancy reduction model (Nelson \& Narens, 1990). According to this model, people set a target level according to their motivation for the given scenario and study each item until they consider their knowledge to be satisfactory. This process seems to also be applied to a problem-solving task: people set a criterion for their confidence level, and continue to search for better solutions until they judge their chance for success to be satisfactory (Evans, 2006). Thus, for both memorizing words and solving problems, the discrepancy reduction model suggests that lengthy processing positively correlates with the chance for success. In line with this model, Koriat et al. (2006) associated goal-driven effort with a positive time-judgment correlation.

Considering the final form of time-judgment correlation, if people progress in their goal pursue until they reach the judgment level they consider as satisfactory, we would expect to find no correlation between time and judgment. This is because people are expected to stop investing effort when their judgment passes the preset goal regardless of the time it takes to reach this perceived knowledge level. However, studies of both memorizing and problem solving
repeatedly found that negative correlations dominated timejudgment relationships (e.g., Begg, Duft, Lalonde, Melnick, \& Sanvito, 1989; Koriat et al., 2006). In particular, in problem solving, this negative time-confidence correlation was found even when reaction times were not valid as predictors of success (Ackerman \& Zalmanov, 2012; Topolinski \& Reber, 2010). In these studies the participants were more confident when they provided the solutions quickly than when they provided the solutions after lengthy thinking, regardless of the actual chance for success. These findings are puzzling: Why do people stop investing effort when they knowingly provide solutions with low confidence? Is investment of time perceived as a waste of time, with no progress in the assessed chance for success?

Previous explanations for the consistent negative timejudgment correlation were based on bottom-up fluency (Koriat, Ackerman, Adiv, Lockl, \& Schneider, in press; Koriat et al., 2006), Ackerman and Zalmanov (2012) included. In light of the goal-oriented nature of problemsolving tasks (Evans, 2006), the present study offers a topdown explanation for the findings. According to the proposed Diminishing Criterion Model (DCM), as people invest longer in a problem, their confidence in the currently considered solution option increases in a goal-driven manner, aiming to improve the chance for success, as is also derived from the discrepancy reduction model. However, the stopping criterion does not remain constant along the solving process, but diminishes, reflecting an increased compromise as more time is invested. That is, if an immediate solution option comes to mind with high confidence, higher than the initial stopping criterion, this solution would be provided. If the confidence regarding the initial solution is lower than the criterion, more consideration time is invested, until reaching a satisfying level of confidence. Importantly, a confidence level which may not satisfy the solver regarding a quickly produced solution may satisfy him or her after lengthy consideration.

But what if the confidence after lengthy thinking remains very low and no way to find a better solution is found? In this case, people may prefer to respond with "don't know", stemming from their desire to provide solutions with reasonable confidence. In this case, a "don't know" response may be more socially acceptable than a solution accompanied by a very low confidence (Ackerman \& Goldsmith, 2008). The question is whether the "don't know" option would eliminate the negative time-confidence slope and lead respondents to provide only high confidence solutions. The prediction by the DCM is that it would not, because if a great deal of time is already invested, people compromise and refer to quite low confidence levels as satisfactory.

Two hypotheses derived from the DCM were examined in two experiments, one with regular problems and the other with misleading problems often used in studies of the dualprocess approach. The first hypothesis was that judgments are positively correlated with time while the final timeconfidence correlation is negative. The second hypothesis
was that the opportunity to respond with "don't know" would not eliminate this pattern of results.

## Experiment 1

The task in Experiment 1 was the Compound Remote Associate (CRA) test. In this test, participants are presented with a word triplet and their task is to find a fourth word that forms a compound word or two-word phrase with each cue word separately. In an attempt to solve these problems, immediate associations for each word are expected to come up (Wiley, 1998). However, an association that fits only one or two of the cue words does not satisfy the requirements. For example, for the triplet PINE/CRAB/SAUCE, the word PINE might initially elicit PINECONE rather than the correct PINEAPPLE. Recognition that the initial solution option does not fit should trigger a search for a better solution (Thompson et al., 2011; Thompson et al., in press). In Ackerman and Zalmanov (2012) these problems yielded a strong negative time-confidence correlation.

In the present study there were two groups. The intermediate ratings group was asked to provide ongoing confidence ratings regarding the solution options they considered at each point in time (see also Ackerman \& Goldsmith, 2011; Metcalfe \& Weibe, 1987; Vernon \& Usher, 2003). The "don't know" group provided intermediate ratings as well, but also had the option to respond with "don't know".

## Method

Participants. Forty-four undergraduates participated in the experiment for course credit or for payment $\left(\mathrm{M}_{\text {age }}=24.8\right.$; $50 \%$ females). They were randomly assigned to working with or without the "don't know" option, with 22 participants in each group.

Materials. Thirty-four CRA problems were used. Two problems were used for demonstration and two for selfpractice. Pretesting verified that all problems were solvable by the target population.

Procedure. The experiment was conducted on two to eight participants in parallel, in a small computers lab. The instruction booklet detailed the procedure, explained what constituted a valid solution, and illustrated the procedure using two problems. Pressing the "Start" button brought up a problem. Respondents had to type the solution and press the "Continue" button. Response time was measured from when participants pressed "Start" to when they pressed "Continue". This exposed the question, "How confident are you that your answer is correct?", and a horizontal scale ( $0 \%-100 \%$ ). Pressing the "Next" button cleared the screen for the next problem.

The participants were asked to report on intermediate confidence ratings interspersed with solving each problem. The ends of each scale were marked as "I still have no idea", and "I'm sure I found it". The first scale, appeared
three seconds after the problem's presentation. Later on, an additional scale appeared every 15 seconds and the previous scale became inactive, even if no rating was entered. This way the repeated request to enter a rating was clearly noticeable. The screen could present up to five intermediate scales. The participants could enter the answer at any time, rate their final confidence, and move on to the next problem. The times for entering the intermediate confidence ratings were documented. The only difference for the "don't know" group was that adjacent to the space for answer entry, there was a "don't know" button. Pressing this button deactivated the confidence rating scale.

After demonstration with two problems, the two other practice problems appeared first, and the rest were randomly ordered for each participant. The session lasted 30 minutes.

## Results and Discussion

The participants provided meaningful solution words (rather than "XXX", for example) for $97 \%$ of the problems. Overall, the results were highly similar to those of the group reported in Ackerman and Zalmanov (2012), which was drawn from the same population and solved the problems without intermediate ratings. In the "don't know" group, 19 participants of 22 used the "don't know" option. Percent correct (with "don't know": $M=56.5 \%, S D=20.3$; without a "don't know" option: $M=48.0 \%, S D=16.8$ ) and confidence ratings were somewhat higher with the "don't know" option than without it, but the differences were not significant; both were $p s>.13$. The mean response time was shorter with the "don't know" option (with "don't know": $M$ $=29.0 \mathrm{sec}$., $S D=13.1$; without a "don't know" option: $M=$ $41.6 \mathrm{sec} ., S D=12.6), t(42)=3.27, p<.01$. This finding may indicate that the "don't know" option allowed participants to avoid providing the results of their lengthy solving processes. Indeed, the "don't know" responses ( $M=$ 56.9, $S D=26.6$ ) were provided after more time than the provided solutions, $t(18)=5.90, p<.0001$. This finding suggests that the participants provided the "don't know" response after deliberation, rather than for moving quickly to the next problem.

To examine the ongoing progress of the confidence ratings, the data was split for each participant for his/her own quarters of final response times, with seven or eight problems in each quarter. The points on the black lines in Figure 1 represent the mean final times and confidence for each quarter, with (panel A) and without (panel B) the "don't know" option. A two-way Analysis of Variance (ANOVA) examining the effects of the Group (2) and Quarter (1-4) on final confidence ratings, revealed only the main effect of the quarter, $F(3,126)=136.49, M S E=$ 218.32, $p<.0001$. No difference was found among the groups, $F<1$, and the interaction was not significant, $F(3$, 126) $=1.64, M S E=218.32, p=.18$. Thus, confidence ratings were higher for the quickly provided solutions than for the lengthy solutions, and this pattern did not differ among the groups.

The progress of the problem-solving process exposed by the intermediate confidence ratings is also plotted in Figure 1. Because there was no data on all points for all participants, we used the initial confidence (by the first intermediate scale) and final confidence to statistically examine the progress in the ratings. The analysis was based on participants who provided initial confidence under all four quarters $(N=26,59 \%)$. A mixed three-way ANOVA Group (2) $\times$ Quarter (1-4) $\times$ Rating (initial vs. final confidence) yielded no main effect of the group, $F<1$. The main effect of the quarter was significant, $F(3,72)=90.92$, $M S E=352.64, p<.0001$, reflecting that the ratings fell from the first to the fourth quarters. The main effect of the rating was also significant, $F(1,24)=90.78, M S E=404.03$, $p<.0001$, supporting the increase from the initial to the final confidence ratings. Importantly, the triple interaction was insignificant, $F<1$, suggesting a similar pattern of results with and without the "don't know" option.

Figure 1: Experiment 1 - The intermediate and final confidence ratings on the timeline of solving the problems, divided by final response time quarters (1-4). Each panel presents the results of one group.

Overall, the results of Experiment 1 support the hypotheses derived from the DCM. There was a positive relationship between the time in which each rating was provided and the progress of the confidence ratings and a negative relationship between the total invested time and final confidence ratings. Importantly, this was the case even with the "don't know" option, which suggests that the participants found low confidence solutions provided after lengthy thinking as satisfactory for that point in time. It is also clear from Figure 1 that confidence levels that were not considered satisfactory in initial stages of the problemsolving process (e.g., the mean of the FOR ratings in the second quarter in panel A , which is 33 ), were provided if a similar level of confidence was reached after lengthy deliberation (e.g., the mean final confidence rating at the fourth quarter in panel A, which is also 33).

## Experiment 2

Misleading problems are commonly used in the literature related to dual-process theories to differentiate between the fast intuitive (T1) solutions and the results of more deliberate processing (T2). For example: "A bat and a ball cost $\$ 1.10$ in total. The bat costs $\$ 1$ more than the ball. How
much does the ball cost? $\qquad$ cents" (Kahneman, 2003). The immediate solution that comes to mind is 10 cents, while the correct solution is 5 cents. From a metacognitive point of view, these problems allow dissociation between the confidence and accuracy in their relationship with response time, since the very first solutions tend to be accompanied by high confidence but a low chance for being correct, in particular when presented in an open-ended format (Ackerman \& Zalmanov, 2012).

What should we expect with regard to final confidence in solutions provided after lengthy thinking? In cases where the respondent reaches the correct solution, he or she may be aware of the successful processing and be highly confident of the found solution. High confidence after deliberate processing can also be expected to accompany wrong solutions in cases such as over-generalized rules without appropriate exceptions, or investing effort in finding support for the initial and wrong solution (Stanovich, 2009a). Indeed, Ackerman and Zalmanov (2012) found higher confidence ratings regarding lengthy solutions with misleading problems than regarding CRA problems. However, despite this finding, a negative correlation between time and confidence was found even with the misleading problems. This might indicate that even with these problems, people see relatively low confidence levels as satisfying after lengthy thinking, as suggested here. To examine this possibility, Experiment 2 examined whether the "don't know" option allows the participants to avoid the low confidence solutions, with the hypothesis that it will not. Like in Experiment 1, all participants provided intermediate confidence ratings. One group worked with and one without the "don't know" option.

## Method

Participants. The 40 participants were drawn from the same population $\left(\mathrm{M}_{\text {age }}=25.2 ; 36 \%\right.$ females $)$. The participants were randomly assigned to the "don't know" conditions, with 20 participants in each group.

Materials. The problems used by Ackerman and Zalmanov (2012) were used for this experiment. They included twelve experimental problems and a practice problem for demonstrating the procedure. The experimental problems included the three problems used by Frederick (2005; the bat and ball, water lilies cover half a lake, and machines that produce widgets at a certain rate), the drinks version of Wason's selection task (Beaman, 2002), the A-is-looking-at-B problem (Stanovich, 2009b), and a conditional probability problem (Leron \& Hazzan, 2009). The other problems were misleading problems adapted from preparation booklets for the Graduate Management Admission Test (GMAT).

Procedure. The procedure was highly similar to that used in Experiment 1. The practice problem appeared first, and the rest were randomly ordered for each participant.

## Results and Discussion

The participants provided meaningful solution words (rather than "XXX", for example) for all the problems. In the "don't know" group, only six participants of 20 utilized the "don't know" option. As in Experiment 1, percent correct (with "don't know" option: $M=47.2 \%, S D=16.4$; without the "don't know" option: $M=43.9 \%, S D=15.5$ ) and confidence ratings were equivalent in both groups, both $t \mathrm{~s}<$ 1. In this case, no difference was found also for response time, $t<1$. Like in Experiment 1, the results were highly similar to those found by Ackerman and Zalmanov (2012), where there were no intermediate confidence ratings.

In this experiment, there were only 12 problems, so they were divided into thirds rather than quarters, with four problems in each third. As can be seen in Figure 2, the overall pattern of results remained with (Panel A) and without (Panel B) the "don't know" option, although confidence levels were higher than in Experiment 1.

Figure 2: Experiment 2 - The initial feeling of rightness (FOR), and intermediate and final confidence ratings on the timeline of solving the problems, divided by final response latency thirds (1-3). Each panel presents the results of one group.

A two-way ANOVA examining the effects of the Group (2) and Third (1-3) on final confidence ratings, revealed only a main effect of the third, $F(2,76)=60.37, M S E=$ $67.82, p<.0001$. No difference was found among the groups, $F<1$, and no interactive effect, $F(2,76)=1.73$, $M S E=67.82, p=.18$. Thus, confidence ratings were higher for the quickly provided solutions than for the lengthy solutions, but this pattern did not differ among the groups. A mixed three-way ANOVA Group (2) $\times$ Third (1-3) $\times$ Rating (FOR vs. Final confidence) was based on participants who provided FORs under all thirds $(N=20,50 \%)$. The main effect of the group was not significant, $F(1,18)=2.29, M S E$ $=1399.72, p=.15$. The main effect of the third was significant, $F(2,36)=29.25, M S E=163.62, p<.0001$, reflecting that the ratings dropped from the quickly provided to the slowly provided solutions. The main effect of the rating was also significant, $F(1,18)=95.80, M S E=948.31$, $p<.0001$, supporting the increase from the initial FORs to the final confidence ratings. The triple interaction was again insignificant, $F(2,36)=1.84, M S E=180.92, p=.17$ suggesting a similar pattern of results with and without the "don't know" option.

The results of Experiment 2 support the two hypotheses derived from the DCM as well. This experiment generalizes the results of Experiment 1 with a different type of problems, in which one may expect to find high confidence ratings after lengthy thinking. Even with these problems, the time-confidence relationship is neither positive nor flat. It is consistently negative, even when participants could avoid low confidence solutions by utilizing the "don't know" option.

## General Discussion

The motivation for the present study stemmed from the puzzling inconsistency between the goal-driven nature of the problem-solving task - which leads to the expectancy of positive or no correlation between time and confidence - and the empirical findings of persistent negative correlation between them, even when people are free to regulate their solving time (Ackerman \& Zalmanov, 2012; Koriat et al., 2006). The proposed DCM suggests that the cognitive process indeed progresses in a goal-driven manner, with a positive correlation between time and confidence. It also suggests that people stop investing effort when their metacognitive monitoring passes their stopping criterion. Until this point the process accords with the wellknown discrepancy reduction models (Nelson \& Narens, 1990). The unique characteristic of the proposed DCM is the suggestion that the negative correlation stems from the willingness of people to compromise on the satisfactory level of their chance for success. These predictions were supported by the two experiments, with two task types: nonmisleading and misleading problems. It was found that although the final time-confidence relationship is negative, the process progresses with a positive correlation between them. The "don't know" procedure was used to ensure that the negative correlation does not stem from the desire to move on to the next problem, even if a satisfactory solution was not yet found. The results suggest that people find the relatively low confidence they experience after lengthy thinking to be satisfactory, even though the same confidence levels were not acceptable if reached earlier in the process.

The present study suggests a difference between the stopping rules for T 1 and for T 2 . Thompson and her colleagues (Thompson et al., 2011; Thompson et al., in press) suggested that FOR is the basis for the stopping rule for T1 and for triggering T2. If FOR is high enough, people provide the first answer that comes to mind. Otherwise they activate T2. The present study extends this idea to the decision to stop T2. While time allocation for T1 was explained to be based on fluency in which the first solution option comes to mind, in a bottom-up manner, the stopping rule for T 2 is explained here as stemming from a goaldriven, top-down, effort investment. Importantly, this does not rule out fluency effects on final confidence ratings as well, but suggests that the goal-driven decision dominates the process.

To conclude, metacognitive studies traditionally focus on memorizing word lists. Investigating more complex tasks
brings to the fore additional factors that may have broader ecological validity. The present study evolved from considering problem-solving tasks, which are generally understudied from the metacognitive point of view, and which highlight puzzling aspects of time investment and its relationship to metacognitive regulation. By proposing the DCM, this paper aims to shed light on the processes that lead people to end up with low confidence in their success, even when they can potentially avoid it by continuing improvement attempts or admitting failure.

## Acknowledgments

The study was supported by a grant from the Israel Foundation Trustees (2011-2013).

#### Abstract

When listening to music, we form implicit expectations about the forthcoming temporal sequence. Listeners acquire knowledge of music through processes such as statistical learning, but how do different types of statistical information affect listeners' learning and memory? To investigate this, we conducted a behavioral study in which participants repeatedly heard tone sequences varying within a range of informationtheoretic measures. Expectedness ratings of tones were collected during three listening sessions, and a recognition memory test was given after each session. This enabled us to examine how statistical information affects expectation and memory for tone sequences over a period of increasing exposure. We found significant correlations between listeners' expectedness ratings and measures of information theory (IT), and although listeners demonstrated poor overall memory performance, the IT properties significantly impacted on musical memory. Generally, simple sequences yielded increasingly better memory performance. High-information sequences, for which making accurate predictions is difficult, resulted in consistently poor recognition memory.

Keywords: Music cognition; information theory; computational approach; predictive models.

## Introduction

Music is a fruitful domain for exploring the mechanisms responsible for learning structured temporal sequences, a type of learning that subserves a wide range of human behaviors. Research by Krumhansl (1990), Pearce \& Wiggins (2006), Huron (2006), and others shows that listeners implicitly acquire knowledge about the statistical structure of music. But is this implicit learning influenced by the information contained in the musical signal and, if so, how? Using computational methods, the pitch structure of music can be manipulated systematically to help reveal the ways in which various information-theoretic properties of melody interact and influence human learning and memory.

This paper examines the process of learning novel music over time, with a focus on mental anticipatory processing and musical structure. By using carefully constructed tone sequences, we are able to test how the statistical structure of music, as measured using information theory, affects the expectedness of tones, as well as memory for specific exemplars, over a period of increasing exposure.

## Information Theory and Music

Information theory has contributed to fields as diverse as engineering and linguistics by describing and quantifying the information contained in a signal. This is especially useful for clarifying how the brain processes temporal signals; and indeed, information-theoretic measures such as entropy, a measure of uncertainty, have successfully described and predicted how the human brain anticipates forthcoming sensory input, such as music and language (e.g., Manning \& Schutze, 1999; Abdallah \& Plumbley, 2009). Within the domain of music, there has been a longstanding interest in anticipation and prediction, and statistical and probabilistic approaches to learning have been influential for decades (consider Krumhansl \& Kessler, 1982; and Saffran, Johnson, Aslin, \& Newport, 1999). Computational models such as IDyOM (Pearce, 2005) derive information-theoretic properties of music that accurately reflect and predict listeners' expectations during music listening (Pearce \& Wiggins, 2006; Pearce et al., 2010).

While statistical and computational approaches have modeled human performance on a variety of music perception tasks, these approaches have not yet been extended to modeling the learning trajectory of listeners: we do not yet know how information-theoretic measures capture musical learning over increasing exposure to musical exemplars, and how much exposure is necessary to
learn the statistical regularities of novel music. The following research addresses these questions.

## Behavioral Experiment

In the present study, computational techniques were used to create a set of tone sequences varying systematically across several information-theoretic measures. Varying the sequences' statistical structure allows us to assess which factors have the greatest impact on listeners' musical expectations and memory for tone. We focused on testing the relative influence of three information-theoretic factors based on the information theoretic concepts of entropy rate, multi-information rate (a kind of redundancy), and predictive information rate (see Abdallah \& Plumbley, 2009). These measures are defined for a random process with a known probability distribution, and hence thought of as 'objective'. However, listeners cannot know these probability distributions; they can only estimate them from observations, and so we defined variants of each measure appropriate for an observer processing events sequentially as they happen, updating its estimated probability model as it goes along: they are dynamic information measures based on an adaptive probabilistic model. Since they depend only on the actual observed sequences (rather than a theoretical statistical ensemble) and any prior expectations built into the listener model (which we may think of as summarizing the listener's previous musical experience), we can usefully think of these as 'subjective' information measures.

In our experiments, the listener model was an adaptive first-order Markov chain, as described by Abdallah and Plumbley (2009), which assumes that notes are sampled from a Markov chain with an unknown transition matrix, and tries to estimate the transition matrix from the observations. The model is supplied with an initial expectation (a Bayesian prior) that the transition matrix is similar to a first-order transition matrix derived from a large corpus of Western tonal music in a major key.

The three information measures examined in this paper are Information Content (IC), Coding Gain, and Predictive Information. IC is a measure of the subjective unexpectedness of an observation. Coding Gain measures how much temporal structure or pattern there is in the sequence. And Predictive Information quantifies how much the current observation improves the listener's predictions about future observations (assuming knowledge of the previous observations). High predictive information is also associated with temporal structure or pattern, but of the sort that has more variation, requiring the observer to continually pay attention in order to follow the pattern.

These three measures are defined in the Markov model as follows: at any integer time $t$, let $x_{t}$ be the note occurring at that time, and $\theta_{t}$ be the estimated transition matrix using information available before $t$. Then, the IC at time $t$ is the negative $\log$ probability of $x_{t}$ given the context and the estimated model: $-\log p\left(x_{t} \mid x_{t-1}, \theta_{t}\right)$, where the relevant transition probability is extracted from the matrix $\theta_{t}$. Coding Gain at time $t$ quantifies how much the model's
ability to predict the current observation depends on having observed the preceding observations, and is a difference of $\log$ probabilities: $\log p\left(x_{t} \mid x_{t-1}, \theta_{t}\right)-\log p\left(x_{t} \mid \theta_{t}\right)$, where the latter term is derived from the stationary distribution of the transition matrix. Predictive Information is quantified as the distance between two probability distributions over the next symbol $x_{t+1}$, representing the observer's probabilistic beliefs about $x_{t+1}$ before and after the observation of $x_{t}$. The average of each of these three measures was computed for every tone sequence in the present study, henceforth referred to as sequence statistics.

To investigate the processes underlying musical learning, listeners were exposed to tone sequences and tested on recognition memory over several listening sessions. In each listening session, participants heard tone sequences and rated the expectedness of a tone (termed the "probe tone") within each sequence. Probe tones varied in terms of information content (representing unexpectedness) across sequences. A recognition memory test followed each listening session. This format enabled us to compute information-theoretic measures for every tone sequence, and compare the effect of these measures on probe tone ratings.

We also examined how IT measures impacted on recognition performance in the test sessions. We hypothesized that sequences featuring generally highentropy would be difficult to remember, and probe tones would be rated with lower expectedness. Because each tone sequence was presented in every listening session, we also aimed to clarify the learning trajectory for the different classes of tone sequence; that is, how music represented in short-term memory gradually becomes more richly encoded in long-term memory, and how musical information and complexity, as measured using IT, influence this process over time.

## Method

## Participants

Twenty-three students ( 12 female and 11 male; mean age $=21.0 \mathrm{yrs}$ ) at Cornell University participated in this study for extra credit in a psychology course. The participants had an average of 1.61 years ( $S D=1.88 \mathrm{yrs}$ ) playing music in the previous five years, and an average of 5.82 years $(S D=$ 4.54 yrs ) of lifetime experience playing an instrument.

## Materials and Procedure

After receiving written and verbal instructions, participants listened to tone sequences in three sessions, each lasting approximately 15 minutes and followed by a brief test session. In the listening sessions, participants heard each of the 24 tone sequences (presented in a different order in each session) and were asked to rate the expectedness of a particular tone (the probe tone) within each sequence. This tone was identified visually on the computer screen via a clock counting down on the subsequent tones of the sequence. When the clock returned to midnight, participants rated the expectedness of the concurrently sounding tone on
a scale from 1 to 5 , where ' 1 ' represented highly unexpected and ' 5 ' represented highly expected.

Each listening session was followed by a test session. Sixteen test stimuli were presented in each of the three test sessions, where 8 sequences were Old (had been presented previously) and 8 were New. After each test sequence, participants responded "Yes" or "No" to whether they had heard the sequence before. Upon responding, the listener made a confidence rating on a scale from 1 to 5 where ' 1 ' represented not confident and ' 5 ' represented very confident.

The 24 sequences of the listening sessions each comprised 24 isochronous tones, played in a piano timbre. Each tone was 500 ms in duration, yielding sequences that were 12-seconds-long each. The sequences were generated with an alphabet of 7 pitches (representing one octave of the diatonic scale). A first-order Markov transition matrix was derived (Pearce, 2005) from the scale degrees of Canadian folk songs/ballads, Chorale melodies, and German folk songs in a major key (the same corpus described in Table 2 of Pearce and Wiggins, 2006). To construct the tone sequences, many transition matrices were generated randomly using a process biased towards the tonal transition matrix. From each matrix, one sequence of 24 notes was sampled. A subset of these was then selected manually to ensure a good spread in the 3 -dimensional subjective information space formed by the information theoretic measures described above.

A distinct 500 ms white noise clip was played after every tone sequence in the listening and test sessions as a perceptual "reset" to ensure that expectedness ratings and memory judgments were based only on the current trial. The study was administered on a MacBook Pro laptop, and stimuli were presented and responses collected using Psychophysics Toolbox (Version 3) within the programming environment of MATLAB 2010a (MathWorks, Inc). Participants listened to stimuli over headphones set to a comfortable listening volume.

## Results and Discussion

## Whole-Sequence IT measures and Expectedness During Listening Sessions

To examine how the information-theoretic properties of each sequence influenced the expectedness of probe tones, correlations were analyzed between the IT factors and Average Expectedness Ratings. In terms of whole-sequence statistics, both Sequence IC and Sequence Predictive Information were significant predictors of Average Expectedness Ratings. As shown in the top graph of Figure 1, Sequence IC was correlated with Average Expectedness Ratings such that more predictable sequences (lower Sequence IC values) yielded higher expectedness ratings of probe tones, $R^{2}=.29, F=28.87, p<.01$. The second graph of Figure 1 displays the correlation between Sequence Predictive Information and Average Expectedness Ratings, $R^{2}=.34, F=36.23, p<.01$. The third graph shows

Sequence Coding Gain and Average Expectedness Ratings, also significant in this analysis, $R^{2}=.37, F=41.54, p<.01$.

Figure 1: The main effects of Sequence IC, Sequence Predictive Information, and Sequence Coding Gain (in nats, where 1 nat $=1.44$ bits) on average expectedness ratings during the listening sessions.

Sequences with high average IC values contain unexpectedness; the tones comprising these sequences have high average Information Content. Therefore, it is logical that sequences containing many unexpected, unpredictable tones would yield lower expectedness ratings as shown below.
Regarding the effects of Sequence Predictive Information, information is inextricably associated with unexpectedness: an event cannot be informative if the observer knew it was going to happen, because it will not change the observer's beliefs about the future. (Mathematically, Predictive

Information is upper-bounded by the Information Content.) Hence, sequences with higher average Predictive Information will necessarily have moderately high average information content and thus we would expect the probe tones to see relatively lower expectedness ratings.

Coding Gain is a measure of how much information was gained about the current observation from the preceding context. Therefore, the greater the average Coding Gain of the sequence, the greater the predictability of the sequence and so we would predict higher expectedness ratings in such cases.

Expectedness and Probe Tone IC To examine which factors in the listening sessions had the greatest impact on expectation, a multiple regression analysis was performed with Probe Tone IC, Sequence IC, Sequence Coding Gain, Sequence Predictive Information, and Listening Session as independent measures, and Expectedness Ratings as the dependent measure (note that all expectedness ratings were used, not the average rating for each stimulus). Listeners were included as a random effect in the analysis. There was a significant main effect of Probe Tone $I C, F=181.74, p<$ .001, with high-IC tones rated as less expected. As for the whole-sequence IT measures, there were also main effects of Sequence IC, $F=3.92, p<.05$, and Sequence Predictive Information, $F=9.67, p<.01$. In addition to these main effects, there were also significant interactions between Probe Tone IC and all three of the IT measures of sequences statistics: Sequence IC X Probe Tone IC, F = 22.34, p< .001, and Sequence Coding Gain X Probe Tone IC, F = 35.72, $p<.001$, and Sequence Predictive Information X Probe Tone IC, $F=91.65, p<.001$. Listening Session did not contribute significantly to the results indicating that pitch expectation remained constant overall during the study.

Figure 2: Probe Tone IC as a predictor of average expectedness ratings of probe tones.

Probe Tone IC had the largest effect in the listening sessions, with a significant linear relationship with Expectedness Ratings, $R^{2}=.69, F=154.20, p<.01$. In Figure 2, the average expectedness rating for each melody is shown to display more clearly the main effect on a continuous rather than discrete scale. Low IC tones do
receive reliably higher expectedness ratings than high-IC probe tones over the course of listening.

## Recognition Memory in Test Sessions

Data from the test sessions are reported in Table 1 as Proportion Correct Response. Chance performance is 0.5 , and the similarity of performance for Old and New items indicates little bias towards either response.

Table 1: Recognition memory test performance (proportion correct) for Old and New sequences across listening sessions.

| Listening <br> Session | Old/ <br> Correct <br> (Hits) | Old/ <br> Incorrect <br> (Misses) | New/Correct <br> (Correct <br> Rejections) | New/Incorrect <br> (False Alarms) |
| :---: | :---: | :---: | :---: | :---: |
| Session 1 | 0.67 | 0.33 | 0.64 | 0.36 |
| Session 2 | 0.63 | 0.37 | 0.65 | 0.35 |
| Session 3 | 0.70 | 0.30 | 0.65 | 0.35 |

Despite little evidence for an increase in overall memory performance over the course of the experiment, we investigated whether certain types of statistical information were being learned, and examine whether performance differed depending on the properties of the individual sequences. Therefore, to examine the effects of the IT measures on recognition scores across listening sessions, a logistic regression was performed with Sequence IC, Sequence Coding Gain, Sequence Predictive information, Familiarity (Old or New stimulus), and Listening Session as factors, and Correct Response as the binary dependent variable.

All three whole-sequence statistics showed significant main effects: Sequence $I C, \chi^{2}=16.21, p<.01$; Sequence Predictive Information, $\chi^{2}=12.09, p<.01$; and Sequence Coding Gain, $\chi^{2}=4.27, p<.05$. Listening Session interacted with each of the whole-sequence IT measures: Sequence IC X Listening Session, $\chi^{2}=6.14, p<.05$, Sequence Predictive Information X Listening Session, $\chi^{2}=7.98, p<.05$, and Sequence Coding Gain X Listening Session, $\chi^{2}=6.53, p<$ .05, were all significant interactions.
The only significant interaction including Familiarity was with Sequence Predictive Information, $\chi^{2}=12.15, p<.01$. As shown in the top plot of Figure 3 below, New sequences that are high in Predictive Information yield more correct responses than those with low Predictive Information. Conversely, Old sequences show the opposite trend, with worse recognition memory performance on high Predictive Information sequences. Note that Proportion Correct Response is used in Figure 3 rather than the categorical variable Correct Response for clarity of illustration.

Figure 3: The differential effect of Sequence Predictive Information on Proportion Correct Response during recognition memory tests for New and Old sequences.

Confidence Ratings Confidence ratings of recognition memory judgments were collected after every test sequence; responses were made on a $1-5$ scale where on a where ' 1 ' represented not confident and ' 5 ' represented very confident. A logistic regression was performed with the same factors as those used above: Sequence IC, Sequence Coding Gain, Sequence Predictive Information, Familiarity (Old or New stimulus), and Listening Session. This analysis yielded significant effects of Sequence IC, $\chi^{2}=16.44, p<.01$, and Sequence Coding Gain, $\chi^{2}=15.33, p<.01$, and interactions of these two factors with Listening Session: Sequence IC X Listening Session, $\chi^{2}=21.94, p<.01$, and Sequence Coding Gain X Listening Session, $\chi^{2}=23.10, p<.01$.

As expected, listeners made more confident memory judgments when sequences had lower IC and higher Coding Gain. For Sequence IC, there was a decrease in confidence (fewer 4 and 5 responses) over the course of the experiment, which was especially noticeable for low-IC sequences (because high-IC sequences rarely received 5 responses throughout the study). Similarly, there was also a decrease in highly confident ratings (4 and 5 responses) for Sequence Coding Gain over the course of the experiment, which was more apparent in the high-Coding Gain sequences (lowCoding Gain sequences elicited few 5 responses).

## Conclusion

The analyses above highlight the significant roles that measures of entropy and predictability have on musical learning and memory. The three information-theoretic measures examined here, Sequence IC, Sequence Predictive Information, and Sequence Coding Gain, all impacted on learning over time (as evinced by their significant interactions with Listening Session). In the first memory test, Sequence IC had little effect on the correctness of participants' responses. In the subsequent listening sessions, a trend was displayed between increasing Sequence IC and number of incorrect responses ( $p<.01$ ). Similarly, Sequence Coding Gain did not have a significant effect on response in the first listening session, but was positively correlated ( $p<.01$ ) with correct response in the second and third listening sessions. Sequences with high average Coding Gain were more likely to yield correct responses in the memory tests. In addition, Sequence Predictive Information did not impact on memory performance initially, but by the third listening session, this measure was negatively correlated with Correct Response such that greater Predictive Information led to fewer correct responses ( $p<.05$ ). Again, Predictive Information is upper-bounded by Information Content (unexpectedness); therefore, high Predictive Information sequences sound relatively unpredictable. To summarize, these results suggest that the global statistical properties of the tone sequences had little bearing on recognition memory judgments initially, but over repeated listenings, sequences higher in information and entropy (those that sounded less predictable) produced both lower expectedness ratings and poorer recognition memory.

As displayed by the interaction between Familiarity and Sequence Predictive Information, New sequences that are high in Predictive Information tend to yield more correct responses (Correct Rejections) compared with Old sequences that are high in Predictive Information, which yield fewer correct responses (Misses). We suggest that sequences with high Predictive information are surprising but also distinctive, making them easier to correctly reject on New trials but harder to remember on Old trials. Listeners display poor recognition memory performance for individual sequences, and appear to respond based on the statistical properties of the sequence. Follow-up studies need to be conducted to explore these complex information dynamics, but it is clear that the information-theoretic measures investigated in this study interact dynamically with both expectedness and learning over a period of increasing exposure to novel tone sequences.

## General Discussion

Information-theoretic approaches have elucidated various aspects of music perception, such as melodic expectation (e.g., Pearce et al., 2010). In the IT study described above, three subjective information-theoretic factors, Sequence IC, Sequence Predictive Information, and Sequence Coding Gain, all significantly influenced expectedness ratings of probe tones during the listening sessions. This reveals that
the perceived expectedness of events is influenced not only by properties of the event itself, but also by properties of the sequence within which it is embedded. These factors also impacted on nuanced memory performance during the recognition tests. It was also interesting to discover a significant interaction between Familiarity and Sequence Predictive Information for memory performance. The increasing effect of IT measures on recognition accuracy may result from listeners gradually learning the underlying Markov model: Upon gleaning the basic information structure of the melodies, Predictive Information has a greater effect on recognition memory. Additionally, sequences that have high average IC can also vary in Predictive Information; that is, tones may be perceived as unexpected, but they can be surprising in either a way that increases listeners' predictions of forthcoming tones, or in a way that is surprising but does not increase predictive accuracy. The significant interaction between Familiarity and Sequence Predictive Information, but not Familiarity and Sequence IC, demonstrates that it is not simply the high-information content of sequences, but rather the Predictive Information of these sequences that listeners can successfully use when making memory judgments.

Generally, sequences that were more difficult to predict (higher IC/Predictive Information) gave rise to worse memory performance. There was also an increasing impact of these factors on memory as exposure increased. The effect of Sequence IC became more pronounced as listeners repeatedly heard melodies (e.g., sequences with low average IC were more likely to be remembered by the third listening session). To our knowledge, this research is the first investigation of the time course of music learning using an information-theoretic approach.

Although listeners struggled with the difficulty of the recognition memory task, they responded differentially based on the statistical properties of the sequences. Listeners may be more adept at learning the statistical rules underlying musical sequences than the specific exemplars themselves, especially with non-stylistic music such as the sequences used in this study (see Saffran et al., 1999; Loui, Wessel, \& Kam, 2010; Halpern \& Bartlett, 2010). Listeners are capable of learning a vast number of songs and themes, therefore more ecological stimuli may lead to better learning and memory performance. Language research (a domain in which listeners have been shown to be proficient in statistical learning of phonological sequences) has historically revealed that people tend to remember the semantics of what is said, not a verbatim account (e.g., Bartlett, 1932). Therefore, it may prove more insightful to test listeners' learning of semantics (musical structure and underlying statistics) across exemplars rather than the individual exemplars themselves.

We see from this IT study that learning individual sequences is possible, but challenging. Because we see effects of the IT properties of the stimuli but no significant effect of Listening Session, it is likely that participants were
learning the rules describing the underlying transition matrices rather than the particular exemplars themselves.

Because it is impossible to perform an exhaustive behavioral investigation into which exemplars and rules listeners learn, future work will develop computer models to simulate and predict the process of musical learning. Computational models can offer insight into this process by analyzing information-theoretic measures to predict human listeners' performance. Future work will also test memory differences between ecological melodies and experimentally controlled tone sequences with an expectation that stylistic, ecological exemplars will aid memory performance.

#### Abstract

Theories of embodied cognition suggest that sensorimotor processes are involved in language comprehension processes. Recent studies suggested that sentences referring to actions that involve a typical effector (e.g. "He kicks the ball") can systematically activate motor cortex areas that are involved in performing such actions (Hauk, Johnsrude \& Pulvermüller, 2004). In behavioral studies, there is mixed evidence regarding the effects of effector-specific words on corresponding actions. In the current study, we investigated the effect of four word groups on subsequent motor responses involving the hand or the foot. The four word groups were (a) action verbs (e.g., kick, grasp) (b) nouns containing the lexeme 'hand' or 'foot' (e.g., handball, football) (c) nouns referring to objects that are typically manipulated by hand or foot (e.g., cup, shoe), and (d) as control items, nouns that have a spatial association with the upper or lower space (e.g., eagle, root) and which are known to activate locational information in paradigms where no reading is required. We found strong effector-specific compatibility effects revealing a facilitation effect in all noun-groups. Surprisingly, this effect was not present for the action-verbs. Implications of these findings will be discussed.

Keywords: Embodied Cognition; Language Comprehension; Effectors

## Introduction

Many of our daily activities involve language. We speak, we listen to people speaking, we read or we write at various occasions every day. However, in research on language processing there is still no agreement on theoretical assumptions concerning the processes and representations that are involved in language processing. For a long time, the propositional, amodal theory of language comprehension was the predominant view (Kintsch \& van Dijk, 1978; Kintsch 1988; McKoon \& Ratcliff, 1992). According to this view, the result of language comprehension is a meaning representation in an amodal propositional format that captures the content of the linguistic input and integrates it with the reader's background knowledge which is also available in this format. Typically, embodied models of language understanding are viewed as the counterpart to these amodal theories of language processing (Barsalou,
1999). The main assumption of this approach is that language processing is closely connected to other cognitive systems, such as perception and action. There is a tremendous number of empirical studies providing evidence for the embodied view of language comprehension (for an overview, see Jirak, Menz, Buccino, Borghi \& Binkofski, 2010). However, in many cases the individual results are somewhat inconsistent, and cannot be integrated into a coherent processing model. As a result, important theoretical questions concerning the embodied view are still unsolved, as for instance the question whether all kinds of sensorimotor activations are functionally relevant for comprehension or in contrast sometimes constitute a kind of epi-phenomenon. Before turning to these important issues, research first needs to investigate in more detail the individual phenomena, with the goal of arriving at more definite conclusions concerning the boundary conditions for the observed effects. In the present study, we aim to address the question, whether motor activation occurs in a specific manner when processing action related verbs (e.g., kick, grasp), or nouns referring to objects that are typically manipulated with the hand or the foot (e.g., brush, shoe).

Evidence for an embodied view of language understanding has been reported in behavioral and neuroimaging paradigms. In the behavioral domain, observed interactions between language and visualprocessing, and between language and motor processing are typically taken as strong evidence for an embodied model of language comprehension. For example, Zwaan, Stanfield and Yaxley (2002) reported that sentence processing can activate very specific visual representations. In their study, participants had to process sentences such as "The girl saw the egg in the frying pan" and subsequently respond to pictures of the target entity (egg). The pictures could either match the shape of the entity described in the sentences (e.g., a fried egg sunny side up) or mismatch the shape (e.g., an unbroken egg). Responses were faster in the matching than in the mismatching conditions, suggesting that readers had available a visual representation of an egg in the frying pan when reading the corresponding sentence.

Evidence for the reactivation of motor representations during language comprehension was reported by Glenberg
and Kaschak (2002) in the so-called action sentence compatibility effect. In their study, participants had to read sentences and judge the sensibility by moving their arm away or towards their body. Responses were faster if the movement direction implied by the sentence matched the response movement (e.g., "You opened the drawer" and a movement toward the participants) compared to when there was a mismatch (e.g., "You closed the drawer" and a movement away from the participants). These results suggest that participants reactivated the described movements when processing the sentences and thus primed the response movements in the matching conditions.
Interestingly, if language understanding indeed relies on motor activation and the reactivation of experiential traces, these language-action compatibility effects should occur in a very specific manner. In other words, reading sentences such as "He throws the ball" versus "He kicks the ball" should result in rather distinct activation in the motor cortex. That is, when processing sentences such as "He throws the ball" hand related motor areas should be active, whereas when processing sentences such as "He kicks the ball" foot related motor areas should be involved. Indeed, Hauk, Johnsrude and Pulvermüller (2004) reported in an fMRI study such effector-specific motor activation during language understanding (for an EEG study, see Pulvermüller, Härle \& Hummel, 2001). They compared the brain areas activated while performing finger, feet and tongue movements with the activation in a passive reading task of face-, foot- and arm-related sentences. This study revealed clear activation in the motor cortex and in the primary motor cortex during language processing, with the activation being similar to the conditions where the participants actually performed the corresponding actions.
In addition to neuropsychological studies, some behavioral studies reported evidence for effector-specific motor activation during language processing. Marino, Gough, Gallese, Riggio and Buccino (2011) investigated the effects of words on hand movements. Their stimuli consisted of Italian nouns referring to concrete objects, which were both hand- or foot-related, and abstract entities. Participants had to decide whether a presented word referred to a concrete object (e.g., pencil) or whether the word referred to an abstract content (e.g., jealousy). Only in case of concrete objects, participants had to press the response key with their index finger. In case of abstract words, they had to withhold responses. Additionally, participants had to wait with their response until a go-signal was delivered, and this could occur early or late after word presentation. The results showed that participants (all right-handed) responded slower with their right-hand to hand-related words compared to foot-related words. In contrast, with their left hand, they were faster to hand-related words than to footrelated words. Those effects were only found in the early go-signal condition. Marino et al. (2011) explained those results with a left hemispheric specialization for language processing. In case of right hand responses, interference took place due to the left hemisphere being activated by
both, language processing and motor response activation, whereby they compete for common resources. The authors argued that this kind of interference was not present for left hand responses because the motor activation took place in the right hemisphere and thus did not overlap with activation from language processing. The authors themselves state that this explanation cannot account for the facilitation effect of the left hand, because no difference between hand and foot-related words would be predicted.

Scorolli and Borghi (2007) also reported influences of sentence understanding on effector-specific behavioral responses for sentences that imply the usage of a specific effector (e.g. hand vs. mouth). Their participants had to judge the plausibility of sentences with nouns and verbs that refer to objects and actions associated with specific effectors, e.g., to unwrap vs. to suck the sweet. In the first block, hand and mouth sentences, and in the second block, hand and foot-sentences were tested. Half of the participants had to react by saying "yes" into a microphone and the other half had to press a foot-pedal. As predicted, they found match effects with mouth- and foot-responses for mouthand foot-sentences, but not for hand sentences However, Scorolli and Borghi (2007) did not differentiate between word-based and sentence-based effects, thus leaving open whether the reported compatibility effects were triggered by single words or the processing of the whole sentence.

In summary, there is evidence supporting the hypothesis that language can activate effector-specific motor processes, but at the same time it seems difficult to come up with a consistent explanation regarding the underlying mechanisms causing facilitation or interference. We therefore consider it worthwhile to investigate this issue in a very basic behavioral paradigm with the focus being on the influence of single words on responding.

In the current study, we will investigate whether processing of single nouns and verbs with an association to the effectors hand and foot, will result in effector-specific compatibility effects if implemented in a task that does not require active reading. This task will be an alternated version of the original color-naming experiment conducted by Stroop (1935). In our experiment, all words will be presented in a color, and the color will determine the response effector, either hand or foot. According to the Stroop literature any meaningful word can potentially cause interference in a color-response task because wordprocessing is seen as more automatic and faster than responding to the word color (for a review, see MacLeod, 1991). Importantly, interference should only be found if automatic word processing interacts with the required response and can result in response conflict (Botvinick, Braver, Barch, Carter, \& Cohen, 2001). For example, in case of action verbs (e.g., kick), this word might automatically activate effector-specific responses (e.g., foot responses) and thus facilitate compatible responses or interfere with incompatible responses (e.g. hand responses).

Indeed, there is a debate regarding the automaticity of effects reflecting interactions between language processing
and motor responses. For example Bub and Masson (2008) only find an effect of words on subsequent reaching tasks if the words have to be actively processed by the participants.

In our study, we compare four different kinds of word categories: First, action-verbs, using the stimulus-set of Pulvermüller et al. (2001). Second, nouns directly related to one specific effector, involving the lexeme 'hand' or 'foot' (e.g., handball vs. football). Third, nouns referring to objects that are typically manipulated by hand or foot (e.g., paint brush vs. stirrup). Forth, nouns referring to objects with a typical location in the vertical space (e.g., bird, root). The fourth word category consists of a reduced set of up/down words used by Lachmair et al. (2011) and Dudschig et al. (2012, 2013). We will use those words as a control in our paradigm, because they can be expected to show strong compatibility effects with responses differing with respect to the vertical dimension (here: hand $=u p$, foot $=$ down) even in tasks that do not demand active reading. As described above, words will be presented in a color, and the color determines the response effector (hand vs. foot). We predict compatibility effects for all word categories, with possibly stronger effects for the verbs, as well as possibly for the nouns involving the lexemes 'hand' and 'foot'.

## Method

Participants were presented with words displayed in one of four colors in each trial. Their task was to respond to the font color. Depending on the color, they either pressed a key with their hand which was located at chest height or a pedal with their foot which was located at the ground.

## Participants

A total of 30 students ( 9 males) of the University of Tübingen, aged from 19 to 34 years ( $M=22.8$ years, $S D=$ 3.5) participated in this study. Twenty-three of the students were right-handed and 7 were left-handed. All participants had normal or corrected-to-normal vision; none of them had impaired color-vision. They were asked to fill in a form of consent before doing the experiment and received course credit for their participation.

## Apparatus and stimuli

Stimuli were presented in center position on a CRTMonitor in size 12 Courier New bold. Responses were recorded via a PST Serial Response Box, Model Number 200A with a foot pedal. The experiment was programmed with E-Prime® (Psychology Software Tools Inc., www.pstnet.com/E-Prime/e-prime.htm).

The participants stood in front of a height-adjustable table with the possibility of leaning against a wall with their backs. Prior to the experiment, the height of the table and with it the monitor was adjusted such that stimulus words were presented at eye-level of the participants. The foot pedal was also adjusted and fixed in a proper distance to the participant. The response box was situated on the table. Every participant reacted with their dominant body side.

We used 192 German nouns and verbs as stimuli, which could be subdivided into four groups: (a) The verbs were adapted from Pulvermüller et al. (2001) ( $\mathrm{N}=64$ ) consisted of 32 hand- and 32 foot-related action-verbs (e.g., grasping vs. kicking). (b) The "explicit nouns" group ( $\mathrm{N}=32$ ) consisted of 16 nouns containing the lexeme 'hand' and 16 nouns containing the lexeme 'foot' (e.g.; handbag, footprint). (c) The "associated nouns" group consisted of 16 nouns referring to an object that was typically manipulated with the hand and 16 nouns referring to an object that is typically manipulated with the foot (e.g., cup, stirrup). (d) Finally, the "up/down nouns" group ( $\mathrm{N}=64$ ) consisted of a shortened set of up/down words from the study of Lachmair et al. (2011) with 32 words referring to an entity typically located in the upper part of the world and 32 referring to an entity typically located in the lower part of the world (e.g., root, roof). See Table 1 for mean frequencies and mean length (number of characters) of the two sets in each group. Frequencies were retrieved from the "Wortschatz Portal" of the University of Leipzig (http://wortschatz.uni-leipzig.de). Words were presented in the colors blue (rgb, $0,0,255$ ), orange (rgb, 255, 128, 0) brown (rgb, 140, 80, 20) and lilac (rgb, 150, 0, 255) on a white background.

Table 1: Mean length and mean frequency of the two sets of words in each word group.

| Word group | Length | Frequency <br> (SE) |
| :--- | :--- | :--- |
| verbs (hand) | 6.88 | $1073(266)$ |
| verbs (foot) | 6.91 | $8385(3313)$ |
| explicit (hand) | 9 | $1811(1458)$ |
| explicit (foot) | 7.4 | $1682(1186)$ |
| associated(hand) | 8.1 | $442(133)$ |
| associated (foot) | 8 | $367(152)$ |
| up-down (up) | 6.25 | $2734(880)$ |
| up-down (down) | 6.13 | $2747(972)$ |

## Procedure and design

Each trial started with a fixation cross, displayed in the center of the screen for 800 ms . Then the stimulus word was presented until response. Between trials a white screen was shown for 1000 ms . Each word was presented 4 times, resulting in a total amount of 768 trials, which were subdivided into 4 experimental blocks. The experiment started with a practice block, in which 8 practice words were presented two times in different colors. Participants received feedback on speed and accuracy in the practice block (but not in the experimental trials). Reaction times were measured.

Participants were instructed to respond as quickly and accurately as possible to the font color of the word. The mapping of colors to response direction was balanced across participants: All possible color pairs occurred equally often.

For the analyses, we collapsed across the two compatible conditions in each group and the two incompatible
conditions in each group. For hand-related words and upwords, compatible conditions consisted of trials in which the correct response involved a key press with the hand at chest height. For foot-related words and down-words, compatible conditions consisted of trials in which the correct response involved pressing the foot pedal on the ground.
The design thus was a 4 (word group) x 2 (compatibility of the response) design with repeated measurement on both variables.

## Results

Responses faster than 200 ms or slower than 2500 ms , as well as errors were excluded from further analyses. This reduced the data by less than $5 \%$. Mean error rate was $3.9 \%$. Mean RTs are displayed in Figure 1.

Figure 1: Mean response times of correct responses as a function of response compatibility and word group.

The analyses revealed a main effect of group, $F(3,87)=$ 5.3, $p=.002$, a main effect of compatibility, $F(1,29)=5.30$, $p=.006$, and a compatibility-by-group interaction, $F(3,87)$ $=3.32, p=.024$. Separate analyses for the four word groups revealed significant compatibility effects for the three noun groups (explicit nouns: $F(1,29)=7.42, p<.05$; associated nouns: $F(1,29)=4.64, p<.05$; up/down nouns: $F(1,29)$ $=8.56, p<.01$ ) but no significant compatibility effect for the verb group $(F<1)$.
To investigate the different compatibility effects in more detail we compared the different pairs of word groups with each other. The verb group differed significantly from all other groups with respect to the size of the compatibility effect (verbs vs. up/down nouns: $F(1,29)=6.41, p<.05$, verbs vs. explicit nouns: $F(1,29)=8.46, p<.01$, verbs vs. associated nouns: $F(1,29)=4.63, p<.05)$. The analysis revealed no significant difference between the different
noun groups with respect to the size of the compatibility effect (all $F$ s < 1.04).

## Discussion

In the present study, we investigated whether processing of single words with an association to the hand or foot results in effector-specific motor activation if implemented in a task that does not require active reading. Our results clearly show such effector-specific compatibility effects which is in line with the view that effector-specific information is automatically activated during word processing. Our results therefore fit well with the idea that readers re-activate experiential traces during word processing that stem from interactions with the respective referents of these words.

In our experiment we compared four different word groups. As predicted we observed compatibility effects for all noun groups. For the up/down nouns we had predicted such an effect because the two responses in this paradigm (hand vs. foot) differed with respect to the location of the response key in vertical space (up vs. down). In previous studies involving hand responses with up- versus down-keys strong compatibility effects were also observed, even in tasks that did not require active reading (Lachmair et al., 2011). Finding a compatibility effect with these nouns in the present paradigm shows that the up/down-effect generalizes to an experimental situation involving responses with different effectors. As such these results provide further evidence for the stability of this effect.

For the remaining two noun groups we had predicted compatibility effects on the basis of the view that readers activate experiential traces during word processing that stem from interacting with the objects these words refer to. If these objects are typically manipulated with one of the respective effectors, then this effector should be primed during processing and a response involving this effector should be facilitated. Interestingly, the observed compatibility effects were equally strong in these two groups, although the association with the effectors was linguistically specified in the explicit noun group but not in the associated noun group. Thus, if linguistic representations had played a prominent role during processing one could have expected stronger compatibility effects for the explicit noun group compared to the associated noun group. The fact that this was not observed can be taken as further evidence for an experiential-trace view of language understanding.

In contrast to our predictions, we did not observe compatibility effects for the action verbs. This is surprising for several reasons. First, in our view the association between these words and the two effectors seems particularly strong, and for this reason we had even expected to find the strongest compatibility effects in this group. Second, and more importantly, neuro-scientific studies involving the exact same set of stimuli repeatedly found evidence for an effector-specific activation during the processing of these words (e.g., Pulvermüller, et al. 2001). What then may be the reason for not finding effector-
specific compatibility effects with verbs referring to actions that are typically performed with the hands or the feet? Several possibilities come to mind.
First, in German, nouns begin with a capital letter, but verbs do not. To present the words in their natural appearance, we presented the nouns with a beginning capital letter, and the verbs in small letters throughout. In principle it seems possible that this difference could account for the different results obtained with nouns and verbs in the present experiment, especially if one considers that active reading was not required by the experimental task. Maybe participants were more successful at ignoring the words when they homogeneously involved small letters than when there was a capital letter at the beginning. But this seems unlikely as the standard Stroop effect and several variants thereof have been observed in different sets of tasks, involving various types of word displays. Thus, we regard it as unlikely that the pure difference in word display, specifically concerning the first letter, can account for the differences between nouns and verbs in the present paradigm.
Another explanation for the missing influence of verbs on responding might be a different time course of verb processing in contrast to noun processing. We consider it conceivable that verbs require more processing effort than nouns, for instance due to differences in breadth of meaning (Gentner, 1981). If it takes relatively long to process verbs, then the information in the verb that potentially triggers the conflict may become active only after the response decision (responding with hand vs. foot) has already been made. This would explain why verbs did not influence responding. If indeed differences in processing times are responsible for the missing effects in verbs, we might find compatibility effects for verbs if a lexical-decision task was being employed instead of a Stroop color-response task (e.g., Mirabella, Iaconelli, Spadacenta, Federico, Gallese, 2012). Critically, in studies using verbs referring to upward or downward directed motion (e.g., rise, fall) similar effects were observed as in a study implementing nouns (e.g., bird, ground), even if implemented in a Stroop-like colorresponse paradigm (e.g., Dudschig, Lachmair, De Filippis, de la Vega \& Kaup, 2012). Thus, a general difference between verb and noun processing cannot fully account for our findings.
Finally an alternative explanation may be that verbs referring to actions are associated with very specific motor plans. Maybe no compatibility effect was observed for the verb group because the overlap between the motor activation involved in understanding these words and pressing a key with the hand or the foot simply was not large enough. After all, a movement such as kicking is a quite different foot movement than pressing a foot pedal, and grasping is quite different from pressing a key with the index finger. If this hypothesis is correct, compatibility effects should be observed with verbs that refer to actions that are similar to the response actions in the experiment. Indeed, the embodied language processing account predicts
that words become associated with experiential traces (e.g., Zwaan \& Madden, 2005). Such an account would predict that experiential traces are rather specific, such that activating a specific effector might not be sufficient for facilitating language understanding.

In summary, our results provide clear evidence for effector-specific activation during single word processing in a very basic color-response paradigm. Especially, participants did not have to actively process the words' meaning and nevertheless subsequent responses were affected. However, this compatibility effect is limited to certain word categories and does not seem to occur in case of verb processing (e.g., kick, grasp). Our results suggest that conflict between words and effector-specific motor responses is not a general effect between words referring to foot or hand related entities and actions, but is rather specific to certain word categories. These results are of interest to both, the embodied language processing models (e.g., Glenberg \& Kaschak, 2002) but also for the conflict monitoring model (e.g., Botvinick et al., 2001). Future studies will be needed to investigate whether difference in processing times are responsible for these effects, or whether the missing effect of action verbs on subsequent responses is due to the fact that very specific motor-plans are activated by the verbs.

## Acknowledgments

This project was supported by a Margarete-von-Wrangell Fellowship appointed to Carolin Dudschig (European Social Fund and the Ministry Of Science, Research and the Arts Baden-Württemberg) and by the SFB833/B4 project of Barbara Kaup (German Research Foundation).

#### Abstract

Ratcliff, Van Zandt, and McKoon (1999, Psych. Rev.) claim that connectionist models fail to simulate many aspects of how individuals select one of two possible responses. Here, these claims are re-evaluated via computational and behavioral investigations of an extended version of the original numerosity judgment task. The results of the experiment indicate that some of the empirical effects that the models failed to capture do not generalize and were likely due to idiosyncratic aspects of the original methodology. The simulations show that a more biologically-plausible model captures the bulk of the new effects, including some trial-by-trial adaptive effects that are outside the scope of models tested against aggregate data, and emergent asymptotic stability that has previously required an explicit leak parameter.

Keywords: response selection, decision making, connectionism, numerosity judgment, overall and trial-by-trial effects

Understanding how one of multiple candidate responses is selected in a given task is a long-standing and critical issue in cognitive science, and is one of the earliest domains to have been investigated with computational models. To date, much of the work has focused on the sub-issue of how individuals perform in tasks in which they must rapidly select one of two possible responses (i.e., speeded two-alternative forcedchoice tasks; 2AFC tasks). This has led to the development of several models that can be fit to data from 2AFC tasks with a high degree of precision (e.g., the diffusion model; Ratcliff, 1978). One of several key limitations of these models, however, is that they are highly domain-specific and are not naturally extendable to studying other intuitively related issues, such as 'closed-set' response selection tasks involving three or more pre-specified candidate responses, or 'open-set' response selection tasks which require the production of novel responses such as nonword naming. These models are also often fit to aggregated data and do not explain how the decision system adapts over time based on its past experiences.

One possible avenue for addressing these limitations is the development of a connectionist model of response selection, given the connectionist framework's grounding in domaingeneral learning, representation, and processing principles that are drawn from systems and cellular neuroscience. Not only might such a model be able to explain the overall and adaptive effects in 2AFC tasks, it should also be readily extendable to the other response tasks described previously. Moreover, insofar as connectionist models fail in these endeavors, this can serve to guide the development of improved
principles which can, by virtue of the domain-general nature of the framework, have wide-spread implications for domains well beyond response selection (e.g., semantic cognition).

Past work by Ratcliff, Van Zandt, and McKoon (1999) provides some initial insight into the performance of connectionist models of 2AFC tasks relative to that of the diffusion model in simulating performance in a numerosity judgment task. In this task, participants were presented with a $10 \times 10$ array which was filled with a number of asterisks sampled from two overlapping distributions with 'low' and 'high' mean numbers of asterisks, and made responses indicating which distribution they believed had been sampled from to generate the stimulus. The model comparisons revealed that the connectionist models failed to capture important aspects of the behavioral data (e.g., latency-accuracy functions, trial-by-trial adaptive effects).

To address some of these limitations, Usher and McClelland (2001) introduced a revised connectionist formalism in the leaky, competing accumulator model. Changes in this model included explicit constraints on the sign of the weights between competing units and from the underlying source of evidence that drives the response units, and the use of a threshold-linear activation function that is not differentiable at all points in time. A critical implication of the latter change is that it violates the mathematical principles that underlie standard gradient descent learning algorithms such as backpropagation (Hinton, 1989). Collectively, these changes rendered the accumulator functionally analogous to the diffusion model, and generally showed identical or superior fits to that model. This notwithstanding, a fundamental issue with this type of domain-specific connectionist model is what strengths of the standard connectionist framework were given up during model development. In particular, the disconnect between these models and standard connectionist learning algorithms prevents these models from being effortlessly extended to other response selection tasks-let alone cognitive processing and learning in other domains.

An alternative approach to developing improved connectionist models of response selection is to focus, instead, on improving the domain-general assumptions of the framework. One way to do this that is independent of the particular constraints needed to simulate response selection is to more accurately instantiate the known connectivity and processing characteristics of the brain. For instance, neurons
are either excitatory or inhibitory-not both, as is the case in standard connectionist models. There are also more excitatory than inhibitory neurons, which biases the type of information that can be encoded by each sub-population: inhibitory neurons serve primarily to regulate overall activation in the information-content-rich excitatory neurons. Connections between brain regions are also typically only excitatory and relatively sparse (or functionally weak), whereas there is dense (or functionally strong) connectivity among both excitatory and inhibitory neurons within a brain region. The activation dynamics of individual neurons are also better approximated by activation functions that do not possess an upper non-linearity as is the case for sigmoidal functions (Usher \& McClelland, 2001), but that are nevertheless differentiable at all points in time, such as the hybrid sigmoid-linear activation function that is presented in detail later.

To date, models that are constrained by the aforementioned characteristics of systems and cellular neuroscience have been found to capture a wide range of empirical effects such as the temporal dynamics of ambiguous word comprehension (Armstrong, 2012) and the ERP correlates of word and nonword processing and of behavioral lexical decision (Laszlo \& Plaut, 2012). The present work extends these investigations by evaluating whether a more biologically-plausible connectionist model can simulate overall and adaptive effects in a simple perceptual task, without abandoning key principles such as learning or adopting ad hoc connectivity constraints.

Prior to the computational work, however, an appropriate set of benchmark data must be identified. Ratcliff et al. (1999) argued that their numerosity judgment task data were representative of results of many tasks and could therefore be treated as a gold standard for model comparison. However, detailed inspection of their results suggests that idiosyncratic and esoteric aspects of their methods may have led to atypical results. For instance, participants were potentially able to adopt sophisticated response strategies beyond those that are incorporated into simple models of response selection (notwithstanding that ultimately, more complex models should account for these data). For instance, participants received extensive experience with the task $(\approx 12,000$ trials). This may have interacted with the fact that participants were also explicitly told that the 'low' and 'high' distributions overlapped and therefore that it would not always be beneficial to adjust their performance following responses that were labeled as 'incorrect' (in contrast to the definitional behavior of error-driven learning and to the behavior observed in Armstrong, Joordens, \& Plaut, 2009). To explore adaptation in the decision system, Ratcliff and colleagues also repeatedly and somewhat predictably manipulated the likelihood of sampling from the 'low' and 'high' distributions ( $\approx 30$ times) effectively changing the optimal threshold for making 'low' or 'high' responses-which may have allowed participants to utilize sophisticated cognitive control mechanisms. Consequently, we first investigated the representativeness of the original data in an extension of the original study.

## Numerosity Judgment Experiment

The experiment assessed the generality of the empirical findings reported by Ratcliff et al. (1999) using a slightly modified version of the original methodology. This involved (a) splitting the distribution of number of asterisks using a fixed threshold rather than two overlapping 'low' and 'high' distributions, so that the feedback provided in the task was perfectly accurate within a mega-block ( 400 trials split into multiple blocks) and could, in principle, provide a basis for learning to respond perfectly, (b) eliminating or minimizing participants' prior experience with potential changes in the threshold value across mega-blocks that would allow them to develop sophisticated response strategies by changing the threshold value at most two times, and (c) only presenting participants with 3 mega-blocks totaling 1,200 trials (vs. 12,000 in the original study, of which the first 1,200 were dropped) to study initial learning when adaptive effects may be larger and more readily detectable. Insofar as these modifications produce divergent results, the data from this experiment may be a superior gold standard for model evaluation.

## Methods

Participants. A total of 121 right-handed Carnegie Mellon undergraduates participated in exchange for course credit.
Apparatus. The experiment was implemented using PsychoPy 1.71.01 (Peirce, 2007). Responses were recorded on standard computer keyboard using the ' $z$ ' and ' $/$ ' keys.
Stimuli and design. The stimuli used in the experiment consisted of a variable number of asterisks in a $10 \times 10$ grid. The number of asterisks was sampled from a trimmed normal distribution (mean $=50, \mathrm{SD}=14, \min =28, \max =72$ ). These stimuli were divided into 'low' and 'high' categories on the basis of whether the number of asterisks fell above or below a threshold value. The threshold that delineated a 'low' response from a 'high' response could be either 4.5 points below or above the mean of the distribution in a given megablock. These parameters are similar to those employed in the original experiment, with the critical difference that there was no overlap between the 'low' and 'high' distributions.

Participants were presented with 10 practice trials followed by three mega-blocks of 400 experimental stimuli. The threshold for making 'low' or 'high' responses could potentially change across each of these blocks. The full set of 16 different combinations of thresholds were run across the three mega-blocks (e.g., 'low/low/low' vs. 'low/low/high' vs. 'low/high/low,' etc.). Preliminary analyses indicated that the data could be grouped based on whether the threshold remained the 'same' between adjacent blocks or 'changed' between adjacent blocks. This allowed the critical number of conditions to be reduced to four for the analyses (same-same, same-change, change-same, change-change). Trials were presented across 25 blocks of 50 trials, except for the first and last blocks, which contained 25 trials.

The frequency with which each number of asterisks would be presented was a multiple of the probability density func-
tion. The stimuli were divided into 'low' and 'high' groups on the basis of the response threshold for the mega-block. Given the threshold levels used in the experiment, $72 \%(36 \% \times 2)$ of trials fell on the tails of the distribution and were always either 'low' or 'high.' The correct response for the remaining $28 \%$ of trials in the center of the distribution depended on the threshold for the mega-block. The positioning of the asterisks within the array and the order of the stimuli were random, with the constraint that no more than five of the same type of stimuli could be presented sequentially.

Procedure. Participants were instructed that they would have to decide whether the number of presented asterisks was either 'low' or 'high.' They would have to learn what constituted a 'low' or 'high' number of asterisks by making responses and learning from the feedback that was provided. Note that in contrast to Ratcliff et al. (1999), participants were not instructed that a given number of asterisks could be produced by either the 'low' or 'high' distributions (because the feedback in the present experiment was accurate within each mega-block), nor were they informed that the threshold that delineated between the 'low' and 'high' distribution might change during the experiment. This was predicted to increase the likelihood that participants would adapt to the changes in the characteristics of the stimuli using simple statistical learning mechanisms based on the feedback that was provided.

Participants were instructed to respond as quickly as they could without making many mistakes. To operationalize this instruction, after each block participants received a message to "try to go faster, even if it means making a few more errors", or to "try to make a few less errors even if it means slowing down." The message that a participant received depended on whether their accuracy was above or below $90 \%$, although this was not known to them. Following the instructions, participants were presented with the practice trials followed by the 25 experimental blocks.

Each trial consisted of (1) a fixation stimulus (+) for 500700 ms , (2) a blank screen for 50 ms , and (3) a number of asterisks, which remained on the screen until participants responded or for a maximum of 5000 ms . If the response was incorrect (4) "INCORRECT" appeared on the screen for 400 ms . The next trial began automatically.

## Results

Initial proficiency. The instructions alone were sufficient for participants to configure their response system in line with the general demands of the task, as assessed via a binomial test on the accuracy of the first practice trial relative to chance (mean accuracy $=63 \% \mathrm{SE}=0.05, p=0.008, n=104$ ).
Overall performance for the same-same condition. Overall performance in the experiment was slightly less accurate and slower than that reported by Ratcliff et al. (1999). This notwithstanding, the qualitative similarity between the studies on a number of metrics was quite high, including accuracy and latency as a function of distance from the response threshold, the latency distribution for correct and in-
correct responses, and the latency-accuracy functions. Figures 1 and 2 plot a subset of these data (the omitted figures, which are not included because of space constraints, showed similar qualitative matches to the model data). Note that because fewer stimuli were presented as distance increased from the response threshold, the data from both the experiment and the simulation becomes increasingly unreliable as distance increases (particularly for incorrect response latency), so later comparisons between the model and the simulation focus on distance from the threshold of 10 asterisks or less.

Sequential effects for the same-same condition. Sequential effects in the same-same condition were examined as a function of the number of blocks for stimuli of different distances from the threshold. In contrast to Ratcliff et al. (1999), the data plotted in Figure 3 showed a continuous decrease in latency as a function of practice, particularly for large distances from the threshold. Similar trends were observed in the accuracy data (not shown), although performance reached an asymptotic state within the first five blocks.

Mixed-effect regression models (Baayen, Davidson, \& Bates, 2008) were used to further explore the effects of a number of characteristics of the preceding trial on the current trial's accuracy and latency. Due to space constraints, only the effects of previous trial accuracy, stimulus type, and response are reported. Significant effects have p-values less than .05 . For the dependent measure of accuracy, previous trial accuracy did not predict significant variance, repetitions of the same stimulus increased accuracy, and repetitions of the same response decreased accuracy. For the dependent measure of correct latency, a previous accurate response and a repetition of the same response both decreased latency, and there was no effect of stimulus repetition. Additionally, the effects of prior accuracy decreased as a function of practice.
Adaptive effects following threshold changes. Figure 4 plots correct latency as a function of trial number for different numbers of asterisks and combinations of constant or changing response thresholds across mega-blocks (participant's accuracy data, not shown, showed similar dynamics). Three groups of asterisks are presented: one fell just below the initial low threshold (37-45), one fell just above the initial low threshold and just below a later high threshold in conditions in which a threshold change occurred later (46-54), and one was well above the initial low threshold but was immediately above a high threshold if the threshold value changed (5563). The results indicated that in both the accuracy and the latency data the adaptation that followed a threshold change occurred over an extended number of trials. Specifically, performance generally did not approach an asymptotic level until approximately 100 trials after the threshold change.

## Discussion

Despite the methodological similarities, many of the effects observed in this experiment diverge from those reported by Ratcliff et al. (1999). Moreover, the analyses of early performance reported here question some of the modeling as-

Figure 1: Latency distributions. [Left] Expt. [Right] Sim.

Figure 3: Correct latency as a function of block number for bins of asterisks of varying distance from the threshold.

Figure 4: Correct latency as a function of trial number for the different conditions.
sumptions reported in that paper that could have contributed to the poor performance of the connectionist models that were tested. For instance, the above-chance initial accuracy during the practice blocks and the consistent performance improvements throughout the experiment suggest that a connectionist model should begin simulating the task with a basic level of proficiency which continues to improve with practice. This contrasts with the simulations conducted by Ratcliff and colleagues, for which either a trained model for which learning had been disabled or an untrained network for which learning was enabled were assessed.

Similarly, the significant effects of the accuracy of the previous trial on the accuracy and the latency of the subsequent trial that were observed in the experimented reported here were not in line with those reported by Ratcliff et al. (1999). These effects are, however, in line with the expected behavior that would result from using an error-driven learning algorithm and with the results observed in other studies (Armstrong et al., 2009). One possible reason for the discrepancy is that the participants used their explicit knowledge of the inconsistent nature of the feedback provided in the original experiment to develop adaptation strategies that override the effects of simple error-driven learning algorithms (but that may be captured by more sophisticated algorithms that do consider such factors; Hinton, 1989).

The adaptive effects observed in the present experiment following the change in the threshold also differed from those reported by Ratcliff et al. (1999). In particular, the rate of adaptation following a threshold change was relatively slow and approximately 100 additional trials were necessary to reach a new asymptotic level of performance. this contrasts with the results of the original experiment, which showed that the new asymptotic level was reached in an order of magnitude fewer trials (5-15). This discrepancy is likely due to participants' extensive experience with threshold changes at semi-predictable intervals in the original task.

Taken together, these discrepancies undermine prior claims about the representativeness of the original task and data as a gold standard for model comparison, and suggest that the present data are a more appropriate gold standard for evaluating the performance of simple models of response selection.

## Numerosity Judgment Simulation

The simulation work evaluates whether a more biologicallyplausible connectionist model produces the same patterns of effects that were observed in the experiment.

## Methods

Participants. Two simulated participants completed each of the main conditions in the experiment (same-same, samechange, change-same, change-change).

Network architecture. The model architecture, based on the biologically-plausible connectivity principles described in the introduction, is presented in Figure 5. The visual inputs were divided into two groups of 100 units, the first of which coded for the presence of an asterisk in a given location, whereas the second coded for the absence of an asterisk in a particular location. This normalizes the overall amount of activity in a similar fashion to on-center/off-surround and off-center/on-surround visual neurons. One response unit coded for 'low' responses and the other for 'high' responses.

Arrows indicate full connectivity from one pool of units to another, with the exception that units were not connected to themselves. Outgoing connections from excitatory units were constrained to be positive and were initialized to a mean value of 0.15 . Outgoing connections from inhibitory units

Figure 5: Network Architecture. $\mathrm{I}=$ Inhibitory unit. Solid arrows = excitatory connections. Dashed arrows = Inhibitory connections.
were constrained to be negative and were initialized to a mean value of -0.4. All of the units received a bias connection with a mean value of -2.19 . Weights were sampled from a uniform distribution centered on the mean and with a range of 1.0 , with the condition that weights below zero for excitatory units and above zero for inhibitory units were clipped at zero. Furthermore, so that the network would not need to learn positional invariance (i.e., that the same amount of excitation should arrive at the hidden layer regardless of where in the array the asterisk was presented) the weights from the units in each visual sub-group were constrained to have the same values. Finally, to reduce the difference in terms of total activation across the different pools, the output from each visual sub-group was normalized to range between 0 and 1 .

All of the hidden and response units integrated their inputs over time $(d t=0.2)$. A unit's output, $o$, was a sigmoid-linear function of its net input, $i$, and of normally-distributed output variability (error), $\varepsilon$, per the following equation:

$$
o(i)= \begin{cases}\frac{1}{1+e^{-i}}+\varepsilon, & \text { if } i<=0 \\ 0.25 i+\varepsilon, & \text { if } i>0\end{cases}
$$

This equation approximates a threshold linear function as a continuous transition from a relatively low and stable activation state regardless of the specific amount of input, to a state wherein the activation of the unit varies linearly as a function of the input (the 0.25 value was selected because it is the derivative of the sigmoid for $i=0$; the equation is therefore continuous and differentiable despite being defined in two parts). The error reflects the variability inherent to neural processing and had a standard deviation of 0.025 for all but the visual units. For those units, error was also intended to capture the uncertainty in an individual's estimate of the number of presented asterisks, and was set to 0.1 .

Representations. The input patterns for the network were generated in the same manner as in the behavioral experiment. The target outputs for the response units were set such that a 'low' number of asterisks had a target of 1.0 for the 'low' unit and 0.0 for the 'high' unit; the complementary pattern was used for presentations of 'high' stimuli. Two sets of 1,200 patterns were created: pre-training patterns and task simulation patterns. The number of pre-training patterns was determined in pilot simulations that found that after approximately 1,200 trials, the model was about as accurate as the human participants at the beginning of the practice trials.

Pre-training and task simulation. The processing of pretraining and task-simulation trials was identical. On each trial, the net input and output of the hidden and response units
were set to -2.19 and 0.1 respectively. The network was then presented with the input pattern and trained for 100 unit updates. Error was calculated for the last 95 unit updates. The error was scaled by a factor of 3.0 for the units that were supposed to be off to encourage the simulation to make slower but mostly-accurate responses. A unit's target activation was adjusted such that it was considered to be correct once it was either below 0.1 or above 0.9 for units that were supposed to be off and on, respectively. Error was calculated using a two-piece error function: cross-entropy error was used for activation values below 0.5 and sum-squared error was used for activation values above 0.5 (Hinton, 1989). Weights were adjusted after each trial using a steepest gradient descent algorithm and a learning rate of 0.01 . Units were considered to have made a response when a response unit's activation exceeded 0.5 . The network's response latency was how many unit updates had occurred prior to responding.

## Results

Overall performance for the same-same condition. The model showed the same qualitative effects (and reasonable quantitative similarity) for accuracy and latency as a function of distance from the response threshold and the hazard functions (not shown), the latency distribution for correct responses (Figure 1), and the latency-accuracy functions up to approximately 10 asterisks, beyond which the both empirical and simulation data are not very reliable (Figure 2).

Sequential effects for the same-same condition. The model showed similar increases in accuracy (not shown) and decreases in latency (Figure 3) as a function of practice, including differential latency decreases for the slowest stimuli that were closest to the response threshold.

Mixed-effect regression analyses of the effects of the characteristics of the previous trial did show some weak patterns of disagreement with the behavioral data, however. For the dependent measure of accuracy, prior accurate responses and repetitions of the previous stimulus decreased the accuracy on the subsequent response, whereas repetitions of the response increased accuracy. For the dependent measure of latency, prior accurate responses non-significantly increased accuracy, repetitions of the previous stimulus type significantly decreased latency, and repetitions of the response nonsignificantly increased latency.
Adaptive effects following threshold changes. Figure 4 shows that the simulation recapitulated the main effects in the behavioral experiment following a threshold change: gradual increases in the latencies for stimuli that were suddenly closer to the new threshold, and gradual decreases in the latencies of stimuli that were further from the new threshold.
Activation trajectories. While running the simulations, an additional emergent property of this architecture was observed: despite employing an activation function for which there is no explicit upper bound, the units tended to settle to stable asymptotic activation levels (Figure 6). This was true both if the input corresponded to a number of asterisks

Figure 6: Activation trajectories for the 'low' (top line) and 'high' (bottom line) response units for a 'low' stimulus (32 asterisks).
that was near or far from the response threshold, although the asymptotic level of activation did differ across these two cases. This property is of interest because the leaky accumulator model required an explicit leak current to avoid runaway activation if a stimulus was presented for an extended period.

## Discussion

In contrast to the claims of Ratcliff et al. (1999) the connectionist model succeeded in capturing a substantial portion of the effects observed behaviorally. The main disagreement, in terms of model-behavior mismatch, was in terms of the specific sequential effects of previous trial accuracy, stimulus repetition, and response repetition. Two causes of these discrepancies are currently being investigated: First, the current model may trade off speed and accuracy slightly differently to the human participants, which may be addressed by adjusting the scaling of the error for incorrectly activating a response unit. Second, the current simulation only instantiated memory of prior experience in the form of weight adjustments, whereas these effects may be more accurately captured in a slightly more sophisticated model wherein residual activation from processing the prior stimulus influences subsequent performance (Plaut \& Booth, 2000). Nevertheless, the model did succeed in capturing the overall rates of sequential and trial-by-trial adaptation-effects that are usually outside the scope of models that are typically only evaluated by fitting aggregate data (e.g., the diffusion model) and that are not used to understand how and why model parameters (the weights in the present model) are gradually derived by learning from trial-by-trial experience.

The use of the more biologically-plausible framework also had the effect of inheriting many of the properties of the leaky accumulator model, or at least close approximations thereof, that has been tailored to response selection (e.g., bottom-up excitation, indirect competition between response units via lateral inhibition). Thus, this model gains parsimony and independent support and validity from neurobiology, while also being domain-general and suitable for studying other phenomena such as the ERPs and ambiguous word comprehension (Armstrong, 2012; Laszlo \& Plaut, 2012). Moreover, as shown by the activation trajectories in Figure 6, this framework shows initial promise at generating stable asymptotic states that were not present in the leaky accumulator model without the addition of an explicit leak parameter.

## General Discussion

The simulation's ability to capture most of the effects in the new behavioral data has several important implications. First,
it highlights the importance of careful task analysis and a consideration of the mechanisms that drive performance in identifying an appropriate gold standard task. More generally, it also suggests that a better method for assessing model performance is through the use of a broad range of tasks that generate multiple gold standards, to avoid discrediting certain frameworks on the basis of what may ultimately be established as somewhat atypical effects (notwithstanding that more complex models with appropriate mechanisms should capture those effects). Furthermore, it highlights the value of independently-motivated biological constraints on developing an improved set of domain-general computational principles that can be readily extended to other phenomena (e.g., selecting an appropriate response when naming a nonword). Finally, this work highlights the inherent trade-off between developing tailored quantitatively-precise models versus developing domain-general models: the latter may (at least initially) produce less precise quantitative fits, but they can be extended to a much broader set of phenomena and provide not only an existence proof of model plausibility via data fitting, but a principled explanation of how and why the model performs the way it does. Thus, although much work remains in refining the biologically-plausible framework and the model of response selection, this approach promises to be of broad value to cognitive science.

## Acknowledgments

The bulk of the reported work was conducted as part of BCA's PhD thesis and was supported by the CMU Psychology Department and the Center for the Neural Basis of Cognition (CNBC). We thank Kevin Mickey for discussion and for developing a preliminary simulation as part of the CNBC Summer Research Program.

#### Abstract

In this paper, we test between suppression and activation accounts of metaphor processing by means of a novel metaphor interference paradigm that makes use of mouse-tracking. The goal is to understand how context influences the activation of salient and non-salient features of a concept during the on-line processing of a metaphor. In two mouse-tracking experiments, we examine the activation and availability of conceptual features that were either irrelevant or relevant for understanding a metaphor across various contexts. Our findings support the conclusion that context works primarily by rapidly suppressing salient features of a concept that are not relevant for the particular metaphorical interpretation. What is more, it seems that even further contextual manipulation does not facilitate the activation of non-salient metaphor relevant features.

Keywords: Figurative language, lexical pragmatics, psycholinguistics, mouse-tracking.

## Introduction

Among the most intriguing aspects of language are the creative ways in which we can use it. We often use words and sentences in novel ways that create nonce interpretations of a stable linguistic repertoire for various social and pragmatic purposes. One particularly contentious debate surrounding creative language use is how we understand figurative language. While much research has sought to understand the various linguistic and conceptual mechanisms needed to understand figurative meaning (Glucksberg, 1998, Lakoff \& Johnson, 1980), less attention has been paid to the pragmatic enrichment mechanisms needed to rapidly integrate contextual information into figurative interpretations (Gibbs, 2002).

In this paper, we address this question by using a novel mouse-tracking paradigm in an attempt to better understand how context affects the on-line processing of figurative language. Specifically, we examine metaphorical interpretations, which have received the greatest amount attention in the psycholinguistics literature, and report the results from two experiments designed to test between two contrasting views of how context can aid the comprehension of metaphors; either by suppressing information not relevant for the metaphorical interpretation or by increasing the accessibility of information needed to reach it..

## Metaphors and language processing

Many early experimental studies have demonstrated that metaphor processing is incompatible with the standard "literal-first" Gricean view of pragmatics (Gibbs, 2002). This is because figurative speech is understood just as quickly, and in some cases even more quickly, than literal speech (see Glucksberg, 2001 \& Glucksberg, 2003 for extensive reviews). Processing delays reported in the literature are more likely to occur for unfamiliar metaphors, due to the relative difficulty needed to integrate contextual information into the novel interpretation at hand (Shinjo \& Meyers, 1987), while reaction time differences might ultimately stem from speed-accuracy trade-off issues. McElree \& Nordlie (1999), for example, observed that literal and figurative meanings might be derived equally fast, but the overall accuracy of figurative speech interpretation seems to be lower than that of literal speech at both early and late processing times. These findings suggest that strong contexts should not decrease the processing time for figurative language, but only increases the likelihood that the intended interpretation will be understood.

The finding that both literal and metaphorical speech is understood with the same speed and facility has been a central tenet of numerous theoretical accounts in psychology. One example is the class inclusion model (Hampton, 1988; Glucksberg \& Keysar, 1990), according to which, understanding a metaphor such as "his job is a jail" amounts to updating the topic's category structure by integrating select features of the vehicle 'jail' (e.g. "confinement", "no exit", etc.) into it. Experimental work seems to suggest that this is done by first suppressing basic level meanings of a category (Gernsbacher, Keysar, Robertson, \& Werner, 2001) and then creating ad hoc categories from the combination of topic and vehicle features (Barsalou, 1983).

Another prominent account that incorporates the lack of processing time difference between literal and metaphorical speech is that of Cognitive Linguistics (Lakoff \& Johnson, 1983), which suggests that literal and metaphorical interpretation do not rely on different processing mechanisms. According to this approach, understanding
literal and metaphorical speech involves the recognition of patterns as opposed to complex mappings assumed in other theories; in the case of "my job is a jail", for example, both "job" and "jail" share the "container" relationship.

## Figurative language and lexical pragmatics

In linguistics, researchers have sought to integrate the findings mentioned above into both more formal and processing-oriented theories. For example, Relevance Theory currently offers an account of metaphor as a case of conceptual broadening and narrowing (Sperber \& Wilson 2008). Relying on the aforementioned idea of ad-hoc categories (Barsalou 1983), relevance theorists also hold that nonce conceptual categories are constructed for each contextually specific metaphorical use. For example, in a metaphor such as "the goalie is a spider", the vehicle 'spider' is assumed to encompass encyclopaedic information ("insect", "has 6 legs", "fangs", "catches prey in web", etc.), which is selectively combined into a contextually relevant ad-hoc category SPIDER* (denoting something like "catches things near its web") after certain features of the lexically encoded concept SPIDER are suppressed.

Other accounts seem to rely more on processes of activation when it comes to explaining how context helps process figurative language on-line. The direct access view, for instance, holds that context primes the relevant features needed to interpret the figurative meaning to the extent that figurative meanings are interpreted in an almost identical manner to literal meanings (Gibbs, 2002). This account differs from the relevance-theoretic one in that it predicts that context affects the way in which conceptual/semantic information is accessed from the start rather than further processed once a lexical meaning is retrieved during some decoding process. This view is consistent with Recanati (1995)'s theory of truth-conditional pragmatics, which holds that when interpreting a sentence such as "my job is jail", a strong biasing context would make the properties of the concept JAIL that are needed for the figurative interpretation directly available (e.g. "confined space" as opposed to "punishment").

Prior work investigating suppression and activation in metaphor processing has relied on various priming and lexical decision paradigms (see Glucksberg, 2003 for a review). For example, Rubio-Fernadez (2007) tested the idea of active suppression in a cross modal priming paradigm and found that after reading metaphorical utterances, metaphor relevant properties remained active at longer intervals than metaphor inconsistent properties. This suggests that all properties of a given concept are activated and then properties not relevant for the metaphor are suppressed. One limitation of such studies, however, is that reaction time measurements might mask the continuous changes in the accessibility of properties. In other words, similar reaction times at a given interval might not necessarily reflect equal activation levels. In the present
study, we make use of a novel paradigm to further test how suppression and activation mechanisms are implemented during on-line metaphor comprehension. We use mousetracking because via motor movements it can provide a window into the way in which listeners' access conceptual information during processing, since it "breaks up" the button press (Freeman \& Ambady, 2010). More specifically, we examine how both metaphor relevant and metaphor irrelevant features can interfere with mouse-trajectories toward metaphorical interpretation.

## Overview of Experiments

In the following two experiments, a metaphor interference paradigm (Glucksberg, Gildea, \& Bookin, 1982; Wolff \& Gentner, 2000) was combined with mouse-tracking. This paradigm offers a novel test of the on-line availability and competition of salient and contextually relevant features during the interpretation of a metaphor. Participants read metaphors such as "the goalie is a spider" along with filler items such as "the apple is red". They then clicked on either one of two pictures that best captured the overall meaning of the utterance. In the critical trials, one of these pictures, the correct target, depicted the topic in its metaphorical state (goalie making a save), while the other picture, a competitor image, was either an attribute from the vehicle available in the metaphorical state (spider web) or one only available in its non-figurative meaning (spider close-up). The interference of competitor target images on participants' mouse trajectories was compared across both literal and figurative utterances (Experiment 1) and then across strong and weak contexts (Experiment 2).
Prior to both of these experiments, participants completed a picture norming experiment to determine the relative salience of the various attributes for the metaphorical vehicle and become familiar with the pictures used in the main experiment. For this, they were shown the topic of the metaphor in isolation (SPIDER) and were asked to choose between the two competitor target pictures (web or closeup). This allowed for the experimental items (metaphorical utterances) to be separated into two groups:

1) Salient (metaphor) relevant feature group - the figurative attribute of the vehicle has more baseline salience than the literal attribute.
2) Salient (metaphor) irrelevant feature group - the literal attribute of the vehicle has more baseline salience than the figurative attribute.

## Experiment 1

28 participants at Cardiff University took part in both the picture-norming and main experiment in exchange for course credits. Participants completed both parts of the experiment within 30 minutes.
Stimuli Forty metaphorical sentences were adapted from Jones \& Estes (2006), in which both the topics and vehicles of which had been already been normed for aptness and conventionality. In Jones \& Estes (2006), aptness was
defined as the extent to which the vehicle's figurative meaning expresses an important feature of the topic. Conventionality was defined as the strength of the association between the metaphor vehicle and its figurative meaning. This allowed us to use a variety of metaphors that differed along these parameters.

Various pictures that depicted either relevant (spider web) or irrelevant (spider eyes/fangs) features of the metaphorical topic in this particular context were collected using Google Search. During the collection, multiple candidate pictures expressing the metaphorical meaning of the vehicle were collected (e.g. an outstretched goalie making a diving save, a tall goalie, a goalie stretching, etc.), and several research assistants independently decided which one best expressed the metaphorical meaning of the utterance at hand. The same pictures were used for both the norming and the main parts of experiment.

## Norming experiment

In order to establish the relative salience of the feature pictures prior to the main experiment, participants were presented with the metaphor topics (spider) and had to click on the feature picture that best represented the word. This allowed us to distinguish a relative baseline for which feature picture was more salient for the topic. For example, participants read the word VOLCANO (from "his anger is a volcano") and clicked on either a picture of an inactive volcano (metaphor irrelevant feature) or a picture of hot lava (metaphor relevant feature). In order for an item to be assigned to a group (salient metaphor relevant feature group or salient metaphor irrelevant feature group), the average ratings for a picture response for a given topic had to be above $66 \%$. Two items that were towards chance, i.e. 50/50, were excluded from the analysis of the main experiment. 18 of the 40 metaphor vehicles were rated as having a salient (metaphor) relevant feature and 20 of the 40 metaphor vehicles were rated as having a salient (metaphor) irrelevant feature. This part of the experiment also served as a way of familiarizing participants with the pictures used in the main experiment.

## Main experiment

After completing the norming study, participants were instructed to read a sentence and choose the picture that best corresponds to its overall meaning. For metaphors, participants had to click on the correct target, e.g. a picture of the metaphor topic in its figurative state (goalie making a save). Different feature pictures (metaphor relevant or metaphor irrelevant) were used as competitors to test 1) the amount of interference with the correct target and 2) the stage in processing (early or late) during which the interference occurs. Early interference would suggest that a feature is available during lexical access, whereas later interference would suggest that this feature becomes available at a later stage, i.e. during pragmatic enrichment.

Design and Procedure In the main experiment, participants read metaphors such as "The goalie is a spider" as well as literal filler items such as "The apple is red". The filler items were included to make sure that participants listened until the end of the sentence. Without these sentences, listeners could have made their decisions just after hearing the metaphor topic. In the filler sentences participants would choose between two competing images, which were only distinguished by the final word in the utterance ("The apple is red" vs. "The apple is green"). For the 40 metaphor items, participants saw either one of three target-competitor picture versions for metaphorical items. In the relevant feature condition, participants chose between a picture of the metaphor relevant feature (spider web) and a picture of the topic in its metaphorical state (the outstretched goalie making a save). In the irrelevant feature condition, the same picture of the topic was used, but in conjunction with a metaphor irrelevant feature picture (frontal close up of a spider). In the control condition, the same topic picture was also used, but the competitor picture had no relationship to the topic or vehicle (e.g. an apple). Three lists were created so that each participant saw only one version of each item. To start a trial, the participant would click on the START button at the bottom center of the screen. Each item was presented word by word at an interval of 350 ms per word. Participants were allowed to move the mouse towards a picture target, located at the top corners of the screen, only at the onset of the final word in the utterance. The trial ended once a target was clicked on.

Predictions If participants first access the salient meaning of the concept at hand, then salient picture features should interfere at an earlier point during the response. This should happen for both relevant and irrelevant features, however irrelevant features should not interfere later on in the response, as these features are not part of the figurative meaning, i.e. they become suppressed. Put differently, if a metaphor irrelevant feature is indeed the most salient, this should interfere with responses towards the correct target (picture of topic in metaphorical state) early on during the response because it would be "active" during lexical access. Similarly, if a metaphor relevant feature is not salient, later interference in responses should occur. When metaphor relevant features have higher salience than metaphor irrelevant features, both early and late interference should be noticed because this feature would be active both during lexical access as well as during the construction of the figurative meaning.

## Results and Discussion

Figures 1 and 2 show the mouse paths for correct responses for the relevant and irrelevant features groups, across salient and non-salient items respectively. Control groups were not included because mouse paths went directly to the target. To examine the relative interference of competitor pictures on participants' mouse paths to the correct targets, the average x-coordinates for mouse paths across the feature conditions
and saliency groups were compared. The time points for the x-coordinates from the normalized mouse paths (101 time stamps) were collapsed into 10 groups (or time bins) in order to better operationalize early vs. late processing. A mixed-model was used to analyze the x-coordinates of the mouse paths, which used time-bin, competitor (relevant vs. irrelevant), and feature salience as fixed effects. Subjects and items were used as random effects.
Interaction terms for feature competitors and feature salience were significant at time bins 30 to $40, t=2.83, p<$ .05 and time bins 50 to $60, t=2.51, p<.05$. Figure 2 shows the mouse paths for the relevant and irrelevant feature competitors only for items for which the irrelevant feature was rated as more typical of the metaphor vehicle. A crossover pattern for x -coordinate position is observed, in which metaphor irrelevant features interfere early on in the response (time bins 30-40), whereas the metaphor relevant feature interfere later on (time bins 50-60). This replicates several findings from different paradigms in that salient features seem to be more active, i.e. interfere more, during early processing and less salient features are accessed later, i.e. interfere later during the response. In the next experiment, we sought to replicate the cross-over pattern for feature interference and then investigate how priming versus neutral contexts mediate the availability of features when interpreting metaphors.

## Experiment 1 - Competitor x Likelihood

Figure 1. Time- normalized mouse paths for all conditions (competitor feature type vs. salience groups).

## Experiment 1 - IF High salience

Figure 2. Time- normalized mouse paths for relevant vs. irrelevant features in the salient irrelevant feature group.

## Experiment 2

In this experiment, prior to each metaphor, participants read either a "strong" and "neutral" preceding context. This allowed us to test whether contextual information can rapidly adjust the relative salience of a feature of a concept, as activation accounts would predict. Specifically, "strong" contexts should explicitly promote the status/activation of metaphor relevant features, whereas "neutral", albeit felicitous ones should not. The direct access view would predict that the (late) interference effect found for nonsalient metaphor relevant features should occur at an earlier time bin when preceded by strong contexts because of the increased activation of these features by the context. Suppression accounts, on the other hand, would predict that the early interference account for irrelevant features should be more diminished in strong when compared to weak contexts.

## Norming experiment

Prior to the main experiment, the same norming experiment as Experiment 1 was repeated. The two excluded items from Experiment 1 were rated as having high salience metaphor relevant features, however 1 of the remaining items was now excluded because it did not meet the $66 \%$ threshold. This resulted in 20 items in the high salience relevant feature group and 19 items in the high salience irrelevant feature group.

## Main experiment

The main experiment was identical to Experiment 1 except that items were preceded by either neutral or strong contexts. Details are discussed below.

Stimuli The stimuli were the same used in Experiment 1. The only difference was that items were preceded by a strong or weak context. For example, in our example item "the goalie is a spider", the strong context was: "We had many opportunities to score, but the ball was always
stopped" while the neutral one was: "We had many opportunities to score but couldn't convert our chances".

Design and Procedure The design and procedure were the same as in Experiment 1. The only difference was that contexts were presented prior to the onset of the metaphor or literal utterance. Participants were able to read each context at their own pace and press the enter key in order for the word-by-word presentation of the item to start.

## Results and Discussion

Figures 3 and 4 show mouse paths for the two conditions. Using the same time bins from Experiment 1, a mixed regression model was used to examine the interaction of context, feature competitor, and feature salience. When collapsed across contexts, the same interaction terms for feature competitor and feature salience were significant at time bins 30 to $40, t=1.89, p<.05$ and at time bins 50 to $60, t=3.07, p<.01$. When context was included in the interaction terms, they were not significant; time bins 30 to $40, t=95, p=.69$ and time bins 50 to $60, t=.34, p=71$. Context was, however, a significant predictor at time bins 30-40 for salient irrelevant features when the irrelevant features were the competitor, $t=2.61, p<.03$, but not at time bins 50-60, $t=.75, p=53$.
Experiment 2 replicated the findings from Experiment 1 in that early interference effects were observed for irrelevant features and late interference effects were observed for relevant features when the irrelevant feature was the most salient. Both neutral and strong contexts showed the crossover interaction, however strong contexts only reduced the early interference effects of irrelevant features for items for which irrelevant features were the most salient. Taken together, these findings provide evidence for suppression accounts because relevant features still showed late interaction effects even with strong contexts. This is not predicted by the direct access view.

## Experiment 2 - Weak Context

Figure 3. Time- normalized mouse paths for relevant vs. irrelevant features in the salient irrelevant feature groups in weak (neutral) contexts.

## Experiment 2 - Strong context

Figure 4. Time- normalized mouse paths for relevant vs. irrelevant features in the salient irrelevant feature groups in strong contexts.

> Exp 2 - IF competitor IF high salience

Figure 5. Time- normalized mouse paths for irrelevant features in the salient irrelevant feature groups across weak and strong contexts.

## Conclusion

In two mouse-tracking experiments, we tested the on-line availability of conceptual information when interpreting figurative language. Our main question was whether context acts primarily by suppressing context-independent features during lexical access for metaphorical interpretation or whether it increases the availability of non-salient features needed to understand the metaphor under question. Experiment 1 showed that salient metaphor irrelevant features of the vehicle provided early interference in participants' mouse paths towards correct targets. Nonsalient features of the vehicle relevant to the interpretation interfered much later on in the participants' mouse paths towards the correct target. Experiment 2 tested whether the
presence of a biasing context primes the activation of the salient feature that is relevant to the metaphor earlier on in processing, but the same cross-over pattern found in Experiment 1 was replicated in both the neutral context and the strong context conditions. What context seemed to do was reduce the early interference effect for metaphor irrelevant features when these same features were salient features of the vehicle. Taken together, the findings from Experiment 2 provide support for suppression accounts.

While our paradigm did not find increased activation for non-salient metaphor relevant features in strong contexts, one possibility is that our strong contexts might not have been strong enough to adequately test direct access accounts. We used one sentence introductory context, when classical studies, such as Swinney's (1979) "bug" task, use an entire paragraph of context. In this vein, Noveck, Bianco, \& Castry (2001) showed that longer contexts speed up metaphor processing in comparison to shorter ones. It may well be the case that the priming effects associated with activation accounts operate on a larger time scale than suppression mechanisms. We feel that this is a worthy topic for future research, for which our mouse-tracking paradigm is well suited to test.

#### Abstract

When a visual object is briefly flashed, it appears to lag behind another moving object (flash-lag effect; FLE). Previous studies show that a sudden change to the moving object at the time of the flash presentation can eliminate the FLE. We examined whether the FLE is eliminated when a moving object alternates in color as it moves. Observers viewed a moving disc, the color of which did not change at all, changed only once when another object flashed, or alternated between two colors as it moved before the flash presentation. The results showed that although the magnitude of the FLE was reduced compared with the no-change condition, the FLE observed with the moving object that changed color during motion was significantly stronger than the FLE in the onechange condition. The results are discussed in relation to the object updating account of the FLE.

Keywords: Flash-lag effect; Motion continuity; Object updating

## Introduction

Humans depend heavily on the perceptual system to collect information about the surrounding environment, but the perceptual system is sometimes prone to illusions that lead to inaccurate judgments. In the domain of object localization, one extensively studied illusion is the flash-lag effect (FLE), a perceptual phenomenon where a briefly-flashed stationary object appears to lag behind another moving object even though the two objects are physically aligned when the flash occurs (MacKay, 1958; Nijhawan, 1994). Studies on the FLE have found that this effect occurs in various conditions. For example, the FLE has been reported in objects with continuously changing features (Sheth, Nijhawan, \& Shimojo, 2000), in objects moving in depth (Harris, Duke, \& Kopinska, 2006; Ishii, Seekkuarachchi, Tamura, \& Tang, 2004), in audition, and across modalities (Alais \& Burr, 2003). In addition, the FLE was also found to depend on observers' eye movements (Nijhawan, 2001) and the perceptual organization of the moving object (Watanabe, 2004; Watanabe, Nijhawan, Khurna, \& Shimojo, 2001). Putting the effect in a two-dimensional context, Watanabe and Yokoi (2006) found that the perceived position of the flash is not uniformly displaced, but appears to converge towards a single point behind the position of the moving object.
Ever since Nijhawan (1994) revitalized interest in the FLE within the psychology community, various explanations have been formulated to account for the effect, including motion extrapolation (Nijhawan, 1994, 1997), differential latency in processing for the flashed object and the moving object (Kanai, Carlson, Verstraten, \& Walsh,

2009; Whitney \& Murakami, 1998; Whitney, Murakami, \& Cavanagh, 2000), motion integration and postdiction (Eagleman \& Sejnowski, 2000), and attention (Baldo \& Klein, 1995; Krekelberg \& Lappe, 2000). However, this ongoing debate has not yet been settled.

Moore and Enns (2004) proposed a relatively new explanation of the FLE. They view the effect as the result of an ongoing object updating process based on the principle of object substitution (Enns \& Di Lollo, 1997). They proposed that due to the ongoing updating process, positional information of the moving object acquired immediately after the flash presentation overwrites (replaces) that acquired at the time of the flash presentation, resulting in the illusory perception that the moving object overshoots the flash. In the case where the moving object stops at the time of the flash presentation, since there is no new information about the moving object after the flash presentation that can replace (update) previous information, the alignment of the two objects can be accurately perceived. In the same study, Moore and Enns (2004) further reported that when the visual features of the moving object, such as size and color, changed abruptly at the moment of the flash presentation and changed back immediately after the flash (we refer to this as the "One Change" motion stream), observers tended to perceive that the moving object appeared at two positions (one object with the changed color and aligned with the flash, and the other with the original color located in front of the flash) when asked about the perception at the moment of the flash presentation. The authors explained that the disruption of motion continuity by a large, transient change leads the visual system to interpret the scene as containing two separate objects. When the original object reappears at a new position after the flash, its position and color information is updated, while the information acquired at the moment of the flash presentation (which is interpreted as a different object) is spared from the overwriting process. However, if a scene-based reason is provided for the discontinuity, the object updating process is spared from disruption, preserving the representation of the original object, and thus, the FLE is observed (Moore, Mordkoff, \& Enns, 2007).

According to the idea above, whether object motion continuity is preserved depends on whether only a single (i.e., the same) object is identified throughout the motion scene. The nature of object persistence has been widely studied based on object file theory (Kahneman, Treisman, \& Gibbs, 1992). According to this theory, episodic representations (object files) keep track of the individual entities in a scene over space and time, and are updated
based on spatiotemporal information (i.e., location at different moments). Object files store the representations of persistent objects and mediate conscious perception, informing the observer about "which went where" (Mitroff, Scholl, \& Wynn, 2005), and object identity information can be stored on a scale of seconds (Noles, Scholl, \& Mitroff, 2005). Empirical evidence has suggested that object files encode identity information rather than semantic or precise physical information (i.e., physical features) about objects, and that object file representations are flexible (Gordon \& Irwin, 1996, 2000). Although Mitroff and Alvarez (2007) showed that spatiotemporal information, but not surface features, effectively determines object persistence (as measured by standard object-specific preview benefits; Kahneman et al., 1992), Moore, Stephens, and Hein (2010) demonstrated that abrupt changes in surface features disrupt preview benefits, and an object feature alone could determine object persistence under some conditions. It is therefore still unclear what role object surface features play in the establishment and maintenance of object files.
An interesting question derived from the study of Moore and Enns (2004) is what would be observed if a stream of events consisted of an object moving in a uniform trajectory while its surface feature (e.g., color) keeps changing? This would represent a case in which spatiotemporal continuity suggests only a single object moving throughout the journey, but the information from surface features suggests that multiple units exist. In the present experiment, we investigated this question by introducing two conditionsAlternating stream (in which the color of the moving object alternates between two colors) and Random stream (in which the color of the moving object changes randomly between two colors) - in addition to the One Change and No Change conditions employed in the original study by Moore and Enns (2004). Based on previous work on object file theory, if spatiotemporal information dominates the formation and updating of episodic object files (so that the visual system identifies only one object in the stream), we would expect the FLE to occur even in the Alternating and Random stream conditions. This would also mean that the unexpected and highly salient change at the moment of flash presentation in the One Change stream is a necessary condition for breaking motion continuity (leading the visual system to identify multiple objects in the stream) which eliminates the FLE. In contrast, if object surface features play a significant role in maintaining object files, the history of color change in conjunction with motion would cause the visual system to conclude that multiple objects exist in the motion stream. In this case, the FLE might be eliminated because the process of overwriting previous information at each instant is largely disrupted by the color change.

## Method

To examine the effect of object motion continuity on the magnitude of the FLE, we compared performance across three motion stream conditions (No Change, One Change,
and Alternating or Random) in two separate sessions with two different groups of observers.

## Participants

Twenty-four paid volunteers recruited at The University of Tokyo participated as observers in the experiment. Twelve observers were assigned to the session with the Alternating stream condition, and twelve were assigned to the session with the Random stream condition. All were naïve as to the purpose of the study and had normal or corrected-to-normal vision. Informed consent was obtained from the observers prior to the experiment.

## Stimuli and procedures

The stimuli used in the experiment were developed based on the previous study by Moore and Enns (2004; Part 2), and were programmed in MATLAB R2012b (MathWorks, USA) using the Psychophysics Toolbox extension (version 3.0.8; Brainard, 1997; Pelli, 1997). The stimuli were displayed on a CRT monitor with a refresh rate of 100 Hz (resolution $=800 \times 600$ pixels), controlled by a personal computer running the Windows 7 operating system. Observers viewed the stimuli at a distance of 60 cm in a dark and quiet environment.

All experimental stimuli were presented on a black background (luminance $=0.022 \mathrm{~cd} / \mathrm{m}^{2}$ ). The observer initiated each trial by pressing the space bar on the keyboard. After the space bar was pressed, a white fixation cross consisting of one horizontal line and one vertical line (length $=0.317^{\circ}$, width $=0.0453^{\circ}$ ) appeared at the center of the screen and remained throughout the trial until a response was made. Observers were required to fixate on the fixation cross throughout the trial. When the trial was initiated, a circular target stimulus (diameter $=0.907^{\circ}$ ) in either red or green (luminance $=0.47 \mathrm{~cd} / \mathrm{m}^{2}$ ) appeared either just above or below the central fixation cross at a distance of $4.171^{\circ}$ and remained there for 500 ms . Then, the target stimulus started to move in clockwise or counter-clockwise direction on an imaginary circle (radius $=4.171^{\circ}$ ) around the fixation cross for a random angular distance of $105^{\circ}, 195^{\circ}, 285^{\circ}$, or $375^{\circ}$ at an angular speed of $15^{\circ} /$ frame. Each frame was displayed for 70 ms , and thus, the duration of the motion stream was $490 \mathrm{~ms}, 910 \mathrm{~ms}, 1330 \mathrm{~ms}$, or 1750 ms . One of the following three possible motion streams was presented on each trial: (i) No Change, (ii) One Change, and (iii) Alternating or Random (depending on session assignment). In the No Change stream, the color of the target remained unchanged throughout the trial. In the One Change stream, the target color changed to the other color during the second last frame of the motion (which corresponds to the position just above, below, to the left, or to the right of fixation, and thus is always aligned with fixation), and then changed back to its original color in the last frame of the motion. In the Alternating stream, the color of the target alternated between red and green in each frame of the motion. In the Random stream, the color of the target changed randomly (either red or green) in each frame of its motion.

The flash stimulus was a white disc (diameter $=0.544^{\circ}$, luminance $=2.89 \mathrm{~cd} / \mathrm{m}^{2}$ ) presented at the position just above, below, to the left, or to the right of fixation (i.e., always aligned with fixation) at a distance of $2.901^{\circ}$. The flash was presented at either the third last, second last, or last frame of the motion for a duration of one frame. These three flash conditions resembled the "behind," "aligned," and "ahead" conditions in Moore and Enns (2004; Fig. 1a and 1b). In addition to these three flash conditions, there were also two baseline flash conditions for each stream condition. In the previous study, when the flash appeared, the target disc was presented at the second last position of the motion in the No Change condition, and was presented at the second last and last position of the motion in the One Change condition (Moore \& Enns, 2004; Fig. 1c). However, in the present study, we included both of these baseline conditions in all stream conditions to reduce any possible difference or bias in the magnitude of the FLE elicited by the different baseline conditions in the No Change and One Change streams, thus allowing a better comparison across different stream conditions. Specifically, in the Baseline 1 condition, the target stimulus stream was identical to the "aligned" flash condition, except that the target disappeared along with the flash; in the Baseline 2 condition, the target stream was the same as the Baseline 1 condition, except that an additional target was also presented in the second last frame and disappeared along with the flash. This additional target was presented at the position where the target should appear in the last frame in a non-baseline condition (see the "small change" and "large change" conditions in Fig. 1c of Moore \& Enns, 2004). Therefore, in the two baseline conditions, the target discs were presented up to the second last frame of the motion stream, and only the central fixation cross was displayed in the last frame.

Figure 1: The four motion stream conditions employed in the present study.

Observers were required to judge, upon the disappearance of the target disc, whether the target disc was aligned with the flash (and also the fixation) at the moment when the flash occurred. They were also instructed to respond "aligned" if they saw two target discs and either one of them was aligned with the flash. There were a total of 480 trials (3 Streams conditions $\times 5$ Flash conditions $\times 2$ Starting Positions $\times 4$ Travel Distances $\times 2$ Starting Colors $\times 2$ Motion Directions). Observers were instructed to take a five-minute break halfway through the experiment. The experimental session took about 35 minutes to complete.

## Results

Following Moore and Enns (2004), we plotted the average proportion of trials where the observers reported that the target disc and the flash were aligned for each stream condition. The data are plotted separately for the sessions with Alternating and Random streams (Figure 2; only data for the two baseline flash conditions and the flash condition where the target disc and the flash were physically aligned are shown).

Separate omnibus repeated measures ANOVAs were conducted on the data in the Alternating and Random sessions of the experiment. In the Alternating session, the main effect of Flash condition $[F(2,22)=25.777, p<.001]$, the main effect of Stream condition $[F(2,22)=33.997, p$ $<.001]$, and the Flash $\times$ Stream interaction $[F(4,44)=9.685$, $p<.001]$ were all statistically significant. The main effect of Travel Distance was not significant $[F(3,33)=2.630, p$ $=.066]$. Specific comparisons revealed that when the target disc and the flash were physically aligned (i.e., Aligned in Figure 2), there was a significantly lower proportion of "aligned" responses [i.e., P("aligned")] in the No Change condition compared to the Alternating condition, while there was a significantly higher proportion of "aligned" responses in the One Change condition compared to the Alternating condition (both at $p<.01$, adjusted for multiple comparisons). No significant difference in proportion was found between the three stream conditions in the Baseline 1 condition; a significant difference in the proportion of "aligned" responses was found between the No Change vs. One Change, and between the No Change vs. Alternating conditions (both at $p<.01$ ) in the Baseline 2 condition.

Similar results were found in the Random stream session. The main effect of Flash condition $[F(2,22)=11.581, p$ $<.001]$, the main effect of Stream condition $[F(2,22)=$ 14.137, $p<.001]$, and the Flash $\times$ Stream interaction $[F(4,44)=6.795, p<.001]$ all reached statistical significance. The main effect of Travel Distance was marginally significant $[F(3,33)=2.927, p=.048]$, while pairwise comparisons showed that the four Travel Distance conditions did not differ significantly from each other. Specific comparisons showed that when the target disc and the flash were physically aligned (i.e., Aligned in Figure 2), the proportion of "aligned" responses was significantly lower in the No Change condition compared to the Random condition, whereas there was a significantly higher
proportion of "aligned" responses in the One Change condition compared to the Random condition. Similar to the Alternating session, no significant difference in response proportion was found among the three stream conditions in the Baseline 1 condition; there was a significant difference between the No Change vs. One Change, and between the No Change vs. Random stream conditions (both at $p<.01$ ) in the Baseline 2 condition.
The Baseline 1 condition appeared to more strongly eliminate the FLE than the Baseline 2 condition did. One possible reason for this difference is that, since the experiment was mixed with both baseline conditions, observers were aware that there was a condition where the target disc and the flash were obviously aligned and disappeared together (Baseline 1), possibly leading to lower confidence reporting alignment in the Baseline 2 condition, where there were two discs in different positions.
To summarize, the two sessions of the experiment replicated the finding that inserting a single change in an object's appearance during motion (i.e., the One Change stream) eliminated (or greatly attenuated) the FLE compared with the No Change stream. Furthermore, our experiments demonstrated that a motion stream where the object alternates colors or changes color randomly elicits some degree of FLE. These results imply that (a) the weakened FLE in the Alternating and Random streams may be due to impaired perceptual smoothness of motion compared to the No Change stream, and (b) elimination of FLE in the One Change stream may be due to the exceptionally high salience of the target disc during the second last frame of the motion; in the Alternating and Random streams, the disc may no longer be salient at the moment of flash presentation (cf. the One Change stream) because the surface feature is continuously changing throughout the disc's motion, leading to survival of FLE under these conditions.

To verify these two hypotheses, we conducted short control experiments with five additional observers, where they were requested to judge the smoothness of the motion stream or the salience of the target disc during the second last frame of the motion. In each trial in the sessions where smoothness of motion was evaluated, one No Change stream and one Alternating stream (or a Random stream in a separate session) were presented sequentially in a random order, and observers were asked to indicate which of the two motion streams exhibited greater smoothness in motion. There were 24 trials in each session. In most of the trials, the observers reported that the No Change stream was more smooth than either the Alternating and Random streams (average percentage of trials in which the No Change stream was judged as more smooth in comparison to the Alternating stream $=84.2 \%$, Random stream $=84.2 \%$ ). The sessions testing target disc salience during the second last frame of the motion were conducted in a similar manner, but a One Change stream was presented instead of a No Change stream. Observers were asked to judge which of two sequentially presented streams showed a more salient target disc during the second-last frame of the motion. The
observers judged the target disc to be more salient in the One Change stream compared to the Alternating (85.8\%) and Random (90.8\%) streams. The control experiments therefore suggest that both hypotheses (a) and (b) contribute to explain the reduced, but not eliminated, FLE in the Alternating and Random conditions.

Figure 2: The average proportion of trials the observers reported alignment of the target disc and the flash stimuli for the Alternating (upper graph) and the Random (lower graph) sessions of the experiment; error bars represent the standard error of the mean.

Figure 3: The average proportion of trials that the observers reported the motion of the No Change stream appears to be more smooth than the Alternating/Random stream (left panel), and that the target disc looks more salient at the second last frame in the One Change stream than the
Alternating/Random stream (right panel); error bars represent the standard error of the mean.

## Discussion

The results of the present study showed that under conditions where the target object kept changing color while moving in a uniform trajectory (i.e., Alternating and Random streams), a significant FLE was observed, although it was somewhat attenuated compared to the No Change condition. Furthermore, the results of the control experiments suggested that (a) the attenuation of the FLE under those conditions might be due to lower perceived motion smoothness compared to the No Change stream, and (b) the high salience of the target disc at the moment when the flash occurred might be responsible for the elimination of the FLE in the One Change stream. These results therefore suggest that smooth motion defined by unchanged physical surface features is not a necessary condition for the FLE. As long as the visual system identifies a single entity throughout motion, without a salient transient change (i.e., in the Alternating and Random streams), the observer can still perceive the FLE as in physically smooth motion. A highly salient change that occurs unexpectedly (i.e., in the One Change stream) is required to break continuity and cause the visual system to perceive multiple objects in the stream.
In the context of the FLE, the present results support the notion that spatiotemporal continuity dominates surface feature in processing object persistence (Mitroff \& Alvarez, 2007). Although under some conditions, surface features can guide the mapping and updating of individual objects (Moore et al., 2010), spatiotemporal information is weighted more strongly in the computation of object persistence when both types of information are available (Tas, Dodd, \& Hollingworth, 2012). A brain imaging study by Yi et al. (2008) also provides strong evidence that discontinued spatiotemporal trajectories can cause visually identical faces to be represented as different individual objects, in which the brain area involved was the most staunchly "featural" area of the ventral visual cortex. The determination of object persistence during object motion involves identifying the correspondence between objects over short periods. This is similar to how the visual system computes motion correspondence in the apparent motion phenomenon, in which solutions are sometimes needed to map multiple objects at one instance to multiple objects at other locations at the next instance; in such a case, spatiotemporal information plays an important role in assisting the visual system to arrive at an appropriate solution (Dawson, 1991).

From the results of the control experiments, we infer that the perceived smoothness of object motion and the salience of the transient change during motion mediate the magnitude and determine the survival of the FLE. Our results suggest that observers' subjective perception of smoothness was related to the magnitude of the FLE. In the Alternating and the Random conditions, observers reported less motion smoothness compared to the No Change condition, and the results of the main experiment indicated a significantly smaller FLE in the Alternating and Random conditions compared to the No Change condition. This is
consistent with previous findings that perceived motion smoothness (i.e., sampling rate of the motion trajectory) and the magnitude of the FLE are highly correlated (Khurana, Nijhawan, \& Watanabe, 1998). Such a relationship between motion smoothness and the magnitude of the FLE implies that the maintenance of object files that give rise to the FLE may be associated with smoothness of motion. In the context of the present study, the rapid change in physical features in the Alternating and Random streams impaired perceived motion smoothness, and the maintenance of object files was thus degraded, leading to a smaller FLE. Although the maintenance of object files was interrupted, the visual system still perceived only one object in the motion stream. In terms of the salience of the transient change at the time of the flash, our results are consistent with the proposal of Moore and Enns (2004) that the FLE depends on such a salient and unexpected change in smooth motion, as abrupt changes in object features may disrupt object representations (Moore et al., 2007). One possibility is that the salient and unexpected change in the One Change stream captured observers' attention. At the moment of flash onset, the abrupt change in the moving object increases attention and allows the moving object to be associated with the flash onset at its veridical position, sparing it from the FLE. In the Alternating and Random streams, since the color change was ongoing, any change would become less salient and less able to capture attention, thus preserving the FLE.

To summarize, the present study extended the results of previous FLE experiments (e.g., Moore and Enns, 2004) and showed that the FLE can occur in motion streams where the physical features of the moving object continuously change during motion. The magnitude and survival of the FLE was determined by perceived motion smoothness and the salience of the moving object at the time of the flash. We propose that a rapid change in a physical feature partially degrades the maintenance of the object file, but does not eliminate the overall percept of only one object in the motion stream. At the same time, it mostly reduces the salience of the disc at the moment of flash presentation. Future studies should focus on how attention at the moment of the flash influences the FLE.

# Interface Design and Spatial Cognition: A Case of Virtual Molecule Manipulation 

Trevor J. Barrett (trevor.barrett@psych.ucsb.edu)<br>Department of Psychological and Brain Sciences, UCSB Santa Barbara, CA 93106 USA<br>Mary Hegarty (mary.hegarty@ psych.ucsb.edu)<br>Department of Psychological and Brain Sciences, UCSB<br>Santa Barbara, CA 93106 USA

#### Abstract

Virtual models are a common instructional tool used in chemistry education to help students learn about the 3D structure of molecules. The present study examined effects of two interface design features on participant performance during a molecule orientation task. The features examined were 1) colocation of the visual and haptic workspace and 2) stereoscopic viewing. The results indicate that colocating the interface increased participant accuracy, while providing stereo did not. Neither factor affected response time. The effects of colocation were also reflected in subjective ratings of task demand measured by the NASA-TLX. Spatial ability was predictive of task performance but did not interact with interface effects. The findings are discussed in the context of spatial cognition and interface design for manipulating virtual objects.

Keywords: spatial cognition; interface; virtual; rotation; stereoscopic; colocation; organic chemistry

Computer-based virtual models are becoming an increasingly common instructional medium in science, technology, engineering, and mathematics (STEM) education (Trindade, Fiolhais \& Almeida, 2002). Virtual learning environments have shown promise in fostering meaningful learning, but virtual models vary considerably in the perceptual cues and interfaces that they provide so there is still much to be understood regarding how to best design and implement these technologies. For example, current stereoscopic displays are more expensive and less available, so it is important to know whether they provide a benefit to performance and learning outcomes, or whether monoscopic displays are as effective.

The present study aims to understand the relative value of two factors on which virtual displays vary, (1) colocating the hand-held interface and the displayed virtual image (colocation), and (2) providing stereoscopic 3D viewing (stereo) for a representation matching task in organic chemistry. Stull, Barrett, \& Hegarty (2012), found participants performed this task with greater efficiency using a virtual model system (with stereoscopic display and colocation of visual and haptic workspaces) than when using standard concrete models. Given this efficiency advantage, a goal of this study is to investigate the relative importance of providing stereo and colocation during a virtual object manipulation task.

Klatzy, Wu, \& Stetten (2008) suggest that more perceptually mediated interfaces allow for better performance over cognitively mediated interfaces. Perceptually mediated interfaces decrease demand on spatial working memory, thereby freeing up cognitive resources to allocate to performance or learning. If stereo and colocation increase perceptual mediation, decrease spatial cognitive load, and allow for additional cognitive recourses to be devoted to performance, then participants should show faster and more accurate performance when these cues are provided.

## Stereo and Colocation Technology

Both stereo and colocation technologies have been shown to increase speed and accuracy in virtual object manipulation tasks (Ware \& Rose, 1999, Arsenault \& Ware, 2004, Klatzky et al., 2008), however some studies have shown no significant effect of stereo (Khooshabeh \& Hegarty, 2010) or colocation (Liere, 2005). It is important to note that the majority of studies investigating performance with these technologies have used object translation tasks, rather than a rotation task as in the current study. In general, we should be cautious in generalizing specific interface design effects across various tasks, as different perceptual cues may be important for supporting rotation and translation.

To our knowledge, no study has investigated the effects of varying both stereo and colocation during a virtual object rotation task in the same experiment. The results of the present study will help to elucidate the importance of these cues for increasing perceptual mediation and decreasing cognitive load in a task that involves virtual object rotation.

## Organic Chemistry as a Test-bed

Organic chemistry is a domain rich in spatial representation; diagrams and models of 3D molecular structures are ubiquitous in instruction as well as in cutting edge research environments. Understanding molecular structure is an essential skill all organic chemists must have in order to learn, research, and communicate their science. Diagrams and models serve as a language of spatial connections and structures and therefore are vital in developing understanding of structures and making advancements in the field (Kozma \& Russell, 2005).

Organic chemistry representations serve as an excellent test-bed for studying spatial cognition in virtual environments for these reasons. Virtual models are commonly employed in chemistry education (Barnea \& Dori, 2000, Limniou, Roberts \& Papadopoulos, 2008) to teach students about the 3D structure of molecules and to introduce them to other representations (diagrams, equations etc.). However, little work has investigated interface design for virtual models in chemistry. One aim of the present study is to inform the design of virtual models for chemistry education, by identifying which visual cues and interface functionality best support usability and learning with these models.

The task used in the present study requires that the participant understand the spatial structure of a 3D molecular model, then manipulate the model in order to match to the orientation of a simultaneously displayed diagram of the same molecule. This task is relevant as it is a commonly employed activity for teaching about molecular structure, and also shares similarities with the virtual object orientation matching tasks used in the human-computer interaction literature. Grounding the study in the real-world domain of organic chemistry allows for simultaneous investigation of applied interface design issues as well as theories of small scale spatial cognition and virtual object manipulation.

In addition to performance measures, we assessed selfreports of usability of the virtual models. We predicted that participants who received stereo and colocation would rate the interfaces as more usable. Given the spatial nature of the task and known sex differences in spatial ability (Voyer, Voyer \& Bryden, 1995), we also investigated possible interactions between aspects of the virtual models, spatial ability, and sex. If colocation and stereo displays increase perceptual mediation, we might expect an interaction with spatial ability such that lower spatial ability participants should receive a greater benefit from the additional cues than higher spatial ability participants, who can presumably better handle more cognitively mediated interfaces. We might also expect females to benefit more from the perceptually mediated interface, because they tend to have lower spatial ability (Voyer et al, 1995) and less experience with computers (Waller, 2000).

## Virtual Model System

A 'fishtank' virtual reality system was constructed to allow for colocated naturalistic manipulation of a virtual molecular model in stereoscopic 3D (Earnst \& Banks, 2002). The display was mounted horizontally above the user and faced downward onto a mirror mounted at $45^{\circ}$, which projected the virtual image to the viewer. This configuration allowed the participant to manipulate the input device in the same location as the perceived virtual image of the model, giving an experience similar to direct manipulation of a concrete model. In the displaced condition, the input device
was located to the left and below the image in the natural computer mouse location ( 15 " total displacement). Stereoscopic viewing was provided by Nvidia 3D Vision Wireless Glasses Kit.

The interface was composed of a cylinder that was roughly the same dimensions as the virtual models, and consisted of two halves that freely rotated about the long axis of the interface. One half contained a 3-degree of freedom motion sensor to track yaw, pitch, and roll of the interface, and was used to control global rotations of the virtual models. The opposite half was attached via an optical encoder that tracked twisting rotations of the interface halves, and was used to control local rotations of a bond within the molecule itself (as was necessary on some of the experimental trials). Please refer to Stull, Barrett \& Hegarty (2012) for a more detailed description of the system design.

Figure 1: a) The hand-held interface workspace was colocated with the displayed virtual image. b) The motion sensor is depicted in blue, and the optical encoder is depicted in red. The cords for the two devices emerged at the junction between the two halves.

## Method

## Design

The study had a two (colocation vs. displaced) by two (stereo vs. mono) between subjects design. Dependent variables include accuracy as measured by angular error and response time. Subjective experience ratings, spatial ability, and computer use were also measured.

## Participants

One hundred twenty college students (65 Female) (age: $M=$ 18.7, $S D=1.8$ ) from the psychology subject pool at a research university participated in the study in return for course credit. None of the participants had studied organic chemistry. All participants had normal, or corrected to normal vision. Participants were randomly assigned to each condition.

## Materials

The study materials included an informed consent sheet, a video tutorial, a sheet with descriptions of the task and diagrams, a set of diagram orientation matching task problems, a measure of task load, a measure of computer beliefs and attitudes, two measures of spatial ability, and a post-task questionnaire.

A 10-minute instructional video explained the conventions of the models and diagrams, how to find and understand important features of the model (e.g., central carbon-carbon bond), how to write the chemical formula for each molecular subgroup (e.g., $\mathrm{CH}_{3}$ for a methyl group made up of a carbon atom and three hydrogen atoms), the color conventions for the different atoms (e.g., black for carbon, red for oxygen etc.), and how to structurally align the models to each of the three diagram types.

The diagram problems required rotation of the virtual model to match one of two commonly used target diagram types, dash-wedge (side-view) and Newman (end-view). There were 24 problems total, half with dash-wedge target diagrams and half with Newman target diagrams. The starting orientation of the model was such that it maximized the global angular distance to each of the target diagrams. Half of the trials involved a conformation change (local rotation) of the molecular model (i.e., changing the spatial configuration of substituents by rotating the bond between the molecule's two chiral carbons). Six different molecules were used in the 24 trial problems; and were systematically varied with the target diagram type, and local rotation trials. All participants received the trials in the same order, in which two consecutive trials never showed the same target diagram or molecule.

Figure 2: Participants manipulated the 3D molecular model to match the orientation depicted by either a Newman (left) or Dash-Wedge (right) diagram.

Items from the NASA Task Load Index (TLX) (Hart \& Staveland, 1988) were administered to assess participants' subjective experience of the task with regard to six criteria: mental demand, physical demand, temporal demand, own performance, effort, and frustration. Participants rated each
of these criteria on a scale from 0 to 100 with 0 being the lowest and 100 being the highest rating.

Participants were administered two tests of spatial ability, a mental rotation test (MRT) (Vandenburg \& Kuse, 1978), and a three dimensional perspective taking test, Visualization of Viewpoints (VoV) (Guay \& McDaniels, 1976).

Items from Waller's (2000) computer use questionnaire were administered to assess participants' attitudes and experience with computers. Participants rated 10 statements on a scale of 1 (completely disagree) through 7 (completely agree).

## Results

The following results include 108 participants ( 56 female). Data from 12 students were excluded from the analyses as they had much lower accuracy (angular errors of $>30^{\circ}$ ) suggesting they did not understand the task or were unmotivated. The four interface condition groups had approximately equal numbers of males and females. Response times that were greater than 2.5 standard deviations from a participant's mean response time were replaced with their mean response time. The groups did not significantly differ on the MRT, $F(3,104)=0.8, p=.56$, VoV, $F(3,104)=1.7, p=.17$, computer experience, $F(3$, $104)=0.43, p=.73$, or attitudes toward computers, $F(3$, 104) $=1.0, p=.42$.

The mean angular error for the different experimental groups is shown in Figure 3. Overall, participants had an average angular error of $13.7^{\circ}(S D=6.6)$. A significant effect of colocation was found on error, $F(1,104)=6.6, p$ $=.01, \eta_{p}{ }^{2}=.06$. Marginal means showed that participants provided with the colocated interface had a lower average angular error (i.e., greater accuracy) of $12.1^{\circ}(S D=5.7)$, than those using the displaced interface $15.4^{\circ}(S D=7.1)$. No significant effect of stereo was observed, $F(1,104)=$ $0.6, p=.46$. There was no observed interaction between colocation and stereo $F(1,104)=2.5, p=.12$.

Figure 3: Effects of providing stereo and colocation on participant accuracy $(M \pm S E)$.

Overall, participants had an average response time of 33.8 s ( $S D=15.2$ ). No significant effect of colocation was found on response time, $F(1,104)=1.5, p=.22$. Also, no significant effect of stereo was observed, $F(1,104)=1.2, p$
$=.28$. There was no observed interaction between colocation and stereo, $F(1,104)=0.6, p=.43$.

Figure 4: Effects of providing stereo and colocation on participant response time $(M \pm S E)$.

NASA-TLX ratings are shown in Table 1. On average, participants provided with a colocated interface rated their experience as having significantly less physical demand and frustration than those with the displaced interface. Further, participants with colocated interfaces rated their own performance to be significantly greater than those with displaced interfaces. No main effects of stereo were found on any of the six task demand ratings.

Significant interactions between stereo and colocation were observed on ratings of effort, $F(1,104)=4.3, p=.04$, $\eta_{\mathrm{p}}{ }^{2}=.04$, and frustration, $F(1,104)=8.3, p=.005 \eta_{\mathrm{p}}{ }^{2}=$ .06. When colocation was provided, participants using stereoscopic displays reported less task effort ( $M=58.1$, $S E$ $=4.6$ ) than participants using monoscopic displays ( $M=$ $72.3, S E=4.8$ ). Further, when provided stereo, participants using colocated interfaces reported less frustration ( $M=$ 19.4, $S E=5.1$ ) than those using displaced interfaces ( $M=$ $45.6, S E=5.3$ ).

Table 1: Effect of stereo and colocation on NASA-TLX ratings.

| Task Demand | Colocated | Displaced | ANOVA |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $M(S E)$ | $M(S E)$ | $d f$ | F | $p$ | $\eta_{\mathrm{p}}{ }^{2}$ |

[^7]Table 2: Correlations between dependent measures, spatial ability, and computer use.

|  | RT | Ang. <br> Error | MRT | VoV | Comp. <br> Att. | Comp. <br> Exp. |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| RT | 1 | - | - | - | - | - |
| Ang. | $.36^{* *}$ | 1 | - | - | - | - |
| Error | $-.25^{*}$ | $-.25^{* *}$ | 1 | - | - | - |
| MRT | $-.32^{* *}$ | $-.36^{* *}$ | $.45^{* *}$ | 1 | - | - |
| VoV | $-.32^{* *}$ |  |  |  |  |  |
| Comp. <br> Att. <br> Comp. <br> Exp. | -.17 | -.07 | $.30^{* *}$ | $.34^{* *}$ | 1 | - |

* $p<.05, * * p<.01$, two-tailed; $\mathrm{N}=108$

As shown in Table 2, MRT scores showed small but significant correlations, while VoV scores showed somewhat higher correlations with response time and accuracy. In order to investigate possible interactions between spatial ability and aspects of the interface and display, scores from the MRT and VoV were standardized and averaged to produce a combined spatial ability score. A median split was used to separate high and low spatial ability participants, and was then used as a factor in the analysis. As expected, high spatial ability participants completed the task faster and had greater accuracy than low spatial ability participants $F(1,100)=7.9, p=.006, \eta_{p}{ }^{2}=$ .07. High spatial ability participants had an average response time of $29.3 \mathrm{~s}(S D=12.2)$ and low spatial ability participants $38.1 \mathrm{~s}(S D=16.6)$. For accuracy, high spatial ability participants had a lower average angular error of $11.2^{\circ}(S D=5.6)$ than low spatial ability participants $16.2^{\circ}$ $(S D=6.5)$, this finding was also significant $F(1,100)=$ $13.2, p=<.001, \eta_{p}^{2}=.12$. Interactions of spatial ability with stereo and / or colocation did not reach significance.

Participants' level of experience with computers showed a small significant correlation with accuracy, but no significant correlation with response time. As shown in Table 2, there were moderate correlations between computer attitude and experience with both the MRT and VoV scores. A median-split was used to separate participants into high and low groups for computer attitude and computer experience. When used as a factor in the analysis, there was no main effect of either attitude or experience on performance. Further, there were no significant interactions of computer attitude or experience with stereo and / or colocation.

Overall, males were significantly more accurate than females, $F(1,106)=5.1, p=.025, \eta_{\mathrm{p}}{ }^{2}=.05$. Males had an average angular error of $12.3^{\circ}(S D=6.6)$ and females $15.1^{\circ}$ ( $S D=6.3$ ). Males and females did not significantly differ in response time, $F(1,106)=0.5, p=.50$. However, a significant interaction of gender with colocation is evident in response time, $F(1,104)=5.0, p=.028, \eta_{p}{ }^{2}=.05$.

Pairwise analysis revealed that female participants performed significantly faster with a colocated interface ( $M$ $=29.9 \mathrm{~s}, S E=2.8$ ) than with a displaced interface $(M=$ $39.8 \mathrm{~s}, S E=2.8), F(1,104)=6.2, p=.014, \eta_{\mathrm{p}}{ }^{2}=.06$. Response times for males were not affected by colocation, $F(1,104)=0.4, p=.49$. There were no other significant interactions with gender.

## Discussion

The main purpose of this study was to examine the importance of providing stereoscopic 3D viewing and colocation of the haptic interface and virtual image during a virtual object orientation task using molecular models. The results demonstrate that providing colocation had a small but significant impact on accuracy. The experiment failed to demonstrate an effect of stereo on accuracy. The results failed to show an effect of colocation or stereo on task completion speed. Overall, these findings suggest that colocation of haptic and visual information enabled perceptual mediation of the task to some degree, whereas stereo did not significantly increase perceptual mediation or decrease cognitive load for this particular task.

Our results can be compared with previous studies investigating the effect of colocation on virtual object rotation. Ware and Rose (1999) found that colocation led to $35 \%$ faster performance during an object rotation task, however no effect on accuracy was found. In a later study, Ware and Arsenault (2006) found that colocation led to faster response times, however they did not have a measure of accuracy because trials were automatically terminated when the manipulated object was within $5^{\circ}$ of the target orientation. Other studies investigating effects of colocation are difficult to compare with the present study; the majority of tasks used involve object translation rather than pure object rotation, as in our task.

The findings of the present study demonstrate an accuracy advantage, rather than the speed advantages demonstrated in the previous studies. In regard to the Ware and Rose (1999) result, it is important to note the authors' task involved repeatedly rotating a single simple shape and did not require any local manipulation of the object, as in our task. It is possible that when task demands are greater, providing colocation benefits accuracy more than response time. In regard to Ware and Arsenault (2006), the accuracy advantage from colocation found in the present study would translate into a response time benefit had the trials required a minimum angular error for completion; thus it is likely that the findings are complementary. Despite the relatively small effect on accuracy, this study adds to the body of literature demonstrating a performance benefit from colocating visual and haptic workspaces for virtual object rotation tasks. Further, this study shows that when rotating different complex structures to match a given orientation, providing colocation of haptic and visual information may benefit precision more than speed.

Numerous studies have demonstrated performance advantages from providing stereoscopic 3D viewing in virtual object manipulation tasks (Ware \& Franck, 1996; Hu, Hellen, 2000; Arsenault \& Ware, 2004; Liere, Kok, Martens, 2005). However, many of these studies involve virtual object translation tasks, rather than rotation tasks, as in the present study. One must use caution in generalizing effects of interface design on translation tasks to rotation tasks, as the two processes are independent (Wang, MacKenzie, Summers, \& Booth, 1998; Ware \& Rose, 1999). Other studies comparing stereo and mono displays that involved tasks other than translation often find no beneficial effect of stereoscopic viewing (Hoffmeister, Frank, Cuschieri, \& Wade 2001, Kooshabeh \& Hegarty, 2010).

Another possible explanation for the null result of providing stereo is that the task had low demand on depth perception. The task used in the present study was purely an object rotation task, the models manipulated were regular structures that rotated around a fixed origin in space, and the task did not require making difficult judgments about relative distances in depth. The tetrahedron structure of the molecules may have allowed for necessary judgments of depth to be made via monocular depth cues such as occlusion, motion, linear perspective, and shadowing. It is possible that the depth perception demands of the task could be supported by monocular cues alone. Despite the growing excitement surrounding 3D stereoscopic displays, performance on certain tasks and applications may not benefit from providing the latest display technology. Future research is needed to elucidate the specific task qualities and learning situations under which providing stereo actually benefits the user.

Results from the NASA-TLX measure of participants' subjective experience were consistent with the performance data, and further demonstrated the importance of providing colocated visual and haptic workspaces and the null effect of viewing the display in stereo. Participants with the colocated interface reported the task to be significantly less physically demanding, less frustrating, and rated their perceived performance higher than participants who used the displaced interface. Participants were more comfortable and confident when the interface was colocated; this provides further evidence that although the performance effects were small, they were meaningful in that they were associated with the perceived task demands of the users. Stereo did not affect ratings of subjective experience, further demonstrating its unimportance for this task.

Males performed the task more accurately than females. An interesting result is that females performed trials about 10 seconds faster when provided with colocation. This result suggests that females have a more difficult time dealing with visual and haptic mismatches, which might be attributed to differences in spatial ability, experience with computers, or both.

This study demonstrated that providing colocated haptic and visual workspaces had a small beneficial impact on accuracy during a virtual object orientation matching task, while providing stereo had no significant effect on accuracy. Further, neither factor affected overall response time. It will be important to examine whether results found on representation matching performance generalize to meaningful learning of the spatial structures. Future studies will investigate how specific interface design features relate to students' ability to understand concepts regarding 3D molecular structure and whether this learning can be maintained and utilized during novel situations in which models are no longer available. In addition to providing basic information regarding the perceptual cues that facilitate virtual object manipulation, this research will inform the design of virtual models for science learning.

#### Abstract

We set forth to show that lexical connectivity plays a role in understanding early word learning. By considering words that are learned in temporal proximity to one another to be related, we are able to better predict the words next learned by toddlers. We build conditional probability models based on data from the growing vocabularies of 77 toddlers, followed longitudinally for a year. This type of conditional probability model outperforms the current norms based on baseline probabilities of learning given age alone. This is a first step to capturing the interaction between a child's productive vocabulary and their learning environment in order to understand what words a child might learn next. We also test different types of variants of this conditional probability and find that not only is there information in words that are learned in proximity to one another but that it matters how models integrate this information. The application of this work may provide better cognitive models of acquisition and perhaps allow us to detect children at risk for enduring language difficulties earlier and more accurately.

Keywords: word learning, semantics, language acquisition, co-occurrence, development, longitudinal data, CDI

## Introduction

Do children learn words systematically? There is a lot of evidence that words are not all learned equally. Perhaps not surprisingly, for example, parents' vocabulary is related to their children's vocabulary (e.g., Weizman \& Snow, 2001; Veen, et al., 2009). That is, the child will learn the words in his or her environment. In addition, some concepts, and therefore the words that name them, may be easier to learn than others. For example, concrete nouns are learned earlier than verbs and adjectives (e.g., Sandhofer, Smith, \& Luo, 2000; Gentner, 2006). Furthermore, the child may bring some preferences and constraints to the task of word learning. For example, children may become particularly interested in dinosaurs or construction equipment or even tea sets (DeLoache, Simcock, \& Macari, 2007). That is, in characterizing the forces that guide word learning, there is evidence that at least three distinct but not necessarily mutually exclusive sources of information can come to bear: a) the structure and composition of the linguistic environment, b) the structure of the concepts and categories being named, and c) the characteristics of the learner itself. In this paper we focus mostly on this third source of variability by constructing conditional probability models from longitudinal trajectories of word learning that make predictions at the word level, for individual children. That
is, we ask: can we use the words a child knows now to predict the words that a child will learn next?

## Measuring the developing lexicon

One well-established way to characterize toddlers' lexicons is to use vocabulary checklists, such as the MacArthur-Bates Communicative Development Inventory (CDI; Fenson et al., 1994). These parent-reported measures have been shown to be effective in evaluating children's communicative skills up to 30 months of age (e.g., Thal et al., 1999). The CDI: Words \& Sentences Toddler form is a checklist of over 700 early words that at least $50 \%$ of children typically say at 30 months of age. By pooling data over thousands of children, the CDI provides norms of the percentage of children who say each of these words at a given age from 16 to 30 months of age, month by month. Aside from being shown to be a valid measure of communicative skills for this age group, the CDI has been recently shown to be an effective tool for sorting toddlers at the low and high end of the acquisition distribution into late talkers and typically developing children (Heilmann, et. al, 2005). This might allow us to see universality in learning but it also masks some of how the process works-the aggregate cannot explain individual differences but models of learning necessarily must.

The CDI norms can be used to build models of growth. For example, Hills and colleagues (2009) have used CDI norms to build growth models based on networks of words connected by feature similarity or associative strength. Beckage, Smith and Hills (2011) used the connectivity of language within the vocabulary of young learners and showed that there are differences in the structure of the vocabularies of children at risk for language impairments and those of typically developing children.

Note that these approaches presuppose that there is information in the relationships between words. If this is the case, there should be predictive power in looking at the between-word dependencies over time. We do this by exploiting the statistical regularities present in the developing vocabularies of 77 children, followed longitudinally for a year, at monthly intervals.

## Rationale

We propose a simple way of uncovering the interaction between the language environment and learning and thus uncovering more of the systematicity of word learning. Instead of just considering the frequency of production for a
given word conditioned on the age of a child, as with the CDI norms, we suggest that there might be additional information in the structure of the language knowledge itself, in the set of words that are known. To pursue this claim, we build the most naïve notion of relatedness and leverage this information in order to predict what words a child might learn next. We define relatedness to be the conditional probability of a word given the child knows another word. For the sake of this paper, we consider words learned in temporal proximity to be related. We build up these values from the longitudinally collected CDIs by considering a connection between words that are learned at the same time (within the same month). We then compute the conditional probability as follows:

$$
\begin{equation*}
\operatorname{Pr}(a \mid b)=\frac{P(a \bigcap b)}{\operatorname{Pr}(b)} \tag{1}
\end{equation*}
$$

For example, we compute the probability of knowing "cat" given "dog" by calculating the probability of a child learning "cat" and "dog" in the same month, normalized by the probability of knowing "dog" in the population as a whole. We can then use a variety of methods to combine these conditional probabilities into a single probability of learning word $i$ given that they know a set of words $\mathbf{J}$. That is, for each not-yet-known word, we can calculate the probability that the child will learn that word next, given the set of words the child already knows.

In order to combine the conditional probabilities given the set of known words, we need to integrate over the conditional probability given each of the words known. Here we test three different models of this: the Additive model assumes that every conditional probability contributes equally. In the additive model we simply sum up the conditional probability of $i$ given every $j$ in the set of known words. This gives us a proportion of learning for every word not yet learned. The issue with this model is that it requires a large amount of information and storage. One rudimentary simplification would be to assume that only the maximum conditional probability was used. This model we call the Maximal model because we use only the strongest conditional probability between $i$ and some $j$ from the set of known words $\mathbf{J}$. Finally in the Threshold model we compare a model that considers conditional probabilities in an additive fashion but considers links only as present or absent. The link is determined as present when the conditional probability strength is above a certain threshold (in our case the median of all conditional probability values) and absent otherwise. We compare these conditional probability models to two population-based models, one based on the CDI norms (norm-baseline), another based on the observed frequencies (observed-baseline), as well as the null model (the assumption that all words will be learned with equal chance). We evaluate the conditional probability models by comparing their predictive power to the population-based models, and use 5 -fold crossvalidation to evaluate the model's performance in predicting untrained trajectories.

## Methods

## Vocabularies and Co-occurrences

We utilize CDI measured vocabularies collected at the University of Colorado Boulder. Seventy-seven toddlers between 15.7 and 18.6 months (mean starting age 17 months) were recruited as part of a year-long longitudinal study. These participants completed monthly behavioral tasks as well as vocabulary assessments. The vocabulary assessments were conducted through parent report using the CDI Words \& Sentences toddler forms. These CDIs were collected for 12 consecutive months with the majority of parents completing the forms each month. On average we have 9.8 months for each child.

In our study, we include a total of 650 words from the full form, marking duplicate words with parts of speech (such as "orange" as a noun and "orange" as an adjective). We included words that were both on the full form and had norms available online (http://www.sci.sdsu.edu/cdi/). Words that were not part of our modeling included words like above, after, on and off. All together we have 77 children and a total of 684 CDI forms. For the sake of this paper we consider each month to be independent of every other month. That is, we build associative structure only from words that are learned during the same month (or words that are known at the beginning of the study.) This limits the co-occurrence measure to capture only short-term dependencies. In the future we plan to extend this work to include cross-sectional vocabularies as well, which will allow us to capture long-term dependencies.

To derive the strength of connectivity, we simply take a count of the number of times two words appear in the same vocabulary (i.e. are learned in the same month) normalized by the population level knowledge as measured from our sample for the words. This provides the basic counts that are then used to compute an 'activation level' that will then give rise to predictions of the next word learned. We then calculate the probability of learning word $i$ given that a child already knows word $j$. This is then compared to the models based only on population level data as well as a model that assumes uniform learning.

## Models

We compute two population-based measures. The first normed model is based on the CDI norms where we consider the likelihood of a child learning the specific set of words we observe to be a function of the population level age of acquisition (AoA) norms (Dale \& Fenson 1996). The second measure is calculated analogously, but computing the likelihood according to the AoA as observed in our own sample. We also compare these and all other models to a straw-man baseline measure (the null model) that gives every unlearned word equal probability of being learned.

We compare these population level models to conditional probability models. For the additive model we calculate the probability that each word is learned as proportional to the sum of the conditional probability of all known words.

$$
\begin{equation*}
\operatorname{Pr}(a \mid \mathbf{B}) \propto \sum_{b_{i} \in \mathbf{B}} \frac{\operatorname{Pr}\left(a \bigcap b_{i}\right)}{\operatorname{Pr}\left(b_{i}\right)} \tag{2}
\end{equation*}
$$

In effect, the probability of learning word $a$ is computed such that we sum across the conditional probability of each known word $b$ in the set of known words $\boldsymbol{B}$. For example if a child knows words "cat" and "dog" then the probability that the child will learn word "pet" is proportional to the sum of the probability of learning "pet" given "cat" plus the probability of learning "pet" given "dog". This assumes a level of independence that does not exist in language itself.

Using similar methods, in the maximal model we consider only the maximum conditional probability to be proportional to the probability of learning a given word. We test this model because it requires only one point of information per word as opposed to considering all possible combinations of known and unknown words.

$$
\begin{equation*}
\operatorname{Pr}(a \mid \mathbf{B}) \propto \arg \max _{b_{i} \in \mathbf{B}}\left\{\frac{\operatorname{Pr}\left(a \bigcap b_{i}\right)}{\operatorname{Pr}\left(b_{i}\right)}\right\} \tag{3}
\end{equation*}
$$

This simplification may still capture much of the variance if the maximal connection dominates the additive model or if strong connections in the learning environment really do highlight words to be learned next.

We also consider thresholded conditional probability. The idea here is that the learner has access to most of the conditional probability space but only at a coarse level. The learner is considered to maintain only the strongest conditional probabilities and that these are considered as present or not. Mathematically, the threshold model is:

$$
\begin{equation*}
\operatorname{Pr}(a \mid \mathbf{B}) \propto \sum_{b_{i} \in \mathbf{B}} \mathbb{I}_{\left\{\operatorname{Pr}\left(a \mid b_{i}\right)>c\right\}} \tag{4}
\end{equation*}
$$

Here $\mathbf{I}$ is the indicator function and is valued only when the conditional probability is greater than some constant c . For this analysis we let c be the median conditional probability across all children. This adds an additional variable to our model but it is set a priori and thus has little significance on the complexity of the model. From an information processing point of view, this model may take less effort since we consider only the presence and absence of a link and not the weight, reducing the complexity of the space.

While we do not consider it here, even these very simple models can quickly be extended to other types of more sophisticated models. First, conditional probability is at best a first order approximation to the full complexity that language embodies. The model can only be as good as the measure used to inform it which in this case is simple cooccurrences. Further, these co-occurrences are based on one month time slots, we could consider data at other time scales, or multiple timescales. Finally, we have chosen to integrate the conditional probability information here in the simplest ways. These models can be seen as network models which allows us to consider not only what words are predicted to be learned next but how these mechanisms for learning transform the semantic structure present in the network. We mention this to highlight the implications of testing these basic assumptions on the larger word learning models (e.g., Vitevitch, 2008; Hills et al, 2009).

## Evaluation

We begin by looking at the percent of vocabularies better fit than the null model and the percent likelihood improvement. This tells us some information about the general variability of the input and the ability of the model to account for this variability but little about which model is best. Thus we consider the percent of vocabularies that are better than each of the population based models. This tells us the proportion of vocabularies better fit by the model but not how much better (or worse) of a fit the models give us for our sample. Thus we include the total likelihood of the test data given each of the models. We then compare the likelihood fits across models in order to understand how a model is performing in comparison to other models. We also look at the percent of vocabularies best fit by a given model.

This gives us a good deal of information about the performance of the models and the ability of the models to utilize and combine information in order to predict words learned next at the level of an individual child's vocabulary. To be sure that we are capturing actual signal we want to calculate the conditional probabilities based on a different set of vocabularies than those on which we test the models. Thus, we use cross validation and iteratively build up the necessary associations that the models require from $80 \%$ of the vocabularies and then test on the remaining $20 \%$. We do this at the child level since sequential vocabularies are not independent of the child (an issue we've ignored up to this point). We randomly select the $20 \%$ test group and repeat this 5 times such that every observed set of vocabularies for a given child is in the test set once. This allows us to test how well the model can predict the vocabulary growth of a child it has no direct information about. We compare the average performance on the five different test sets.

## Results

We know what specific words a child learned in a given month, and we use our model to calculate the probability of a given set of words. Some models give a zero probability to learning certain words and thus we first want to look at what percentage of our population cannot be fit by a specified model. This will give us information about how constrained the models are in their ability to fit the wide range of data present in our sample. Column 1 of Table 1 shows the results. In general the models are able to capture the learned words fairly well. The worst model is the Threshold model which is due to the fact that many words are assigned a zero probability under this model since connections that are not above the median strength are considered absent-this results in about 4\% of the observed vocabularies not being explainable under the strictest definition of the model. The model based on the CDI norms also has some difficulty accounting for some ( $2 \%$ ) of the vocabularies seen. In practice, this means that some children learned words earlier than the normed CDI measures would have predicted-that is, in the vocabularies used to build up the norms, there were no children in the sample that learned some words that children in our study did. This is even more extreme for our
observed CDI norms-which is probably an effect of sample size. In general a large majority of the 684 vocabularies could be fit under the models we constructed; a total of 633 overlapped across all models. We constrain our model comparisons to this subset in all further evaluations.

The next major question is whether or not the constructed models outperform the null model in which each word is given equal probability of being learned. The answer, in short, is that all models perform better than the null model when we consider the total likelihood across all vocabularies. Further, the minimum number of vocabularies better fit by our models than the null model was $82 \%$. This suggests that there is systematicity to the order in which children learn words. In fact we don't only fit the observed data better we get a fairly substantial improvement in overall likelihood when we utilize these models. We have at last $8 \%$ improvement and at most $19 \%$ improvement.

Table 1: Model performance compared to null model. We consider \% of vocabularies not fit, improvement over null and $\%$ of vocabularies better fit by a given model.

| Model | vocabs not <br> fit (\%) | improvement <br> over null (\% llk) | vocabs. better <br> than null (\%) |
| :--- | :--- | :--- | :--- |
| Normed | 2.37 | 14.54 | 81.99 |
| Observed | 3.97 | $\mathbf{1 9 . 0 4}$ | $\mathbf{9 0 . 5 2}$ |
| Additive | 0 | 18.22 | 89.10 |
| Maximal | 0 | 8.39 | 86.41 |
| Threshold | 4.05 | 18.66 | 82.94 |

However, showing that words are not acquired randomly does not answer the question of how individual children build up a vocabulary. Returning to the ideas from the introduction, this does not rule out the effect of the structure of the environment. Children learning words proportional to the frequency they encounter them in the environment could explain these results. This would maintain independence between the words a child knows and the words the child is going to learn next. The two baseline models maintain this independence as well: the model based on the normed CDIs and the model fitting to the observed CDIs. In contrast, the other models assume conditional probability plays a role in prediction of vocabulary growth and uses this to link known words to what words will be learned next. Thus, to get at our original question we want to compare these population level models to the other models that require conditional information. We already have a bit of information about the overall model performance when we look at the total likelihood across all vocabularies. We see that we get the largest improvement in likelihood when we utilize the observed CDIs. And we also see that this model gives us the most vocabularies that are fit better than random acquisition.

The gains resulting from using conditional probability are clearer when we consider which vocabularies were best fit rather than looking at the overall likelihood which could be easily inflated by isolated vocabularies that are particularly difficult for a given model to fit. With cross-validation, the
threshold model outperforms all others, as shown in Table 2. This improvement is non-trivial as it accounts for the best model in over $50 \%$ of vocabularies. This is maintained when we look across children as well-most children are best fit by the threshold model. The observed norm model does provide the best fit for $22 \%$ of the data suggesting that there is some predictive powers in the population level rate and time of acquisition. When we look across the population level models we see that over $70 \%$ of vocabularies are better fit by a conditional probability model than by a population level normed model. Critically, this suggests that there is some added information in conditional probabilities.

Table 2: Performance with cross-validation. Overall ability to account for the data as well as percent of vocabularies best fit by a given model. For comparison the model performance is directly compared to population models.

| Model | \% vocabs <br> best fit | \% better <br> normed | \% better <br> observed |
| :--- | :--- | :---: | :---: |
| Normed | 7.28 |  | 30.82 |
| Observed | 22.04 | 69.17 |  |
| Additive | 10.23 | 75.20 | 54.29 |
| Maximal | 10.31 | 25.63 | 17.67 |
| Threshold | $\mathbf{5 0 . 1 1}$ | $\mathbf{7 7 . 3 8}$ | $\mathbf{6 0 . 5 2}$ |

To show the extent of improvement offered by conditional probabilities, we consider the percent of vocabularies better fit by a given model and the CDI data. In Table 2, column 2 and 3, we see that most of the models perform much better than the normed model with roughly $75 \%$ of children being better fit under a given model than the published norms and further that many vocabularies are better fit when compared to the norms based on our particular population of toddlers in boulder. This suggests that the norms may be predictive for some children but that in general accounting for the words that are learned previously as well as the relationship of words that are learned together may help us predict what word a child will learn next. Further, the way we combine the type of joint information about word learning may influence our ability to capture vocabulary growth.

## Discussion

These results suggest that conditional probabilities do aid in accounting for word learning trajectories. That is, the words that a child already knows can help predict the words that they are going to learn in the future. This implies that there is some sort of systematicity in word learning and that it is not explainable by structure of the environment alone or by conceptual complexity but rather by the interaction of the structure of concepts and meaning within the knowledge of the individual child. The two models that are based on normed data can be seen as independent of individual variation. That is, for these models to perform well at predicting what words a child will learn next, children across a variety of settings and in a variety of learning
environments would be expected to learn words in similar proportion and at a similar rate. This could suggest that the input is structured in a systematic way or that the learning strategy is the same across all children and not dependent on the child's productive vocabulary at any point in time. We did see that these models in general can be fairly predictive of word learning and in fact the total likelihood of the data was minimized under the model that built norms from CDIs collected in our lab. This suggests that these models capture some important aspect of learning. However if we are interested in understanding the different styles of how children learn and capturing the variability across children, these models, inherently, cannot help us with these types of questions as they average out variability.

Looking more closely at the overall likelihood of the models, we see a strong trend that the population models are not as able to adapt to new data. When we fit the models on the full data (that is we included the test set in the training set) the observed CDI norms had a much better total likelihood. However, this model took a big hit in the crossvalidation method (results not shown in this paper) suggesting that the observed CDI norms may have overfit the data. The fact that conditional probability models performed better than the population level models in predicting unseen data suggests that the whole story is not in the input alone, but that there is an interaction between a child's productive vocabulary and what words the child will learn next. Even with very simple models of conditional probability we were able to increase our ability to predict and account for the ways vocabularies expand. Thus, if we were to refine our models to include other types of relationships (or more meaningful semantic relationships) between known words and words learned we might be able to understand how children take in their language environment and combine this with their individual vocabulary knowledge to learn new words. The work presented here only begins to look at this by testing models that combine the relationship of co-learned words in different ways, but refinement on these types of models could provide a way for us to uncover not just how children learn new words but also how they integrate a variety of information in order to develop representations of the world. For example, here we considered the median and as our cutoff in the threshold models, but in theory this could be a free parameter fit at the level of individual children (or at the population level conditioned on age) and could hold added information about how children interact with the learning environment. It is true that this threshold model has an additional variable but by setting this before looking at the data we have dealt with any issues in comparing this model to the other models. In the future we plan to do more extensive parameter fits as well as extend the basic models in complexity. For example, we would like to allow the number of maximal values included in our maximal model to be n instead of just 1 , where n is a free parameter itself.

The first model (the additive model) tested combined conditional probabilities by maintaining connections and
weights and summing up all of the conditional probabilities between the word candidate and all known words. This resulted in a model that was able to fit much of the data and often better than the population level models. But this was not the best fitting model suggesting that this model might have required too much information, accumulating a ratio that included significant noise in addition to the signal. A huge simplifying assumption that led to our next model was one that suggested that children would maintain only the strongest relationship between a word candidate and known words. This model performed poorly-returning a total likelihood significantly worse than the normed models and the closest to the null model. However, the children's vocabularies that were better fit by this model than the CDI norm models were vocabularies that were often best fit overall by this model. The best model is the model that forces a threshold on the conditional probability matrix. This suggests that strong connections may be the important ones and that the weight of the connection is not important just that it is present.

We do not only gain insight from looking at what models succeed but also what models failed and how. The CDI norming data had difficulty capturing individual vocabularies. It is important to note that in some way this model was handicapped from the beginning. None of the observed data was used in building up the norms. On the other hand, the frequencies noted in the norms were accrued over thousands of children, as opposed to our much smaller sample. Nonetheless, even when the other models were handicapped in the same fashion, the discrepancy in performance still exists. This highlights one of the major weaknesses in utilizing normed data in order to help predict future vocabulary progression. First, it fails to exploit the temporal dependencies available when using longitudinal data. Second, it fails to utilize the dependencies between subsets of words. Of course the poor performance of the norm baseline could be due to a variety of other reasons which would plague any attempt to characterize universals from individual data, and which pose problems to the traditional norming studies. For example, geographic changes between where the norms are collected and Boulder, CO, where our vocabularies were collected could produce variation thus restricting the generalizability of the norms. Or there could be cohort differences due to the fact that the world in which our current children are growing up has a different underlying structure in small but significant ways than the world of the children who contributed data to the norms 20 years ago. This suggests a need for us to consider other tools and methods in order to build up a robust and predictive measure of infant word learning.

## Conclusions and Further Directions

Altogether, our findings demonstrate that the conditional probabilities contain information that captures the relationship between the words known by a child at a specific time point and the words that child will learn next. Further, our results show that it matters how we integrate
these probabilities. For example, the maximal model is utilizing only minimal information from the conditional probability (the strongest conditional probability between known and candidate words only) and this model performs very poorly. This suggests that, even though conditional probabilities do contain useful information, not every use of it improves predictive power. The fact that the threshold model does best, suggests that understanding how to combine information can increase fit of the model and allow us to make more accurate future predictions. Interestingly, the model that integrated over the complete conditional probability matrix did not perform better than the model with less information. This result is not atypical for the world of child language acquisition and suggests that perhaps taking into account memory or other cognitive constraints may be useful, if not necessary, in capturing early learning (e.g. Phillips \& Pearl, 2012).

This work offers evidence that word learning is affected by a combination of forces and understanding these forces may allow us to predict words that a child would be likely to learn next. We would like to extend these results. Specifically we would like to more closely examine what types of relationships might exist and ways to measure them. If we understand the language environment where a child is learning as well as the way in which the child might be integrating this information with their current vocabulary we should be able to predict which words a child may learn next. This matters because this may allow us to capture children who have learning strategies leading to language difficulty or impairment. These types of models could let us diagnose such children earlier and may allow us to provide effective and child specific interventions.

Another potential direction is the development of tools and techniques that allow us to understand temporal dependencies at different time scales other than a month. Time series analysis combined with graph clustering on the semantics may allow us to expand this work from joint probability to a more complex probability space giving us better temporal resolution as well as more predictive models. Along those same lines, we may be able to finetune these models with cognitive theory (which are not included at all in these models, see Hills et al, 2009 for a paper that does consider this) to test generative and process motivated theories of word learning. This would allow us not only to build new computational tools but to refine and expound upon theories of word learning.

At the onset of this paper we asked whether it would be possible to predict the words a child will learn next from the words she knows now. Our findings, even with this simple set of models, suggest that the answer to that question is yes. Significantly, this opens up doors that have far-reaching implications. If we understand how children utilize their environment, conceptual understanding and semantic connectivity as they interact with the world and build up a vocabulary, we can design individualized teaching paradigms that may allow us to build upon, or compliment, what the child already knows aiding in language acquisition.

#### Abstract

We present a novel learning rule for learning transformations of sophisticated neural representations in a biologically plausible manner. We show that the rule, which uses only information available locally to a synapse in a spiking network, can learn to transmit and bind semantic pointers. Semantic pointers have previously been used to build Spaun, which is currently the world's largest functional brain model (Eliasmith et al., 2012). Two operations commonly performed by Spaun are semantic pointer binding and transmission. It has not yet been shown how the binding and transmission operations can be learned. The learning rule combines a previously proposed supervised learning rule and a novel spiking form of the BCM unsupervised learning rule. We show that spiking BCM increases sparsity of connection weights at the cost of increased signal transmission error. We also demonstrate that the combined learning rule can learn transformations as well as the supervised rule and the offline optimization used previously. We also demonstrate that the combined learning rule is more robust to changes in parameters and leads to better outcomes in higher dimensional spaces, which is critical for explaining cognitive performance on diverse tasks.

Keywords: synaptic plasticity; spiking neural networks; unsupervised learning; supervised learning; Semantic Pointer Architecture; Neural Engineering Framework.

In this paper, we demonstrate learning of cognitively relevant transformations of neural representations online and in a biologically plausible manner. We improve upon a technique previously presented in MacNeil and Eliasmith (2011) by combining their error-minimization learning rule with an unsupervised learning rule, making it more biologically plausible and robust.

There are three weaknesses with most previous attempts at combining supervised and unsupervised learning in artificial neural networks (e.g., Backpropagation [Rumelhart, Hinton, \& Williams, 1986], Self-Organizing Maps [Kohonen, 1982], Deep Belief Networks [Hinton, Osindero, \& Teh, 2006]). These approaches 1) have explicit offline training phases that are distinct from functional use of the network, 2) require many layers with some layers connected with supervised learning and others with unsupervised learning, and 3) use non-spiking neuron models. The approach proposed here

[^8]overcomes these limitations. Our approach 1) remains functional during online learning, 2) requires only two layers connected with simultaneous supervised and unsupervised learning, and 3) employs spiking neuron models to reproduce central features of biological learning, such as spike-timing dependent plasticity (STDP).

Online learning with spiking neuron models faces significant challenges due to the temporal dynamics of spiking neurons. Spike rates cannot be used directly, and must be estimated with causal filters, producing a noisy estimate. When the signal being estimated changes, there is some time lag before the spiking activity reflects the new signal, resulting in situations during online learning in which the inputs and desired outputs are out of sync. Our approach is robust to these sources of noise, while only depending on quantities that are locally available to a synapse.

Other techniques doing similar types of learning in spiking neural networks (e.g., SpikeProp [Bohte, Kok, \& Poutre, 2002], ReSuMe [Ponulak, 2006]) can learn only simple operations, such as learning to spike at a specific time. Others (e.g., SORN [Lazar, Pipa, \& Triesch, 2009], reservoir computing approaches [Paugam-Moisy, Martinez, \& Bengio, 2008]) can solve complex tasks like classification, but it is not clear how these approaches can be applied to a general cognitive system. The functions learned by our approach are complex and have already been combined into a general cognitive system called the Semantic Pointer Architecture (SPA). Previously, the SPA has been used to create Spaun, a brain model made up of 2.5 million neurons that can do eight diverse tasks (Eliasmith et al., 2012). Spaun accomplishes these tasks by transmitting and manipulating semantic pointers, which are compressed neural representations that carry surface semantic content, and can be decompressed to generate deep semantic content (Eliasmith, in press). Semantic pointers are composed to represent syntactic structure using a "binding" transformation, which compresses the information in two semantic pointers into a single semantic pointer. Such representations can be "collected" using superposition, and collections can participate in further bindings to generate deep structures. Spaun performs these transformations by using the Neural Engineering Framework (NEF; Eliasmith \& Anderson, 2003) to directly compute static connection weights between populations. We show that our approach can learn to transmit, bind, and classify semantic pointers.

## Theory

## Cognitive functions with spiking neurons

In order to characterize cognitive functions at the level of spiking neurons, we employ the methods of the Semantic Pointer Architecture (SPA), which was recently used to create the world's largest functional brain model (Spaun; Eliasmith et al., 2012), able to perform perceptual, motor, and cognitive functions. Cognitive functions in Spaun include working memory, reinforcement learning, syntactic generalization, and rule induction.

The SPA is implemented using the principles of the Neural Engineering Framework (NEF; Eliasmith \& Anderson, 2003), which defines methods to 1) represent vectors of numbers through the activity of populations of spiking neurons, 2) transform those representations through the synaptic connections between those populations, and 3) incorporate dynamics through connecting populations recurrently. In the case of learning, we exploit NEF representations in order to learn transformations analogous to those that can be found through the NEF's methods.

Representing semantic pointers in spiking neurons Representation in the NEF is similar to population coding, as proposed by Georgopoulos, Schwartz, and Kettner (1986), but extended to $n$-dimensional vector spaces. Each population of neurons represents a point in an $n$-dimensional vector space over time. Each neuron in that population is sensitive to a direction in the $n$-dimensional space, which we call the neuron's encoder. The activity of a neuron can be expressed as

$$
\begin{equation*}
a=G\left[\mathbf{\alpha e} \cdot \mathbf{x}+J_{b i a s}\right], \tag{1}
\end{equation*}
$$

where $G[\cdot]$ is the nonlinear neural activation function, $\alpha$ is a scaling factor (gain) associated with the neuron, $\mathbf{e}$ is the neuron's encoder, $\mathbf{x}$ is the vector to be encoded, and $J_{\text {bias }}$ is the background current of the cell.

The vector (i.e., semantic pointer) that a population represents can be estimated from the recent activity of the population. The decoded estimate, $\hat{\mathbf{x}}$, is the sum of the activity of each neuron, weighted by an $n$-dimensional decoder.

$$
\begin{equation*}
\hat{\mathbf{x}}(t)=\sum_{i} \mathbf{d}_{i} a_{i}(t) \tag{2}
\end{equation*}
$$

where $\mathbf{d}_{i}$ is the decoder and $a_{i}$ is the activity of neuron $i$.
Neural activity is interpreted as a filtered spike train; i.e.,

$$
\begin{equation*}
a_{i}(t)=\sum_{s} h\left(t-t_{s}\right)=\sum_{s} e^{-\left(t-t_{s}\right) / \tau_{P S C}} \tag{3}
\end{equation*}
$$

where $h(\cdot)$ is the exponential filter applied to each spike, and $s$ is the set of all spikes occurring before the current time $t$.

The decoders are found through a least-squares minimization of the difference between the decoded estimate and the actual encoded vector.

$$
\begin{equation*}
\mathbf{d}=\Upsilon^{-1} \Gamma \quad \Gamma_{i j}=\int a_{i} a_{j} d x \quad \Upsilon_{j}=\int a_{j} \mathbf{x} d x \tag{4}
\end{equation*}
$$

Transforming semantic pointers through connection weights The encoders and decoders used to represent semantic pointers also enable arbitrary transformations (i.e., mathematical functions) of encoded semantic pointers. If population A encodes pointer $X$, and we want to connect it to population B , encoding pointer $Y$, a feedforward connection with the following connection weights transmits that semantic pointer, such that $Y \approx X$.

$$
\begin{equation*}
\omega_{i j}=\alpha_{j} \mathbf{e}_{j} \mathbf{d}_{i} \tag{5}
\end{equation*}
$$

where $i$ indexes the presynaptic population A , and $j$ indexes the postsynaptic population B . Other linear transformations are implemented by multiplying $\mathbf{d}_{i}$ by a linear operator. Nonlinear transformations are implemented by solving for a new set of decoding weights. This is done by minimizing the difference between the decoded estimate of $f(\mathbf{x})$ and the actual $f(\mathbf{x})$, rather than just $\mathbf{x}$, in Equation (4).

## Supervised learning: PES rule

MacNeil and Eliasmith (2011) proposed a learning rule that minimizes the error minimized in Equation (4) online.

$$
\begin{align*}
\Delta \mathbf{d}_{i} & =\kappa \mathbf{E} a_{i} \\
\Delta \omega_{i j} & =\kappa \alpha_{j} \mathbf{e}_{j} \cdot \mathbf{E} a_{i} \tag{6}
\end{align*}
$$

where $\kappa$ is a scalar learning rate, $\mathbf{E}$ is a vector representing the error we wish to minimize, and other terms are as before.

When put in terms of connections weights $\left(\omega_{i j}\right)$, the rule resembles backpropagation. The quantity $\alpha_{j} \mathbf{e}_{j} \cdot \mathbf{E}$ is analogous to the local error term $\delta$ in backpropagation (Rumelhart et al., 1986); they are both a means of translating a global error signal to a local error signal that can be used to change an individual synaptic connection weight. The key difference between this rule and backpropagation is that the global-tolocal mapping is done by imposing the portion of the error vector space each neuron is sensitive to via its encoder. This limits flexibility, but removes the dependency on global information, making the rule biologically plausible. We will refer to Equation (6) as the Prescribed Error Sensitivity (PES) rule.

## Unsupervised learning: Spiking BCM rule

A Hebbian learning rule widely studied in the context of the vision system is the BCM rule (Bienenstock, Cooper, \& Munro, 1982). This rule has been used to explain orientation selectivity and ocular dominance (Bienenstock et al., 1982). Theoretically, it has been asserted that BCM is equivalent to triplet-based STDP learning rules (Pfister \& Gerstner, 2006).

The general form is

$$
\begin{equation*}
\Delta \omega_{i j}=a_{i} a_{j}\left(a_{j}-\theta\right) \tag{7}
\end{equation*}
$$

where $\theta$ is the modification threshold. When the postsynaptic activity, $a_{j}$, is greater than the modification threshold, the synapse will be potentiated; when the postsynaptic activity is less than the modification threshold, the synapse will be depressed.

The modification threshold reflects the expectation of a cell's activity. It is typically calculated as the temporal average of the cell's activity over a long time window (on the order of hours). The intuition behind BCM is that cells driven above their expectation must be playing an important role in a circuit, so their afferent synapses become potentiated. Cells driven less than normal have synapses depressed. If either of these effects persists long enough, the modification threshold changes to reflect the new expectation of the cell's activity.

However, BCM as originally formulated is based on nonspiking rate neurons. We implement BCM in biologically plausible spiking networks by interpreting neural activity as spikes that are filtered by a postsynaptic current curve.

$$
\begin{align*}
\Delta \omega_{i j} & =\kappa \alpha_{j} a_{i} a_{j}\left(a_{j}-\theta\right) \\
\theta(t) & =e^{-t / \tau} \theta(t-1)+\left(1-e^{-t / \tau} a_{j}(t)\right), \tag{8}
\end{align*}
$$

where $a$, the activity of a neuron, is interpreted as a filtered spike train, as in Equation (3), and $\tau$ is the time constant of the modification threshold's exponential filter.

With our spiking BCM implementation, we aim to test the claim that BCM is equivalent to triplet STDP rules. Functionally, we hypothesize that unsupervised learning will have a small detrimental effect on the function being computed by a weight matrix, but will result in weight sparsification.

## Simultaneous supervised and unsupervised learning: hPES rule

The PES rule gives us the ability to minimize some provided error signal, allowing a network to learn to compute a transformation online. However, biological synapses can change when no error signal is present. More practically, transformation learning may be easier in more sparse systems. For these reasons, we propose a new learning rule that combines the error-minimization abilities of the PES rule with the biological plausibility and sparsification of the spiking BCM rule. The rule is a weighted sum of the terms in each rule.

$$
\begin{equation*}
\Delta \omega_{i j}=\kappa \alpha_{j} a_{i}\left(S \mathbf{e}_{j} \cdot \mathbf{E}+(1-S) a_{j}\left(a_{j}-\theta\right)\right) \tag{9}
\end{equation*}
$$

where $0 \leq S \leq 1$ is the relative weighting of the supervised term over the unsupervised term. Note that this rule is a generalization of the previously discussed rules; if we set $S=1$, this rule is equivalent to PES, and if we set $S=0$, this rule is equivalent to spiking BCM.

We hypothesize that the unsupervised component helps maintain homeostasis while following the error gradient defined by the supervised component. Because of this, we call the rule the homeostatic Prescribed Error Sensitivity (hPES) rule. We hypothesize that this rule will be able to learn the same class of transformations that the PES rule can learn, and that this class includes operations critical to cognitive representation, such as semantic pointer binding.

Note that a similar combination can be done with other supervised learning rules that modify connection weights. A more general form of Equation (9) would replace the local error quantity $\mathbf{e}_{j} \cdot \mathbf{E}$ with $\delta$, which could be determined through
any method. However, for clarity, we will use hPES to refer to the specific form in Equation (9).

## Methods

We performed three experiments in order to test our hypotheses about the hPES rule. Experiments were implemented in the Nengo simulation environment, in which we implemented the PES, spiking BCM, and hPES learning rules. All experiments use leaky integrate-and-fire neurons with default parameters. The scripts used to implement and analyze these experiments are MIT licensed and available at http://github.com/tbekolay/cogsci2013.
Experiment 1: Unsupervised learning We constructed a network composed of two populations connected in a feedforward manner such that one population provides input to the other. The network can be run in a "control" regime, in which the weights between the two populations are solved for with the NEF's least-squares optimization and do not change, or in a "learning" regime, in which the weights are the same as the control network, but change over time according to the hPES rule (9) with $S=0$ (i.e., according to the spiking BCM rule [8]). This experiment tests the hypothesis that the unsupervised component of the hPES rule increases sparsity of the connection weight matrix.
Experiment 2: Supervised learning We constructed a network composed of two populations connected in a feedforward manner, and one population that provides an error signal to the downstream population. The network can be run in a "control" regime, in which the weights between the two populations are computed to transmit a three-dimensional semantic pointer, or to bind two three-dimensional semantic pointers into one three-dimensional pointer. The network can be run in a "learning" regime, in which the weights between the two populations are initially random and are modified over time by the hPES rule. This experiment tests the hypothesis that the hPES rule can learn to transmit and bind semantic pointers as well as the control network and the supervised learning rule (i.e., hPES with $S=1$ ).
Experiment 3: Digit classification In order to investigate how simultaneous supervised and unsupervised learning scales in higher dimensional situations, we constructed a network similar to that in Experiment 2, but whose input is handwritten digits.* In order to be computationally tractable, the 28-by-28 pixel images were compressed to a 50dimensional semantic pointer using a sparse deep belief network that consists of four feedforward Restricted Boltzmann Machines trained with a form of contrastive divergence (full details in Tang \& Eliasmith, 2010). Those 50-dimensional pointers were projected to an output population of 10 dimensions, where each dimension represents the confidence that the input representation should be classified into one of the 10 possible digits. The classified digit is the one corresponding

[^9]to the dimension with the highest activity over 30 ms when a 50 -dimensional input is presented. 60,000 labeled training examples were shown to the network while the hPES rule was active. The network was then tested with 10,000 training examples in which the label was not provided. The results are compared to an analogous control network, in which the 50-dimensional pointers are classified with a cleanup memory whose connection weights are static, as in Eliasmith et al. (2012). This experiment examines how well the hPES rule scales to high-dimensional spaces.
Learning parameters While there are many hundreds of parameters involved in each network simulation, the vast majority are randomly selected within a biologically plausible range without significantly affecting performance. Some parameters, especially those affecting the learning rule, can have a significant performance effect. These significant parameters and the values used in specific simulations are listed in Tables 1 and 2. These parameters were optimized with a tree of Parzens estimators approach, using the hyperopt package (Bergstra, Yamins, \& Cox, 2013).

Table 1: Parameters used for transmitting semantic pointers

| Parameter | Description | Value |
| :--- | :--- | :---: |
| $N / D$ | Neurons per dimension | 25 |
| $\kappa$ | Learning rate | $3.51 \times 10^{-3}$ |
| $S$ | Supervision ratio | 0.798 |
| $\kappa$ for $S=1$ | Learning rate (PES) | $2.03 \times 10^{-3}$ |

Table 2: Parameters used for binding and classifying SPs

| Parameter | Description | Value |
| :--- | :--- | :---: |
| $N / D$ | Neurons per dimension | 25 |
| $\kappa$ | Learning rate | $2.38 \times 10^{-3}$ |
| $S$ | Supervision ratio | 0.725 |
| $\kappa$ for $S=1$ | Learning rate (PES) | $1.46 \times 10^{-3}$ |

## Results

## hPES replicates STDP results

Previously, Pfister and Gerstner (2006) have theorized that BCM and STDP are equivalent. Our experiments support this theory. Varying the amount of time between presynaptic and postsynaptic spikes results in an STDP curve extremely similar to the classical Bi and Poo (2001) STDP curve (Figure 1).

However, these STDP curves do not capture the frequency dependence of STDP. In order to capture those effects, modellers have created STDP rules that take into account triplets and quadruplets of spikes, rather than just pre-post spike pairings (Pfister \& Gerstner, 2006). These rules are able to replicate the frequency dependence of the STDP protocol. Figure 2 shows that, despite being a much simpler rule, the hPES rule with $S=0$ also exhibits frequency dependence.

Figure 1: STDP curve replicated by two neurons connected with the hPES rule, $S=0$. Solid and dashed lines are best fits of the curve $a e^{-x / \tau}$ for the experimental and simulated data, respectively. Experimental data from Bi and Poo (2001).

## hPES encourages sparsity while increasing signal transmission error

When the hPES rule is applied to a network that has been optimized to implement semantic pointer transmission, the hPES rule with no supervision ( $S=0$ ) increases signal transmission error at a rate proportional to the learning rate. Figure 3 (top) shows the gradual decrease in accuracy over 200 seconds of simulation with an artificially large learning rate. Figure 3 (bottom) shows that the sparsity of the weight matrix, as measured by the Gini index, increases over time. Therefore, the hPES rule with $S=0$ increases network sparsity at the cost of an increase in signal transmission error.

## hPES can learn cognitive functions

The error in the learned networks relative to the mean of 10 control networks can be seen decreasing over time in Figure 4. The parameters used for Figure 4 are listed in Tables 1 and 2. The transformations are learned quickly (approximately 25 seconds for transmission, 45 seconds for binding). Therefore, the central binding and transmission operations of the SPA are learnable with the hPES rule.

Critically, while hPES without error sensitivity introduces error while increasing sparsity (see Figure 3), with error sensitivity, this error can be overcome. Interestingly, binding, the intuitively more complex operation, is more reliably learned than transmission. This is due to how effectively the NEF can optimize weights to perform linear transformations like transmission in the control networks.

As a proof of concept that the hPES rule scales to highdimensional spaces, Table 3 shows that the learned handwritten digit classification network classifies digits more accurately than Spaun's cleanup memory (Eliasmith et al., 2012).

Figure 2: STDP frequency dependence replicated by two neurons connected with the hPES rule, $S=0$. This also demonstrates the effect of different $\theta$ values on the frequency dependence curve. Experimental data from Kirkwood et al. (1996).

This supports the suggestion that the hPES rule scales to high-dimensional spaces. While the hPES rule with $S<1$ achieved higher classification accuracy than hPES with $S=1$, not enough trials were attempted to statistically confirm a benefit to combined unsupervised and supervised learning for classifying handwritten digits.

Table 3: Classification accuracy of handwritten digits

| Classification technique | Accuracy |
| :--- | :--- |
| Cleanup memory (Spaun) | $94 \%$ |
| hPES learning, $S=1$ | $96.31 \%$ |
| hPES learning | $98.47 \%$ |

## hPES is less sensitive to parameters

The parameters of the hPES rule were optimized with $S$ fixed at 1 for 50 simulations of binding and transmission. A separate parameter optimization that allowed $S$ to change was done for 50 simulations of binding and transmission.

Surprisingly, despite optimizing over an additional dimension, when $S$ was allowed to change, error rates were lower during the optimization process for the binding network but not the transmission network. In both cases, the interquartile range of the hPES rule's performance when $S$ was allowed to change is lower. Figure 5 summarizes the performance of all 200 networks generated for parameter optimization. While in all four cases parameters were found that achieve error rates close to the control networks, hPES was more robust to changes in parameters when $S$ was allowed to change. This suggests that unsupervised learning may be beneficial in high-dimensional nonlinear situations.

Figure 3: Data gathered from 50 trials of Experiment 1; filled region represents a bootstrapped $95 \%$ confidence interval. (Top) Accuracy of signal transmission. Accuracy is proportional to negative mean squared error, scaled such that accuracy of 1.0 denotes a signal identical to that transmitted by the NEF optimal weights with no learning, and accuracy of 0.0 represents no signal transmission (i.e., the error is equal to the signal). (Bottom) Sparsity of the connection weight matrix over time, as measured by the Gini index. This demonstrates the expected tradeoff between sparsity and accuracy.

## Discussion

In this paper, we have presented a novel learning rule for learning cognitively relevant transformations of neural representations in a biologically plausible manner. We have shown that the unsupervised component of the rule increases sparsity of connection weights at the cost of increased signal transmission error. We have also shown that the combined learning rule, hPES, can learn transformations as well as the supervised rule and the offline optimization done in the Neural Engineering Framework. We have demonstrated that the combined learning rule is more robust to changes in parameters when learning nonlinear transformations.

However, it is still the case that the parameters of the learning rule were optimized for each transformation learned. This is a challenge shared by all learning rules, but in the context of biologically plausible simulations, there is the additional question of the biological correlate of these parameters. It could be the case that these parameters are a result of the structure of the neuron, and therefore act as a fixed property of the neuron. However, it could also be the case that these parameters are related to the activity of the network, and are modified by each neuron's activity, or by the activity of some external performance monitoring signal. Examining these possibilities is the subject of future work.

Figure 4: Error of learning networks over time compared to the mean error of 10 control networks. Each type of network is generated and simulated 15 times. For the binding network, every 4 seconds, the learning rule is disabled and error is accumulated over 5 seconds. For the transmission network, every 0.5 seconds, the learning rule is disabled, and error is accumulated over 2 seconds. Filled regions are bootstrapped 95\% confidence intervals. Time is simulated time, not computation time.

#### Abstract

Fairness and efficiency are important aspects that influence cooperation in social dilemmas. During a repeated interaction, they have the potential to serve as competing goals for the decision maker. The ability to balance between fairness and efficiency depends, among other things, on available information regarding mutual accountability for the outcomes in an interaction. In this paper, we examine how information regarding mutual interdependencies influences the interplay between fairness and efficiency in repeated Chicken Game. We distinguish between three possible types of fair behavior: mutual cooperation, alternating cooperation, and mutual destruction. Our results show that the first two types of fairness are positively correlated with the availability of social information. In contrast, mutual destructive fairness is not sensitive to the availability of information and is generally avoided. We also find that without information regarding mutual interdependencies, unfairness increases in parallel with efficiency. When social information is available, however, increases in fairness is coupled with a decrease in efficiency, and the best compromise between fairness and efficiency is reached when mutual interdependencies are learned through repeated experiences. We highlight the significance of our results for fair and efficient interaction in repeated social interactions.

Keywords: Efficiency; Fairness; Cooperation; Game Theory; Interdependence; Information; Social Interaction

## Introduction and Background

In our daily lives, we constantly face situations in which our well-being and success depends on the actions of others. Whether the interactions occur between individuals or between organizations, there is mutual accountability for the outcomes. For example, the interaction between two toddlers that learn to share a toy by taking turns holds some similarities with the interaction between companies that adopt a competitive brinkmanship pricing policy while trying to gain control over a certain market. If the toddlers are not willing to behave in a fair manner they will both end up screaming and none of them will play with the desired toy. An alternative behavior is that both toddlers decide simultaneously to switch interest to other toys and thus eliminate the conflict. A more mutually beneficial behavior is where the toddlers will share the toy so one can play with
it for a while and then the other will have the joy of playing with the desired toy as well. However, if only one of the toddlers gets to play with the toy and the other does not get the same opportunity, feelings of unfairness and frustration that might lead to aggressive behavior when facing similar conflicts in the future can arise.

Such social conflicts are well captured in Game Theory using the Chicken Game (CG), as introduced by Russell (1959). According to this game, two drivers are heading towards each other on a single lane road from opposite directions at full speed. Just before colliding, each of the drivers has to choose simultaneously and independently between driving straight towards a possible collision (i.e., Dare) or turning the steering wheel (i.e., Swerve) and avoiding the accident. As represented in the game's payoff matrix (see Table 1), this is a prototypical dangerous game, because a player has to risk the lowest payoff [-10] to have a chance of winning the highest payoff [10]. Under reasonable assumptions for single-trial CG, the best outcome is for a player that Dares while the other player Swerves [10,-1]; the second-best for each is if both Swerve [1,1]; the third-best is for a player that Swerves while the other player Dares [$1,10]$; and the worst for each is if both Dare [-10,-10], because then the outcome is mutually destructive. Thus, the best strategy in single-trial CG depends on the opponent's expected behavior and a player can maximize the outcome by doing the opposite of what the other player does. However, for repeated CG (infinitely repeated in theory; finitely repeated with unknown endpoint in practice), successful alternations, where one player wins the highest payoff in one round and then the other player wins the highest payoff in the next round, is the best strategy to obtain a joint maximum outcome. This type of cooperation corresponds well to the situation where, over time, the wellbeing of one player depends of the well-being of the other.

The need to consider the well-being of the other challenges traditional economic theories, which assume that people act selfishly. In contrast, there is growing experimental evidence that actual behavior is also shaped by factors inconsistent with pure selfishness (e.g., Dufwenberg \& Kirchsteiger, 2004; Fehr \& Schmidt, 1999; Roth, 1995). The psychology literature also provides evidence for other
factors that individuals consider, beyond their own wellbeing, and acknowledges the importance of reciprocity by incorporating it into models of human behavior. Heider (1958) introduced the idea that causal inference, where one takes into account another person's motives and situational constraints, as an important cognitive process for perceiving social contexts. Similarly, Game Theory incorporates these ideas by considering altruism and fairness (Bolton \& Ockenfels, 2000; Fehr \& Schmidt, 1999). Altruism can be simply defined as an interaction in which people care not only about their own well-being but also about others. This over-simplified definition is extended through fairness into different directions by incorporating distributive concerns (Bolton \& Ockenfels, 2000), inequity aversion (Fehr \& Schmidt, 1999), and reciprocity theories (Rabin, 1993).

CG is particularly suitable to studying different aspects of fairness in social interaction. In its basic form, fairness is achieved when one player's outcome is identical to the other player's. Considering the payoff matrix presented in Table 1, fairness can happen when both players make the same decision in a given round. It is possible that both players selected Dare (i.e., mutual Dare) and therefore received an outcome of $[-10,-10]$, or when both players selected Swerve (i.e., mutual Swerve) and received the outcome of $[1,1]$. Repeated CG adds another kind of fair interaction where the players alternate for consecutive rounds, $[10,-1]$ followed by $[-1,10]$ and so on, resulting in alternating cooperation. This type of fairness is also the optimal strategy in repeated CG (the one that results in the highest long-term outcome). It is possible that fair coordination like [1, 1] would be easier to achieve than alternating coordination because the latter require a more complex coordination of choices. However, once a state of alternating coordination is achieved, it might be more stable compared to simple coordination (Rapoport, Guyer, \& Gordon, 1976).

One common but unrealistic assumption in research on strategic social interaction is that players possess full information about their interdependence, usually presented using a payoff matrix. However, several studies demonstrated the value of certain types of information in well-known social games, such as the repeated Prisoner's Dilemma (Camerer, 2003; Rapoport \& Chammah, 1965). Recently, Gonzalez and Martin (2011) proposed the Hierarchy of Social Information (HSI), a theoretical framework for conceptualizing and organizing the major categories of interpersonal information that may play a role in social interactions. Martin, Gonzalez, Juvina, and Lebiere (2012) used this framework to examine the effects of information on cooperation in repeated Prisoner's Dilemma. Their findings reveal a generally positive impact of information on joint performance and satisfaction. They showed that an increase in cooperation with an increase in the availability of social information was driven in part by players' greater willingness to reciprocate the other player's prior cooperation, and concluded that players possessing more interdependence information were more likely to enforce social norms of reward and retribution. Such social
norms depend heavily on perceptions of fairness and how it is expressed in repeated interaction. Furthermore, the availability of interdependence information can influence awareness of fair and unfair aspects of the interaction. Thus, it is possible to assume that having enough information to compare between one's own and another's payoffs might be a minimal requirement for fairness. However, it is currently unclear how more information systematically influences fairness, and more specifically the impact of different types of fairness that can occur as part of the interaction between two interdependent players. Furthermore, there is a need to understand the costs of maintaining fairness during a social interaction. Some social settings emphasize the tradeoff between fairness and performance. For example, in one-shot Ultimatum Game, a proposer maintains fairness and cooperation with a responder by decreasing her own personal gain. Other social settings completely disentangle such relationship between fairness and performance like in one-shot Dictator Game, where there is no need to maintain fairness and the proposer can keep all the gains for herself. Forsythe and colleagues (1994) demonstrated that on average offers in the Ultimatum game were higher than in the Dictator Game, confirming the tradeoff between efficiency of cooperation and fairness. However, people do care about fairness and in some situations are willing to sacrifice some of their own to maintain fairness (Bolton \& Ockenfels, 2000, Güth, Kliemt, \& Ockenfels). Thus, it is possible that a fair distribution of payoffs is appealing from a social perspective, but it might have some negative influence on performance in repeated interaction.

Table 1: Chicken game payoff matrix, with Action A denoting Dare and Action B denoting Swerve. The cells show a pair of outcomes $(x, y)$ where $x$ is the payoff to Player 1 and y is the payoff to Player 2.

|  | Player 2 Action |  |  |
| :--- | :---: | :---: | :---: |
|  |  | $\mathrm{A}($ Dare $)$ | B (Swerve) |
| Player 1 | A (Dare) | $-10,-10$ | $10,-1$ |
|  | Bction | B (Swerve) | $-1,10$ |

The current paper presents an experiment to examine how information regarding mutual interdependencies can influence fairness in CG. We start by providing background information on a repeated CG game that was used to collect the behavioral data, and present the four levels of information proposed in the HSI framework (Gonzalez \& Martin, 2011). Then, we distinguish between three types of fair outcomes in repeated CG and examine the interactions between fairness and the availability of social information. Following that, we focus on the relations between fairness and efficiency in alternating cooperation. Finally, we discuss how awareness of interdependence may encourage efficient and fair behavior in real-world interactions and describe potential future directions of this research.

## Experiment

## Participants and Procedure

Participants ( $\mathrm{N}=240 ; 120$ pairs, $45 \%$ of whom were women, $\mathrm{M}_{\text {age }}=22.8, \mathrm{SD}_{\text {age }}=4.53$ ) were recruited to a computer laboratory at Carnegie Mellon University, and randomly paired to play 200 rounds of repeated CG over the laboratory's network. Players were not told the number of rounds in the game, and the rounds were not numbered in the course of play. In each round, the two anonymous members of a pair (seated in different rooms without having met one another) chose simultaneously between buttons labeled Action A and Action B with payoffs as in Table 1. These payoffs were converted to incentive pay (one cent per point) beyond $\$ 10$ base pay. One pair was excluded from the analysis due to communication failure during the experiment.

## Information Conditions

All participants saw their own action and payoff in each round. Thirty pairs ( 60 participants) were assigned to each of the four conditions that determined the amount of information available about their interdependence. These conditions were modeled after the layers of the Hierarchy of Social Information (HSI) outlined by Gonzalez and Martin (2011). We briefly describe each of the information conditions here.

In the "Individual" condition, players were not informed that they were interacting with another player, so the selection of an action in each round was most likely perceived as an independent binary choice between two options with probabilistic payoffs. Participants may have realized that the outcome probabilities for each of the two actions were not static, as they in fact varied with the other player's actions, but this could more easily be attributed to a computerized process that shifted exogenously or in response to their own actions.

In the "Minimal" condition, players knew that their outcomes depended on the actions of another player and vice versa, yet they still did not know the other's specific actions and payoffs. With this information, individuals may have been able to speculate about the other's motivations, but it would remain difficult to infer the other's actions and payoffs.

Next, pairs in the "Experiential" condition saw each other's actions and outcomes in each round. This information allowed players to reason about the mutual interdependencies through repeated experiences.

Finally, in the "Descriptive" condition, in addition to seeing each other's actions and outcomes, players were shown the complete payoff matrix (as in Table 1) from the outset and throughout the repeated interaction.

## Results

We analyzed the three different fair outcomes described above: mutual Swerve, where both players receive a small
positive payoff of +1 with the risk of experiencing a moderate loss of -1 if the other player deviates from fairness; mutual Dare where both players lose 10 points with the potential of winning +10 if the other player deviates; and the alternating cooperation, which requires that both players successfully alternate between Swerve and Dare in a way that the payoffs in one round are $[+10,-1]$ and players then get $[-1,+10]$ in the following round.

## General Fairness Preferences

Overall, the joint proportion of fair interactions increased with more information given: .38 in the Individual condition, .50 in the Minimal condition, .71 in the Experiential condition, and .74 in the Descriptive condition. However, as illustrated in Figure 1, behavior varied for the different types of fairness. Next, we examine each of the fair interactions separately.

## Alternating Cooperation

The average proportion of alternating cooperation varied significantly across the four information conditions and generally increased with greater availability of information, $F(3,115)=7.086, p<.001$. As shown in
Figure 1, the average proportion of alternating cooperation in the Individual condition was extremely low ( $\mathrm{M}=.03$, $\mathrm{SD}=.05$ ). Knowing that the payoffs depend on the decisions of another human player provided in the Minimal condition ( $\mathrm{M}=.1, \mathrm{SD}=19$ ) increased the alternating cooperation significantly, $t(57)=2.106, p=.040$. The average proportion of alternating cooperation increased substantially more in the Experiential condition ( $\mathrm{M}=.29, \mathrm{SD}=.34$ ), where each player observed the actions and payoffs of the other player, and was significantly higher than the Individual and Minimal conditions, $t(58)=4.202, p<.001$ and $t(57)=2.575$, $p=.012$, respectively. Similarly, in the Descriptive condition ( $\mathrm{M}=.22, \mathrm{SD}=.28$ ) the average proportion was significantly higher than the Individual condition and marginally higher than the Minimal condition, $t(58)=3.765, p<.001$ and $t(57)=1.880, p=.065$, respectively. No significant differences were found between the Descriptive and Experiential conditions, $t(58)=.847, p=\mathrm{ns}$.

## Mutual Swerve

The average proportion of mutual Swerve varied significantly across the four information conditions, $F(3,115)=2.78, p=.044$. As shown in Figure 1, on average, the proportion of fair rounds where both players swerved increased with the availability of information: $\mathrm{M}=21$ ( $\mathrm{SD}=.23$ ) in the Individual condition, $\mathrm{M}=.21$ ( $\mathrm{SD}=.17$ ) in the Minimal condition, $\mathrm{M}=.27(\mathrm{SD}=.24)$ in the Experiential condition, and $\mathrm{M}=0.36$ ( $\mathrm{SD}=.27$ ) in the Descriptive condition. The average proportion of mutual Swerve in the Descriptive condition was significantly higher than in the Individual and Minimal conditions, $t(58)=2.341, p=.023$ and $t(57)=2.466, p=.017$, respectively. These results suggest that participants in the Descriptive condition tended to prefer the less risky option that could yield a small gain but also a
small loss compare to the risky option that could yield a large gain or a large loss. Also, the ability to see the interdependencies as they are represented by the payoff matrix highlights the fairness of mutual Swerve. Thus, it is possible that some synergy between these two interpretations of the social information can explain the increased proportion of mutual Swerve.

## Mutual Dare

When both players select Dare in the same round, they both receive the same negative payoff. As seen in Figure 1, the average proportion of mutual Dare was not affected by the availability of information, $F(3,115)=.37, p=\mathrm{ns}$. The average proportion of rounds where both players dared remained similar while the available information increased: $\mathrm{M}=.15$ ( $\mathrm{SD}=.08$ ) in the Individual condition, $\mathrm{M}=.18$ ( $\mathrm{SD}=.10$ ) in the Minimal condition, $\mathrm{M}=.15$ ( $\mathrm{SD}=.11$ ) in the Experiential condition, and $\mathrm{M}=.16(\mathrm{SD}=.21)$ in the Descriptive contrition. The SD in the Descriptive condition is relatively higher compared to the other conditions, mainly due to two pairs in the Descriptive condition who mutually dared in more than $80 \%$ of the 200 rounds.

Figure 1. Average proportion of fair outcomes for four levels of social information across 200 rounds.

## Efficiency and Fairness tradeoff in Alternating Cooperation

Rapoport et al. (1976) suggested the alternating cooperation index $(k)$ as a measure suitable for evaluating cooperation between two players in games where the optimal collective strategy is coordinated alternations. This measure uses the frequencies of the asymmetric payoffs in the following form: $\mathrm{k}=(\mathrm{DS})+(\mathrm{SD})-|(\mathrm{DS})-(\mathrm{SD})|$

Where DS and SD refer to the number of times that the asymmetric payoffs occurred. The maximal value of $k$ is achieved when DS and SD occur exclusively and with equal frequencies, which would correspond to perfect alternation.

Considering the setting of the study presented here, the maximal value of $k$ is 200 and it is achieved when $\mathrm{DS}=\mathrm{SD}=100$. The minimal value of $k$ is 0 and it represents a
game in which one player dominated the other player throughout the 200 rounds, resulting in $\mathrm{DS}=200$ or $\mathrm{SD}=200$.

The sum of DS and SD reflects the exclusiveness of the asymmetric payoffs compared to other possible payoffs. Thus, it represents the efficiency of the alternating cooperation. On the other hand, the absolute value of the difference between DS and SD reflects the balance or fairness between the two players and serves as a penalty for unfair behavior. The magnitude of the penalty determines whether one player dominated the other. For the sake of simplicity and clarity, we decompose $k$ to its terms (i.e., efficiency and unfairness penalty) and converted them to proportions by dividing each term by the number of rounds (i.e., 200). Furthermore, we use 1 - the proportion of unfairness penalty to calculate the proportion of fairness.

Similar to alternating cooperation, $k$ varied significantly across the information conditions. We observed a general increase of $k$ with more information: $\mathrm{M}=.25(\mathrm{SD}=.18)$ in the Individual condition, $\mathrm{M}=.32$ ( $\mathrm{SD}=.23$ ) in the Minimal condition, $\mathrm{M}=.46$ ( $\mathrm{SD}=.28$ ) in the Experiential condition, and $\mathrm{M}=.39$ ( $\mathrm{SD}=.28$ ) in the Descriptive condition.

To gain a better understanding of how the availability of social information influenced the alternating cooperation index ( $k$ ) and especially the relations between its efficiency and fairness components, we analyzed each of the terms that construct $k$ separately. As seen in Figure 2, fairness increased significantly with the availability of social information, $F(3,115)=12.778, p<.001$. The average fairness in the Descriptive condition ( $\mathrm{M}=.91, \mathrm{SD}=.11$ ) was significantly higher than the average fairness in the Individual ( $\mathrm{M}=.61, \mathrm{SD}=.26$ ) and Minimal ( $\mathrm{M}=.72, \mathrm{SD}=.28$ ) conditions, $t(58)=5.826, p<.001$ and $t(57)=3.601, p<.001$, respectively. Similarly, the average fairness in the Experiential condition ( $\mathrm{M}=.88, \mathrm{SD}=.18$ ) was significantly higher than in the Individual and Minimal conditions, $t(58)=4.817, p<.001$ and $t(57)=2.869, p=.005$.

As shown in Figure 2, the analysis of the efficiency term also indicated that efficiency varied significantly across the information conditions, $F(3,115)=3.030, p=.032$. However, we found an trend opposite of fairness, where efficiency in the Descriptive condition ( $\mathrm{M}=.48, \mathrm{SD}=.25$ ) was significantly lower compared to the Individual ( $\mathrm{M}=.64$, $\mathrm{SD}=.21$ ) and Minimal ( $\mathrm{M}=.61, \mathrm{SD}=.17$ ) conditions, $t(58)=-$ 2.756, $p=.008, t(57)=2.296, p=.025$.

The analysis above indicates that the availability of social information influenced the alternating cooperation index in general and differentially influenced the efficiency and fairness terms that compose it. It seems that the relatively high fairness in the Experiential and Descriptive came at the cost of decreased efficiency. However, the decrease in efficiency when moving from the Minimal condition to the Experiential condition is not significant, while the increase in fairness is. This suggests that best compromise between fairness and efficiency was reached in the Experiential condition.

Figure 2: Average proportion of efficient and fair alternating cooperation for four levels of social information across 200 rounds.

To gather a better understanding of the relations between fairness and efficiency, we analyze efficiency and fairness at the pair level, for each of the information conditions (see Figure 3). Results indicate that efficiency and fairness were strongly and negatively correlated in the Individual and Minimal conditions, $r=-.73, p<.001$ and $r=-.56, p=.002$, respectively, in contrast to the Experiential and Descriptive conditions, where no significant correlations were found, $r=.10, p=\mathrm{ns}$. and $r=-.02, p=\mathrm{ns}$. This finding suggests that as the efficiency of alternating cooperation increased in the Individual and Minimal conditions, fairness between the two players decreased. This means that one player dominated the other more often, resulting in an unfair and heedless behavior.

## Discussion and Conclusion

We tested how fairness is influenced by the availability of social information regarding mutual accountability in a social dilemma, as represented by the Chicken Game. Drawing upon Gonzalez and Martin's (2011) Hierarchy of Social Information, we find that fairness in such social dilemmas depended on the availability of information and in general increased when more information was available to the decision makers. Thus, information availability moderates unfairness and can increase fair social behaviors.

First, the overall high proportion of fair outcomes in the Descriptive and Experiential conditions implies that the availability of detailed information regarding interdependencies with others elicit fair behavior. This holds mainly for the two constructive interactions (mutual cooperation and alternating cooperation), which leads to positive outcomes for both sides of the conflict. On the other hand, when there is no awareness of the counterpart's conditions, unfairness increases on the expense of fairness. This results in an antisocial interaction where one exploits the other, even unintentionally and without being aware of

Figure 3: Correlations between proportions of efficiency and fairness in alternating cooperation for each pair, for four levels of social information, across 200 rounds.
the nature of the interaction.
Mutual destructive fairness stands out from the other two types of fairness as it was not influenced by the availability of information. Even without the knowledge of interdependence, players managed to avoid the mutually destructive escalation of the conflict which leads to negative outcomes for both sides. However, individuals possessing interdependence information were more likely to behave in a social manner and preferred other fair interactions. In contrast, individuals that did not possess such information were more likely to exhibit unfair and unsocial behavior where one exploits the other.

We also find that when only experiential information is available, the proportions of mutual cooperation and alternating cooperation are relatively similar. In contrast, when descriptive information is also provided, there is a greater preference towards the fair outcome resulting from mutual cooperation, compared to alternating cooperation. This might relate to the increased complexity of coordination that alternating cooperation requires, compared to mutual cooperation (Rapoport et al., 1976). Alternatively, it is possible that players concluded from the descriptive information (i.e., the payoff matrix) that there is a relatively low risk in choosing to Swerve compared to Dare and thus preferred this option more.

The alternating cooperation index ( $k$ ) provided us with important insights regarding the relations between fairness and efficiency within this type of interaction. Both fairness and efficiency were influenced by the availability of social information. While fairness increased with more information regarding mutual accountability, efficiency decreased. Moreover, increases in fairness between the information conditions were steeper and more drastic, compared with decreases in efficiency. This finding suggests that under certain conditions, increases in fairness
might have some cost, and lead to a minor decrease in the interaction's efficiency. This finding in repeated interaction is consistent with the tradeoff between efficiency and fairness in one-shot Ultimatum Game (Forsythe et al., 1994; Güth et al., 2003). However, it seems that for repeated interactions, fairness is more sensitive to the changes in the availability of social information compared to efficiency. The best compromise between fairness and efficiency was achieved when mutual interdependencies were learned only through repeated experiences. In this condition, fairness increased significantly while any decrease in efficiency was insignificant. This suggests that the availability of complete information, as in the Descriptive condition, do elicit fairness, but not necessarily the most efficient kind of fairness.

Examining the relations between fairness and efficiency at the pair level provided supporting evidence for these ideas. Where there is no or limited information regarding mutual accountability (i.e., the Individual and Minimal conditions), we find a decrease in fairness as the efficiency of a pair increases. This stands in contrast to the Experiential and Descriptive conditions, where we find no correlation between fairness and efficiency at the pair level. This demonstrates how overall the availability of information serves as a guard for fairness, and the efficiency of the interaction within the boundaries of fair behavior, depends on the specific interaction between individuals.

A key implication of this study is the importance of information to the fair resolution of conflicts. We show that social fairness is sensitive to the availability of information regarding mutual interdependencies between the members of the community. It is illuminating to see that the mere knowledge of interdependence with another person given in the Minimal condition is insufficient to promote alternating cooperation compared to the Individual condition. Further availability of social information increases cooperation and fairness. Thus, a preliminary requirement of fair conflict resolution should involve sharing information that sheds light on the interdependencies between the different entities involved in the conflict.

Even though it seems that overall fair behaviors in the Descriptive and Experiential conditions were somehow similar and less sensitive to the different way in which social information was conveyed, studies of individual decision making distinguish between these two sources of information (descriptive and experiential), and demonstrate how decisions from experience and description differ (e.g., Hertwig \& Erev, 2009). Recently, a similar distinction has been made in social dilemmas involving more than one decision maker (Martin et al., 2012). We believe that descriptive and experiential information influences the way fair behavior evolves over time. Thus, further analysis should carefully examine and compare the dynamics of fair interaction over time for different levels of social information.

# Beyond Rule versus Rote? Processing of Distinctive Dative and Genitive Case Markers in German 

Christian Bentz (cb696@cam.ac.uk)<br>Department of Theoretical and Applied Linguistics, Sidgwick Avenue<br>Cambridge, CB3 9DA UK

#### Abstract

The rule versus rote distinction is one of the most debated issues in recent psycholinguistics. Dual route accounts hold that words can either be stored whole in the mental lexicon or computationally derived by simple combinatorial rules such as stem+affix. Within this framework, response latencies in lexical decision tasks have been applied to point out the difference between rote memorization, on the one hand, and combinatorial rule manipulation, on the other. However, this paper argues that there may be alternatives to this distinction. It will be shown that German nouns, which can be distinctively marked for number, case or both number and case, do elicit differing reaction times. Crucially, this effect can neither be explained by surface frequency effects nor by internal morphological structure. Rather, it seems to be triggered by the degree of embedding into usage-based units.

Keywords: Rule versus rote; lexical decision; German case marking; usage-based units.

## Introduction

The rule versus rote distinction in psycholinguistic theories of lexical access has been fiercely debated (see Pinker \& Ullman, 2002 as well as McClelland \& Patterson, 2002 for a review). Lexical decision tasks (LDT), priming studies, event related potentials and fMRI studies (see Clahsen, 1999 for a review) have been applied to answer the question whether lexical processing of morphologically simplex and complex items is rule-governed or associative, or both. It has been argued that lexical decision latencies can help us to distinguish processes involving abstract rule manipulation from mere memorization effects (Pinker \& Ullman, 2002; Taft, 2004; Clahsen, 1999, Clahsen, Eisenbeiss \& Sonnenstuhl-Henning, 1997; Marslen-Wilson \& Tyler, 2007, Sonnenstuhl \& Huth, 2002). In this context, the absence of frequency effects for regularly derived forms has been explained by abstract rule manipulation, whereas the occurrence of frequency effects was associated with rote memorization of irregular forms (see for example Clahsen 1999: 998, but also Hahn \& Nakisa 2000 for critical remarks). If these assumptions hold, then processing difficulties in lexical decision tasks must stem from:
a) The low frequencies of test items (in the case of memorization);
b) The difficulty of parsing by means of grammatical rules applied to derive the internal structure of a morphologically complex word (symbol manipulation).

However, the study presented here suggests that the 'grammatical load' of inflections is another potential factor
relevant for processing difficulty, depending on word external rather than word internal factors. Along those lines, it will be argued that a usage-based account of lexical access can provide an alternative explanation of the processing difficulties reflected in lexical decision tasks.

To this end, a lexical decision experiments was designed which involved German words with $-(e) n$ and $-s$ plural marking, which can additionally encode dative and genitive case. It will be shown that forms with more grammatical load, i.e. forms encoding both case and plural meaning, elicited significantly longer response latencies than unmarked forms. Crucially, these prolonged latencies can neither be explained by token frequency effects nor by word-internal parsing, rather, the participants seemed to have invoked redundantly case marked articles or prepositional phrases triggering case marking. This way they could decide whether the case marked word is a possible word form in German. This strategy prolongs reaction times (RTs) for morphologically complex forms.

Therefore, this paper will argue that the distinction between rule governed processes and memorization effects in LDT research lacks an important aspect of language processing: the embedding of items in phrases and sentences, i.e. usage-based units. In the following, the case marking and plural paradigms of nouns in German will be sketched in section 1. In section 2 the methods and results of the LDT will be presented and discussed in section 3.

## 1. German Dative and Genitive Inflections

German has four distinct case marking paradigms: nominative, accusative, genitive and dative (Engel, 1991: 505; Griesbach, 1986: 294; Kempe \& MacWhinney 1998: 549). However, since there is a fair amount of syncretism between case markers and singular/plural markers across different noun classes, the only markers that are distinctive inflectional case markers ${ }^{l}$ are the -(e)s genitive marker for a subset of singular masculine and neuter nouns as well as the -(e)n dative marker in the plural for all genders (Griesbach, 1986: 294; Engel, 1991: 505). Hence, distinctively case marked forms are restricted to these $-(e) s$ and $-n$ inflections for some nouns.

For example, the high frequent noun Haus (house) is inflected as Häus-er (houses) for all plural forms except for the dative, for which Häus-er-n (houses.DAT) is the

[^10]grammatically correct form. Likewise, the singular form Haus is the same for all cases except for the genitive: Hauses (house's).

Now, with regards to the design of a lexical decision task, two groups of target words were distinguished: Words ending in $-n$ and words ending in $-s$ (N-Group and SGroup). Furthermore, these two groups were then split up according to the 'grammatical load' of the suffixes, which renders three subgroups each (N1, N2-PL, N3-PL-DAT, S1, S2-SG-GEN, S3-PL-GEN) as depicted in table 1.

Table 1: Dative and genitive groups with grammatical load indicated by colors.

|  | Grammatical load | Example |
| :---: | :--- | :---: |
| Group N1 | -n part of stem (low) | Zah $\underline{n}$ <br> (tooth) |
| Group N2- <br> PL | -n denoting plural for all <br> cases (medium) | Rabe- $\underline{n}$ <br> (ravens) |
| Group N3- <br> PL-DAT | -n as distinctive dative <br> plural marker (high) | Stiefel- $\underline{n}$ <br> (boots.DAT) |
| Group S1 | -s part of stem (low) | Gleis <br> (platform/track) |
| Group S2- | -s as genitive singular <br> marker (medium) | Pferde- $\underline{s}$ <br> (horse's) |
| SG-GEN |  |  |
| Group S3- | -s as genitive singular and <br> PL-GEN <br> plural marker for all cases <br> (high) | Zoos, zoo's) |

*Umlaut was avoided, except for Ästen (branches)

As can be seen in Table 1, the groups are put together according to different functions of the final $-n$ and $-s$. They might not have any grammatical function (groups N1 and S1), they can have one specific function, namely denoting the plural (group N2-PL) or the genitive singular (S2-SGGEN), or they can represent two different grammatical functions - both plural and case marking - as in groups N3-PL-DAT and S3-PL-GEN.

In order to also control for potential frequency effects, the WEBCELEX ${ }^{2}$ database was used to select 20 target words for each of the 6 groups. These 120 target words were matched for surface frequency (ranging from 20-1 per $\sim 5$ million) and length in letters (ranging from 3-10 letters per word). Additionally, data on other frequency measures such as stem frequency, type frequency, family size and family frequency ${ }^{3}$ was also included.

[^11]
## 3. Lexical Decision Experiment

### 3.1 Methods

Participants. A lexical decision task was performed with 26 participants volunteering to participate in the study, all of them native speakers of German with a mean age of $\sim 27$ (14 females, 12 males).

Materials. The aforementioned 120 target words - split up into 6 groups (N1-S3) - were selected from the WEBCELEX database and matched for surface frequency and length in letters within groups. Additionally, 120 random filler words were selected from WEBCELEX, as well as 240 non-words of which 120 were produced by manually changing two or three letters of the stem (of other words in WEBCELEX), and 120 by changing potential affixes. This way, subjects were prevented from relying solely on recognition of stems for their lexical decision. All non-words adhered to the phonotactic rules of German. All filler words and non-words were chosen to reduce possible priming effects with regards to the target words. Overall the number of words and non-words added up to 480 items.

Items were presented by using the SuperLab 4.5.2 stimulus presentation software (Abboud, Heller, Matsak, Schultz \& Zeitlin, 2011). To present the stimuli, the item list was split up into three blocks with 160 items each, which all contained roughly the same ratio of target words, filler words and non-words. Items were presented as black Tahoma letters in font size 20 against a light turquoise background. They were preceded by a black fixation point in the center of the screen for 500 ms before stimulus onset. There was no time limit for responses. Participants responded to stimuli by using a Cedrus response pad (model RB-730) with green and red buttons for word and non-word decisions.

For statistical analyses and data plotting the software $R(\mathrm{R}$ Development Core Team, 2012) was used. Additionally, the software packages lme4 (Bates \& Maechler, 2010) and languageR (Baayen, 2010; cf. Baayen, 2008) as well as ggplot2 (Wickham \& Chang, 2012) were used to construct linear mixed-effects models and for plotting.

Procedure. In the instructions participants were told to decide as quickly and accurately as possible whether the
been shown to play a role in reaction time experiments (Nagy, Anderson, Schommer, Scott \& Stallman, 1989; Alegre \& Gordon, 1999). Moreover, the family size of a word is the stem frequency + the number of derived words (e.g. health/health-y) and the number of compounds (e.g. table/tablecloth) (Schreuder \& Baayen, 1997; Bertram, Baayen \& Schreuder, 2000). Finally, the family frequency of a word is the sum of frequencies of all the forms belonging to the same morphological family.

Besides this class of token frequencies, which are used to predict RTs for lexical entries and lemmas of words, there is the concept of type frequencies, too, which captures the number of different words inflected with a particular marker (e.g. the number of verbs which are inflected with regular -ed versus the number of irregular verbs) (Bybee, 2007; Marcus, Brinkmann, Clahsen, Wiese \& Pinker, 1995: 212).
presented items are German words or not. They were explicitly told that forms with plural and case inflections can be part of the stimulus set. Then they were presented with a test trial containing 8 words and 8 non-words. Both dative and genitive marked words were represented in this set of test items. In the test trial items remained on the screen until the participant had pressed the correct button. The instructor remained in the room during the test trail and participants were able to ask questions. After that the instructor left the room and participants were presented with the three blocks of 160 items each (with one minute pauses in between). The testing took 15-20 minutes.

After finishing the main experiment, participants were presented with a questionnaire to clarify 1) whether they had guessed what the exact purpose of the experiment is; 2) whether they had issues with specific items; 3) whether they had used any specific strategy to decide on words with dative and genitive marking. Participants could use the keyboard to type their answers, but they were also told that they can just type "no" if they did not want to answer the questions.

### 3.2 Results

A pre-analysis of the data revealed that 4 participants had to be excluded from the dataset because they had guessed the purpose of the experiment. Also, three of the items ${ }^{4}$ were excluded because their per item error rate exceeded $50 \%$. The error rates per subject ranged from $1.6 \%$ to $21 \%$. No further subjects were excluded. This left 22 subjects and 117 items to be analyzed. Furthermore, RTs were cleaned by excluding all RTs of less than 300 ms for reasons of lower processing bounds (Baayen, 2008: 243). Also, all RTs longer than 3000 ms were excluded because both inspection of quantile-quantile plots (Baayen, 2008: 243) as well as considering 2-3 standard deviations from the overall mean (mean: 959 ms ; SD: 934 ms ) as a cut-off point suggested that 3000 ms are a realistic upper bound for RTs. Moreover, for the analysis of reaction times all incorrect responses were excluded from the sample. These cleaning procedures caused an additional data loss of $\sim 8 \%$.

In the following, the RTs for the N -Groups and S-Groups are analyzed separately. Plotting the subgroups and logarithmically transformed RTs for each group reveals that there are differences in mean reaction times (see figure 1a and $1 b$ ).

In order to check the significance of these results linear mixed-effects models (Baayen, 2008.; Baayen, Davidson \& Bates, 2008; Barr, Levy, Scheepers and Tily, 2013) with RTs (logarithmically transformed) as dependent variable and group as predictor variable (fixed effect) as well as subjects and items as crossed random effects were used. In accordance with Barr et al. (2013) random intercepts for subjects and items as well as random slopes for subjects were included. P-values are based on likelihood ratio tests

[^12]for comparisons of the original models with null models (no fixed effects).

Figure 1: Boxplots for $\log (\mathrm{RTs})$, inflectional categories (x-axes), and grammatical load indicated by color.

Model validation was performed by checking homoscedasticity and normality for plots of residuals versus fitted values.

These models reveal that subgroup membership for both dative (N1, N2-PL, N3-PL-DAT) and genitive (S1, S2-SGGEN, S3-PL-GEN) is a significant predictor of RT (dative: $\chi^{2}(2)=8.6, p=0.01$; genitive: $\left.\chi^{2}(2)=13.12, p=0.001\right)$, longer RTs being associated with subgroups of higher grammatical load.

Now, in order to contrast these results with the predictive power of frequency effects on RTs, two more mixed-effects models were designed. This time surface frequency, stem
frequency and family frequency ${ }^{5}$ were added as fixed effects besides group, again with random intercepts for subjects and items and random slopes for groups by subjects. The likelihood ratio tests for the full models versus the null models (without the frequency measures but with group as predictor) rendered a non-significant result for both the dative data $\left(\chi^{2}(3)=4.19, p=0.24\right)$ and the genitive data $\left(\chi^{2}(3)=2.72, \mathrm{p}=0.43\right)$. This suggests that adding different token frequencies as predictors does not render a better model. Note that these results are not affected by potential multicollinearity effects, since the variance inflation factor (VIF) was < 2 for all predictors in both models.

Finally, it should be noted that all the linear mixed-effects models presented in this section are more or less "stressed" for longer response latencies. This follows logically from the fact that RT distributions are somewhat skewed, exhibiting longer right tails. However, as will be argued in the following section, it is exactly the occurrence of nonnormally prolonged response latencies that is interesting for the overall interpretation of the data.

## 4. Discussion

The results reported for the lexical decision task suggest that there are systematic differences between nouns for which the $-n$ and $-s$ suffixes are grammatically meaningless (N1 and S1 subgroups in table 1) and nouns which are grammatically highly loaded (N3-PL-DAT, S3-PL-GEN). Moreover, subgroups which are inflected for plural or case only (subgroups S2-SG-GEN and N2-PL) lie somewhere in between the unmarked nouns and the heavily marked nouns in terms of reaction times. Interestingly, the observed patterns of reaction times per subgroup are not predicted by measures of token frequency. Token frequencies could not be shown to be significant predictors of RTs in post-hoc regression analyses.

However, it is important to be aware of the fact that type frequencies are tied with subgroups N1-S3 since they reflect the 'inflectional status' of a word, which is in turn the grouping factor for further divisions of the N -Group and S Group. For example, all the words in N1 have a type frequency of $15926 / 35315$ ( $45 \%$ of all the nouns in WEBCELEX), whereas all the words in N3 have a type frequency of $3140 / 35315$ (8.9\%). Likewise, all the nouns in N 1 share the inflectional status of being unmarked for case or plural and all the nouns in N3 share the inflectional status of being marked for plural and case. These were basically the search criteria for finding appropriate nouns in WEBCELEX. Hence, type frequency and subgroup membership are two sides of the same coin.

At this point the question arises what actually causes the longer response latencies. According to dual route accounts there are two possible explanations: a) Differences in token frequencies have an impact via the direct lexical access

[^13]route - this has been ruled out by controlling for surface frequency in the experiment and by including other measures of token frequencies in a post-hoc multiple regression model; or b) The differences in RTs stem from parsing difficulty for complex morphological structures within the words (see parsing example in figure 2 ).

Figure 2: Potential word internal structure for the morphologically complex noun Häusern (houses.DAT) with both plural and dative marking.

However, according to this rationale we would not expect the groups N2-PL and N3-PL-DAT as well as S2-SG-GEN and S3-PL-GEN to exhibit differing reaction times. This is because we chose words that do inflect for both number and case by simply adding either -n or -s (see table 1). Hence the word internal parsing difficulty and the decision latencies should be the same for all these groups. However, the RTs actually differ most between these groups.

This requires an alternative explanation: A third possibility is that the differences in RTs are due to the additional grammatical and conceptual load that these suffixes carry. This means, rather than analyzing structures within the word, it would be more interesting to analyze the context these words are typically embedded in. See, for example, a typical sentence involving the noun Häusern in German (figure 3).

This figure illustrates the grammatical relationships between the word internal and word external structure. The dative marking is triggered by a preposition hinter (behind) (i.e. lexical case). Moreover, the plural form needs to agree with the DAT.PL of the article die.SG, i.e. den.DAT.PL. Hence the word Häusern is embedded into a construction that involves a preposition and a case marked article. We could think of more such examples with other prepositions (e.g. auf (on top of), in (in), mit (with)).

"The wood behind the houses"
Figure 3: Grammatical relationships between elements of a sentence involving dative marking.

Crucially, note that the type frequency of this dative plural marker, i.e. the range of words it is applied to, hinges upon the productivity of such prepositional constructions (plus the productivity of dative forms in other contexts). This would suggest that increased processing difficulty in the LDT for grammatically loaded words stems from the strength of embedding into common or uncommon constructions.

Of course, there needs to be further research with and beyond LDTs to further elaborate this hypothesis. However, first hints suggesting that this explanation is along the right lines can be found in the questionnaire.

### 4.1 Questionnaire

When the first participant came across the German word Messers (knife's) in the trial set, he kept pressing the 'nonword' button several times, although this is a grammatically correct form and the item kept occurring on the screen. When the instructor noted that this is a genitive form of the word Messer, the participant said: "... auf Messers Schneide!" A German idiom directly translated as: "on knife's blade", meaning: "to be on a knife-edge".

Evaluating the post-test questionnaire revealed that this spontaneous associative reaction might not have been a single coincidence. When asked (question 2) whether they had particular problems with specific items, 10 ( $45 \%$ ) of the participants answered "no", 6 (27\%) of the participants had problems with either dative, genitive or plural forms, and the rest ( $28 \%$ ) named non-words and potential foreign words as problematic. Most intriguingly, when subjects were more specifically asked (question 3 ) whether they had problems with case marked words (by giving them some examples of the target set) 13 ( $52 \%$ ) answered with "no", 6 ( $24 \%$ ) had imagined the correct articles to take a decision, and $5(20 \%)$ had even used phrases like "die Spitze des Doms" (the cathedral's spire) or prepositional phrases "wegen des Kochs" (because of the cook) to take their decision.

To test whether the strategies named here might have prolonged reaction times, participants were post-hoc divided into two groups: one group (no-context group) for subjects that had negatively answered questions 2 and 3 (or who had named other difficulties like non-words and foreign words), and another group for subjects that had answered affirmative and noted that they used context related strategies to take lexical decisions (context group). Interestingly, for these two groups the mean RTs for S3 and N3 taken together differ: For the context group the mean RTs for words in S3 and N3 is higher ( 956 ms ) than for the non-context group ( 939 ms ), although this difference is not significant ( $\mathrm{p}=0.33$ ).

However, the fact that 12 (55\%) of the participants either had problems with dative and genitive markers or used "minimal phrases" as disambiguation strategy suggests that this is at least partly the reason for prolonged response latencies. Note that the rest of the participants (10, 45\%) did not necessarily use some other strategy or no strategy at all.

Rather, participants could just type "no" if they did not want to bother with the questionnaire in the first place. Overall, the insights from the questionnaire suggest that there are systematic reasons for prolonged response latencies, namely, whether forms are more or less embedded into usage-based units.

## 5. Conclusion

In the past, lexical decision tasks have been invoked to find out whether certain lexical items are processed as a whole or decomposed into stem+affix. In this context, it has been argued that for units stored whole in the lexicon there should be surface frequency or other token-related frequency effects observable, whereas for morphologically complex and regular items symbolic rules will be applied. These are not sensitive to frequency effects (Marcus et al., 1995; Clahsen, 1999; Pinker \& Ullman, 2002). However, the results reported in this paper suggest an alternative to this binary distinction.

First of all, it has been shown that token frequencies are not a significant predictor when it comes to morphologically complex nouns in German, whereas grammatical load and type frequencies do still correctly predict longer reaction times for these forms. Thus, instead of trying to explain response latencies by analyzing morphological structures within the lexical items, this study suggests that the relevant factor is the embedding of these items in more or less frequent phrases. This is in line with accounts arguing that statistical learning and frequency effects are not only relevant for "lexical entries" but also for whole constructions (Ellis \& O'Donnell, 2012).

In conclusion, there are measurable processing differences between grammatically marked and unmarked nouns in German. Hence, it is correct, on principal, to distinguish between words that are perceived as "basic" or "default" and words which are perceived as grammatically complex. However, this does not necessarily entail that such morphologically complex forms are composed out of simpler units by means of symbolic rule manipulation. Rather, such forms carrying more 'grammatical load' are more likely to be associated with whole phrases and sentences even in isolation. And this embedding in redundant and disambiguating structures is what makes them belong to the grammatical rather than the lexical domain in the first place.

# Social and Environmental Contributors to Infant Word Learning 

Elika Bergelson (elikab@psych.upenn.edu)<br>Department of Psychology, 3401 Walnut St, 400a<br>Philadelphia, PA 19104 USA<br>Daniel Swingley (swingley@psych.upenn.edu)<br>Department of Psychology, 3401 Walnut St, 400a<br>Philadelphia, PA 19104 USA

#### Abstract

Infants demonstrate comprehension of early nouns (e.g. "hand") around six months, and comprehension of early non-nouns (e.g. "eat") around 10 months. In two experiments, we explore the reasons for this lag. Expt. 1 is a gaze-following study, the results of which suggest an improvement in point-following around ten months, and reveal correlations between pointing and both overall and non-noun vocabulary. Expt. 2 is a set of corpus analyses, the results of which suggest that word frequency does not explain the difference between noun and non-noun age of acquisition, while suggesting that the co-presence of words and their referents may play an important role. The results of these experiments contribute to our understanding of word-learning across word classes, and lend support to environmental and social factors as having an impact on the trajectory of word learning in the first year of life.

Keywords: language acquisition; word learning; cognitive development; infancy; psycholinguistics; corpus analysis

## Introduction

Infants learn words by taking in the environment around them and, over time, creating links between bits of language and bits of the world, with abstraction at both ends. Not all words are learned with equal ease, a phenomenon having the potential to help explain how word learning works. Diary studies and databases of parental checklists show that infants' early comprehension and production vocabularies, while quite broad, numerically favor nominals over action words, modifiers, and social expressions (Benedict, 1979; Dale \& Fenson, 1996).

These findings agree with comprehension studies in which infants who were asked to look at referents of nouns like "apple" and "hand" succeeded by 6 months of age (Bergelson \& Swingley, 2012a; Tincoff \& Jusczyk, 1999, 2012), but did not reliably show understanding of non-nouns like 'uh-oh' and 'eat' until around 10 months of age (Bergelson \& Swingley, 2013; See table 1).

The reasons for this developmental lag could rest within the child, within the nature of the linguistic elements, or within the environment. Here, we examine several broad hypotheses about the source of this lag, which we consider in light of new behavioral research (Expt.1) and corpus analyses (Expt. 2). These hypotheses are not new,
and have been the focus of a great deal of research, primarily among children older than the infants we consider here. Studies show that each of the factors we examine is very likely to be important at some point in development. What we begin to address here is the extent to which they might explain the developmental course we have found in infants' word understanding.

## Frequency

The Frequency hypothesis maintains that nouns are more frequent than non-nouns in infants' early experience, and that this leads to their being learned earlier, once a sufficient mass of exposure has occurred. Frequency may aid learning because learning is incremental over exposures, or because with more tokens the likelihood of a very useful exposure instance increases (Medina, Snedeker, Trueswell, \& Gleitman, 2011).

This hypothesis has several forms. The simplest is that infants just hear the non-nouns less often than the nouns. A more specific hypothesis is that infants hear nouns in isolation (in one-word utterances) more often than nonnouns, which might lead to earlier learning of nouns (Brent \& Siskind, 2001). We can evaluate whether frequency differences might explain infants' relatively late learning of non-nouns by measuring whether there are corpus frequency differences between the tested nouns and non-nouns.

## Environment

The Environment hypothesis we consider here maintains that nouns and non-nouns differ in the degree to which the contexts of their typical use support learning, where "support" refers to environmental conditions that prior research suggests are relevant to word learning. For example, non-nouns may appear in a broader number of situation-settings (e.g. playing, eating) than nouns, or may involve different amounts of attention-getting movement. Parents' use of nouns may go along with tactile support or clear signs of visual attention. Nouns may be used more often while the referent is present than is the case for nonnouns. All of these features are reasonable candidates as factors that support word learning (e.g., Kersten \& Smith, 2003; Meyer, Hard, Brand, McGarvey, \& Baldwin, 2011; Tomasello \& Kruger, 1992).

## Social Skill

The Social Skill hypothesis maintains that between six and ten months infants gain skills of social cognition that underlie the capacity for learning more abstract wordsskills that might not be criterial for learning nouns but which, by hypothesis, may be imperative for learning non-nouns. Existing research points to important changes in social-cognitive skills in the second half of the first year. For example, gaze-following improves substantially over this period, and may facilitate word learning (Morales, Mundy, \& Rojas, 1998). Evidence of increasing social skills around $9-10$ months indirectly supports the possibility that a social skill that was not necessary for learning nouns may be necessary for learning non-nouns. Prior experiments testing gaze-following showed that $10-$ and 11-month-olds but not 9-month-olds were more likely to follow the gazer's regard when his eyes were open than when they were closed, and that this skill correlated with language scores at 18 months (Brooks \& Meltzoff, 2005; Brooks \& Meltzoff, 2008).

## Conceptual Difficulty

The Conceptual hypothesis proposes that non-nouns are harder to learn because of the nature of the concepts and categories involved. Instances of a word like 'uh-oh' vary more and thus may be harder to recognize as having a common semantic core than instances of 'hand'. This hypothesis can be expressed as stemming from higherlevel differences in the kinds of linguistic roles played by nouns in contrast with adjectives, exclamations, verbs, and social greetings. It can also be thought of as a lowlevel difference in what 'features' must be summed over: in the noun case, visual features such as shape, size, and color, in the case of e.g., banana, which may be easily graspable from the environment, while non-nouns require more abstract (perhaps second-order) features that are harder to posit or grasp. A related hypothesis concerns biases in word-learning; it could be the case that in the absence of further evidence, infants choose to posit that a new content word they have isolated from the speech stream refers to a noun before they consider that it may refer to another part of speech.

## Overview of the Present Research

The hypotheses laid out above overlap; for example, conceptual difficulty might cause a need for social skills in learning non-nouns. Still, evidence can be brought to bear that favors or disfavors these hypotheses. Our two concrete research questions are:

1) Do we find evidence that gaze- and/or pointfollowing correlate with early word comprehension in laboratory tasks and/or vocabulary checklists?
2) Are there frequency-based or environmental differences between nouns and non-nouns when examining naturalistic interactions between infants and their caregivers?

In Expt. 1 we tested 6-14 month olds ( $\mathrm{n}=37$ ) in a gazefollowing task. Parents also completed vocabulary checklists (MCDI, Dale \& Fenson, 1996). Most of these subjects ( $\mathrm{n}=25$ ) also participated in a noun comprehension eyetracking study on the same day. The goal of this experiment was to look for specific mappings between social behaviors and word understanding. To date we have tested individual infants on nouns and on gaze following, with the intent to examine non-nouns and gaze following as well; this study speaks to the Social Skill Hypothesis.

In Expt. 2 we investigated how nouns and non-nouns appear in infants' environment, through analyses of audio and video corpora of infants interacting with their caregivers, with the goal of gaining a better understanding of whether the environment of these two types of words differs in relevant ways. If frequency and environmental factors affect noun and non-noun learning differentially, we expect to find differences in these measures across the word types in the corpus. This study speaks to the Frequency and Environment hypotheses.

In both studies we used a set of nouns and non-nouns tested in previous eyetracking studies (Bergelson \& Swingley, 2012a, 2013). See Table 1.

For both sets of items a corpus of 16 mothers speaking to their infants (Brent \& Siskind, 2001), and a database of vocabulary checklists (MCDI, Fenson et al., 1994) were used to select a pool of items that were used often by most mothers and reportedly understood by a large percentage of 12-18 m.o. infants. Items were then selected among candidates based on imageability, and phonological properties.

The nouns are all foods and body parts, as the authors had a secondary interest in these abstract categories as such. , Given that infants early vocabularies are indeed a smorgasbord of different parts of speech (Benedict, 1979), and that is it not always easy to determine that the word class an item belongs to for a young infant corresponds to its word class in adults' vocabulary, the non-nouns were simply the most common imageable words heard by infants that were not concrete objects

| Non- | all gone, bye, dance, drink, eat, hi, hug, kiss, <br> Nouns <br> more, sleeping, smile, splash, uh-oh,wet, |
| :--- | :--- |
| Nouns | apple, banana, bottle, cookie, ear, eye/s, face, <br> foot/feet, hair, hand/hands, leg/s, milk, mouth, <br> nose, spoon, yogurt |

Table 1: Previously Tested Nouns and Non-Nouns

## Experiment 1

## Methods

## Participants

The gaze-following study tested 37 infants ( $\mathrm{R}=6.0$ 14.9 mo., $\mathrm{M}=9.8 \mathrm{mo}$.), of which 25 infants also participated in a word-comprehension study just prior to the gaze-following study ( $\mathrm{R}=6.6-12.8 \mathrm{mo}$., $\mathrm{M}=9.2 \mathrm{mo}$.).

All participants were healthy, typically-developing monolingual English-exposed full-term infants with normal hearing and vision, recruited in the Philadelphia area. 8 additional infants were excluded from the gazefollowing study (technical error, $\mathrm{n}=5$; fussiness, $\mathrm{n}=1$; parental interference $n=1$, premature birth status $n=1$ ); 10 additional infants were excluded from the wordcomprehension study (technical error, $\mathrm{n}=6$; fussiness, $\mathrm{n}=2$; parental interference $\mathrm{n}=1$, premature birth status $\mathrm{n}=1$ ).

## Design

All parents first completed consent, background, and vocabulary checklist forms. Infants sat on their parent's lap and watched short video clips on a computer outfitted with a remote eyetracker (Eyelink, SR Research). Parents wore a visor to block their view of the screen, but not of their child. Infants wore a small sticker on their forehead to facilitate tracking. After calibration, infants saw a series of 16 test trials. In each test video, infants saw an actress with two toys, one on either side of her. At the beginning of each clip, the actress looked down at the table (2s), looked up at the camera and smiled (3s), and then turned her head to the left or right and gazed (gaze trials, $\mathrm{n}=8$ ) or gazed and pointed (point trials, $\mathrm{n}=8$ ) to one of two toys ${ }^{1}$. She kept her gaze there until the trial ended ( 5 s ; this was the time window of interest, hereafter "postturn window"). Each video was 10 s long, and side of look, point, and toy were counterbalanced within and across subjects.

For the infants in the word comprehension study, the design was identical to that in Bergelson \& Swingley, (2012a), except that the experimenter spoke the words in lieu of the parent (as in Bergelson \& Swingley, 2012b). Briefly, infants were presented with images of foods and body-parts, one of which was named by the experimenter, while their eyegaze was monitored.

## Data Analysis

We quantified infants' performance in the gaze-study as proportion target looking. For each subject, we computed a difference score consisting of the proportion of infant gaze to the target, minus the proportion to the distracter, averaged over trials. This measure ignores gaze at the actor's face or hand and compares correct and incorrect looks. Indiscriminate looking at target and distracter would yield, on average, a score of zero.

Given our interest in infants' increased comprehension of non-nouns at ten months, we split subjects into two groups around this age.
We also correlated infants' performance in the gazefollowing study with two different vocabulary measures: MacArthur CDI scores and noun-comprehension subject

[^14]means. MCDI scores were calculated based on the number of words parents said their child understood or said on the MCDI; we looked at MCDI scores overall, and at the specific sets of nouns and non-nouns for which we found a developmental lag (Bergelson \& Swingley, 2012a; 2013, see Table 1). Noun-comprehension subject means were calculated from infants' performance in the noun-comprehension experiment that preceded the gazefollowing study. ${ }^{2}$

Figure 1: Expt. 1 Subject Means by Age in the Gaze- and Point-Following Task. Each dot represents each subject's proportion of target looking averaged over trials, for each condition. The symbol used for the dot represents infants' vocabulary size, binned into three groups (see legend). Infants performed above chance in the Gaze \& Point condition in the over-10 month age group (the right side of the right graph).

## Results

Across both age groups, infants failed to look more to the side the actress looked at on gaze trials ( $<10 \mathrm{mo}$.: $12 / 26$ infants with positive performance, $\mathrm{M}=.012$, $\mathrm{Mdn}=-$ $.00019, \mathrm{p}=1 ;>10 \mathrm{mo} .: 8 / 11$ infants, $\mathrm{M}=.031$, $\mathrm{Mdn}=.041$ $\mathrm{p}=.10) .^{3}$ For point trials, infants under 10 months performed at chance ( $14 / 26$ infants, $\mathrm{M}=.023$, $\mathrm{Mdn}=.018$, $\mathrm{p}=.35$ ), while infants over 10 months succeeded ( $9 / 11$ infants, $\mathrm{M}=.13$, $\mathrm{Mdn}=.15 \mathrm{p}=.008$ ).

We next examined the correlations between infants' vocabulary size, as reported by their parents, and their gaze-following behavior. Infants' MCDI scores correlated with proportion target looking on point trials, but not on gaze trials (point trials: (Kendall's) $\tau=.26, \mathrm{p}=.024$; gaze trials: $\tau=.09, \mathrm{p}=.43$ ). Looking at the MCDI subset containing nouns and non-nouns that were tested in previous eyetracking studies (Bergelson \& Swingley, 2012a, 2013), we found correlations between point trials and non-noun vocabulary $(\tau=.28, \mathrm{p}=.019)$ and a marginal

[^15]correlation between point trials and noun vocabulary ( $\tau=.21, \mathrm{p}=.080$ ). Noun and non-noun correlations with gaze trials were not significant (non-nouns: $\tau=.022$, $\mathrm{p}=.89$, nouns: $\tau=.11 ; \mathrm{p}=.37$ ). For the subset of subjects in the noun-comprehension study ( $\mathrm{n}=25$ ), performance in the gaze-following study and noun-comprehension study were not significantly correlated (gaze trials: $\tau=.11$, $\mathrm{p}=.44$, point trials: $\tau=-.05, \mathrm{p}=.73$ ). See figure 1 .

## Discussion

These results suggest that around ten months, when infants begin to show comprehension of non-nouns, they show an increase in their ability to follow pointing and gaze, but not gaze alone. This ability is correlated with non-noun and overall vocabulary, assessed by parental checklist.

While previous work has found links between infants' gaze-following and vocabulary size at 18 months (Brooks \& Meltzoff, 2005), here we find a correlation between point-following and current vocabulary size, and in particular, with knowledge of non-nouns tested in previous work.

The finding that infants' noun comprehension task behavior did not correlate with point-following is in keeping with the marginal correlation we found on the MCDI noun subset. The possibility remains that although noun comprehension is evidently not strongly correlated with point-following ability, non-noun comprehension may be, a hypothesis we cannot address directly yet.

Vocabulary size and age are correlated ( $\tau=.46$, $\mathrm{p}<.0001$ ). This makes it difficult to untangle their relationship to point-following ${ }^{4}$. However, the results suggest that point-following seems to be a categorical ability attained around ten months (See figure 1). Before ten months, performance is variable and centered around zero; after ten months virtually all children are above zero. This, coupled with the result that age and residualized vocabulary both predict pointing suggests that age and vocabulary are not redundant predictors.

Thus, in answer to our first question, the timing of point-following success and correlations between MCDI and point-following data provide indirect evidence for the Social Skills Hypothesis. Thus, point-following is a strong candidate social skill that might be useful in nonnoun learning but which is apparently not necessary for noun learning, inasmuch as our somewhat exaggerated pointing materials test point-following in natural contexts. An alternate possibility is that a third skill emerges around ten months, and that this skill mediates both pointfollowing and non-noun learning.

Thus, with evidence for the social hypothesis garnered in Expt. 1, we turn to a set of corpus analyses that will allow us to assess the roles of frequency and

[^16]environmental factors in the lag between noun and nonnoun learning.

## Experiment 2

## Methods

We examined mothers' use of the set of nouns and nonnouns that we have tested in eyetracking experiments in both the Brent Corpus (an audio corpus of 16 mothers interacting with their $9-15$ m.o. infants; Brent \& Siskind, 2001), and in 20 videos of the Providence Video Corpus (5 mothers interacting with their young children; we selected a subset in which children ranged from 11 to 18 mo; Demuth, Culbertson, \& Alter, 2006). In the Brent Corpus we compared frequency counts in isolation (i.e., in one-word utterances) and overall. In the Providence corpus we extracted 919 utterances in which both the caregiver and child were clearly visible, and in which one of our words of interest was said.

These utterances were coded for a number of features, including whether the referent of the word was present (e.g. is there an apple when 'apple' is said, is someone eating when 'eat' is said, did something fall accidentally when 'uhoh' was said, etc.), what the parent was looking at/touching, what the child was looking at/touching, the situation the word was used in, what (if anything) was moving, whether the word was said before, during, or after attention to the relevant referent transpired, and what was present in the room. In the case of body-parts, coders noted 'presence' only when the relevant part was involved in the interaction in any important sense: e.g., if the mother was looking at a child who had yogurt all over her mouth and said "look at your messy face!" this counted as 'presence' of the word 'face'; in contrast, if the mother was holding her crying child while singing "if you're happy and you know it clap your hands", this did not count as an instance in which 'hands' were considered 'present'.

## Results

A series of analyses was conducted to test whether the difference in eyetracking-task performance between nonnouns and nouns might be due to higher frequency of the nouns rather than something more fundamental about the words' meanings. Frequency was estimated using the Brent corpus. There was not a significant difference in the frequency of the nouns and non-nouns ${ }^{5}$. Descriptively, each noun occurred $45-562(\mathrm{M}=262$, $\mathrm{Mdn}=244)$ times within the corpus while each non-noun occurred 33-1292 ( $\mathrm{M}=453$, $\mathrm{Mdn}=219$ ) times. Across each set of words, the total number of usages did not vary significantly (244 vs. $219, \mathrm{p}=.98$ by Wilcoxon test). Given that previous research supports a link between word learning and

[^17]frequency of isolated word tokens (Brent \& Siskind, 2001), we also examined this variable here. The sets of words were not differentially likely to occur in isolation either: nouns occurred 2-92 ( $M=26$ ) times and non-nouns occurred 0-1091 times $(\mathrm{M}=152)$; this difference was not significant (noun $\mathrm{Mdn}=19$, non-noun $\mathrm{Mdn}=11 ; \mathrm{p}=.95$ by Wilcoxon test.).

Analyses of the Providence Corpus subset revealed that there too, our nouns and non-nouns occurred with similar frequency: each non-noun occurred 1-94 times ( $M=37$, Mdn=23), there were 523 non-nouns total. Nouns occurred 5-46 times ( $\mathrm{M}=21$, $\mathrm{Mdn}=19$ ), with 396 nouns tokens total (estimated difference per word type: 7 words; $\mathrm{p}=.29$ by Wilcoxon test over words). Similarly, nouns and non-nouns as a group did not differ in number of isolated occurrences ( 72 isolated non-noun tokens total, $R=1-7$ over words; 35 isolated noun tokens total, $R=1-3$ over words; estimated difference 1.8 words; $\mathrm{p}=.13$ by Wilcoxon test over words).

Hand-coding of interactional features during parental use of the tested words revealed a large word-type (noun versus non-noun) difference in whether the referent of the word was present as part of the interaction. Non-nouns were said much more often than nouns when their referent was not present-e.g., saying "hi!" when no-one was newly on the scene, or "kiss" when there were no evident attempts at kissing. By contrast, nouns ("a banana!") were more often spoken in the presence of the referent (an actual banana, or a picture of one). For non-nouns the referent was not present $39 \%$ of the time; for nouns, $15 \%$. This pattern held for $5 / 5$ children in the corpus, and was significant over words (estimated difference $=.24$, $\mathrm{p}<.012$ by Wilcoxon test over words). See figure 2.

No significant difference between word-types was found in what mothers or children were touching or looking at, the number of situation-types that the word occurred in (e.g. playing, eating, interacting, bookreading), what in the scene was moving (e.g. child or mom, their hands, other objects, etc), whether the word was said before, during, or after attention to the relevant referent transpired, nor what was present in the room (all ps $>.05$ by Wilcoxon tests, and not significant predictors in logistic regressions of word-type). In short, on most coded variables, nouns and non-nouns did not differ in various features of the learning environment-except whether the referent was present or not. ${ }^{6}$

## Discussion

Expt. 2 showed that nouns are used in speech to infants when their referents are present; non-nouns are used when their intended referents are present about $60 \%$ of the time. However, nouns and non-nouns appear to be said at equivalent rates both in sentence context and as one-word utterances.

[^18]These findings fail to support the Frequency Hypothesis, and lend support to the Environmental Hypothesis, insofar as we found non-nouns were said more often in less ideal learning environments (i.e. when the referent was not present). While it remains possible that other environmental factors varied across the words as well, of those we coded this was the only one that differed significantly across word groups.

One limitation of this study is that the videos were of infants older than ten months, leaving open the possibility that at younger ages there are other word-type differences. Such an account would stipulate that parents interact differently with children once children know some nonnouns.

Thus, in response to our second question, when examining naturalistic interactions between infants and their caregivers, we did not find support for frequencybased differences between nouns and non-nouns, but did find support for environmental differences.

Figure 2: Referent Presence as a function of Word-type in the Providence Corpus Subset. This figure depicts the counts of instances of nouns and non-nouns of interest (see table 1). Color distinguishes whether the referent was present as an image (top), present (middle) or not present

## General Discussion

In two studies we have explored the underpinnings of early word learning, seeking to explain why infants are able to understand different types of words at different ages. More specifically, through a gaze-following experiment and corpus analyses, we have sought to explain infants' ability to understand nouns around six months and non-nouns around ten months.

We found some support for the Social Hypothesis, in that point-following emerged around ten months and was correlated with overall vocabulary and, more strongly, non-noun vocabulary. We found support for the Environmental Hypothesis in that nouns were used in the presence of their referent with much greater regularity than was the case for non-nouns. We did not find support for the Frequency Hypothesis, or for other versions of the

Environmental hypothesis related to situation, attention, or motion-related factors.

Both of these experiments leave open the Conceptual Hypothesis, whereby non-nouns are learned later because they are more complicated, either due to the inherent linguistic word-class that the words belong to, or due to the nature of the visual features that need to be tracked to learn non-nouns as opposed to nouns. One way to examine this hypothesis is to teach infants novel nouns and non-nouns in very similar linguistic and environmental conditions to examine whether with equivalent exposure some types of words may be, simply put, harder to learn. Such work is ongoing in our lab.

The hypotheses we tested here are not new to this research, and so our evidence supporting these notions (in some cases) corroborates prior work. Perhaps most surprising, then, are the null effects: little evidence for the importance of frequency (among these already frequent words), and little evidence for a broad range of environmental variables that would, a priori, seem reasonable predictors of infants' success in learning. Of course, it is always possible that more sensitive measures would reveal influences that did not emerge here; however, a strength of the present approach is that we are testing learning that takes place in infants' ordinary, daily-life experience.

It is unlikely that any one cause is responsible for infants' later learning of non-nouns than nouns. It is probable that skills underlying pointing and the environmental conditions in which words appear play a role in how easily and at what age words are learned. But a simple frequency-based account does not seem viable for accounting for this difference. Further work is needed to examine the interactions of conceptual, environmental, and social factors in early word-learning of different word types.

Our findings about the developmental timeline of noun and non-noun acquisition suggest that it takes infants nearly as long to learn their first non-nouns as it took to learn their first nouns. Understanding the mechanisms underlying this lag, which we have begun to explore here, requires understanding the intertwined roles of social development, the structure of the world, and the structure of concepts as expressed in natural language. This line of research, in turn, has implications for word-learning, language acquisition, and cognitive development on a much broader scale.

#### Abstract

Mental representations of environments are embodied in cognitive maps. Cognitive maps enclose spatial and distance distortions, which appear due to transcription errors based on processing of map information. Participants processed complex cartographical maps of varying amounts of visual details like topography, boundaries and grid to examine their effects on recall and orientation performance. The results indicate that the presentation of boundaries, topographies and a square grid significantly reduced distortion errors compared to a blank map, whereas a presentation of more than one visual element did not further reduce the distortions.

Keywords: Cognitive Maps; Complexity; Visual Boundaries; Square Grid; Distance Distortions; Spatial Cognition

## Introduction

A map, as a symbolic two-dimensional image of spatial relations, is a complex display of different kinds of stimuli, like object names, shapes, colors, spatial relationships and distances (Thorndyke \& Stasz, 1980). Orientation on a map, thus, must be seen as a complex skill, which involves encoding a broad set of verbal and spatial information as well as combining and constructing a mental representation of the visual stimulus. Furthermore, all information is given simultaneously, which forces the map reader to evaluate and process the information in procedures running parallel.

The mental representations of environments are embodied in cognitive maps (Tversky, 1993). In a cognitive map, elements are structured and can be mentally inspected (Tversky, 1992). However, cognitive maps are not miniaturized models of the reality, but rather a derivation of the reality (Barkowsky, 2002). Examining the mental representation of knowledge acquired from simple maps, it can be shown that these representations are systematically distorted affecting both the participants' recognition and orientation performance (McNamara, 1986). Such
distortions have been shown to follow the principles of perceptual grouping. For example, cities that are connected by lines are found to be recalled as lying closer together (Klippel, Knuf, Hommel \& Freska, 2004; McNamara, Ratcliff, \& McKoon, 1984). Moreover, omissions and additions that cannot be retrieved in the reality are present (Mark et al., 1999). To examine the representation of cognitive maps and distortions of real maps, previous research has focused on subsets of cartographical tools. Okabayashi and Glynn (1984), for instance, analyzed straight and curved boundaries on simple white maps and came to the conclusion that participants who studied the curved boundary maps made more distortion errors than those who studied the straight boundary maps and noboundary maps. Furthermore, Sadalla and Magel (1980) showed that landmarks also distort the space around them. The hierarchical organization of landmarks was examined by Hirtle and Jonides (1985), who found a clustering of landmarks on the basis of non-spatial attributes. Moreover, they were able to point out that the clusters have consequences for participants' performance in distance estimations. In addition, Hommel, Gehrke and Knuf (2000) and Hurts (2005) showed a clustering due to boundaries or rivers.

As introduced above, previous research mainly focused on the examination of simple maps, and it still remains open whether such distortions are also observed when using higher complex cartographic material. Moreover, based on cognitive principles, square grids are commonly used in cartography as an artificial tool to guide a map reader's attention and to reduce spatial distortions, but this hypotheses has not been tested empirically yet. Therefore, the maps presented in this study were created at different levels of visual complexity, varying in the amount of visual details displayed at three dimensions: (1) territorial
boundaries: no boundaries vs. boundaries, (2) topography: no topographic details vs. maps containing topographic information (e.g., mountains), (3) grid: no grid vs. overlaid square grid. The goal is to evaluate the orientation and memory performance when participants learn the location of unknown cities at the different types of cartographic maps.

## Methods

## Participants

Sixty-two participants ( 30 male, 32 female) aged between 19 to 34 years [ $M=23,1 ; S D=3,4$ ] participated voluntarily in the study. All participants gave written informed consent before inclusion in the study.

## Materials

Eight different maps ( $680 \mathrm{px} \times 510 \mathrm{px}$ ) were created as study material. The first map was a blank white map, the second map included a network of red boundaries and the third included a colored topography. The fourth map comprised both the topography and boundary lines. Maps 5-8 copied these maps but additionally were overlaid by an artificial square grid (170 px x 170 px ) (see Figure 1). The other design parameters of the grid, such as the color and width of the grid line, are based on the map grids standardly used in printed German topographic maps (scale $1: 25,000$ ). In addition, a pool of 28 newly created city names of eight-letter-length was established. Based on this pool, seven cities were pseudorandomly overlaid on each of these maps illustrated as red dots (so that no city was presented twice for any participant).

## Design

The study consisted of a three-factorial $2 * 2 * 2$ mixed design comprising the within-subjects factors boundaries and topography, and the between-subjects factor grid (see Figure 1). Participants were randomly divided into two groups. Both groups received the same maps with the same arrangement of cities, boundaries and topography, but one group with an overlaid square grid and the other without. All participants were told to study the seven cities on each map. For each city they had to remember the localization on the map as well as the name.

Each trial began with a study phase of two minutes, which was followed by a two minute interval with filler tasks. After the interval participants had to recall the seven cities on the same map, which now only included the background but not the red dotted cities. Participants were instructed to complete the task as accurate and as fast as possible by placing the cities on the map, using the cursor. After the placement of each city, participants had to type in the cityname. The trial was confined to three minutes. Furthermore, the presentation order of the different map types was randomized for each participant. The cartographic visualization of the maps was made with Adobe ${ }^{\circledR}$

Illustrator® CS5. The final maps (RGB color model) were exported as vector data sets and, in a further step, imported into Adobe ${ }^{\circledR}$ Flash ${ }^{\circledR}$ CS5. Here, based on the objectoriented language ActionScript 3.0, the maps were imbedded into an animated application used to execute the computer-based trial.

Figure 1: Schematic visualization of the four maps of the paradigm. Maps 2, 6, 4 and 8 include boundary lines. Maps $3,7,4$ and 8 include a colored topography. Maps in the second row are overlaid by an artificial square grid.

## Statistics

The orientation and memory performance was assessed by measuring the distance between the recalled place location compared to the original location of the city from the studyphase map. The Euclidian distance was measured in pixels. A city was rated correct in case the recalled location fell within a distance smaller than $28,4 \mathrm{px}(=1 \mathrm{~cm})$ from the study location (Okabayashi \& Glynn, 1984). A mixed threeway $2 * 2 * 2$ ANOVA comprising the within-subjects factors boundaries and topography and the between-subjects factor grid was computed for the number of correctly recalled cities and the mean distances of correctly positioned cities within the 1 cm radius at a given significance threshold of $\mathrm{p}=.05$.

## Results

The repeated measures ANOVA for mean distances of correct placements with grid versus no-grid as a between subject factor revealed a significant main effect of grid $\left[F(1,60)=6.359, p=.014, \eta_{p}{ }^{2}=.096\right]$, but no significant main effects of topography ( $p=.69$ ) and boundaries ( $p=$
.21). Moreover, a significant interaction between topography and grid was observed $[F(1,60)=6.464, p=$ $\left..014, \eta_{p}{ }^{2}=.097\right]$. Post-hoc $t$-tests showed that distances significantly decreased with the presentation of grids when no topography was present $[t(122)=3.631, p<$. 001].Distances for maps without topography and without grids are higher compared to those with topography and either without or with grids $[t(122)=2.069, p<.043 ; t(122)$ $=2.287, p<.024]$ whereas the presentation of the grid has

Figure 2: Mean distances between original and correctly recalled cities (a city was rated correct, when the recalled location fell within a distance smaller than $28,4 \mathrm{px}$ ) on maps with topography or no topography and overlaid with a square grid or without. $*=p<.05 ; * * *=p<.001$
no effect when a topography is present $(p=.770)$ (Figure 2).
The ANOVA on distances also revealed a significant interaction between boundaries and grid $[F(1,60)=5.821$, $\left.p=.019, \eta_{p}{ }^{2}=.088\right]$. The results of the post-hoc $t$-tests indicate that distances significantly decrease with the presentation of grids when no boundary is present $[t(122)=$ 3.676, $p<.001$ ] and distances are higher compared to maps with boundaries and either without or with grids $[t(63)=$ 2.471, $p<.016 ; t(122)=2.874, p<.005]$, whereas the presentation of the grid has no effect when boundaries are present ( $p=.560$ ) (Figure 3). The interactions between topography and boundary ( $p=.40$ ) and between grid, topography and boundary ( $p=.21$ ) were not significant (for means and standard deviations see Table 1).

Table 1: Distances in pixels between original and correctly recalled cities [mean $(S D)$ ] for the different map types.

|  | no topography |  | topography |  |
| :---: | :---: | :---: | :---: | :---: |
|  | no boundary | boundary | no boundary | boundary |
| no grid | $18.1(5.0)$ | $14.8(5.8)$ | $15.0(4.6)$ | $14.2(4.6)$ |
| grid | $12.6(4.6)$ | $13.4(5.3)$ | $14.2(4.7)$ | $14.6(4.5)$ |

The repeated measures ANOVA for mean percentages of correctly recalled cities with grid versus no-grid as a between subject factor revealed a significant main effect of topography $\left[F(1,60)=4.976, p=.029, \eta_{p}^{2}=.077\right]$. No other main effect reached significance (grid, $p=.12$; boundaries,

Figure 3: Mean distances between original and correctly recalled cities (a city was rated correct, when the recalled location fell within a distance smaller than $28,4 \mathrm{px}$ ) on maps including boundaries or without and overlaid with a square grid or without. $*=p<.05 ; * * *=p<.001$
$p=.06)$. Moreover, significant interactions between grid and topography $\left[F(1,60)=10.762, p=.002, \eta_{p}^{2}=.152\right]$, and between grid, topography and boundary $[F(1,60)=10.245$, $\left.p=.002, \eta_{p}{ }^{2}=.146\right]$ were observed. Although the presentation of a grid did not show any effect if a topography was present, the recall of city-locations was significantly better among maps without topography if a grid was present $\left[F(1,60)=8.717 p=.004, \eta_{p}{ }^{2}=.127\right]$ (Table 2). The interactions between grid and boundaries ( $p=.17$ ), and between topography and boundaries ( $p=.44$ ) were not significant (for means and standard deviations see Table 2).

Table 2: Percent of correctly recalled cities [mean $(S D)$ ] on the different map types.

|  | no topography |  | topography |  |
| :---: | :---: | :---: | :---: | :---: |
|  | no boundary | boundary | no boundary | boundary |
| no grid | $38.8(24.1)$ | $42.9(25.1)$ | $57.1(24.3)$ | $49.6(29.5)$ |
| grid | $63.8(23.6)$ | $44.3(25.3)$ | $51.9(22.0)$ | $51.4(21.7)$ |

## Discussion

The inclusion of visual boundaries, topographic information and of a square grid significantly modulate distance distortions and recall performance of complex cartographic maps, probably due to altered cognitive representations of the spatial relations. Following the analysis of the distance
distortions a clear picture emerges in that adding of visual elements significantly reduces distances relative to the original locations. Of particular note is that no further additive effects of these visual elements were observed. For example, no further advantage of boundaries or the displayed topography is visible in orientation performance when a square grid is already present - but also no disadvantage. Participants seem to set different additional visual information apart from an other to enhance their orientation performance and thus to reduce distortions (Figures 2 and 3), but the transfer to combination of visual information is missing.

In general these result support the notion of structured cognitive maps derived from environmental (visual) information - as the present paradigm rules out effects of previous knowledge (Barkowsky, 2002; Tversky, 1992). A likely way to use such complex visual information is to build visual hierarchies (Eastman, 1985; Hirtle \& Jonides, 1985) forming frames of representation that clusters the visual elements. Thus, cartographic details seem, in accordance with our initial hypothesis to guide the processes of cognitive map formation. It will be a question of future research to examine why no additive effects of the visual elements were visible, a first hypothesis would need to consider a kind of visual overkill, which if it can be replicated would affect the designing of cartographic material.

Regarding the recall performance of cities, topography had an overall effect, whereas grids again only improved the orientation on simple maps. This matches the results of the distance distortion analyses. Future studies should include different grid types to examine this result and to improve the use of grids, but also the presentation of topographic details and boundary information as assistant cartographic elements. Topographic details and boundaries should be modified in density and spacing to receive an impression of the degree in which the adding of visual elements effects distance distortion. Additionally, different grid types in combination with the assistant cartographic elements should be analyzed in terms of a coordination of cartographic elements to support the map reader. Furthermore, general investigations in navigation performances should be pursued based on these results.

## Acknowledgments

The study was funded by the German Research Foundation (DFG, DI 771/7-1) to F.D. and L.K.

#### Abstract

It is generally assumed that the character position targeted within a particular word is not under direct cognitive control, but is rather determined by oculomotor processes sensitive only to word length and distance. An alternative view is that readers target more distant characters in words when they have parafoveally processed these words more. These possibilities are difficult to distinguish because the actual landing site within a word has large effects on subsequent word processing measures. In two experiments, we decoupled the targeted location from the actual landing site by shifting the text 3 characters during the saccade into a target word. Results show that subsequent word processing time given a particular landing site was lower/higher when the eyes would have landed further forward/backward in the word. This effect remains significant in some cases when controlling for saccade launch site. These data provide evidence against the oculomotor theory and support a cognitive account of saccade targeting.

Keywords: eye movements; reading; display change

## Introduction

Reading is a complex process that requires the combination of language processing with visual information to make decisions about when and where to move the eyes. These decisions are made very rapidly: saccades in reading take around 150 ms to program (Rayner, Slowiaczek, Clifton, \& Bertera, 1983), yet fixation durations in reading are around 200250 ms , leaving only $50-100 \mathrm{~ms}$ to decide when and where to send the eyes next. Given these temporal requirements, one central question of reading research is the extent to which these decisions are made by the cognitive system - and thus are sensitive to ongoing linguistic processing - or made by faster, low level oculomotor heuristics. Much of this debate has focused on how readers decide when to make a saccade, e.g., investigating the sensitivity of the distribution of fixation durations to the linguistic properties of a fixated word such as its frequency or predictability (Staub, White, Drieghe, Hollway, \& Rayner, 2010; Staub, 2011; Feng, 2009b). It is generally assumed, however, by researchers on both sides of this debate that it is via oculomotor heuristics that readers decide where within a word to target their eyes. ${ }^{1}$ In this paper, we provide evidence against this view, suggesting that characterlevel saccade targeting decisions are under cognitive control, and thus supporting a view in which even the fine details of eye movements are sensitive to ongoing linguistic processing.

## Character-level saccade targeting

It has been known since Rayner (1979) that the eyes' modal landing position in (medium and long) words is slightly left

[^19]of the center, and Rayner initially suggested that readers may intentionally send their eyes to this position because it is the most efficient location from which to process the word (cf. O'Regan, 1981). However, Rayner, Well, Pollatsek, and Bertera (1982) found evidence from a display change paradigm in which they controlled the amount of preview - visual information available about the next word - by replacing some letters with Xs that readers send their eyes further into the following word when they had received more preview. They suggested a cognitive account of character-level saccade targeting, in which readers target a position further into a word when they have already processed more of the word. For example, if readers are able to identify initial letters in a word, they no longer need visual information about those letters, and it is an efficient reading strategy to target the eyes at the latter, still-unidentified part of the word (Rayner, McConkie, \& Zola, 1980). However, it is possible that Rayner et al.'s (1982) results do not reflect normal reading behavior, and may instead reflect an experiment-specific strategy, e.g., making shorter saccades when the next word contains more Xs.

McConkie, Kerr, Reddix, and Zola (1988) investigated this issue with an analysis of the effect of preview on saccade targeting in a corpus of naturalistic reading. To assess the effect of preview, McConkie et al. investigated the effect on landing position of launch site, the distance of the previous fixation from the beginning of the word. Because the quality of visual information rapidly decreases away from the fovea, nearer launch sites would be expected to yield more preview, and - under Rayner and colleagues' cognitive account - landing positions further into the word. McConkie and colleagues' results confirmed this prediction, showing that the modal landing position was more rightward for nearer launch sites. However, McConkie et al. presented analyses suggesting that this result was not best explained by the cognitive account. Specifically, they presented evidence that the relationship between launch site and modal landing position was linear, and argued that an account that explains the shift in modal landing position in terms of parafoveal preview should predict a non-linear relationship. Because readers only obtain significant information about letter identities from 7 or so characters away (Underwood \& McConkie, 1985), they argued that a preview account would predict that the effect of launch site on landing site should asymptote by launch sites of 7 characters. McConkie and colleagues presented evidence that the shift in modal landing position was well modeled as a linear function of launch sites from 1 to 7 characters, with no evidence of becoming smaller near 7 characters. Neverthe-
less, because they did not analyze launch sites past 7 characters, this is not strong evidence against the cognitive account. Based on their evidence, however, McConkie et al. (1988) proposed an oculomotor account of character-level saccade targeting, in which the functional target of the eyes is always the center of the word, but in which systematic error biases saccade lengths toward 7 characters (and happens to do so linearly). They further suggested that this systematic error is related to range error found in other saccadic (Kapoula, 1985) and manual (Poulton, 1981) tasks, which biases saccades toward the mean saccade length. This oculomotor account of saccade targeting has since become the dominant theory, and is encoded in all major models of eye movement control in reading (e.g., Reichle, Pollatsek, Fisher, \& Rayner, 1998; Engbert, Nuthmann, Richter, \& Kliegl, 2005).

## Goals

In the present work, we tease apart the cognitive and oculomotor accounts by testing their predictions for word processing that occurs after landing on a new word. This is difficult to disentangle in natural reading, because there are large effects of the actual landing site on eye movement measures that indicate word processing time, such as gaze duration and refixation rates (e.g., O'Regan, 1981; McConkie, Kerr, Reddix, Zola, \& Jacobs, 1989; Rayner, Sereno, \& Raney, 1996). Here, we experimentally decouple intended landing site from actual landing site using a sentence shift paradigm, which allows us to investigate the relationship between target word processing and where a reader would have landed in the word. The cognitive account, in which readers direct their eyes to later character positions in upcoming words when they have performed more parafoveal processing of the beginnings of these words already, predicts that - when controlling for actual landing site - readers will require less time to finish processing a word when they had targeted a later character. The oculomotor account, which holds that where a reader lands in a word is purely a function of launch site, does not obviously make this prediction. However, because parafoveal preview should be larger when the eyes are closer to the word (i.e., for closer launch sites), the oculomotor account may also make this prediction, because it predicts that landing sites are correlated with launch site. Crucially, though, in the oculomotor account, all effects of original landing position (i.e., the position at which the eyes would have landed had we not shifted the sentence) must be mediated by launch site. The cognitive account by contrast, under the assumption that the amount of parafoveal processing performed is variable even for a constant launch site, predicts that word processing times will be smaller when the eyes would have landed further into the word, even when controlling for effects of launch site. (Note, however, that a large amount of the amount of parafoveal preview obtained is likely to be correlated with launch site even on this account). We test these predictions in the following two experiments.

## Experiment 1

We use a sentence-shifting paradigm (McConkie, Zola, \& Wolverton, 1980; O’Regan, 1981; Inhoff, Weger, \& Radach, 2005; Nuthmann, 2006; Feng, 2009a) to tease apart effects of intended landing site from actual landing site. In our first experiment, we shift the sentence to the right during the saccade into a target word, as described below. This paradigm allows us to align actual landing sites and compare two cases: (1) when the actual site was the intended landing site (when no shift occurred), and (2) when the intended landing site was, instead, further into the target word (when the sentence shifted to the right). The cognitive account predicts that the latter case - when more distant locations were targeted - is more likely to reflect instances in which readers had parafoveally processed the word to a greater extent. Thus, the account predicts that word processing times on the target word should be reduced compared with the control, no shift condition. The oculomotor account may make this same prediction, but only as mediated by effects of launch site, since under this view landing position is strictly a function of launch site, and closer launch sites may yield more parafoveal preview. We thus seek to answer two questions: (1) whether any information about upcoming word processing can be recovered from original landing site, as measured by whether there is an effect of shift on subsequent eye movement measures aligned by actual landing site, and (2) whether this effect is completely mediated by launch site.

## Method

Subjects All subjects were students at the University of California, San Diego who received course credit for participation. All were naive to the purpose of the experiment and reported that they were native speakers of English with normal or corrected-to-normal vision. Data from 40 subjects were included in our analyses. Five additional subjects participated in the experiment but were excluded from analysis for reasons discussed below.
Apparatus Eye movements were monitored with an SR Eyelink 2000 eye tracker (SR Research Ltd., Kanata, Ontario, Canada) sampling at 1000 Hz . The system was configured in 'tower mode' and equipped with a chin rest. While subjects read binocularly, only one eye (the right eye by default) was tracked. Sentences were displayed on an HP p1230 20 in. CRT monitor with refresh rate set to 150 Hz and resolution set to $1024 \times 768$ pixels. Viewing distance was approximately 60 cm . Approximately 2.4 characters were encompassed by $1^{\circ}$ of visual angle. We used custom software (EyeTrack, developed at the University of Massachusetts, Amherst) to present and update the display.
Materials One hundred and sixty experimental sentences were included in this study. Eye movement measures were obtained from a single, pre-selected target word (always a 7letter verb) within each sentence, which was immediately preceded by a 3- or 4-letter noun. Each sentence appeared alone

```
    Pre-shift: The seasoned fig! couples well with goat cheese.
    No shift: The seasoned fig couples well with goat cheese.
Right shift: The seasoned fig couples well with goat cheese.
    Left shift: The seasoned fig couples well with goat cheese.
```

Figure 1: Example sentence. The first line depicts an experimental sentence and a boundary (invisible to subjects but shown here after the pre-target word 'fig') that, when crossed, will trigger a display change. The target word is 'couples'. The second line shows the control condition in which the sentence remains in place after the boundary has been crossed. The final two lines depict rightward (Experiments 1 and 2) and leftward shifts (Experiment 2 only) respectively.
on a single line of the screen in Courier New 14 pt. font.
Procedure After giving informed consent and receiving experimental instructions, subjects placed their heads in the chin rest and performed a 3-point horizontal calibration. Subjects then read 6 practice sentences, all without display changes, before beginning the experiment. Subjects read each experimental sentence silently for comprehension. For each subject, the order of sentence presentation was randomly and independently selected. After one third of trials, a simple comprehension question was presented to encourage attentive reading. Breaks were offered approximately halfway through the experiment and were available at any other time upon request. We used the gaze-contingent boundary technique (Rayner, 1975) to update the display when subjects' eyes crossed an invisible boundary placed after the last letter of the pre-target word. When this boundary was crossed, on half of the trials the display was re-drawn so that the entire sentence was shifted 3 characters to the right (the Right Shift condition, see Figure 1). In the remaining half of trials, the sentence was simply re-drawn in its original location (No Shift). The assignment of items to shift conditions was counterbalanced.
Analysis Data were processed using a suite of custom software developed at the University of Massachusetts, Amherst and the University of California, San Diego. Fixations shorter than 80 ms that occurred within a single character width (11 pixels) of an adjacent fixation were combined, and those that did not were removed. Trials containing a fixation longer than 1000 ms or a blink on or immediately preceding or following the target word region were also excluded. ${ }^{2}$ Trials were also excluded if the display change completed more than 9 ms after the beginning of the following fixation. Subjects were excluded from analysis for excessive data-loss, defined as $25 \%$ or more of trials being excluded for blinks or $50 \%$ or more of trials being excluded for late display changes. Trials were also excluded if the eyes (1) would not have landed on the target had no shift taken place, or (2) would have landed on the target under natural circumstances but were 'thrown off' by the shift. This requirement meant that all data from the shift condition was limited to actual landing positions $1-4$. In our statistical analysis of the effect of shift, we thus com-

[^20]pared the two shift conditions at only these four positions. ${ }^{3}$ Finally, in order to increase the probability that all fixations were intended for the target word, and not mislocated fixations intended for the previous word, we also excluded cases in which the previous word was skipped. Note that it is possible that two classes of unintentional fixations of the target word remain in the data: (a) fixations intended to be refixations of the previous word and (b) fixations that were intended to skip over the target word and fixate a subsequent word. However, each of these possibilities is unlikely to represent a substantial portion of the dataset, as the refixation probability for words of length 3-4 is very low (about $13 \%$ for words of length 4 and even lower for words of length 3; McConkie et al., 1989) and the probability of skipping over a 7-letter word is only about 10\% (Drieghe, Brysbaert, Desmet, \& De Baecke, 2004). ${ }^{4}$

We analyzed two measures of word processing: (1) gaze duration, defined to be the summed duration of all fixations made on a region prior to leaving it and (2) refixation probability, defined as the probability of making more than one fixation on a region prior to leaving it. We analyzed the effect of shift on gaze duration with linear mixed-effects regression (Pinheiro \& Bates, 2000) and on refixation probability with logistic mixed-effects regression (Agresti, 2002). In addition to a fixed effect of shift, all models included random intercepts and random slopes for shift for both subjects and items. As a control variable, the actual (post-shift) landing site was included as an unordered categorical fixed effect, and random slopes for landing site were included for subjects and items. In cases of nonconvergence, we iteratively removed random slopes of landing site until the model converged. We do not report control variable effects. Outlier gaze durations were excluded by removing all gaze durations more than 2 standard deviations from a subject's mean, without respect to experimental condition.

We report two analyses to answer the two questions described above. The first analysis seeks to determine whether any information about upcoming word processing can be recovered from original landing position by testing for an ef-

[^21]

Figure 2: Effect of shift on gaze duration and refixation rates by actual (post-shift) landing site for Experiment 1. Error bars show the standard error of the mean, computed after aggregation by subjects. Note that effects mediated by launch site have not been parceled out of this figure.
fect of shift on word processing controlling for actual landing site. The second tests whether this effect is completely mediated by launch site (as predicted by the oculomotor account) by including launch site as an unordered, categorical control predictor. To assess significance for the linear gaze duration models, we report the $t$ statistic. For datasets of this size, this statistic will be approximately normally distributed (Baayen, Davidson, \& Bates, 2008), meaning that $|t|>1.96$ indicates a significant effect $(p<.05)$ and $1.64<|t|<1.96$ indicates a marginal one (. $10<p<.05$ ). For logistic refixation models, we report the $z$ statistic, which has the same interpretation, and also give effect sizes in logits, which is the difference in the log-odds of making a refixation between conditions (Agresti, 2002).

## Results

The effects of shift are plotted in Figure 2, aligned by actual, post-shift landing position. There is an effect of shift on gaze duration: gaze durations are estimated to be significantly faster $(-19 \mathrm{~ms}, t=-3.1)$ when the eyes would originally have landed further into the word (i.e., after a rightward shift). Refixations are estimated to be 0.2 logits less likely after a rightward shift, but this is not significant $(z=-1.1)$. In analyses including launch site as a control predictor, the effect of shift on gaze durations was reduced to an insignifi-
cant $10 \mathrm{~ms}(t=-1.4)$, and the effect on refixations remained similar $(-0.2$ logits, $z=-1.1)$.

## Discussion

The results of Experiment 1 confirmed that original landing position does provide some information about upcoming word processing, as cases in which the eyes would have landed further forward in the word result in 19 ms shorter gaze durations. While this result is predicted by the cognitive account, the oculomotor account can also predict it, but only to the extent that it is completely mediated by launch site. In analyses controlling for launch site, the results from this experiment were unclear, however, and there was only an insignificant trend for gaze durations to be 10 ms shorter when the eyes would have landed further forward in the word. Thus, the results of this experiment are consistent with both models.

## Experiment 2

One limitation of the design of Experiment 1 is that it is possible that the effects we saw on gaze duration and refixation rate were merely low-level responses to shifting the sentence rather than true effects of prior processing of the target word. To allay this concern, in Experiment 2, we tested both right and left shifts of the sentence. While a simple, low-level response to the detection of a shift may be expected to affect eye movement measures similarly for leftward and rightward shifts, the cognitive account of saccade targeting makes opposite predictions for these two conditions. By the same logic as described for Experiment 1, this account predicts that gaze duration and refixation rates should be reduced in the rightward shift condition relative to the no shift condition when aligning on actual landing site. This is because the saccades in the rightward shift condition were directed further into the word, which on this account is caused by readers having performed more parafoveal processing. Analogously, this account predicts that these measures should be increased in the leftward shift condition relative to the no shift condition when aligning on actual landing site, since the leftward shift saccades were directed further back in the word than those in the no shift condition. The oculomotor account once again makes the same predictions as the cognitive account, but again requires that these effects be solely mediated by launch site. Experiment 2 thus allows us to test two predictions. First, if the simple, low-level shift effect is correct, we should find similar patterns of data for leftward and rightward shifts. Second, if we instead find opposite patterns of data for leftward and rightward shifts (as outlined above), examining whether these effects are solely driven by launch site will allow us to distinguish between the oculomotor and cognitive accounts of saccade targeting.

## Methods

Experiment 2 was identical to Experiment 1 with two exceptions. First, while 40 subjects were again included in our analysis, 7 were excluded (for reasons explained above). Second, while sentences remained static, once again, in half of trials,

Figure 3: Effect of shift on gaze duration and refixation rates by actual (post-shift) landing site for Experiment 2. Error bars show the standard error of the mean, computed after aggregation by subjects. Note that effects mediated by launch site have not been parceled out of this figure.
they shifted 3 characters to the right in one quarter of trials and shifted 3 characters to the left in the remaining quarter. An example is given in Figure 1.
Analysis Analysis was similar to that in Experiment 1 except that we now separately analyze the effect of left and right shift, comparing each to the no shift condition. Because we again exclude cases in which the eyes would have skipped the target or were 'thrown off' the target by the shift, this means that the data from the right shift condition are at actual landing sites $1-4$ and the data from the left shift condition are at actual landing sites $4-7$. We thus analyzed data from only these landing site ranges in each analysis.

## Results

The effects of shift are plotted in Figure 3, aligned by actual, post-shift landing position. For right shifts, the effect on gaze durations and refixation rates is again estimated to be in the predicted direction ( $-7 \mathrm{~ms},-0.3$ logits), but neither effect is significant ( $t=-0.7 ; z=-1.5$ ). For left shifts, the effects are in the opposite direction, and are larger ( $20 \mathrm{~ms}, 0.6$ logits) and significant $(t=3.7 ; z=6.1)$.

As before, we also performed analyses in which launch site is a control predictor, to determine whether these effects are exclusively mediated by launch site. For right shifts, this
analysis revealed insignificant effects on gaze duration ( 3 ms , $t=0.3)$ and refixation rates $(-0.3$ logits, $z=-1.4)$. The effect of left shifts controlling for launch site was estimated to be slightly smaller than when not controlling for launch site ( $18 \mathrm{~ms}, 0.5$ logits), but still robust $(t=2.9 ; z=4.5$ ).

To gain more power to assess the possible effects of rightward shifts, we performed a further, post-hoc analysis on the pooled data from for landing positions 1-4 from Experiments 1 and 2. This analysis revealed a significant effect of rightward shifts for gaze duration $(-16 \mathrm{~ms}, t=-3.2)$ and a marginal trend for refixation rate ( -0.2 logits, $z=-1.8$ ). An analysis controlling for effects of launch site revealed an insignificant 6 ms trend on gaze durations $(t=-1.0)$ and a marginal effect on refixation rates $(-0.2$ logits, $z=-1.8)$.

## Discussion

This experiment revealed, first, that leftward and rightward shifts produced opposite patterns of results, contrary to the predictions of the simple, low-level shift detection account: gaze duration and refixation rate were lower and higher in the rightward and leftward shift conditions respectively as compared with the static control condition, although this was only significant for the leftward shift condition. Because both the cognitive and the oculomotor accounts predicted this pattern of data, we also analyzed the data when controlling for launch site, a factor that should, according to the oculomotor view, entirely account for these results. These analyses revealed results more consistent with the cognitive account than the oculomotor account. In the leftward shift condition, gaze duration and refixation rate were significantly elevated even when controlling for launch site. For rightward shifts, pooling data across the two experiments also provided suggestive evidence in favor of the cognitive account of saccade targeting, suggesting that the effect was not entirely driven by launch site.

## Conclusion

In summary, we described two alternative accounts of how readers decide where, precisely, to aim their eyes when planning a saccade to an upcoming word. According to the cognitive account, readers send their eyes further into a word after having parafoveally processed it more. According to the oculomotor account, readers always target the center of a word, but are subject to systematic error, which is a function of launch site. We presented evidence in favor of the cognitive account from two sentence-shift experiments. As predicted by the cognitive account, the word processing measures of gaze duration and refixation rate suggested that readers perform less subsequent processing of a word when they would have landed further into it, and more subsequent processing of a word when they would have landed further back, controlling for actual landing site. This was a significant effect for rightward shifts in Experiment 1 and for leftward shifts in Experiment 2. Crucially, we found evidence that this effect was not fully mediated by launch site, as required by the oculomotor account. When controlling for launch site, in Experiment 2 , the effect of leftward shifts was fully reliable, and when
pooling data across Experiments 1 and 2, the effect of rightward shifts was marginal for refixation rate. This evidence thus suggests that readers decide where to target their eyes within a word based on how much processing of the word they have accomplished, and not just based on the current position of their eyes. Such an account requires that the details of saccade targeting are sensitive to ongoing cognitive, linguistic processing.

There is, however, one way in which the oculomotor account may still be able to accommodate these findings. As was pointed out above (see Expt. 1, Analysis), some trials included in our analysis may represent unintentional fixations on the target word: failed attempts (a) to refixate the pretarget word and (b) to skip the target word. If these trials represent a substantial portion of our data, the oculomotor account could also predict our findings, since (a) failed refixations would tend to land at the beginning of the target word and represent cases in which the target word was not yet the focus of processing and (b) failed skips would tend to land at the end of the target word and represent cases in which the target word was already processed. Further analyses will be required to determine whether the likely rates of such possibilities would be sufficient to render this account of our data plausible.

The data are certainly consistent, however, with the view that character-level saccade targeting is under cognitive control. Specifically, these results are predicted by an account in which readers send their eyes further into a word when they have obtained more parafoveal preview of it. Since this effect is not mediated by launch site, this means that where a reader's eyes land in a word provides information about how much they processed the word on that particular trial, which is not only a function of the location of their eyes on the previous fixation. If this account is correct, it would support the notion that fine-grained eye movements decisions in reading are tightly linked to the details of ongoing linguistic processing, suggesting that readers do not merely rely on heuristic strategies to guide their eyes. More generally, our results support a view in which humans optimize the fine details of their behavior to maximize their efficiency in linguistic tasks such as reading (Bicknell \& Levy, 2010; Lewis, Shvartsman, \& Singh, in press) and in cognition more broadly.

# Fusiform Face Area in Chess Expertise 

Merim Bilalić (merim.bilalic@med.uni-tuebingen.de)<br>Department of Neuroradiology, Hoppe-Seyler Str. 2<br>Tübingen, 72076, Germany

#### Abstract

The ability to recognize faces is arguably one of the most important and most practiced skills. The possible functions of the fusiform face area (FFA), generally believed to be responsible for face recognition, also feature these two characteristics. On the one hand, there are claims that the FFA has evolved into a face specific module due to great importance of face processing. On the other, the FFA is seen as a general visual expertise module that distinguishes between individual examples within a single category. The previous studies used experts and novices on stimuli such as cars, birds or butterflies with ambiguous results. Here this research stream is extended to the game of chess, which does not share visible features with faces. The first study shows that chess expertise modulates the FFA activation when complex multi-object chess positions were presented. In contrast, isolated single chess objects did not produce different activation patterns among experts and novices. The second study confirmed that even a couple of isolated objects do not differently engage the FFA among experts and novices. The two studies provide support for the general expertise view of the FFA function, but also extend the scope of our understanding about the function of the FFA. The FFA does not merely distinguish between different exemplars. It also seems to engage into parsing complex multi-object stimuli that contain numerous functional and spatial relations.

Keywords: face perception; expertise; pattern cognition; chess; fMRI.

## Introduction

Faces are arguably the most important and most practiced stimuli. We start practicing face perception from our early moments and we are highly dependent on correctly distinguishing individual faces. It is fitting that the proposed functions of the fusiform face area (FFA), possibly the most important brain area in face perception, center on these two characteristics: importance and practice. On the one side, we have researchers who believe the FFA, due to, among other things, its importance in our lives, has evolved into a brain module exclusively specialized for perception of faces (Kanwisher, McDermott, \& Chun, 1997; Kanwisher \& Yovel, 2006). On the other side, in contrast to this facespecificity hypothesis, we have researchers that advance the claim that the FFA is a general expertise module (Gauthier, Skudlarski, Gore, \& Anderson, 2000; Gauthier, Tarr, Anderson, Skudlarski, \& Gore, 1999). According to the expertise hypothesis, the FFA is responsible for perceptual processes associated with differentiating among different objects within a single category stimulus (e.g., visual individuation), without regard of the type of stimuli. We
investigated the expertise hypotheses using the game of chess as a model for visual expertise.

The neural basis of face perception has been extensively investigated (for a review, see Kanwisher \& Yovel, 2006). Different category types have been used to investigate the expertise hypothesis, ranging from birds (Gauthier et al., 2000), cars (Gauthier et al., 2000; Gilaie-Dotan, Harel, Bentin, Kanai, \& Rees, 2012; Grill-Spector, Knouf, \& Kanwisher, 2004; McGugin, Gatenby, Gore, \& Gauthier, 2012; Xu, 2005), butterflies (Rhodes, Byatt, Michie, \& Puce, 2004), to novel object types (Gauthier et al., 1999). The results are mixed and their interpretation has been the focus of an extensive debate (Bukach, Gauthier, \& Tarr, 2006; Nancy Kanwisher \& Yovel, 2006; Op de Beeck \& Baker, 2010). Among factors complicating the interpretation is the visual similarity between faces and other categories employed - cars, birds, and even butterflies all have facelike features (Kanwisher \& Yovel, 2006).

The game of chess offers a way around the resemblance problem. Chess entails both individual objects and complex "chess positions" made out of individual objects. None of chess objects resemble faces and chess positions do not have much in common with face, at least not at the superficial perceptual level. Individual chess objects can be, however, differentiated just like individual faces. Expert chess players have accumulated extensive knowledge about chess objects and are quicker in recognizing them as well as their relations than novice chess players (Bilalić, Kiesel, Pohl, Erb, \& Grodd, 2011; Kiesel, Kunde, Pohl, Berner, \& Hoffmann, 2009; Saariluoma, 1995). The real (chess) expertise lies, however, in using knowledge to quickly size the gist of chess positions (Bilalić, Langner, Erb, \& Grodd, 2010; Bilalić, Turella, Campitelli, Erb, \& Grodd, 2012; Gobet \& Simon, 1996). This expertise process of automatically parsing complex multi-object environment bears similarity to that found in face perception. Both processes are automatic, quick, and efficient in binding individual features into meaningful units.

These characteristics make chess a suitable domain for investigation of the FFA expertise hypothesis. A recent study showed that expertise in chess is negatively correlated with the performance on face perception (Boggan, Bartlett, \& Krawczyk, 2012). One possible interpretation would be that both skills engage similar processes that compete for the resources in the same brain areas. Indeed, we (Bilalić, Langner, Ulrich, \& Grodd, 2011) recently showed that chess expertise mediates the activation in the FFA regardless of the task (domain specific or not) as long as the stimuli
feature naturalistic chess positions (but see Krawczyk, Boggan, McClelland, \& Bartlett, 2011). However, it is unclear how the FFA will behave with individual chess objects instead of multi-object positions. Here I present two studies that test the FFA responses with individual chess objects and complex chess positions. In the first study we presented participants with single isolated chess objects and chess positions during a 1 -back task. In the second study we used only a couple of isolated chess objects in chess specific tasks (see Bilalić et al., 2011).

## Study 1

## Method

The first study involved a 1-back task where participants indicated whether the current stimulus was the same as the previous one.
Participants Table 1 presents the information about the number of experts and novices, their mean age (with SD), and their chess ability score [mean Elo rating with SD; available only for experts] in both studies. All participants were male and right-handed. The sample size is relatively small, but it reflects the rarity of the studied group and is comparable to recent behavioural studies using chess experts (e.g., Bilalić et al., 2008a, 2008b, 2009; Brockmole et al., 2008; Kiesel et al., 2009). The small sample size is offset by the large differences between experts and novices. We also used exclusively male participants as they outnumber female chess players and we were not interested in gender differences. Written informed consent was obtained in line with the study protocol as approved by the Ethics Committee of Tübingen University.

Table 1: Participants - Overview

| Study | Group | Age $\pm$ SD | Elo $\pm$ SD | $n$ |
| :--- | :--- | :---: | :---: | :---: |
|  |  |  |  |  |
| 1 | Expert | $24 \pm 8$ | $2116 \pm 125$ | 12 |
|  | Novice | $27 \pm 6$ | ---- | 14 |
|  |  |  |  |  |
| 2 | Expert | $29 \pm 7$ | $2130 \pm 147$ | 8 |
|  | Novice | $29 \pm 5$ | --- | 8 |
|  |  |  |  |  |

Localizer Participants first passively watched pictures of faces and objects to localize face related areas (for more details, see Bilalic et al., 2011). The area used in further analysis, the right FFA and the right posterior superior temporal sulcus ( pSTS ) were then identified (contrast faces vs. objects; $p<.0001$ uncorr.) and isolated for the use in Study 1 and 2 - see Figure 1.
Stimuli and procedure The 1-back task in Study 1 featured the following stimuli: faces, isolated chess objects (pieces), and chess positions (see Figure 2). The stimuli of
each category were blocked in 12 second units that featured 6 individual stimuli (each stimuli taking 1.75 s with a break of 0.25 s between them). There were ten blocks of each category spread over two different runs. Baseline ( 18 s of black screen with a cross in the middle) was presented between the blocks of stimuli.
MRI acquisition and data analysis fMRI data were acquired using a 3-T scanner (Siemens Trio) with a 12channel head coil. All measurements covered the whole brain using a standard echo-planar-imaging (EPI) sequence with the following parameters: TR, 2 s ; FOV, $192 \times 192$; TE, 30 ms ; matrix size, $64 \times 64$; 32 slices with thickness of 3.2 and 0.8 mm gap resulting in voxels with the resolution of $3 \times 3 \times 3.2 \mathrm{~mm} 3$. Finally, anatomical images covering whole brain with 176 sagittal slices were obtained after the functional runs using an MP-RAGE sequence with a voxel resolution of $1 \times 1 \times 1 \mathrm{~mm} 3$ (TR, 2.3 s ; TI, $1.1 \mathrm{~s} ; \mathrm{TE}, 2.92$ ms ). SPM software package was used for analysis. All functional data were first preprocessed using standard SPM routines for realignment, coregistration, normalization and smoothing ( 8 mm ). Blocks of individual stimulus categories as conditions of interest were then modeled using the standard canonical response function. The ROI analysis was performed on the mean percentage signal change extracted using Marsbar SPM Toolbox from all the voxels within the selected region - FFA and pSTS.

Figure 1: FFA (upper picture - inferior view) and pSTS (lower picture - lateral view) used as regions of interest (ROI) in the studies.

## Results and discussion

The faces unsurprisingly activated the FFA more than the two chess categories, but chess positions also elicited more activation than chess objects (ANOVA for main effect of stimulus category $-F(2,48)=79, p=.001)-$ see Figure 2.

There was no overall effect of expertise $(F(1,24)=0.3$, ns.) but the expertise modulated activation depending on the stimulus category (ANOVA for interaction expertise x stimulus category $-F(2,48)=4.5, p=.016)$. While there were no differences between experts and novices on chess objects and faces, experts' FFA was more activated on the chess positions than the FFA of novices $(t(24)=2.2, p=$ $0.039)$.

Figure 2: FFA activation pattern among experts (blue) and novices (red) on faces, chess positions, and chess objects in Study 1.

Unlike with the FFA, in the pSTS there were no expertise effects $(F(1,24)=1.6, n s)$ nor there was interaction between expertise and stimulus categories $(F(2,48)=0.2$, $n s$ ) - see Figure 3. Faces again elicited most activation, which resulted in the significant main effect of stimulus categories $(F(2,48)=11.6, p=.001)$.

This is the first time both isolated and complex chess stimuli were used in a single study. The results confirm the previous study on chess expertise (Bilalic et. al., 2011) and its finding of FFA sensitivity to expertise on complex chess positions. Here it is shown that the same pattern of activation does not generalize to single isolated objects. When isolated chess pieces were presented, expertise did not modulate the FFA activity.

## Study 2

## Method

The second study again used chess stimuli in chess specific tasks but this time they were neither completely isolated they always featured two objects. The study has been published (Bilalić et al., 2011) but here we use the unpublished ROI analysis on the FFA and pSTS.
Participants Information about participants is presented in Table 1.
Task, stimuli and procedure There were three tasks (Figure 4). In the check task, participants had to indicate if

Figure 3: pSTS activation pattern among experts (blue) and novices (red) on faces, chess positions, and chess objects in Study 1.
the white king is given check (one of the most important aspects in the game of chess) by the present black piece. In the identity task, the participants were presented with the same stimuli as in the check task, but this time they had to identify the black piece presented. In the control task, chess pieces were changed for geometrical shapes and the participants had to indicate the identity of the shape (diamond or square). We again used block design (for more details, see (Bilalić et al., 2011) with blocks of 13.5 s containing 4 trials.
MRI acquisition and data analysis This part of the study was the same as the previous study, except that this time a different EPI sequence was used: TR, 2.5 s ; FOV, $192 \times 192$; TE, 35 ms ; matrix size, $64 \times 64 ; 36$ slices with thickness of 3.20 .8 mm gap resulting in voxels with the resolution of $3 \times 3 \times 4 \mathrm{~mm} 3$. We again specified condition of interest as blocks, convolved it with HRF and analyzed responses in the selected ROIs using MarsBar toolbox.

## Results and discussion

Unlike in the previous study, there were no differences among experts and novices in the FFA activity in none of the three tasks (ANOVA for expertise, $F(1,14)=0.1$, $n s$ ) see Figure 4. There were no differences between the tasks (ANOVA for task, $\mathrm{F}(2,28)=1.1, \mathrm{~ns}$ ) nor there were differences between the task among the groups (ANOVA for task x expertise interaction, $\mathrm{F}(2,28)=0.9$, ns).

Similarly, the pSTS also did not produce different responses among experts and novices in all three tasks ( $\mathrm{F}(1$, $14)=1.8, \mathrm{~ns})$ and there was no main effect of task $(\mathrm{F}(2,28)$ $=5.1, \mathrm{~ns})$ nor interaction with expertise $(\mathrm{F}(2,28)=0.04$, ns).

Figure 4: FFA activation pattern among experts (blue) and novices (red) on control task (identifying geometrical shapes), identity task (identifying chess objects), and check task (identifying check relations among objects) in Study 2.

Figure 5: pSTS activation pattern among experts (blue) and novices (red) on control task (identifying geometrical shapes), identity task (identifying chess objects), and check task (identifying check relations among objects) in Study 2.

## General Discussion

Our previous study (Bilalić et al., 2011) showed that the FFA is sensitive to expertise as long as chess positions were present, even when the task at hand did not require specific chess activity. Here this result is extended to other kind of chess stimuli - isolated chess objects. Study 1 showed that chess positions, stimuli featuring several chess objects, produced an expertise effect, confirming our previous study. There were no, however differences when isolated chess objects were presented. The lack of expertise modulation with isolated chess objects was further confirmed in Study 2. Even when two objects formed a relation, the FFA was not responding differently in experts and novices.
Chess objects (as featured in Study 1) and chess relations (as featured in Study 2) are main building blocks of chess positions and the very same stimuli that consistently elicit
expertise effects in the FFA. It is thus surprising to find a lack of expertise effect in the FFA when it comes to isolated chess objects and their relations. One reason could be that Study 1 did not use explicit individuation between chess objects. Study 2, however, did use the differentiation between chess objects (based on which the tasks could be only done), not to mention that individuation processes are assumed to be implicit and automatic. It is, of course, possible that the lack of expertise effects in the FFA was due to low power of the studies. After all, the studies featured dozen participants in each group at most and the non-significant results should not be confused with a complete absence of effects. It is nevertheless the case that chess positions produced significant expertise effects in FFA in this and previous study, although both studies did not have large samples.
The FFA seems to be the only face area involved in chess perception. Here it was again shown that the pSTS does not differentiate between experts and novices on chess stimuli. As with the previous non-significant effect, one needs to be careful with conclusions. It seems reasonable, however, to conclude that the role of pSTS in chess expertise is arguably not as pronounced as that of FFA.
Although visually different, chess positions are essentially rather similar to faces. They are also made out of different individual parts (chess objects and relations between them). These parts are perceived as such only by beginners. Experienced chess players perceive chess positions rather as meaningful units, not unlike most of us perceive faces. The stored knowledge structures in memory (Gobet \& Simon, 1996) that enable them to quickly recognize situations on the board. In that sense, processes involved into parsing chess positions are much closer to those involved in face perception that are the processes involved in recognition of chess individual objects.
The exact role of FFA in chess expertise remains to be determined. Our previous study (Bilalic et al., 2011) demonstrated that experts' FFA reacts to chess positions without regard of the executed task. Even task that were not chess related (e.g., counting the number of all chess objects on the board) elicited expertise effects in the FFA. This indicates that the chess related processes in the FFA are automatic and stimulus, not task, dependent. In contrast, the other chess areas identified in our studies (Bilalić et. al., 2010; 2012), such as a part of the collateral sulcus and retrosplenial cortex, are also sensitive to task demands in addition to stimuli. How these regions are connected and how and to what extend they enable chess expertise remains an important question for future research.

The results also revise the expertise hypothesis by providing evidence against individuation as the primary function of the FFA. Study 1 did not involve explicit individuation as the individual chess objects were only passively observed. Study 2, however, involved explicit identification of a single chess objects (Identity task) and there were still no expertise-modulated response in the FFA. Only chess positions, consisting of numerous chess objects
and relations between those objects, produced different activation in the FFA of experts and novices. These results support previous studies demonstrating the importance of holistic parsing of individual parts of faces as the main FFA function (Arcurio, Gold, \& James, 2012; Gold, Mundy, \& Tjan, 2012), and put under questions is role in individuation.
They also revise the expertise hypothesis by providing evidence that complexity of stimuli and the processes that enable their fast and efficient perception are at the heart of the FFA function, and not only individuation.
These two chess studies, together with the previous work on the similarities between face and chess perception (Bilalić, et al., 2011; Boggan, 2012), underline the suitability of chess as an exploration vehicle in cognitive neuroscience.

## Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (DFG BI 1450/1-2). I am grateful for the help of all expert and novice chess players, I would also like to thank to Robert Langner, Michael Erb, Wolfgang Grodd and Rolf Ulrich for the help with the presented project.

#### Abstract

Novices often lack metacognition and self-regulation skills that are important for effective learning. Betty's Brain, an open-ended computer-based learning environment helps students practice and develop metacognitive strategies as they learn science topics. We extend previous work on sequence mining methods to discover students' frequentlyused behavior patterns from their activity sequences. Our results show that it is possible to interpret aspects of students' learning strategies and their effectiveness by taking into account the context of their activities in the system.

Keywords: open-ended learning environments, metacognition, measuring metacognition, scaffolding, sequence mining.

## Introduction

Cognitive scientists have established that metacognition and self-regulation are essential for developing effective learning strategies in the classroom and beyond (Bransford et al, 2000; Zimmerman, 2001). However, novice learners often have ineffective self-regulation profiles, which may be attributed to their lacking the well-organized domain knowledge structures of experts. This affects their ability to break down their learning and problem solving into distinct task understanding, planning and solution generation, monitoring and evaluation phases, leading them to use suboptimal learning and problem solving strategies (Chi et al, 1988; VanLehn, 1996).

Our research group has developed Betty's Brain, an openended learning environment (OELE), to study how students develop metacognitive strategies that include constructing information and monitoring as they learn science topics (Leelawong and Biswas, 2008). Our approach utilizes trace methodologies derived from students' actions and activity patterns in the environment to infer aspects of their metacognitive abilities (Aleven et al, 2006; Azevedo, et al., 2012; Hadwin et al, 2007). This is based on a metacognition as events hypothesis, which theorizes that the use of metacognitive strategies manifests as continually unfolding events that can be inferred from learners' behaviors.

In this paper, we extend our previous work on using sequence mining methods to discover students' frequently-
used behavior patterns from their activity sequences as they work in the Betty's Brain system (Kinnebrew \& Biswas, 2012). In particular, we extend our techniques for analyzing students' action sequences by (i) interpreting and characterizing behavior patterns using a cognitive/metacognitive model of the task, (ii) mapping students' frequently observed cognitive and metacognitive process patterns back into their overall activity sequences, and (iii) using metrics to evaluate the effectiveness of these processes. The results in this paper represent a post hoc analysis of student behaviors, but our longer term goal is to use such results to monitor and measure students' cognitive and metacognitive processes online as they work on their learning and problemsolving tasks, and use these results to develop adaptive scaffolding mechanisms that support student learning.

## Background

Metacognition is often described as being made up of two constituent parts (Flavell et al, 1985; Veenman, 2012): (1) Metacognitive knowledge, which is declarative and deals with the interplay between knowledge of one's abilities to perform tasks, the nature of the task, and the strategies one can employ to successfully perform the task; and (2) Metacognitive monitoring and regulation, which includes activities related to planning, monitoring, and evaluating one's cognitive processes in order to better regulate those processes in the future.

Researchers have established strong links between learners' metacognitive abilities and their effectiveness in executing cognitive processes. Winne (1996) characterizes cognition as dealing with knowledge of objects and operations on objects (the object level) while characterizing metacognition as the corresponding meta-level that contains information about cognitive processes. Metacognitive monitoring brings the two levels together, as it describes the process of observing one's own execution of cognitive processes at the object level and exerting control over the object level using metacognitive knowledge and strategies.

An important implication of the interplay between cognition and metacognition relates to the dependence of metacognition on cognition (Land, 2000). In other words, metacognitive knowledge may not be sufficient for achieving
success in learning and problem solving, especially for learners who lack the cognitive skills and background knowledge necessary for interpreting, understanding, and organizing critical aspects of the problem under study (Bransford et al, 2000). Learners may also lack knowledge of effective strategies (e.g., the ability to extract relevant information when reading a science text), and, therefore, resort to suboptimal strategies in performing their tasks (Azevedo, 2005; Kinnebrew \& Biswas, 2012). Poor selfjudgment abilities result in difficulties for monitoring and evaluating one's own effectiveness and progress, which can be a significant stumbling block in selecting and implementing relevant strategies in a timely manner.

However, research studies have shown that with proper scaffolding, middle school students can improve their metacognitive awareness and develop effective metacognitive strategies (Kramarski \& Mevarech, 2003). Our system, Betty's Brain is designed to help middle school students develop metacognitive knowledge and strategies as they learn about science topics. Other systems with similar goals include MetaTutor (Azevedo, et al., 2012) and Crystal Island (Rowe, et al., 2011).

## Betty's Brain

Betty's Brain (Figure 1) is an open-ended learning environment (Land, 2000) that provides students with a learning context and a set of tools for pursuing authentic and complex learning tasks. Students teach a virtual agent, Betty, about science topics by constructing a causal map. The goal for students using Betty's Brain is to teach Betty a map, whose correctness is determined in relation to a hidden, expert causal map.

The students' learning and teaching tasks are organized around three activities: (1) reading hypertext resources to learn the domain material, (2) building and refining a causal map, which represents the domain material, and (3) asking Betty to take a quiz. Students explicitly teach Betty by constructing a causal map. For example, they may draw a causal link between garbage and landfills and methane to represent the relationship garbage and landfills increase methane (a greenhouse gas). Students can check what Betty knows by asking her questions, e.g., if garbage and landfills decrease, what effect does it have on polar sea ice? To answer questions, Betty uses qualitative reasoning that operates through chains of links from the source concept to the target concept (Leelawong \& Biswas, 2008). The learner can further probe Betty's understanding by asking her to explain her answer. Betty illustrates her reasoning by explaining her thinking and animating her explanation by highlighting concepts and links on the map as she mentions them.

Learners can assess Betty's (and, therefore, their own) progress in two ways. After Betty answers a question, learners can ask Mr. Davis, a pedagogical agent that serves as a mentor, to evaluate the answer. Learners can also have Betty take a quiz on one or all of the sub-topics in the resources. Quiz questions are selected dynamically to reflect the current state of the student's map; questions are chosen (in pro-
portion to the completeness of the map) for which Betty will generate correct answers. The remaining questions produce incorrect answers, and they direct the student's attention to incorrect and missing links.

After Betty takes a quiz, her results, including the causal map she used to answer the questions appear on the screen as shown in Figure 1. The quiz questions, Betty's answer, and the Mentor's assigned grade, i.e., correct, correct but incomplete, or incorrect appear on the top of the window. Clicking on a question will highlight the causal links that Betty used to answer that question. To help students keep track of correct and incorrect links, the system allows students to annotate them with a green check-mark (correct), a red X (incorrect), or a gray question mark (not sure).

Figure 1: Betty's Brain Interface with Quiz Window

## Cognitive/Metacognitive Process Model

To interpret students learning behaviors on the system, we have developed a model that takes into account the tight connection between the cognitive and metacognitive processes needed to address the learning task effectively. Overall, this model includes four primary processes that students are expected to engage in while using Betty's Brain: (1) Goal Setting \& Planning, (2) Knowledge Construction (KC), (3) Monitoring (Mon), and (4) Help Seeking. In this work we focus on the KC and Mon process models.

Knowledge construction includes metacognitive strategies for (1) information seeking, i.e., determining when and how to locate needed information in the resources, and (2) information structuring, i.e., organizing one's developing understanding of the domain knowledge into structural components (e.g., causal links). In executing these metacognitive processes, learners have to apply relevant cognitive processes listed under information seeking and structuring. Seeking information, for example, requires that students to identify the causal information by reading the resources and making sense of the content. Similarly, information structuring captures the process of successfully converting the acquired information into causal links and adding them to the causal map.

Monitoring processes include (1) model assessment, i.e., assessing the correctness of all or a part of the causal model, and (2) progress recording, i.e., making explicit annotations to mark parts of the causal model as correct, which makes it easier to focus on parts of the map that need more work. Successful execution of monitoring metacognitive processes relies on students' abilities to execute cognitive processes for assessing the causal model (via questions, explanations, quizzes, and question evaluations) and recording progress (via note taking and annotating links with correctness information). The cognitive and metacognitive process model provides a framework for interpreting students learning activities and behaviors (activity sequences) on the system.

## Measuring Cognition and Metacognition

We have developed a set of data mining methods for analyzing students' learning activity sequences and assessing their learning processes as they work in Betty's Brain. In addition, we have developed visualization methods for measuring how student behaviors evolve during the course of the intervention depending on the type of feedback and support that they received from the Mentor agent. In particular, we were interested in studying whether students' suboptimal behaviors were replaced by more optimal strategies as the intervention progressed.

To assess student activities with respect to our cognitive/metacognitive model, we calculate four measures: map edit effectiveness, map edit support, monitoring effectiveness, and monitoring support. Map edit effectiveness is calculated as the percentage of causal link additions, removals, and modifications that improve Betty's causal map. Map edit support is defined as the percentage of causal map edits that are supported by previous reading of pages in the resources that discuss the concepts connected by the manipulated causal link. Monitoring effectiveness is calculated as the percentage of quiz questions and explanations that generate specific correctness information about one or more causal links. For example, all of the links used in a quiz question whose answer is marked correct, must be correct. If the answer to a question is incorrect, at least one of the links used in the answer must be incorrect. Finally, monitoring support is defined as the percentage of causal link annotations that are supported by previous quiz questions and explanations. For support metrics, a further constraint is added: an action can only support another action if both actions occur within the same time window, and we calculated support for a ten minute time window.

The information for calculating the measures and deriving student behavior using sequence mining is extracted from $\log$ files. For example, if a student accesses a page in the resources, this is logged as a Read action that includes additional information, e.g., the page accessed. In this work, students' activity sequences contain six categories of actions: (1) Read, (2) Link Edit, (3) Query, (4) Quiz, (5) Explanation, and (6) Link Annotation. Actions were further distinguished by context details, such as the correctness of a link edit. Sequence mining techniques are applied to discov-
er frequent behavior patterns for students in a given group (Kinnebrew, et al., 2013; Kinnebrew \& Biswas, 2012). Students' use of metacognitive processes was determined by interpreting the patterns using the cognitive and metacognitive model.

## Method

The present analysis used data from a recent classroom study with Betty's Brain in which students learned about the greenhouse effect and climate change. The study tested the effectiveness of two support modules designed to scaffold students' understanding of cognitive and metacognitive processes important for success in Betty's Brain. The knowledge construction (KC) module provided support on how to identify causal relations in the resources, and the monitoring (Mon) support module helped students understand how to use Betty's quizzes to identify correct and incorrect causal links on the causal map. Participants were divided into three treatment groups. The KC group (KC-G) used a version of Betty's Brain that included the KC support module and a causal link tutorial that they could access at any time during learning. The tutorial allowed students to practice identifying causal relations in short text passages. The Mon group (Mon-G) used a version of Betty's Brain that included the Mon support module and a marking links correct tutorial that they could access at any time during learning. The tutorial presented practice problems in which students used the results of graded quiz questions and the causal map used to answer those questions to select the links that could be marked as correct. Finally, the control group (Con-G) used a version of Betty's Brain that included neither the tutorials nor the support modules.

The KC module was activated when three out of a student's last five map edits were incorrect, at which point Mr. Davis would begin suggesting strategies for identifying causal links during reading. Should students continue to make incorrect map edits despite this feedback, the KC module activated a second tier of support: guided practice. During guided practice, students were moved to the causal link tutorial where they read short text passages and expressed the primary idea in the passage as a causal relation. When they worked on the tutorial, students were not permitted to access any other portion of the program. Students completed the tutorial session once they solved five problems correctly without making a mistake.

The Mon module was activated after the third time students did not use evidence from quizzes and explanations to annotate links on their map. At this time, Mr. Davis began suggesting strategies for using quizzes and explanations to identify and keep track of which links were correct. Additionally, Mr. Davis discouraged students from annotating links as being correct without using the suggested strategies. Should students continue to use quizzes and explanations without annotating links correctly, the Mon module provided students with guided practice. Like the KC tutorial, students had to complete five problems correctly on the first try to complete the tutorial session.

Seventy-three seventh grade students from four middle Tennessee science classrooms, taught by the same teacher, participated in the study. Because use of Betty's Brain relies on students' ability to independently read and understand the resources, the system is not suited to students with limited English proficiency or cognitive-behavioral problems. Therefore, data from English as a Second Language (ESL) and special education students were not analyzed. Similarly, we excluded the data of students who missed more than two class periods of work on the system. Our experimental analysis used data collected from fifty-two students who participated in the study.

Learning was assessed using a pre-post test design. Each written test consisted of five questions that asked students to consider a given scenario and explain its causal impact on climate change. Scoring was based on the causal relations that students used to explain their answers to the questions, which were then compared to the chain of causal relations used to derive the answer from the expert map. One point was awarded for each causal relationship in the student's answer that came from or was closely related to an expert causal link. The maximum combined score for the five questions was 16 . Two coders independently scored a subset of the pre- and post-tests with at least $85 \%$ agreement, at which point the coders split the remaining tests and individually coded the answers and computed the scores.

Performance on the system was assessed by calculating a score for the causal map that students created while teaching Betty. This score was computed as the number of correct links (the links in the student's map that appeared in the expert map) minus the number of incorrect links in the student's final map. We also used the log data collected from the system to derive students' behavior patterns, interpret them using our cognitive/metacognitive model, and study the temporal evolution of the observed KC and Mon strategies over the period of the intervention.

Study duration was 9 school days. During the first 60 minute class period, students completed the pre-test. During the second and third class periods, researchers introduced students to causal modeling and reasoning with causal models, and how to identify causal relations in text passages. During this time, students completed paper-and-pencil group exercises involving causal reasoning and identifying causal relations. During the fourth class period, students were provided with hands-on system training by the researchers. Students then spent four class periods using their respective versions of Betty's Brain with minimal intervention by the teachers and the researchers. On the ninth day, students completed the post-test.

## Results

Figure 2 presents the overall learning and performance results for each condition in the intervention. Repeated measures ANOVA performed on the data revealed a significant effect of time on test scores ( $\mathrm{F}=28.66, \mathrm{p}<0.001$ ). Pairwise comparison of the three groups revealed that the MonG had marginally better learning gains than KC-G, which
had better learning gains than the Con-G group. The Mon-G learning gains were significantly better than the Con-G gains at the 0.1 significance level ( $\mathrm{p}<.075$ ), indicating the two interventions may have resulted in better understanding of the science content. The small sample size and the large variations in performance within groups made it difficult to achieve statistical significance in these results. However, one positive aspect of this finding is that while students in the Mon-G and KC-G spent an average of $10 \%$ and $17 \%$ of their time in guided practice, respectively, they learned, on average, just as much, if not more, than the Con-G students.

Figure 2: Pre-post Test Results (mean (std dev)) and Final Map Score

To assess students' overall behaviors, we calculated the effectiveness and support measures, which are illustrated in Table 1. The KC-G students had the highest scores on both map editing effectiveness and support, suggesting that the KC feedback did help students more effectively and systematically read and construct their causal maps (however, only the map edit support showed a statistically significant difference, KC-G > Con-G, $p=0.02$, and the map edit effectiveness illustrated a trend, KC-G > Con-G, $p=0.08$ ). However, the monitoring support did not help the Mon-G students do better than the other two groups for monitoring effectiveness or support. The Mon-G students did have the highest monitoring effectiveness, but it was not statistically significant. Further, the Con-G students had the monitoring support average ( $p<0.10$, when comparing with other groups). It is not clear why the Mon or KC support and tutorials resulted in students performing less supported monitoring activities tan the Con-G students.

Table 1: Effectiveness \& Support Measures
((mean (std dev)) by Group

| Measure | Con-G | KC-G | Mon-G |
| :--- | :--- | :--- | :--- |
|  | 0.46 | 0.52 | 0.5 |
| Map edit effectiveness | $(0.13)$ | $(0.07)$ | $(0.12)$ |
|  | 0.43 | 0.64 | 0.55 |
| Map edit support | $(0.25)$ | $(0.19)$ | $(0.23)$ |
|  | 0.3 | 0.32 | 0.4 |
| Monitoring effectiveness | $(0.22)$ | $(0.21)$ | $(0.20)$ |
|  | 0.61 | 0.32 | 0.33 |
| Monitoring support | $(0.30)$ | $(0.4)$ | $(0.32)$ |

In order to investigate student learning behavior in more detail, we employed sequence mining analyses to identify 143 different action patterns that were observed in the majority of students. Table 2 lists the 10 most frequent patterns that employed at least two actions and could be interpreted as a metacognitive strategy in our cognitive/metacognitive model. Each pattern is defined by two or more primary actions, and each action is qualified by one or more attributes. For example, a [Read] $\rightarrow$ [Add correct link, relevant to recent actions] pattern describes a KC behavior, where the student added a correct causal link to the map after a [Read] action where the student read a page that discussed the added link. In contrast, the action labeled [Read] $\rightarrow$ [Add incorrect link, relevant to recent actions] implies the student added an incorrect link even after reading a page that contained information about the link. The $\rightarrow$ symbol implies that the action to the left of the arrow preceded the action to the right of the arrow.

The average frequency represents the average number of times students used a particular behavior pattern when they worked on the system. These numbers are broken down for the three conditions. The last column represents our interpretation of the type of strategy a particular behavior represents. In this study, the strategy corresponding to a behavior was determined by the category of the cognitive process ( KC or Mon) implied by the individual actions that made up the behavior Therefore, some behaviors, e.g., pattern \#3: [Quiz] $\rightarrow$ [Remove incorrect link], span KC and Mon (KC+Mon) strategies.

The frequency numbers indicate that for almost all of the top 10 behaviors the CON-G showed a higher frequency of use than the two experimental groups. This may be partly attributed to the time the KC-G and Mon-G groups spent in tutorials, therefore reducing the amount of time they spent on the map building task. However, an equally likely reason may be that the CON-G students used more trial-and-error approaches, spending less time editing and checking the correctness of their maps in a systematic way. This is further supported by looking at the highest average frequency behaviors for each of the groups. The top five behavior strategies for the Mon-G students are primarily Mon or $\mathrm{KC}+\mathrm{Mon}$ related (patterns $1,3,5,7$, and 9 ), involving quizzes, map editing, and explanations. KC-G students, on the other hand, more often employed KC strategies related to adding and removing links along with a couple of strategies that combine KC and Mon activities. The Con-G students seem to have employed KC and Mon strategies in about equal numbers, but they were less effective in using these strategies.

An interesting strategy is pattern \#10: [Add incorrect link (AIL)] $\rightarrow$ [Quiz (Q)] $\rightarrow$ [Remove incorrect link (RIL)]. This may represent a strategy where a student first adds a link (which happens to be incorrect) and then takes a quiz to determine if the quiz score changes. Depending on the outcome (in this case, the score likely decreased), the student determines that the link added was incorrect, and, therefore, removes it. This represents a trial-and-error strategy. While
students in all three groups used this strategy, the Mon-G group used it with lower frequency than the other two groups, and this may be attributable to the effectiveness of the Monitoring scaffolding. To study this pattern further we developed two measures: (1) a measure of cohesiveness of the pattern, i.e., in what percentage of the AIL $\rightarrow \mathrm{Q} \rightarrow$ RIL patterns was the delete action supported by the quiz result; and (2) a support measure, i.e., in what percentage of the AIL $\rightarrow \mathrm{Q} \rightarrow$ RIL patterns was the addition of the link supported by recent actions. The MON group had higher cohesiveness ( 41.9 to 38.0 and 37.3 for the CON and KC groups) and support ( 27.7 to 20.3 and 187.7 for the CON and KC groups) measures, implying that they used this pattern in a more systematic way than the other two groups.

## Discussion and Conclusions

The results presented in the previous section provide evidence that a combination of theory-driven measures and da-ta-driven mining techniques can be successfully employed to produce a more complete description of the metacognitive strategies use in their learning and problem-solving tasks. In our work on investigating cognitive and metacognitive processes in Betty's Brain, we had to carefully instrument the system to collect rich data on the students' activities and the context associated with those activities. Post hoc mining and analysis of this data revealed a number of interesting results. Perhaps most important, the results show (i) that it is possible to infer aspects of students' use of strategies as they learn through these data mining and analysis techniques combined with a cognitive/metacognitive model of the task, and (ii) that tracking student performance and related context information with respect to their activities allows us to better characterize these strategies as suboptimal versus optimal.

Our analyses in this study focused on students' knowledge construction and monitoring strategies. Knowledge construction strategies include seeking out information, thinking deeply about the material to develop a sufficient understanding to apply it to model building and problem solving tasks. In particular, information structuring strategies in Betty's Brain help students with their map-building activities, which include understanding the structure of the causal model, the ability to construct it in parts, the ability to add links correctly to an existing structure, and also the ability to reason (e.g., answer questions, formulate hypotheses) with the evolving structure. The primary monitoring strategies relate to determining when and how to check the correctness of the current causal map, and then, in more detail, using the quiz (assessment) results to determine the correctness of individual links, and what parts of the map are incomplete or still need work.

In summary, the analysis presented in this paper successfully employed our metacognition measurement framework to evaluate the effects of scaffolding support for metacognitive and cognitive processes important for success in Betty's Brain. In particular, we applied these analyses to a comparison of different versions of Betty's Brain, a version that pro-

Table 2: Comparison of Pattern Frequencies across Conditions

| Rank | Pattern | Avg. Frequency |  |  | Model <br> Category |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | CON | KC | MON |  |

#### Abstract

The current study investigates whether mentalizing, or taking the perspective of your interlocutor, plays an essential role throughout a conversation or whether it is mostly used in reaction to misunderstandings. This study is the first to use a brain-imaging method, MEG, to answer this question. In a first phase of the experiment, MEG participants interacted "live" with a confederate who set naming precedents for certain pictures. In a later phase, these precedents were sometimes broken by a speaker who named the same picture in a different way. This could be done by the same speaker, who set the precedent, or by a different speaker. Source analysis of MEG data showed that in the 800 ms before the naming, when the picture was already on the screen, episodic memory and language areas were activated, but no mentalizing areas, suggesting that the speaker's naming intentions were not anticipated by the listener on the basis of shared experiences. Mentalizing areas only became activated after the same speaker had broken a precedent, which we interpret as a reaction to the violation of conversational pragmatics.

Keywords: Language; Pragmatics; Precedents; Common Ground; Conversation; MEG.

## Introduction

Humans have the special capacity to think about what others are thinking or feeling (Tomasello et al., 2005) and employ such "mentalizing" in everyday conversations. In the current study, we employ Magneto encephalography (MEG) to investigate the neural basis of mentalizing and how this process interacts with other brain areas during interactive language use. We focus on the critical question of whether mentalizing plays an immediate and constant role in conversation, or whether it mainly comes into play to enable interlocutors to detect and recover from misunderstandings.

In a conversation, it is important to know what is in "common ground" between you and your interlocutor. For example, you need to make sure that you are talking about the same thing, when referring to an object. One of the strategies interlocutors use in this situation is to establish conceptual pacts (Brennan \& Clark, 1996) or conversational precedents (Barr \& Keysar, 2002). This entails that, once they have agreed on (or "grounded", Clark \& Brennan, 1991) a certain referential expression for the object (e.g., 'salami' for a particular piece of meat), interlocutors in a certain conversation will continue referring to that same referent with the same term. Listeners generally expect speakers to adhere to this strategy. Thus, if a speaker
"breaks" the precedent and suddenly uses a different term (e.g., 'sausage') for the same referent, this is expected to confuse the listener; perhaps the speaker now refers to a different object? Such confusion, resulting in longer latency times to look at objects, has indeed been attested in eyetracking studies (Brown-Schmidt, 2009; Metzing \& Brennan, 2003; Kronmüller \& Barr, 2007). However, to test whether this confusion was not just related to "egocentric" processing, because this was the last name the listener heard for this object, a second speaker was introduced. This second speaker, unaware of the precedent that the first speaker had set, also breaks the precedent. This situation should be much less confusing to the listener as there has never been a common ground with the second speaker. All studies cited above consistently showed evidence of perspective-taking at some point after breaking the precedent; listeners were slower to look at the intended object when the same speaker broke a precedent than when a different speaker did so. However, the eye-tracking studies did not conclusively distinguish between two different theoretical accounts. First, a shared perspective could be maintained throughout the conversation. In that case, listeners can easily anticipate speaker's naming intentions, if the object and its name are in common ground. Thus, breaking a precedent would immediately lead to confusion, but only by the same speaker. This was supported by some research (Metzing \& Brennan, 2003), whereas other research suggests that, in first instance, breaking a precedent leads to confusion regardless of the speaker (Kronmüller \& Barr, 2007). This latter result implicates that listeners might not use common ground in the form of a shared perspective with the speaker by default, instead, only when it becomes necessary due to a pragmatic violation. According to this view, the speaker's referential intentions would not be anticipated based on the previously shared perspective (i.e., mentalizing), but rather, perspective-taking would only be engaged after a violation has taken place.

Using MEG within a "precedents" paradigm offers unique insights into whether mentalizing is used to interpret language throughout a conversation, or whether it is only engaged in reaction to pragmatic violations. Like eyetracking research, MEG has an excellent temporal resolution that allows effects to be localized in time, while also localizing these effects in the brain. We devised a paradigm that allowed for live interactive dialog between a participant in the MEG scanner with two different (confederate)
speakers. The speakers and the participant/listener viewed pictures of everyday objects on separate computer monitors (see Figure 1). The experiment was divided into a series of blocks, each consisting of an "interactive" phase in which precedents were established for various pictures, and a later "test" phase in which some of these pictures were named once again by either the same or a different speaker. For example, in the test phase, the listener might see a picture of a piece of meat (see Figure 1, right) that had been called 'salami' during the interactive phase, but now hears the (same or different) speaker say 'sausage'. Based on how the test-phase speaker named their object, listeners had to decide whether or not the speaker saw the same object as them. This task provided a cooperative reason why the (same) speaker might break the precedent, namely to signal that this was a different sausage than the salami that they saw together before. This "broken precedent" condition was contrasted with a baseline "no precedent" condition in which the picture named in the test phase had been referred to by its location (i.e., not named), during the interactive phase (see methods). Importantly, in the test phase, listeners viewed the picture for 800 milliseconds before the object was named. Also, the speaker for a particular block of testtrials was announced in advance. Thus, listeners could anticipate the referential expression based on the picture and the speaker, before the name was actually given.

We hypothesized that listeners would engage episodic memory areas (medial temporal lobe, e.g., Baddeley, 2000; lateral prefrontal cortex, Sakai \& Passingham, 2004; Kessler \& Kiefer, 2005) together with language areas (e.g., temporal pole, Imaizumi et al., 1997) in this anticipation period and possibly after naming. Especially objects that had been named during the interactive phase (in contrast to objects without a precedent) should engage these areas, since the picture would serve as a retrieval cue for retrieving the precedent. Episodic memory might be activated even more for objects that had been named by the same speaker, if speaker identity is used as a further retrieval cue.

For our research question, the involvement of mentalizing networks (i.e., temporo-parietal junction: TPJ, ventromedial prefrontal cortex: vmPFC, and possibly precuneus: PC; e.g., van Overwalle \& Baetens, 2009) and the timing of such involvement was of particular importance. The "anticipation" account would predict that episodic retrieval of common ground information while viewing the picture would lead to anticipation of the speaker's naming intentions, by employing mentalizing areas, already before naming. Crucially, such anticipation of naming intentions is only very meaningful when the current speaker has named this picture before. In contrast, the "egocentric" account would predict that, despite episodic retrieval of common ground information, mentalizing areas would not be employed to anticipate naming preferences based on these memories. Instead, this account would predict late, deliberate, post-naming activation of the mentalizing network, suggesting that it is only called upon to make sense of the experienced violation.

## Methods

## Participants

Seventeen British students from Glasgow University (8 males) with English as their native language participated in the MEG experiment, with approval of the local ethics committee. They were paid for their participation and gave their informed consent. One female participant was excluded from the analyses because she clicked the wrong picture too often in the interactive phase (22 times).

## Materials and Apparatus

Materials consisted of 320 experimental pictures that could be named in two roughly equivalent ways (based on a pilot study) and 640 filler pictures. The names for the test phase (320 experimental names and 190 filler names) were recorded beforehand, divided equally among the two confederates. Some of the filler names were presented with a hesitation, to make naming on-the-spot more plausible. The experimental names were always preceded by 800 ms of recording noise ( 600 to 1200 ms for the fillers).

MEG data were acquired using a 248 -channel 4DNeuroimaging magnetometer system, sampled at 508.63 Hz and band-pass filtered between 0.1 and 400 Hz .

Figure 1: Example of the participants' screen in the interactive phase (left) and the test phase (right).

## Procedure

Participants were first prepared for the MEG, including head digitization, in about 45 minutes. They were introduced to the confederates ("the speakers"), who would talk to them from separate rooms and were not able to hear each other. Participants had the role of listener. After two practice blocks in which the participants had the role of listener and speaker, 20 experimental blocks followed, all consisting of an interactive and a test phase, divided into 5 parts of 20 minutes each, with breaks in between. In the interactive phase, participants saw 9 pictures on the screen at a time (see Figure 1, left). In each interactive phase, one speaker asked them to click on one of these pictures, for a total of 42 times. Each critical picture was clicked on twice by the participants, using a trackball. Eight critical pictures were named and another eight were referred to by their location (e.g., 'top left'; participants were told that the speaker saw a question mark in place of these pictures). Participants could
freely interact with speakers in this phase. In the test phase, the speaker was the same as for the preceding interactive phase in half of the cases and different in the other half. Participants saw one picture at a time on the screen (see Figure 1, right) and were told that the speaker also saw one picture and had to name that picture. Participants had to indicate whether the speaker saw the same or a different picture than they, with a button press. The listeners were instructed not to interact with the speaker in this phase as they were unaware of hearing recorded utterances. Each phase consisted of 8 broken precedent trials (named differently than in the interactive phase), 8 no precedent trials (indicated by their location in the interactive phase), 4 maintained precedent fillers (named the same way in the interactive phase) and some new fillers.

## Data analysis

Pre-processing and statistical analysis of MEG data was conducted using the Fieldtrip Matlab® toolbox (Oostenveld, Fries, Maris, \& Schoffelen, 2011). We extracted epochs from 500 ms before the picture was shown until 500 ms after the response for all test trials. These epochs were detrended, denoised, and subjected to ICA to remove eye, heart, and movement artefacts. For evoked responses (ERF), trials of the same condition were averaged per participant, with a baseline of 200 ms prior to picture onset and a bandpass filter between 0.5 and 35 Hz . For these averages, planar gradient representations were calculated prior to sensor level analysis. For time-frequency representations, the power of frequencies between 2 and 30 Hz was calculated over time using a Hanning taper with a window of 4 cycles. For statistical analysis, we used the cluster-based approach implemented in the Fieldtrip toolbox (Maris \& Oostenveld, 2007), to circumvent the multiple-comparisons problem. We employed 2-step analyses for emulating the interaction between two factors. We first calculated a t-statistic for the difference between two conditions per participant and then included these $t$-values into a group statistic that compared a second difference. To identify sources underlying the sensor-level effects, individual single-shell head models were generated based on the individual MRI ( 6 mm voxel size) aligned with the MEG sensor array, subsequently normalized to a standard brain. A Linearly Constrained Minimum Variance (LCMV) beam former (van Veen and Buckley, 1988), common for all conditions (to increase SNR), was used for ERFs to transform individual conditions into source space for comparisons between conditions. Dynamic Imaging of Coherent Sources (DICS) beam formers (Gross et al., 2001) were used for theta source analysis. In this case we used condition-specific spatial filters to reveal qualitative differences between conditions.

## Results

## Behavioural results

As shown in Figure 2, the proportion of "different picture" responses was increased when a precedent was broken by
both same $(\mathrm{t}(15)=-5.63, \mathrm{p}<.001)$ and different speakers $(\mathrm{t}(15)=-3.97, \mathrm{p}=.001)$, but this was more pronounced for same speakers $(\mathrm{F}(1,15)=21.15, \mathrm{p}<.001)$. Participants were slower when an established precedent was broken, but only when the same speaker broke the precedent $(t(15)=3.47$, p $=.003$ ), resulting in an interaction $(\mathrm{F}(1,15)=8.43, \mathrm{p}=$ .011). Thus, listeners experienced greater confusion when a speaker broke his or her own precedent than when a speaker broke another's precedent (confirming Metzing \& Brennan, 2003; Kronmüller \& Barr, 2007). Note that this does not imply that common ground is considered by default or in anticipation, since it might also mean that listeners still experience conflict when a different speaker breaks the precedent, but resolves the conflict more quickly and/or in a different way than when the same speaker does so.

Figure 2: Behavioural responses in the test phase: proportion of "different" responses (left) and RTs (right).

These behavioural data confirmed our approach to look at the interaction effect in the MEG data (using the two-step analysis, see Data analysis), which we did for the theta source analysis (see Theta Oscillatory Results). Furthermore, on the basis of these behavioural data, it is most likely that mentalizing occurred for trials in which a precedent was broken by the same speaker and where participants responded to have seen a different picture. By this behavioural response, they show that they are aware of the conflict between the precedent and the new term and have resolved this by deciding that the speaker probably sees a different picture now. Next to that, especially slow responses, probably reflecting confusion upon hearing the new term, could also reflect the engagement of mentalizing processes. In contrast, in trials that elicited a quick "same picture" response, listeners might not even be aware of the conflict. Thus, we selected the "different"-responses plus one third of the slowest "same"-responses for the same speaker/broken precedent condition and refer to them as "deliberation trials". We used separate analyses of these trials as corroborative evidence when necessary (see ERF Results), next to analysing all trials of this condition.

## ERF Results

In a cluster analysis between 300 and 500 ms after naming (on the basis of visual inspection), a significant cluster was found for same speaker between 318-454 ms (p $=.009$ ) and a marginally significant cluster for different speaker between $300-415 \mathrm{~ms}(\mathrm{p}=.048)$ (see Figure 3, panel A). The topography of the effects was slightly more anterior (left) for the same speaker and more posterior (left) for the
different speaker. However, a direct comparison between the two contrasts did not reveal significant clusters. We also analysed the deliberation trials between -800 and 1000 ms . This revealed a cluster with a similar topography and timing of peak activity as the previous analysis ( $67-680 \mathrm{~ms}$ after naming, $\mathrm{p}<0.00001$, Figure 3, panel B right) plus two clusters in an early time interval before naming, when the target object was visually presented, ( 550 to 23 ms before naming onset, $\mathrm{p}=.004$, and 306 to 0 ms before naming onset, $\mathrm{p}=.004$; Figure 3, panel B left). This strongly suggests anticipatory processing in deliberation trials.

Figure 3: Sensor level ERF. A: comparisons for "broken vs. no precedent" for same speaker (left column) and different speaker (right column). B: comparisons for the deliberation trials (dotted dark blue line) compared to the no precedent trials (light blue line), within the same speaker condition. Significant clusters for this contrast are indicated pre-naming (left) and post-naming (right).

Source analysis was employed for the comparison between deliberation and no-precedent trials within the same speaker for both time intervals. The post-naming analysis between 300 and 500 ms revealed one significant, spatially distributed cluster ( $\mathrm{p}<0.00001$ ) and the prenaming analysis between -350 and -150 ms also revealed one significant, spatially distributed cluster, ( $\mathrm{p}<0.00001$ ). Table 1 lists the brain areas included in the pre- and postnaming clusters. See Bögels et al. (submitted), for figures and a more detailed description of these source-level results.

In both intervals, we found activation related to episodic memory processing, suggesting that participants were continuously retrieving the episodic context for a particular target object. Parahippocampal gyrus has been associated primarily with episodic encoding of the visuo-spatial context (e.g., Epstein \& Kanwisher, 1998), but more
recently also with integration of social, communicative, and paralinguistic context (e.g., Rankin et al., 2009). Thus, this activation might reflect retrieval of the episodic context of the interaction with the target object, including information about the speaker and the used name. We also found language-related areas, possibly indicating retrieval of the referent established during the interaction (in the prenaming interval, cf. Duff \& Brown-Schmidt, 2012) and semantic matching processes between the object and the used name (in the post-naming interval, e.g., Grabowski, Damasio et al., 2001; Pobric et al., 2007). We found differences in visual (attention) areas in the early interval which could suggest more visually detailed episodic retrieval of previously named objects, when anticipating a naming by the same speaker. In the late interval, we found activation of motor areas which could reflect more intense or more conflicting motor preparation. Anterior cingulate cortex activity was found in both intervals, suggesting an anticipation of conflict in the early and monitoring of conflict during the late interval. Most importantly for our research question, we found activation of so-called "mentalizing" areas only after naming. These areas have been found to be part of a mentalizing network, for example involved in social judgments (van Overwalle \& Baetens, 2009), in visuo-spatial perspective taking tasks (Blanke et al., 2005), and in reasoning about other's beliefs (Samson et al., 2004).

Table 1: Brain areas involved in the pre- and post-naming interval for ERFs in the deliberation trials vs. no precedent same speaker comparison ( $1 / \mathrm{r}$ : left and right hemispheres).

| Brain areas | Pre-naming | Post-naming |
| :--- | :--- | :--- |
| Episodic <br> memory | Parahippocampal <br> gyrus (l), <br> dorsolateral <br> prefrontal cortex (r) | Parahippocampal <br> gyrus (l) |
| Language | Temporal cortex (r) | Temporal pole (l) |
| Visual <br> (attention) | occipital cortex (r), <br> occipital temporal <br> cortex (r), parietal <br> occipital cortex (r) |  |
| Motor <br> (conflict) | Anterior cingulate <br> cortex (ACC) $(\mathrm{r})$ | ACC(l), <br> premotor cortex(l), <br> supplementary <br> motor area(l) |
| Mentalizing |  | TPJ (r), vmPFC (l/r) |

## Theta Oscillatory Results

Time-frequency analysis ( -800 to 1000 ms ) revealed a significant cluster ( $\mathrm{p}=.012$ ) in the theta range $(4-6 \mathrm{~Hz})$ for "same speaker, broken precedent" compared to "same speaker, no precedent" in a time window around 350-650 ms after naming onset. No results were found in the corresponding comparison for different speaker.

We localised the sources of this theta effect in a postnaming time-window ( $200-800 \mathrm{~ms}$ ) for 3 to 7 Hz , using a two-step analysis to look at the speaker by precedent
interaction ( $\mathrm{p}<.008$; see Bögels et al. (submitted) for more details and figures). In Figure 4, results are displayed of another two-step analysis within same speaker, comparing anticipatory and reactive intervals ( $\mathrm{p}<.01$ ).

Figure 4: Theta sources comparing same speaker (broken vs. no precedent) effects before and after naming.

Again, both analyses show episodic (working) memory areas (parahippocampal gyrus: blue circle in Figure 4; prefrontal cortex). Together with stronger activation of visual (attention) areas (occipital cortex: yellow circles in Figure 4) in the early than the late interval, this suggests stronger episodic retrieval in the right hemisphere along with stronger visual reactivation in response to the naming. In both analyses, we also see language (green circles in Figure 4) and motor areas (black circles in Figure 4) again, as in the ERF analysis. Importantly, mentalizing areas in right TPJ, right precuneus and vmPFC showed stronger theta effects for the same speaker contrast than the different speaker contrast, but also within the same speaker contrast in the post- vs. the pre-naming interval (pink circles, Figure 4).

## Discussion

Our results indicate that brain areas related to language, vision, episodic (working) memory, and mentalizing are dynamically and jointly involved in encountering and resolving conflict after a previously negotiated precedent is broken by the same speaker, and more so than when it is broken by a different speaker.

Episodic memory (together with language and vision) areas were engaged already in anticipation, suggesting a retrieval of the circumstances in which this picture was encountered before. Specifically, seeing a picture that was named before by the same speaker resulted in a stronger involvement of episodic memory (Theta localisation results), suggesting that the name was retrieved based on the picture and the identity of the speaker. We found especially strong anticipatory episodic memory activation for the trials in which listeners later on decided that the speaker saw a different picture ("deliberation trials", only for the time
domain). Successful retrieval of the name and speaker on the basis of the picture probably allowed listeners to notice the conflict with the actual name that was given by the speaker and decide that the speaker might see a different picture.

With regards to our main research question, we found (both in the time and the frequency domain) that mentalizing areas were clearly more engaged in response to the violation than in response to the other conditions (in accordance with Kronmüller \& Barr, 2007; Metzing \& Brennan, 2003). Crucially for our research question, however, mentalizing was not engaged more strongly in the anticipatory time interval in the condition in which the same speaker was going to name an object he or she had named before. Thus, while retrieval of the precedent and probably the speaker associated with that precedent took place on the basis of the picture, this did not lead to inferences of the current speaker's naming intentions using mentalizing. One might argue that listeners will try to infer the speaker's intentions in every condition. However, only in the case in which the same speaker has named this object before, does the listener really have grounds to use the speaker's perspective for this anticipation. Therefore, we argue that it would be expected, under the anticipation view, that mentalizing areas should be involved more strongly in precisely that condition, but this is not corroborated by our findings. Even when focussing only on "deliberation" trials (only for the time domain), where mentalizing was most likely to occur, since listeners show that they are aware of the conflict, we found no evidence for anticipation of the speaker's referential intentions (mentalizing).

These findings are in accordance with earlier eye-tracking results by Kronmüller and Barr (2007), showing that common ground is not taken into account by default since a broken precedent at first leads to confusion regardless of the speaker. In this context, recent approaches involving a second-person perspective (e.g., Schilbach et al., 2012) could also be of interest. A different processing "mode" and differential activation of brain areas is assumed for observation of others or "third person perspective" (as was used in most previous research) and for direct interaction with others, or "second person perspective". The latter type of processing (which might involve the posterior temporal sulcus; Tylén et al., 2012), related to fine temporal coordination during interaction, might be involved throughout a conversation, dealing for example with building up common ground by setting up new precedents. In the current study, all conditions probably involve such processes, resulting in no differential effects. In contrast, the pragmatic violations listeners encounter in the current study could invoke a mode that resembles the third person perspective, since listeners try to infer why the speaker breaks the precedent, involving the "classic" mentalizing areas (e.g., vmPFC; Tylén et al., 2012).

In conclusion, anticipating the speaker's referential intentions based on previously established common ground does not seem to be a default process. In contrast,
anticipation seems to rely only on episodic retrieval of visual and linguistic associations without any inference of the speaker's current mental states. Mentalizing about the other's perspective seems to be engaged "on demand" once a pragmatic violation or misunderstanding has occurred.

# Discovering Processing Stages by combining EEG with Hidden Markov Models 

Jelmer P. Borst (jelmer@cmu.edu)<br>John R. Anderson (ja+@cmu.edu)<br>Dept. of Psychology, Carnegie Mellon University

#### Abstract

A new method is demonstrated for identifying processing stages in a task. Since the 1860 s cognitive scientists have used different methods to identify processing stages, usually based on reaction time ( RT ) differences between conditions. To overcome the limitations of RT-based methods we used Hidden Markov Models (HMMs) to analyze EEG data. The HMMs indicate for how many stages there is evidence in the data, and how the durations of these stages vary with experimental condition. This method was applied to an associative recognition task in which associative strength and target/foil type were manipulated. The HMM-EEG method identified six different processing stages for targets and repaired foils, whereas four similar stages were identified for new foils. The duration of the third, fifth and sixth stage varied with associative strength for targets and re-paired foils. We present an interpretation of the identified stages, and conclude that the method can provide valuable insight in human information processing.

Keywords: EEG; HMM, processing stages.

## Introduction

One of the main goals of cognitive science is to understand how humans perform tasks. To this end, scientists have long tried to identify different processing stages in human information processing. The first to do this in a systematic manner was probably Franciscus Donders. Almost 150 years ago, Donders proposed a method to measure the duration of cognitive stages (1868). By subtracting the RTs of two tasks that were hypothesized to share all but one processing stage, the duration of that stage could be calculated. A strong - and often problematic - assumption of Donders' subtractive method is the idea that it is possible to add an entire stage without changing the duration of other stages. To test whether different stages exist in the first place, Sternberg proposed the additive-factor method (1969). Although Sternberg overcame a limitation of Donders' method, the additive-factors method has its own drawbacks: it can only indicate the minimum number of stages in a task and it does not yield duration estimates of the stages. To improve on these inherent problems of RTbased methods and get better insight in stage existence and duration we propose a new method that uses HMMs (e.g., Rabiner, 1989) to analyze EEG data.

The basic idea of our method is to fit HMMs with different numbers of states to the EEG data (note that we use 'processing stages' and 'HMM states' interchangeably throughout the paper). The optimal number of states can then be determined by comparing the log-likelihoods of the fitted HMMs. Subsequently, the durations of the different states can be inspected, as well as how these durations vary
with condition. Using this information, and by comparing EEG signatures between states and experimental conditions, one can interpret the functional characteristics of the identified processing stages.

Our approach is based on a similar method that was used to analyze fMRI data (Anderson \& Fincham, in press; Anderson et al., 2010). For instance, Anderson and Fincham (in press) applied the method to mathematical problem solving, and discovered four stages: encoding the problems, planning a solution strategy, solving the problems, and entering a response. Although these results were promising, the temporal resolution of fMRI is severely limited, both by having scans that typically last one to two seconds and by the sluggish nature of the hemodynamic response. EEG, on the other hand, has a millisecond resolution, allowing for the discovery of processing stages in fast-paced tasks.

We applied the HMM-EEG analysis to an associative recognition task. During the study phase of this task, subjects were asked to learn word pairs. In a subsequent test phase - during which EEG data were collected - subjects were again presented with word pairs, which could be the same pairs as they learned previously (targets), rearranged pairs (re-paired foils), or pairs consisting of novel words (new foils). Subjects had to decide whether they had seen the pair during the study phase or not. Successful discrimination required remembering not only that the words were studied (item information), but also how the words were paired during study (associative information).

A conventional EEG analysis and a classifier analysis of this study were reported elsewhere (Borst et al., submitted). Currently, we are interested in finding out how many stages the subjects went through while determining a correct response.

## Methods

## Subjects

Twenty individuals from the Carnegie Mellon University community participated in a single 3-hr session for monetary compensation ( 9 males and 11 females, ages ranging from 18 to 40 years with a mean age of 26 years). All were right-handed and none reported a history of neurological impairment.

## Design

The experiment consisted of a study phase in which subjects learned word pairs and a test phase in which they were tested on these word pairs. In addition to probe type (targets, re-paired foils, or new foils), we manipulated word length and associative strength. Words could either be short (4 or 5
letters) or long (7 or 8 letters). Associative strength was manipulated by varying the number of word pairs a particular word occurred in. This is referred to as associative fan, and is known to have a strong effect on RT and accuracy (for a review, see Anderson \& Reder, 1999). Words in our experiment could have a fan of 1 or 2 , that is, they could occur in one or two word pairs. Both words in a word pair always had the same associative fan. New foils (foils consisting of words that were not presented in the study phase) always had an associative fan of 1 , they only appeared in a single word pair. Thus, there were 10 conditions: 2 (Probe: target or re-paired foil) $\times 2$ (Word Length: short or long) $\times 2($ Fan: 1 or 2$)+$ short and long new foils.

## Materials

Word pairs were constructed from a pool of 464 words selected from the MRC Psycholinguistic Database (Coltheart, 1981). Half of the words were nouns of 4 or 5 letters and composed the short word list. The other half of the words were nouns of 7 or 8 letters and composed the long word list. Word frequency and imageability ratings were matched between those lists. The 232 words of each length were divided randomly into two lists - a 24 -word study list and a 208 -word new foil list - such that the lists were matched on word frequency, imageability, and word length according to $t$-tests (all $p \mathrm{~s}>.1$ ).

The lists were used to create three sets of probes: targets, re-paired foils, and new foils. A set of 32 target word pairs was constructed from the study lists such that there were eight word pairs for each combination of length (short or long) and fan (1 or 2). Both words in short pairs were 4 or 5 letters and both words in long pairs were 7 or 8 letters. Each word in a fan 1 pair appeared only in that pair, whereas each word in a fan 2 pair appeared in two pairs. A corresponding set of 32 re-paired foil pairs was constructed in a similar manner by combining words from different target pairs of the appropriate length and fan. A set of 208 new foil word pairs was constructed from the new foil lists such that there were 104 word pairs for each length (all fan 1). The randomization of words and their assignment to conditions were unique for each subject.

## Procedure

The study phase started with each target word pair presented onscreen for 5000 ms , followed by a $500-\mathrm{ms}$ blank screen. Subjects were instructed to read each pair and make an initial effort to memorize it. Following target presentation, subjects completed a cued recall task designed to help them learn the word pairs. On each trial they were presented with a randomly selected target word and had to recall the word(s) paired with it (two-word responses were required for fan 2 words). The self-paced responses were typed and feedback (in the form of the correct response) was provided for 2500 ms following errors. If a target word elicited an error, it was presented again after all other target words had been presented. A block of trials concluded when all 48
target words had elicited a correct response. Subjects completed a total of three blocks of cued recall.

After the study phase, subjects entered the EEG recording chamber and completed the test phase. Each trial began with a centrally presented fixation cross for a duration sampled from a uniform distribution ranging from 400 to 600 ms . Following fixation, a probe word pair appeared onscreen (one word above the other) until the subject responded with a keypress to indicate whether the probe had been studied during the training phase. The probe was either a target, repaired foil, or new foil. Targets required "yes" responses (indicated by pressing the J key with the right index finger) and foils required "no" responses (indicated by pressing the K key with the right middle finger). Subjects were instructed to respond quickly and accurately. Following the response, accuracy feedback was displayed for 1000 ms , after which a blank screen appeared for 500 ms before the next trial began. Subjects completed a total of 13 blocks with 80 trials per block. All 10 conditions occurred equally often in random order in each block, resulting in 104 trials per condition during the test phase. Targets and re-paired foils were repeated during the test phase (they each appeared once per block), but each new foil appeared only once in the entire experiment.

## EEG recording

Subjects sat in an electromagnetically shielded chamber. Stimuli appeared on a CRT monitor placed behind radiofrequency shielded glass and set 60 cm from the subjects. The electroencephalogram was recorded from $32 \mathrm{Ag}-\mathrm{AgCl}$ sintered electrodes (10-20 system). Electrodes were also placed on the right and left mastoids. The right mastoid served as the reference electrode, and scalp recordings were algebraically re-referenced offline to the average of the right and left mastoids. The vertical electrooculogram (EOG) was recorded as the potential between electrodes placed above and below the left eye, and the horizontal EOG was recorded as the potential between electrodes placed at the external canthi. The EEG and EOG signals were amplified by a Neuroscan bioamplification system with a bandpass of 0.1 to 70.0 Hz and were digitized at 250 Hz . Electrode impedances were kept below $5 \mathrm{k} \Omega$.

## EEG preprocessing

Recording artifacts in the EEG data were removed based on visual inspection. Following artifact rejection, the data were decomposed into independent components. Components associated with eye blinks were visually identified and projected out of the EEG recordings. A $0.5-30 \mathrm{~Hz}$ band-pass filter was applied to attenuate high-frequency noise. Trials were extracted from the continuous recording and baselinecorrected using a linear baseline, such that the 200 ms before stimulus onset and $80-160 \mathrm{~ms}$ after the response were on average 0 (visual inspection showed no condition difference at this interval after the trial). Incomplete trials due to artifact rejection were excluded, as well as trials containing voltages above $+75 \mu \mathrm{~V}$ or below $-75 \mu \mathrm{~V}$. In
addition, all incorrect trials and correct trials with RTs exceeding three standard deviations (SDs) from the mean per condition per subject were removed. For the HMM-EEG analysis we also removed trials with RTs longer than 3000 ms . In total, $16.1 \%$ of the trials was excluded.

For efficiency, the EEG data were down-sampled to 50 Hz . Every four samples were then combined into a single 'super-sample', by quadrupling the number of channels. That is, from four $20-\mathrm{ms}$ samples with 32 channels we created one $80-\mathrm{ms}$ super-sample with 128 channels. A super-sample contained information about the mean voltage in each channel, as well as about whether this voltage increased or decreased over the 80 ms interval. Next, we normalized each channel to a mean of 0 and a SD of 1 , and applied a principle component analysis (PCA) to the 128 channels. The results of the PCA were again normalized; the first 20 PCA components were used for the HMM-EEG analysis.

## The HMM-EEG Analysis

The HMM-EEG analysis consists of two main parts: (1) determining the optimal number of states and (2) computing the properties of the identified states. Both parts of the analysis depend on fitting HMMs to the preprocessed EEG data. We will therefore first discuss the structure and parameter estimation procedure that was used for the HMMs. We then explain how these HMMs were used to find the optimal number of states and how we computed the properties of these states.

## HMM structure and parameter estimation

An HMM simulates a system that is at any given time in one of a set of distinct states, between which it transitions at certain times (e.g., Rabiner, 1989). In our analysis, each state represents a processing stage in the task (e.g., encoding the stimulus, executing a response). A state is associated with a brain signature $M_{i}$ that represents the average EEGactivation pattern during this processing stage, and with a gamma distribution $G_{i}$ that represents the state's durations over the trials in the experiment. For current purposes, we only consider HMMs with a linear structure, that is, state 1 always transitions to state 2 , state 2 to state 3 , etc.

An example of a four-state HMM is shown in Figure 1. At the top of the figure EEG data is shown for three channels over three trials of the experiment, at the bottom the HMM with associated brain signatures and gamma distributions.

Figure 1. Overview of the HMM-EEG analysis. EEG data comes in at the top and is preprocessed into PCA components. At the bottom a fitted 4-state HMM is shown, with state signatures and gamma distributions. The center graph shows the probability of each sample $j$ for each state given this HMM. The connections between sample likelihoods and states are shown for states 1 and 3.

HMM algorithms can be used to find parameters $M_{i}$ and $G_{i}$ that yield the optimal interpretation of the data given an HMM with $r$ states (see Anderson \& Fincham, in press, for a more detailed explanation for the kind of HMMs that are used in this paper; Rabiner, 1989; Yu \& Kobayashi, 2006). To calculate the solutions we adapted software that minimizes the summed log-likelihood of the HMM over all trials (Yu \& Kobayashi, 2006).

Figure 1 shows the result of such an optimization procedure for a 4 -state HMM. Given the optimal state signatures and gamma distributions, the probability that each sample $j$ belongs to a state is depicted in the center of the figure. As expected, the first samples in each of the three trials probably belong to state 1 (blue), the next samples to state 2 (green), etc. In addition, state 1 is always two samples long in the three trials in the figure, matching the gamma distribution of this stage. State 3, on the other hand, is much more variable in duration.

For clarity the explanation above assumes a gamma distribution for each state. In the actual analysis we used separate gamma distributions for each condition and state, allowing for different duration estimates per condition.

Figure 2. State signatures and gamma distributions.

## Number of states and state properties

Above we explained how an $r$-state HMM can be determined that gives an optimal interpretation of the data. However, what we are really interested in is finding the optimal number of states to describe the data. A simplistic approach would be to compare the log-likelihoods of HMMs with different numbers of states. However, because HMMs with more states have more parameters to fit the data, they will typically yield a better fit. What we want to know is if the extra parameters explain enough extra variance to be warranted. To this end we applied leave-oneout cross validation (LOOCV).

Our LOOCV method estimated state signatures for $n-1$ subjects, and calculated the log-likelihood of the $n^{\text {th }}$ subject given these signatures while allowing for different state durations for the $n^{\text {th }}$ subject (to accommodate speed differences between subjects, unlike Anderson \& Fincham, in press). This process was repeated for all subjects.

The LOOCV procedure was repeated for HMMs with different numbers of states. To select the best model we used a sign-test: if a $k$-state model fitted the data of $x$ out of $n$ participants better than all $(l<k)$-state models we choose it as the winner. The underlying idea is that while a $(k+1)$ state model will fit the data of $n-1$ subjects better in the estimation phase than a $k$-state model, it is at least as likely to fit the $n^{\text {th }}$ subject worse (Anderson \& Fincham, in press). According to a sign-test, a significant increase is reached when 15 out of 20 subjects improve ( $p=.04$ ).

After determining the optimal number of states, we computed the properties of the identified states. First, we estimated an optimal HMM on the data of all subjects. We used the state signatures of this model to estimate optimal gamma distributions for each subject. These gamma distributions were used to calculate the average state duration for each subject and condition, which were used in subsequent ANOVAs to determine which states change in duration with condition. In addition, the subject-specific
models give us the probability for each sample in the data to be in a certain state (center of Figure 1). This was used to calculate differences in EEG activation between conditions.

## Results

For reasons of brevity we do not report behavioral results separately. RTs can be inferred from Figure 3. For targets and re-paired foils, $\operatorname{Fan}(F(1,19)=65.42, p<.001)$, Probe $(F(1,19)=45.10, p<.001)$, and the interaction between Fan and Probe $(F(1,19)=31.40, p<.001)$ had a significant effect on RT, as indicated by a repeated measure ANOVA. In addition, new foils were responded to much faster than the other probe types, which was expected given that no associative information has to be retrieved for new foils.

## Number of stages

Because new foils are very different from the other probe types - no associative information has to be retrieved for new foils - we decided to run separate analyses for new foils and targets/re-paired foils. For targets and re-paired foils a 6 -state HMM turned out to be the winner. It was better for at least 16 subjects than HMMs with fewer states, and no HMM with more states had a higher log-likelihood for more than 9 subjects. The new foils also showed evidence for 6 states: 17 subjects fitted better with a 6 -state HMM than with 4 states. However, the 4 -state solution compares better to the 6 -state solution of targets and repaired foils. ${ }^{1}$ Although there might be more stages in the data, we can be secure in the assumptions that there are at least 6 states for targets and re-paired foils and 4 states for new foils and in whatever conclusions these assumptions lead to. Thus, we will focus on the 4 -state solution for new foils in this paper.

## Stage properties

Figure 2 shows the gamma distributions and state signatures of the 6 -state HMM for the targets/re-paired foils and the 4 state HMM for the new foils. Interestingly, the first two states of both solutions seem very similar. Correlations between the state signatures confirm that stage 1 and stage 2 in both HMMs resemble each other closely: 0.98 and 0.97 .

The estimated gamma distributions in Figure 2b are averaged over conditions and subjects. They show that stage 1 has a very fixed duration, of two samples or 160 ms . The other stages are more variable. A duration of 0 means that the state is skipped, which happens most often (in $50 \%$ of the trials) for stage 4 of the targets/re-paired foils. For the other stages these percentages are under $30 \%$.

Figure 3 shows the state durations in more detail, split out for conditions. We will only list major effects with $p$-values $<.01$ (repeated measure ANOVAs), as these are used below to interpret the results.

[^22]

Figure 3. State durations. A shows how the state durations add up to form a complete trial, whereas B illustrates the effect of condition on state duration.

State 1 and 2 seem stable over the different conditions, even between the two different HMMs. This matches the observation that their state signatures are very similar. Stage 3 is longer for fan 2 items than for fan $1(F(1,19)=15.14, p$ $<.001$ ). Stage 4 seems to be an intermediate stage that is often skipped for the targets/re-paired foils, and it does not change with condition. For the new foils, stage 4 is the final stage. It does not change in duration with word length. Stage 5 varied strongly in duration with both Fan $(F(1,19)=$ 16.12, $p<.001$ ) and $\operatorname{Probe}(F(1,19)=20.32, p<.001)$. Stage 6, the final stage for targets/re-paired foils, is longer for fan 2 items than for fan 1 items $(F(1,19)=21.55, p<$ .001). In addition, there is an interaction between Fan and Probe $(F(1,19)=16.75, p<.001)$, with the fan effect being stronger for re-paired foils than for targets.

The HMM-EEG analysis aims to find states with similar brain signatures in the different conditions of the experiment. Although that is the case, there might still be differences between conditions within a stage. Figure 4A shows the differences between conditions for the 6 -state HMM for targets/re-paired foils; Figure 4B for the 4 -state HMM for new foils. These differences were calculated by estimating brain activity for each state, condition, and subject. The resulting values were subjected to t-tests for each electrode.

Figure 4. Differences between conditions in states for (A) targets/repaired foils and (B) new foils. The maps show $t$ values for FDR-corrected $p$-values $<.05$.

Figure 4A shows that long words resulted in less activity than short words in state 1 over left prefrontal electrodes, and in state 6 over central electrodes. Fan 2 items resulted in more activity than fan 1 items in states 3 and 4 over midline electrodes, whereas they showed less activity in state 6 over parietal regions. Finally, targets elicited a little less activity than re-paired foils in state 3 , and more activity in states 5 and 6 over parietal and occipital sites. The largest effect for new foils was in state 2 , where long words resulted in less activity than short words for frontal electrodes.

## Interpretation of the Processing Stages

The underlying reason for wanting to identify processing stages is explaining how tasks are performed. In this section we will give our interpretation of the processing stages discovered by the HMM-EEG method.

The first two stages seem to reflect visually perceiving the two words on the screen. Both stages hardly varied with condition, and are very similar between targets/re-paired foils and new foils - implying that the words are not processed yet in relation to the experimental task. In addition, there are effects of word length on brain activity in stage 1 for targets/re-paired foils and in stage 2 for new foils. Although word length effects are typically strongest in occipital regions, Hauk et al. (2009) showed a left prefrontal effect that appears to match our observation.

We hypothesize that stage 3 reflects item retrieval, to determine whether the presented words were learned during the study phase of the experiment. First, the duration of stage 3 varies strongly with fan and there is also a strong effect of fan on brain activity in stage 3. Existing models of the fan effect assume that the effect originates in declarative memory, implying that this stage is memory related (e.g., Anderson \& Reder, 1999). Second, for new foils this is the stage where information has to be retrieved about whether the words were studied or not. After the third stage there is only a short response stage, which is similar to stage 6 of the targets/re-paired foils. Given the matching time course, we assumed that stage 3 reflects an item retrieval stage for targets/re-paired foils as well.

The idea of an early item retrieval stage and a later associative retrieval stage (stage 5) resembles dual-process theories of recognition (e.g., Rugg \& Curran, 2007). To judge whether a stimulus was experienced before, dualprocess theories assume an early 'familiarity' process, followed by a functionally distinct recollection process. With respect to our experiment, the familiarity phase could correspond to stage 3 - in which it is determined whether the items are familiar - whereas stage 5 could correspond to the recollection stage in which associative information is retrieved.

Familiarity and recollection processes have been related to different ERP components (Rugg \& Curran, 2007). Familiarity elicits a negative response between $300-500 \mathrm{~ms}$ over mid-frontal electrodes, with new items being more negative than studied items. This matches the observation that new foils in our experiment have a more negative brain signature over mid-frontal electrodes than targets/re-paired foils in stage 3. Recollection has been linked to the parietal old/new effect, which is more positive for old than for new items. If our stage 5 reflects recollection of associative information, it should show a parietal positivity for targets versus re-paired foils, which it does.

Stage 4 is skipped in $50 \%$ of the trials. We tentatively hypothesize that it reflects working memory consolidation of the items that are retrieved from memory in stage 3. This is not a necessary process, which might explain why it is skipped in $50 \%$ of the trials.

As explained above, we assume that stage 5 reflects associative retrievals. Not only does it show the parietal old/new effect, but it also varied in duration both with fan and probe type, which are known to influence the length of associative retrievals.

Stage 6 of the targets/re-paired foils and stage 4 of the new foils are the final stages in the task. We assume that they reflect response stages. The duration of stage 6 changes with fan, and shows an interaction between fan and probe type. For new foils this last stage is shorter than for the other conditions. We interpreted these duration differences as an effect of response confidence. Subjects responded faster and more accurate to new foils than to targets/repaired foils, and faster and more accurate to fan 1 items than to fan 2 items - indicating they might have been more confident in those responses.

The effects on brain activity support this interpretation. There were differences over parietal electrodes between targets and re-paired foils (targets being more positive), between fan 1 and 2 items (fan 1 items being more positive), and between new foils and targets/re-paired foils (the signature of new foils is slightly more positive). We hypothesize that these effects resemble a P300, which is known to increase with response confidence (Wilkinson \& Seales, 1978).

## Discussion

In this paper we have presented a new method for identifying processing stages in a task, which uses HMMs to
analyze EEG data. For the associative recognition task, the method yielded a 6 -state solution for targets and re-paired foils and a 4 -state solution for new foils. These solutions seem to be reasonable, and could be interpreted by using information about how the stages varied in length, and how the brain activity within stages differed between conditions. The results matched dual-process theories of recognition, both in expected stage duration and brain activity.

Naturally, other interpretations of these results are also conceivable. For instance, the duration of the last two stages could be explained with an accumulator model, which samples faster for the easier conditions.

That being said, especially in combination with earlier promising effects on fMRI data (e.g., Anderson \& Fincham, in press; Anderson et al., 2010), we think that the HMMEEG method shows great promise for investigating human information processing.

# Pragmatic priming and the search for alternatives 

Lewis Bott (Bottla@Cardiff.ac.uk)<br>School of Psychology, Cardiff University<br>Park Place, CF10 3AT, Cardiff, UK

Emmanuel Chemla (Chemla@ens.fr)<br>Ecole Normale Supérieure, LSCP<br>29 rue d'Ulm, Paris, France

#### Abstract

Meanings of basic expressions can be enriched by considering what the speaker could have said, but chose not to, that is, the alternatives. We report three experiments testing whether there is a single enrichment procedure that stretches across diverse linguistic phenomena. Participants were primed to understand either the basic meaning or the enriched meaning of a sentence. We found that the enrichment mechanism could be primed across some expressions but not others, arguing against a universal enrichment mechanism. Our results have implications for understanding the processing of implied meaning and how linguistic phenomenon should be grouped together.

Keywords: Pragmatics; psycholinguistics; alternatives; implications; structural priming.

Interpreting a sentence requires taking into consideration the combination of words that have been uttered, but also words that have not been uttered, that is, the alternatives. For instance, if a speaker says, "John has read some of the books", the listener can use the alternatives to derive the meaning that John has read some, but not all, of the books. The derivation procedure would be something like (i) accept that John read some (or all) of the books; (ii) identify "John read all the books" as a relevant alternative; and (iii) select this alternative to negate. In this paper we consider how the processor derives the alternatives. Our approach is to apply a structural priming technique (e.g., Raffray \& Pickering, 2010) to test whether the search for alternatives can be primed across and within different inferences.
Enrichment by negation of alternatives is a large phenomenon. There is always some phrase or item that may generate an alternative, and furthermore, there is an infinite range of potentially relevant alternatives. Consider the example above again. In the right context, "John has read some of the books" could imply that Bill/Helen/Mary etc. have not read some of the books, or that John has read the books but not seen the films, or even that John has not written some of the books. The wide variety of possible alternatives raises a serious processing question, however: How does the processor know which alternatives to negate? There have been several theories in the linguistics literature that provide partial answers to this question. Horn (1972) suggested that certain expressions are grouped together in the lexicon to form semantic scales, and the alternatives for a given item are its scale mates. With some for example, some, many, and all form a semantic scale, and the
alternatives for some would be many and all. More liberally, Rooth's (1992) work on focus suggests that alternatives can be any item in the same semantic category as the target (type <e,t> etc.). Intermediately, Katzir (2007) has suggested that alternatives are any items that are less than or equally complex than the trigger, or that are particularly salient in the context. In our study we take a slightly different approach, however. Rather than identifying a set of structural principles for defining the alternatives, we ask whether there is a single procedure that enriches the basic meaning in different linguistic contexts. In doing so, we also seek to find evidence that the seemingly diverse linguistic phenomena share a common root in how they are derived.
Table 1 shows the set of phenomena that we used in our experiments. All of them involve a basic meaning that can then be enriched by negating alternatives. The first column refers to the name of the phenomenon (the expression), the second to the basic (or weak) meaning, the third to a plausible alternative, and the fourth to the result of enriching the basic meaning with the alternative.

| Expression | Semantic | Alternative | Result |
| :--- | :--- | :--- | :--- |
| Some | some or all | All | some but not all |
| Number $n$ | at least $n$ | Number $n+1$ | $n$ but not $n+l=$ <br> exactly $n$ |
| Plural <br> morphology | vacuous | singular <br> Ad horphology | not singular <br> =plural |
|  | There is an <br> A | There is an <br> A and a B | There is an A <br> and not a B. |

Table 1. Experimental phenomena. The semantic form of each expression can be enriched using the negation of alternatives.

The table summarizes the following cases:
(i) some, which trigger the archetypical scalar implicature and for which there exist arguments for the alternatives to be stored in the lexicon (see Horn, 1984, or Levinson, 2000).
(ii) Numbers, which are claimed by some authors to operate in a similar manner to the some cases (e.g., Horn, 1989, van Rooy \& Schulz, 2006) but not by others (e.g., Breheny, 2008). According to the former group, when a speaker says, e.g., "Dave has three children", the weak meaning of the expression, "three," is at least three, but this meaning can be enriched to negate the alternatives, (at least)
four, (at least) five, etc. to form the exactly three reading.
(iii) plural morphology, which have been contentiously linked to the some case, by providing arguments showing that plural morphemes are semantically vacuous, surprisingly, and that the plural reading is obtained via negation of the singular alternatives (e.g., Spector 2007).
(iv) ad hoc implicatures, for which the alternatives are only specifiable given an appropriate context. For example, if a speaker says, "There is an elephant," and the context suggests that it would have been relevant for him to say, "There is an elephant and a lion," the listener is licensed to infer the alternative is not true, suggesting that the speaker meant that there was an elephant but no lion.

In summary, the phenomena are of diverse kinds: the root alternative trigger may be lexical (some and numerals), morphological (plurals) or contextual (ad hoc), and the motivation for these claims may be more or less intuitive and debated, as we described above. They are nonetheless similar in a way that is important for our experiments. The enrichments shown in the Results column are optional. In each case, the listener must derive the basic meaning, but then has a choice about whether to enrich the statement and interpret the meaning with the negated alternatives.

Our experiments test whether the enriched meanings shown in Table 1 are all computed by a single, universal mechanism, or whether separate, individual procedures are applied in each case. There is good reason to suppose either of these possibilities might be true. First, in favour of a universal mechanism, all of the cases shown in Table 1 are arguably derived using the same negation-of-alternative procedures. Grice's Quantity maxim, for instance, could be invoked to generate reasoning along the lines of, "well, if the speaker had meant [alternative], they would have said so," (see Chierchia, 2004, for a wider range of views) and the linguistic contexts that give rise to the enrichment are similar across phenomena. The most simple processing view would be that if these phenomena can be grouped together linguistically, then they should share similar processing mechanisms. Conversely, there are also arguments for different enrichment procedures for different phenomena. For example, numbers may behave differently to quantifiers (see e.g., Breheny, 2008), and Katzir's (2007) theory distinguishes the alternatives involved in ad hoc implicatures from those involved in the some and number cases (as we describe in more detail in Experiment 2). Furthermore, different types of expressions vary in how frequently they are enriched. For example, Zevakhina \& Geurts (2011), show that adjectives in scalar implicatures, such as, "John's cake is ok" (implying John's cake is not delicious) are less likely to undergo enrichment than quantifiers, such as "Some of John's cakes were eaten" (implying not all of John's cakes were eaten). The variation in enrichment could be because different enrichment mechanisms are involved across different cases.

## Overview of Experiments

To test between universal and individual enrichment procedures, we used a structural priming paradigm (see, e.g., Pickering \& Ferreira, 2008). We reasoned that if there were a universal mechanism, it should be possible to prime the procedure, that is, make it more likely that the enriched meaning would be derived. Priming across different phenomena would provide support for a universal procedure for searching alternatives, but priming restricted to particular expressions would support individual enrichment procedures.

There are many different versions of structural priming but we modeled our experiment on Raffray and Pickering (2010), who tested priming of scopal relations. In their experiments, participants had to match one of two pictures to a sentence. The sentence always involved every and $a$, but let the scopal relation free to create an ambiguous sentence, as in Every child climbed a hill (which can be interpreted either as there being a single hill that every child climbed, or multiple hills where every child climbed a separate hill). In the prime trials, the pictures were consistent with only one reading of the sentence. For example, for the Every child climbed a tree sentence, one of the pictures was of a single hill with multiple children climbing it, and the other picture was of something unrelated like cows in a field. In the trial that immediately followed it, the probe trial, participants saw a different every sentence and a further two pictures. One picture was consistent with wide scope reading and one with the narrow scope reading. Participants chose which interpretation best matched the sentence. Raffray and Pickering hypothesized that wide scope prime trials would prime a wide-scope reading in the probe trials and vice versa, which is exactly what they found.

Our experiments were very similar except that we used sentences that involved the constructions shown in Table 1, rather than every. Just like the every sentences, our sentences were ambiguous because implicatures are optional. We hoped to be able to prime whether participants interpreted the sentence with or without the enriched meaning. If either a universal enrichment or an individual enrichment procedure can be primed, we would expect priming within each of the expressions in Table 1. More interestingly, if there is a universal enrichment process, we should observe priming across the different expressions.

## Experiment 1

Participants saw a sentence and had to match the sentence with one of two pictures. All of the sentences referred to the presence of letters in a set, such as "All of the letters are As." In the experimental trials, the sentences invited enrichment, as shown in Table 1. However, because the enrichment was optional, participants could choose to interpret the sentence in its basic form. This meant that the sentences could have either a weak meaning (without enrichment) or a strong meaning (with enrichment). For a
given sentence, three types of pictures were possible: (a) false pictures, that made both readings false, (b) weak pictures, that made the weak reading true but the strong reading false, and (c) strong pictures that made both readings true.

There were two types of prime trials. First, weak primes, which displayed a false picture and a weak picture, so that participants would click on the weak picture and access the weak reading. Second, strong primes, which displayed a weak picture and a strong picture. We reasoned that participants would access the strong reading (the one that makes the two pictures different in a relevant way) and click on the strong picture. An example of the weak some prime is shown in the upper-panel of Figure 1.

Figure 1. Weak some prime (upper-panel), and some probe (lower-panel).

In the probe trials, participants read another experimental sentence and saw two more pictures. One of the pictures was a weak picture, and the other picture was a box with "Better Picture?" written inside it. Participants were instructed that the "Better Picture" option should be selected if they did not feel that the other picture sufficiently captured the sentence meaning. The lower panel of Figure 1 shows the probe trials. We expected that participants should click on the weak picture if they accessed the weak reading, and opt for the "Better Picture" option if they accessed the strong reading. Probe trials immediately followed prime trials. Consequently, priming of the enriched meaning would be observed when a participant selected the weak interpretation option more often after the weak prime than after the strong prime (and vice versa).

In Experiment 1 we used the first three expressions shown in Table 1: (1) some sentences, for which the weak interpretation picture was a box in which pictures were all one type of letter, namely As, and the strong interpretation picture involved a set filled partly with A's and partly with B's. (2) Number sentences, such as "Three of the letters are As," where the target enriched meaning was no more than 3. The weak picture was a box in which 6 letters were A's, and the strong picture was a box in which exactly 3 of the letters were A's. (3) Plural sentences, such as, "There are As," in
which the target enriched meaning was there is more than one $A$. The weak picture involved a single A, whereas the strong picture involved multiple A's.

If (a) all three expressions are related, (b) involve alternatives, and (c) there is a universal enrichment procedure, then priming should be observed within and between the three expressions. If the enrichment mechanism depends on specific structures, priming should be observed only within each expression. We tested within-expression priming by presenting sequences of trials in which the prime from one phenomenon was followed by a probe from the same phenomenon. For example, a some prime, such as "Some of the letters are As" would be followed by a some probe, such as "Some of the letters are Bs". We tested between-expression priming by presenting the prime from one expression followed by the probe from a different expression. For example a plural prime, such as "There is an A" might be followed by a some probe, such as, "Some of the letters are Bs".

## Method

Participants. In each experiment reported in this paper, we used 50 participants, all recruited online using Amazon Turk and all claiming to be native speakers of English. A different set of participants was used for each experiment. They were paid for their participation.

Design and materials. All trials were either probe trials, prime trials, or bias trials. An experimental sequence of trials was two prime trials followed by one probe trial, i.e., prime-prime-probe. We thought the effect of the prime would be greater if the prime trial was doubled. The prime and probe trials were completely crossed so that each participant saw prime-probe sequences of all possible combinations, e.g., some (weak)-number; number (strong)some; some (weak)-plural. This meant that for each expression, there were 6 possible sequences ( 2 withinexpression trials, and 4 between-expression trials), and hence 18 sequences in total. We replicated this set 4 times and so there were 72 probe trials and 144 prime trials.

We also added bias trials to encourage participants to (a) select the "better picture" box, and (b) consider appropriate alternatives to the experimental sentences. For example, we included all trials so that participants would realise the speaker sometimes said all instead of some. There were 12 bias trials per set, and 48 in total.

Sentences were all statements about letters, as shown in Figure 1. The particular letters were randomly chosen for each experimental sequence. Each experimental sequence was presented in a random order.

In the prime trials the expected answer (weak or strong) was on the right for half the trials. In the probe trials, the "better picture" box was always on the right.

## Results and Discussion

Figure 2 shows the proportion strong interpretations during probe trials. The within-expression effect is shown on the left, and the between-expression effect is shown in
the right. A large within-expression priming effect can be seen by the difference between the weak and strong primes, such that there were more strong interpretations after the strong primes than after the weak primes, $F(1,46)=63.25, p$ $<.001$. There was no significant difference in the size of the effect across expressions, however, $F<1$. More interesting was the priming effect between expressions. The betweenpriming effect was marginally significant using an ANOVA with probe type and interpretation (weak vs strong), $F(1,50)$ $=3.063, \mathrm{p}=.086$, and fully significant using a nonparametric bootstrapping test, $p<.05$ (we also replicate a similar between-expression priming effect in Experiments 2 and 3).

Figure 2. Experiment 1 results.
Our findings suggest that for these sorts of linguistic expressions, there is a universal mechanism that enriches the basic meaning. If the mechanism were tied to individual phenomena, we would not have observed betweenexpression priming. In Experiment 2, we consider the enrichment mechanism in more detail.

## Experiment 2

The enrichment mechanism involves two procedures: (1) identifying the appropriate alternatives, and (2) negating them. The results of Experiment 1 are consistent with either (or both) of these: we could have primed the search for alternatives, or the procedure that negates them. To investigate this in more detail we tested the ad hoc expressions shown in Table 1. The ad hoc expressions are similar to those used in Experiment 1 in that they involve negation of alternatives (see Hirschberg, 1991). However, they are different in that the alternatives for the ad hoc expressions must be determined with reference to the context, whereas the alternatives for the other expressions can be determined lexically (they are context-free). It follows that if we were to observe priming within the ad hoc expressions, but not between the ad hoc expressions and the lexical expressions, we could conclude that the effects of Experiment 1 were at least partly due to priming of the search for alternatives and not priming of the negation process. We would also conclude that there were separate processes computing the alternatives for the ad hoc expressions compared to the lexical expressions. Of course, if we found priming across all of the expressions, as we did
in Experiment 1, we could only draw conclusions about the general enrichment process, not the negation of the alternatives.
In Experiment 2, we introduced ad hoc sentences into the priming design from Experiment 1. The ad hoc sentences were sentences like There is an $A$, which, given the visual context, invited enrichments like There is an $A$ but not a $B$. The weak ad hoc prime and an ad hoc probe are shown in Figure 3. The design was exactly the same as Experiment 1 except that we replaced the plural expressions with the ad hoc expressions, which meant that we had some, number, and ad hoc expressions.

Figure 3. Weak ad hoc prime (upper-panel), and ad hoc probe (lower panel).

## Results and Discussion

Proportions of strong responses to the probe are shown in Figure 4. The upper panel shows within-expression priming. For each expression, there were more strong interpretations after the strong prime than after the weak prime, all $t$ 's(49) $>4.11, p$ 's $<.001$, but there was a marginal interaction between probe expression and interpretation, $p=.087$, suggesting less within-expression priming in the ad hoc expressions. The lower-panel shows between-expressions priming. Here, there was robust priming between some and number expressions, $F(1,47)=5.58, p=.022$, but not between some and ad hoc expressions, $F<1$, or number and ad hoc sentences, $F<1$. There was also an interaction between the degree of between-expression priming for ad $h o c$ expressions and the other combinations, $F(2,98)=$ 4.42, $p=.015$.

We did not observe between-expression priming for the $a d$ hoc expressions in Experiment 2. However, the withinexpression priming effect was marginally smaller for the ad hoc expressions than for the others, and there were far fewer strong interpretation responses. Participants might therefore have had more difficulty identifying the alternatives for the ad hoc sentences and consequently, even if betweenexpression priming was occurring, priming effects would have been smaller and more difficult to observe.

Figure 4. Experiment 2 results. The figure shows responses for each probe expression for within-expression priming (upper panel) and each combination of betweenexpression priming (lower panel).

## Experiment 3

In Experiment 3 we hoped to remedy the low rate of strong interpretations in the ad hoc condition by introducing additional items to increase the salience of the alternatives. We reasoned that participants were always selecting the weak interpretation because they were unsure what might make a "better picture" (i.e., whether the alternative would have any relevance). We therefore introduced 20 extra bias trials at the start of the experiment of the form, "There is an A," with the target picture being a single letter.

## Results and Discussion

Figure 5. Experiment 3 results.
Within-expression priming is shown in the upper-panel of Figure 5. The proportion of strong interpretations for the ad hoc expressions is much higher than in Experiment 2, and
the degree of within-expression priming appears larger. As in Experiment 2, significant within-expression priming is observed in each expression, all $t(49)$ 's $>4.76, p$ 's $<.001$, but we found no evidence that the within-expression priming varied among expressions, $\mathrm{F}<1$. The lower-panel of Figure 5 shows the between-expression priming trials. As in Experiments 1 and 2, there was robust priming between some and number expressions, $t(50)=2.12, p=.036$. Critically however, there was no between-expression priming for combinations involving the ad hoc expressions, $t ' s<1$, and there was a significant interaction between the three combinations, $F(2,100)=3.39, \mathrm{p}<.05$.
In this experiment we observed the same sized withinexpression priming effect for ad hoc expressions compared to the other expressions. This suggests that the alternatives for ad hoc expressions were just as available too. Yet we failed to observe any between-expression priming effects involving the ad hoc sentences. These findings suggest that between-expression priming was due to priming of the search for alternatives, and not priming of the mechanism that negates the alternatives. Furthermore, our results suggest that there are separate mechanisms for determining context-free alternatives (the lexical expressions) and context-dependent alternatives.

## General Discussion

Our studies investigated how the processor enriches basic meanings with negated alternatives. An intuitive and parsimonious processing prediction was that there is a single, universal mechanism across diverse linguistic forms. After all, the enriched meanings that we used could all arguably be derived using the same reasoning. Contrary to this prediction, however, we found that whilst enriched readings of some, number, and plural morphology expressions can prime each other, they cannot prime enriched readings of ad hoc expressions, even though all the expressions can prime enriched meanings of their own form. This suggests that there are multiple procedures for enrichment based on alternatives, and that these are split between context-free and context-dependent expressions.
We conceive of context-free enrichment procedures as an instruction to the processor to search a part of the lexicon for the appropriate alternatives. For example, with some, the instruction would be to retrieve appropriate alternatives, such as all, which could then be negated. The contextdependent procedure is different in that it does not involve instructions to search the lexicon, but to search out plausible alternatives from the context. While there might be some overlap between these procedures, the failure to observe priming between the different expressions also provides a robust test that distinguish them.

## What is being primed?

We explain our results by referring to the priming of the search for alternatives. Here we consider other explanations.
One that we can eliminate is that we have primed a
general acceptance of weak statements. Our items are
constructed in such a way that there were informationally weak interpretations (e.g., some and possibly all) and informationally strong interpretations (e.g., some but not all), and a possible explanation of Experiment 1, therefore, is that participants were primed to accept the weaker/stronger interpretation (and also a potential explanation for Raffray \& Pickering, 2010). Experiments 2 and 3 rule out this explanation, however, because the $\mathrm{ad} h o c$ sentences also had the weak/strong distinction but were not primed by the other expressions. More generally, the failure to observe between-expression priming effects with the ad hoc sentences eliminates any explanation that would apply across all of the expressions.
Another possibility is that our findings could be explained by the priming of alternatives, rather than priming of the search for alternatives. Our within-expression priming effects could indeed be explained in this way. For example, the strong primes of some could make the alternative all more salient to the participant, and therefore when presented with the probe, such as "some of the letters are As," the participant might have been more likely to realise that the sentence could have read, "all of the letters are As." This would then have led them to choose the "better option" box more often. This cannot be the whole story, however, because we also observed between-expression priming. Here, the alternatives were different across expressions and so the salience of alternatives from one expression should not influence the rate of strong responding from other expressions. For example, a some strong prime might make all more salient, but the salience of all should not influence the salience of the exactly $N$ reading of the numbers. The between-expression effect cannot be explained by priming of alternatives; it requires priming of the search for the alternatives more abstractly.

## Similarities and differences between phenomena

Our results show that some, the numbers, and plural morphology can be grouped together, but that ad hoc expressions behave differently. This pattern can be related to the linguistic literature that investigates how these particular phenomena are derived.

First, consider the similarity between some, the numbers and plurals. These phenomena are very diverse. For instance, some theorists have argued that the numbers and some should be considered different phenomena (e.g. Breheny, 2008). Our results provide evidence against an extreme form of this view (that the numbers and some are completely unrelated) or the idea that numbers would not involve alternatives. Furthermore, the claim that plurals may be related to the others is an audacious one, which relies on the fully counterintuitive hypothesis that plural morphology is semantically vacuous. Our results provide further striking evidence in favor of this counterintuitive view of plural morphology.

Second, our results also distinguish different phenomena in a meaningful way. Katzir (2007) provides the most precise and complete implementation of alternative
generation. In essence, Katzir argues that there are two separate procedures for calculating alternatives. The first involves replacing a phrase by a simpler, related phrase, e.g., some $=>$ all, or ate a lot $=>$ ate, and the second involves replacing a phrase by a contextually salient phrase which may or may not be simpler $(A=>A$ and $B)$. Interestingly, Katzir specifies different procedures for the computation of ad hoc alternatives and alternatives related to the other three phenomena. This is exactly how our results split the landscape as well (see also Fox 2012 for converging developmental data). Hence, we obtain both a confirmation of the theory, and a natural interpretation of our results.

## Conclusion

We set out to investigate whether there are abstract procedures for enriching basic meanings considering words that were not pronounced, much like the structural priming research has investigated whether there are abstract representations of syntactic structure. Our results show that the scope of the enrichment procedure is wide (e.g., affecting the interpretation of numbers as well as of the plural morphology), and confirm finer-grained properties of the system by distinguishing contextual and non-contexutal alternatives.

# Space is Special: A domain-specific mapping between time and nontemporal magnitude 

Roberto Bottini (bottinir@newschool.edu)<br>Christopher Guarino (guarc637@newschool.edu)<br>Daniel Casasanto (casasand@newschool.edu)<br>Department of Psychology, $805^{\text {th }}$ Avenue, New York, NY 10011 USA

#### Abstract

Across different domains the magnitude of a stimulus is positively correlated with its perceived duration: bigger, brighter or louder stimuli are usually perceived to last longer than smaller, dimmer or softer ones. According to A Theory of Magnitude (ATOM), temporal and nontemporal magnitudes are linked in the human mind by virtue of sharing a common metric. This claim has been challenged by studies in the domains of brightness and loudness suggesting that it is not the difference in magnitude between stimuli, but rather their degree of change from background that modulates duration judgments. But do the same relationships hold between perceived duration and all prothetic dimensions? We tested the influence of stimulus magnitude and relative change on temporal judgment in the domain of space. We found that, unlike brightness and loudness, spatial length can influence duration judgments independently of the degree of change from a common background, and that this effect is context dependent. Thus, an approach based exclusively on the degree of change between stimulus and background is not sufficient to account for the effect of magnitude on temporal judgments. Our results suggest that space has a privileged link with temporal representations compared to other prothetic domains, challenging the hypothesis that space-time relationships are the product of a domain-general magnitude system.

Keywords: ATOM; Metaphor; Space; Time; ATOC

## Introduction

Judgments of duration can be influenced by non-temporal aspects of events such as stimulus magnitude (Walsh, 2003; Xuan, Zhang, He, \& Chen, 2007). Bigger stimuli are judged to last longer than smaller ones (Xuan et al., 2007), brighter stimuli longer than dimmer ones (Xuan et al., 2007; Goldstone et al., 1978), and louder sounds longer than softer ones (Goldstone et al., 1978). Magnitude Effects have often been interpreted as the effect of absolute magnitude on stimulus duration: more intense stimuli seem to last longer (Xuan et al. 2007; Bueti \& Walsh, 2009). It has been suggested that temporal and non-temporal magnitudes are positively correlated in the human mind by virtue of sharing a common metric (Xuan et al. 2007; Walsh, 2003). On this view, magnitudes across different prothetic domains (i.e. domains that can be experienced as 'more than' or 'less than'; Walsh, 2003) are represented in the brain by a generalized magnitude system. Duration and other prothetic domains are linked by a monotonic "more A - more B" mapping (Bueti \& Walsh, 2009) such that "bigger, faster, brighter, further in one domain should correlate with bigger, faster, brighter, further in another" (Bueti \& Walsh, 2009, p.1832).

In spite of a large body of supporting evidence, the hypothesis that stimulus magnitude and its perceived duration are positively correlated has been challenged. It has been suggested (Matthews, Stewart, \& Wearden, 2011) that it is the relative difference between the stimuli and a common background, rather than the absolute magnitude of the stimuli, that modulates the subjective experience of duration. In one experiment (Matthews et al., 2011) participants judged the duration of two successive stimuli that varied both in duration and brightness. When the stimuli were presented on a dark background, brighter stimuli were judged to last longer than dimmer ones, on average. Yet, when the same stimuli were presented on a white (brighter) background, the opposite effect was found: dimmer (less intense) stimuli were judged to last longer than brighter ones. The same results were obtained when louder and softer sounds were presented against quiet or noisy backgrounds. Further experiments also support the hypothesis that duration judgments are proportional to the difference between the stimulus and its background. When an "oddball" stimulus is presented within a sequence of repeated presentations of a standard stimulus, the perceived duration of the oddball is exaggerated compared to the standards (Tse, Intriligator, Rivest, \& Cavanagh, 2004; Ulrich, Nitschke, \& Rammsayer, 2006). In the Oddball Effect the relative difference between the stimulus (the oddball) and the background (the repeated standard stimulus) has been found to predict subjective temporal dilation: The larger the difference between oddball and standard, the larger the temporal dilation (Schindel, Rowlands, \& Arnold, 2011).

Moreover, the absolute magnitude of the oddball appears to be irrelevant for duration judgments. Schindel and colleagues (Schindel et al. 2011, Exp. 2) presented their participants with a series of gray disks (the standard stimulus) that was unpredictably interrupted by an odd disk that was either brighter (more intense) or dimmer (less intense). If the subjective duration of events is positively correlated with the absolute magnitude of these events, then dimmer oddballs should be judged to last less time compared to the brighter standard. At minimum, the absolute brightness of the oddballs should modulate their effect: Even if both brighter and dimmer oddballs were judged to last longer than the standard, the temporal dilation should be more pronounced for the brighter, more intense oddballs. Contrary to these predictions, however, stimulus magnitude had no effect whatsoever on duration judgments: Dimmer and brighter oddballs led to equivalent temporal expansion. Once again, it was the relative difference
between the stimuli and the background that determined changes in subjective duration, and not the absolute magnitude of the stimuli (Shindel et al., 2011).

Altogether, these studies suggest a reinterpretation of "more A - more B" Magnitude Effects (Bueti \& Walsh, 2009). We propose that these effects may be a special case of Stimulus-Background Effects. The subjective duration of a stimulus is proportional to the difference between the stimulus and its background. Magnitude Effects, then, are simply Stimulus-Background Effects for which the relative change happens to be in magnitude. The relative variation does not need to occur in prothetic domains: Similar effects have been found for variation in shape (Tse et al. 2004), complexity (Schiffman, H. R., \& Bobko, 1974), color (Tse et al. 2004) and orientation (Schindel et al. 2011), which are qualitative (metathetic) domains of experience. If indeed Magnitude Effects are a species of Stimulus-Background Effects, they need not depend on any neurocognitive mechanisms that are specific for magnitude representations, but rather on mechanisms that support comparison of values along prothetic and metathetic continuums, alike (see Eagleman \& Pariyadath, 2009 for a similar proposal).

To summarize, we can distinguish two theoretical approaches that seek to explain the effect of non-temporal magnitudes on temporal judgments. A Theory of Magnitude (ATOM; Walsh, 2003) posits that duration is positively correlated with other prothetic domains in the mind and brain by virtue of sharing the same magnitude-specific representational basis (Bueti \& Walsh, 2011; Xuan et al. 2007; Walsh, 2003). Under this assumption, temporal distortions induced by variation in metathetic (qualitative) domains such as color or shape exploit different cognitive and neural mechanisms compared to similar effects induced by variation in prothetic (quantitative) domains. The alternative approach, which we will call A Theory of Change (ATOC), suggests instead that Magnitude Effects are particular cases of Stimulus-Background effects.

The experimental evidence reviewed above favors ATOC over ATOM. There is no special representational link between duration and prothetic dimensions, and no positive correlation between the magnitude of a stimulus and its duration: Temporal illusions attributed to the absolute magnitude of the stimuli can be explained by the relative difference between stimulus and background (Matthews et al., 2011; Shindel et al., 2011).

In this study we seek to investigate whether ATOC can fully explain the relationship between perceived duration and non-temporal magnitudes. Both ATOM and ATOC have in common the assumption that all prothetic domains influence temporal judgments in the same way. On the basis of metaphor theory (Lakoff \& Johnson, 1999; Casasanto \& Boroditsky, 2008), however, we predict that different nontemporal domains will influence temporal judgments differentially, depending on the relationships between these domains in our experience. Specifically, the relationship between perceived duration and non-temporal magnitude should be different for spatial magnitude than it is for other
prothetic domains. That is, the relationship between space and time is special.

## Space and time: an experiential link

Compared to other prothetic domains, space and time seem to be linked in the human mind by a special relationship. Across languages and cultures, spatial expressions are widely recruited to talk metaphorically about time (Lakoff \& Johsnon 1999). These patterns in language have motivated non-linguistic experiments supporting the hypothesis that people use spatial conceptual structures to think about time. Across studies, stimuli that extend farther in space are judged to last longer in time (e.g., Casasanto \& Boroditsky, 2008). This relationship between duration (i.e., temporal magnitude) and length (i.e., a kind of spatial magnitude) has been found in the judgments of children (Casasanto, Fotakopoulou, \& Boroditsky, 2010) and infants (Srinivasan \& Carey, 2010), as well as adults.

Why do many of the world's languages metaphorize duration in terms of length (e.g., a long time), instead of some other prothetic domain such as brightness or loudness (e.g., a bright time; a loud time)? Perhaps this is because space and time are correlated in our experience of the world in a way that brightness and time and loudness and time are not. As a moving object travels farther though space, more time passes. This positive correlation between magnitudes in space and time does not seem to exist between duration and other prothetic domains. Brighter things do not necessarily last a longer time than dimmer things (in fact the opposite may be true), and louder events do not necessarily last longer than softer ones.

Implicitly linking space and time in our minds may be useful because these domains are linked in the world. Knowing that "more space" is generally correlated with "more time" can provide a useful heuristic, facilitating interactions with our physical environment. By contrast, there does not appear to be any analogous link between duration and other prothetic domains in the world. As such, a representational link between temporal and spatial magnitudes in the human brain/mind is functionally motivated, and reflects regularities in our physical experience. But an analogous link between temporal magnitude and brightness or temporal magnitude and loudness would not have the same functional motivation, since these links would not have any clear basis in experiential regularities.

## Testing for a special link between time and space

In this study, we compared the effect of spatial magnitude (specifically spatial length) and relative degree of change on duration judgments. In previous studies (Casasanto \& Boroditsky, 2008; Xuan et al., 2007) the relative degree of change was positively correlated with magnitude (e.g. line length). This correlation made it impossible to tell which of the two factors were driving the effect. We designed the current experiments so that absolute magnitude of the stimuli and relative difference from the
standard/background were orthogonal to each other. If the effect of spatial magnitude on time is due to the relative amount of change, we should expect that when the difference from the background is the same, stimuli with different spatial magnitudes will be perceived as having the same duration. This outcome would support ATOC, and indicate that space stands in the same relation to time as other prothetic domains (e.g., Shindel et al., 2011). Alternatively, if spatial and temporal magnitudes, per se, are linked in the mind, we should observe a magnitude effect yielding longer duration judgments for spatially longer stimuli than for spatially shorter ones. This outcome would suggest the relationship between space and time differs from the relationship between time and other prothetic domains.

## Experiment 1. Long and short oddballs

In this first experiment we used a classic oddball paradigm to test the influence of stimulus magnitude on perceived duration. The standard stimulus was a 5 cm gray line, while the oddballs were lines of either shorter or longer length. If perceived duration is affected by the relative difference between the standard and the oddball (Schindel et al. 2011; Matthews et al. 2011) rather than spatial magnitude per se, both large and small oddballs should lead to the same effect of temporal expansion (i.e. a classic Oddball Effect). On the other hand, if stimulus spatial magnitude influences perceived duration (Casasanto \& Boroditsky, 2008), we should expect that large oddballs should lead to a greater temporal expansion compared to smaller ones.

## Methods

Participants 12 participants were recruited in the NYC area. All had normal or corrected-to-normal vision.

Stimuli. Stimuli consisted of lines of different sizes centered on a black background. The standard stimulus was a 5 cm gray (RGB 128, 128, 128) line. The oddballs were a 2.5 and 10 cm line of the same color. The width of all lines was fixed at 2 mm .

Procedure. Participants were seated in a darkened room and viewed stimuli from a distance of approximately 60 cm . For each trial 9 lines appeared sequentially in the middle of the computer screen. The standard lines $(5 \mathrm{~cm})$ were presented eight times in each trial with the remaining stimulus being the odd line (either 2.5 or 10 cm ). Each oddball appeared unpredictably between the 5th and 8th stimuli. Oddball position was determined randomly on a trial-by-trial basis. Each stimulus was followed by a blank screen during a 300 ms ISI. Standard stimuli were presented for 500 ms , whereas oddballs were presented for $300,400,450,500$, 550,600 or 700 ms . At the end of each trial, a fixation cross appeared in the middle of the screen and participants had to indicate whether the oddball had remained on the screen for more or less time than the standards. Each of the seven oddball durations was presented 10 times for each of the 2 oddballs, for a total of 140 trials. Participants completed the
experiment in three blocks of 42, 42 and 56 trials. Participants responded by pressing a key with the left index finger for "less time" and a key with the right index finger for "more time" or vice versa, with key position counterbalanced between subjects.

Proportions of "more time" responses to each oddball duration were fitted using a Weibull function for individual data sets. The point of subjective equality (PSE), which is the point at which the duration of the oddball is on average judged equal to the duration of the standard, was calculated graphically as the duration corresponding to $50 \%$ of "more time'" responses.

## Results

Long oddballs led to significant temporal expansion: PSE: 480, $t(11)=2.66, p=.02$; while short oddballs led to nonsignificant temporal contraction, PSE: 521, $\mathrm{t}(11)=1.39, \mathrm{p}=$ .19 (Fig.1, left panel).
To examine the effects of spatial length on duration judgment, we fitted a generalized linear model with binomial distribution for time judgments using the seven oddball durations and the two oddball lengths as predictors of "more time" and 'less time" responses. We found that oddball spatial length influenced the oddball effect, with longer oddballs leading to a greater temporal expansion than shorter oddballs, Wald $\chi 2(1)=14.53, \mathrm{p}<.001$.

Fig1. Effect of Long and Short oddballs in Experiment 1 and 2. Error bars depict SEM (corrected for within subjects comparisons).

## Discussion

In Experiment 1 the repetitive presentation of a gray line was unpredictably interrupted by the presentation of either a spatially longer or shorter line of different duration. Even though the two oddball lines had the same relative difference from the standard, spatially longer lines induced a greater oddball effect than spatially shorter ones. Moreover, while longer oddballs led to a significant temporal expansion (compared to the Point of Objective Equality (POE)), shorter oddballs led to a non-significant temporal contraction. These results suggest that the magnitude of the stimulus does influence the subjective experience of duration independently of the relative difference between stimulus and background.

Nevertheless, a different interpretation of the data is possible. Perhaps the difference between the long oddball
and the standards was perceived to be greater than the difference between the short oddball and the standards. Since magnitude judgments for prothetic dimensions, including space, follow Weber's Law, we selected the three values of spatial length according to a logarithmic scale in which the central value was the geometric mean of the two extreme values. Thus, the long and short oddballs should be psychologically equidistant from the standards. Nevertheless, participants may have noticed that the difference between the long line and the standard was numerically greater than the difference between the short line and the standard. This "difference of differences" might have lead to the asymmetric results reported above.

## Experiment 2. Linear scaling

Experiment 2 was designed to rule out the possibility that the difference between the longer oddball and the standard was perceived as greater than the difference between shorter oddball and standard. In this test the differences between the standard line and the longer oddball and the standard line and the shorter oddball were numerically the same.

## Methods

Participants 20 participants were recruited in the NYC area. All had normal or corrected-to-normal vision.

Stimuli and Procedure Stimuli and procedure for Experiment 2 were the same as those in Experiment 1 with the following exception: Long oddballs were 7.5 cm long.

## Result

Longer oddballs led to significant temporal expansion, PSE: $471, \mathrm{t}(19)=2.73, \mathrm{p}=.01$, while shorter oddballs led to a small, non-significant temporal expansion, PSE: 491, t(19)= $0.82, \mathrm{p}=.42$ (Fig.1, right panel).

To examine the effects of spatial length on duration judgments, we fitted a generalized linear model with binomial distribution for time judgments using the seven oddball durations and the two oddball lengths as predictors of " more time" and 'less time" responses.

We found that oddball length influenced the oddball effect, with longer oddballs leading to greater temporal expansion than shorter oddballs, Wald $\chi 2(1)=6.00, p=.01$.

## Discussion

In this experiment the relative difference between oddballs and standards was the same numerically for both longer and shorter oddballs. Yet, long oddballs led to a greater temporal expansion than did smaller ones. The Magnitude Effect observed in both experiments one and two seems to be proportional to the magnitude of the stimuli, independent of the degree of change (relative difference) between the oddball and the standards. These findings again suggest that the spatial magnitude of a stimulus modulates its perceived duration independently from the difference between stimulus and background. An approach based exclusively on the degree of change between stimulus and background is
not sufficient to account for the temporal modulation observed.

Experiments 1 and 2 provided an interesting additional piece of evidence. Long oddballs always led to significant temporal expansion, whereas short oddballs led to nonsignificant contraction (Exp.1) or expansion (Exp.2). In the case of the shorter line, the effect of relative change would lead to temporal expansion (the shorter line is different from the standard), while the effect of magnitude would lead to temporal contraction (the shorter line is indeed shorter than the standard). We can hypothesize that when the two factors are in opposition they cancel each other out, leading to neither temporal expansion nor temporal contraction. That is, both the degree of change and the absolute magnitude of the stimuli contribute to the judgment of duration, and their relative weight seems to be roughly equal. However, the answer may not be so simple.

Seifried and Urlich (Seifried \& Ulrich, 2010) report an experiment in which a smaller stationary disk was presented as an oddball among repetitive presentations of a bigger disk. Even though the oddball had a smaller size compared to the standard it led to a significant effect of temporal expansion (Seifried and Urlich, 2010, Exp. 3, footnote on page 97). This result is inconsistent with the hypothesis of an equal and opposite influence of magnitude and relative change, and with the effect of magnitude reported here. But in Seifried and Urlich's experiment there was only one oddball type, the smaller size-disk, instead of both a larger and smaller one. It is possible that the pattern of interaction between stimulus magnitude and degree of change is context dependent. The weight of each factor in influencing duration judgments depends on the salience of each factor in a given context. In a classic oddball paradigm, with only one kind of oddball, the direction of change (more/less) may be overshadowed by the fact that the oddball is simply different from the standard. The oddness of the oddball is a more salient feature of the event compared to its absolute magnitude. In this context the relative change is a more weighted factor than stimulus magnitude, and even small oddballs would lead to temporal expansion. Conversely, when two oddballs with different sizes are included in the design, absolute magnitude may become more salient: both oddballs are different from the standard but they differ in different ways. The oddballs aren't just odd, but either longer or shorter. The polarity of the magnitude continuum becomes more salient, leading to an increased effect of stimulus magnitude over relative change in influencing duration judgments. We designed Experiment 3 to test this hypothesis.

## Experiment 3: Short oddballs only

In Experiment 3 the only oddball presented was the shorter line. If the interaction between stimulus magnitude and relative difference is context dependent, modulated by the relative salience of each factor, we should expect to see a significant oddball effect (i.e., subjective temporal expansion).

## Methods

Participants. 20 participants were recruited in the NYC area. All had normal or corrected-to-normal vision.

Stimuli and procedure. In this experiment there was only one type of oddball, a gray line (same color as the standard) 2.5 cm long. Each of the seven oddball durations was presented 12 times, for a total of 84 trials. Participants completed the experiment in two blocks of 42 trials each. Otherwise, the stimuli and procedure were the same as those in experiments 1 and 2.

## Results

The subjective duration of the oddballs was exaggerated compared to the standard, PSE: 480, $\mathrm{t}(19)=2.10, \mathrm{p}=.05$. To examine the effects of context on duration judgments, we conducted a generalized linear model with binomial distribution to compare the effect of short oddballs across Experiment 1 and Experiment 3. We found that short oddballs led to a greater temporal expansion in Experiment 3 than in Experiment 1, Wald $\chi 2(1)=6.34, p=.01$ (Fig.2).
The same comparison between Experiment 2 and Experiment 3 didn't produce a significant result (Wald $\chi 2(1)=1.76, p=.28)$.

Fig2. Effect of the short oddball in Experiment 1 and 3. Error bars depict (uncorrected) SEM

## Discussion

Shorter oddballs unpredictably appearing among longer standard stimuli led to a classic expansion of subjective duration, as reported by a previous study (Seifried \& Urlich, 2010). These results support the hypothesis that the effect of stimulus magnitude and degree of change on duration judgment is context dependent. The more relevant one factor is made by contextual features, the more it will contribute to shaping the subjective experience of duration of a given event.

The oddball effect elicited by the short oddball in experiment 3 was significantly greater than the effect produced by the same stimulus in experiment 1, but not in experiment 2 . This outcome can be explained by the fact that, in experiment 2 , the difference between the standard and the shorter oddball was probably perceived as bigger compared to the difference between the standard and the longer oddball, due to linear scaling. This perceptual
asymmetry may have inflated the oddball effect produced by the short-oddball. For this reason Experiment 1, in which geometric scaling was used and the relative difference between oddballs and the standard was equated, constitutes a better basis for comparison.

## General Discussion

The main finding of the current research is that the absolute spatial magnitude of stimuli can influence duration judgments independently from the relative amount of change between stimuli and background. When the difference from the standard (background) was the same, oddballs that were spatially longer than the standard led to a greater subjective temporal expansion than oddballs that were spatially shorter than the standard. Space and time seem to be linked in the human mind by a positive correlation according to which objects that extend farther in space are judged to last longer (Casasanto \& Boroditsky, 2008). Such a positive correlation between absolute magnitude and duration does not hold for other prothetic domains like brightness or loudness: The apparent correlation between duration and brightness and duration and loudness has been explained in terms of the relative difference from stimuli and background that modulates duration judgments, independent of stimulus magnitude (Matthews et al. 2011, Schindel et al. 2011).

Our results support the hypothesis that space and time share a special link in the human mind (Casasanto \& Boroditsky, 2008; Lakoff \& Johnson, 1999). This link is experientially motivated, since space and time are correlated in our everyday experience, in a way that brightness and time and loudness and time are not. The domain specificity of the link we observe between space and time is inconsistent with a domain-general magnitude metric as hypothesized by ATOM: Not all prothetic domains are represented the same way in the human mind.

Moreover, our results cannot be explained entirely as effects of the degree of change between stimuli and background. Therefore, ATOC cannot completely account for the pattern of temporal distortions observed in our experiments, either. Rather, both the spatial magnitude of the stimuli and the relative difference between stimuli and background play a role in shaping duration judgments.

The relative weight of these two factors is context dependent. When there was only one kind of oddball (Exp. 3), which was shorter than the standard, the oddball led to a classic temporal expansion. Yet, when a longer oddball was added to the design (Exp. 1 and 2), shorter oddballs were judged, on average, to have the same duration as the standard. That is, the same oddball embedded in the same sequence of standard stimuli produced different patterns of temporal distortion depending on the context in which it was presented. Such contextual variability is consistent with the hypothesis that the Oddball Effect is not mediated by low level perceptual processes like visual adaptation, but rather depends on higher-level comparison (Schindel et al. 2011) and on the contextual salience of the oddballs (Van

Wassenhove, Buonomano, Shimojo, \& Shams, 2008). When oddness is the salient feature (Exp. 3) a "more change more time" mapping is evident, whereas when the polarity of the magnitude continuum becomes salient (Exp. $1 \& 2$ ), a "more space - more time" mapping is also evident.

There is now considerable evidence that humans' representations of time are grounded in their nontemporal experience as well as in their temporal experience. Why should people systematically incorporate certain kinds of non-temporal information into their temporal thinking? Some non-temporal aspects of events are often good proxies for time, and they may be easier to perceive or remember than time, per se. For instance, the domain general "more change - more time" mapping, which is at the basis of ATOC, is consistent with our experience that greater changes occur over greater durations (see Fraisse, 1984). Often, amount of change may provide a perceptible basis for duration judgments: We cannot see time passing, but we can see physical objects changing (e.g., containers filling, leaves changing color, children growing). Likewise, people may rely on the domain-specific mapping between spatial extent and time because spatial aspects of our experience are generally more perceptible than the associated temporal aspects (e.g., it is possible to see how far a ball rolls (distance) but not to see how long it takes (duration); Casasanto \& Boroditsky, 2008; Casasanto et al. 2010; Lakoff \& Johnson, 1999).

## Conclusions

Spatial magnitude and duration share a representational link that does not extend to other prothetic domains such as brightness and loudness. This domain specificity is inconsistent with a domain-general magnitude metric as hypothesized by ATOM. Our results are also only partly explained by ATOC as effects of a change in the magnitude of a nontemporal aspect of the stimulus. Results are best understood as supporting both ATOC and metaphor theory, in combination.

The pattern of subjective temporal expansion predicted by ATOC was observed most clearly when only one type of oddball stimulus was included, which highlighted the simple fact of a difference (i.e., change) between the oddball and the standard. The pattern predicted by metaphor theory was found most clearly when two oddballs that varied in spatial length were included, which highlighted their magnitudes.

Grounding representations of temporal magnitude in our experiences of relative amount of change (ATOC) and in spatial magnitude (metaphor theory) are both functionally motivated: As objects change, or as they travel farther through space, more time passes. As such, nontemporal aspects of events that correlate reliably with time can serve as perceptible indices of temporal change, which is imperceptible. Grounding representations of temporal magnitude in other prothetic magnitudes, however, would not be functionally motivated: The absolute magnitudes of brightness and loudness, for example, do not appear to be correlated with duration in our everyday experience. From
this functional-experiential perspective, it is unsurprising that our data support ATOC and metaphor theory, but not ATOM. ATOC and metaphor theory appear to be functionally and experientially motivated in a way that ATOM is not.

# Open-Ended Category-Based Induction: The Influence of Associative Strength and Structured Knowledge Representations 

Aimée Kay Bright (aimee.bright@northumbria.ac.uk)<br>Department of Psychology, Northumberland Road, Newcastle upon Tyne, NE1 8ST, UK

Aidan Feeney (a.feeney@qub.ac.uk)<br>School of Psychology, Queen's University Belfast<br>Belfast, BT7 1NN, UK

#### Abstract

Accounts of category-based inductive reasoning can be distinguished by the emphasis they place on associative retrieval processes versus structural knowledge representation. Using an open-ended category-based induction task with a secondary task manipulation, we explored whether the relative importance of these two processes in determining the reasoning output depends upon the availability of mental resources. Regressing indices of strength of association and measures of structured relation against reasoners' inferences showed that people's inductions generated under cognitive load were more strongly predicted by associative strength between base and conclusion category. In contrast, inferences made under no load were best predicted by the measure of the existence of structural relations between base and conclusion category. This suggests that people make use of associative processes and recruit structured knowledge to make inductive inferences, and that the relative importance of these two forms of reasoning is determined by the availability of mental resources.

Keywords: Category-Based Induction; Knowledge; Categorical Inferences; Reasoning.

## Knowledge and Category-Based Induction

Generalizing properties from one category to another is known as category-based inductive reasoning. If people learn that carrots have a certain disease, they might infer that rabbits could also be affected. However, if people are reasoning about shared cells, they might prefer to generalize from carrots to parsnips rather than to rabbits. Understanding how people select relevant knowledge has become central to explaining the mental processes that underlie category-based inductive reasoning (Shafto, Baldwin and Coley, 2007). But is knowledge selection based on a single process, such as the activation of automatic associations in semantic memory (Rogers \& McCllelland, 2004) and the calculation of similarity (Sloman, 1993; Sloutsky \& Fisher, 2004) or the explicit representation of structural relations between categories (Osherson et al., 1990; Tenenbaum, Griffiths \& Kemp, 2007), or does it depend on an interplay between such processes? In this paper, we argue that how people reason is determined by more domain-general factors, such as available cognitive resources.

## Associative Processes in Inductive Reasoning

Associative processes can explain a host of phenomena in category-based inductive reasoning. For example, Sloman's (1993) feature-based induction model assumes that similarity represented by the degree to which premise and conclusion categories activate common features determines the strength of the conclusion. Similarly, Roger and McClelland's application of the parallel-distributed processing model to category-based inductions assumes that generalizations from one instance to another will be strong to the extent that the activated distributed representations of the two instances overlap via their shared attributes. Several predictions follow from the way in which the connectionist model acquires semantic knowledge and makes generalizations. As it acquires knowledge gradually based on experiential input, the internal representations should mirror the structure of the learning environment. For example, if one repeatedly encounters two species in the same context, the internal representations ought to reflect this statistical co-occurrence. Inductive inferences between categories should be stronger to the extent that the categories have repeatedly been simultaneously activated in semantic memory, forming strong associations

## Structural Knowledge Representations

In contrast to models that emphasize associative processes, structured knowledge representations might be necessary to draw accurate inferences where the categories have complex ecological, causal or taxonomic relations. The seminal study by Heit and Rubinstein (1994) demonstrated that people recruited differential knowledge depending upon the type of property they were asked to generalize. Similarly, structured Bayesian models (e.g., Kemp \& Tenenbaum 2009; Shafto et al., 2008) successfully explain phenomena that arise from paying attention to the higherorder interrelationships between categories. For example, reasoning about causal transmission is best predicted by inferences computed over a theoretical model of food web relations, whereas inferences about physiological properties seem to be based on an understanding about taxonomic interrelationships. Use of structural representations can also explain phenomena such as the causal asymmetry effect.

Thus, people believe that diseases are more likely to be transmitted from prey to predator than vice versa (Medin, Coley, Storms \& Hayes, 2003; Shafto et al., 2008).

An interesting question is what factors determine the use of such structural representations. Cross-cultural work and research on experts (e.g. Lopez, Atran, Coley, Medin \& Smith, 1997; Proffitt, Coley \& Medin, 2000) suggests that to some extent, use of structural representations in inductive reasoning depends upon having the appropriate background knowledge. For example, Shafto and Coley (2003) compared commercial fishermen's inductive inferences about marine life to those of US undergraduates. When reasoning about novel diseases, only the fishermen drew on causal/ecological relations between premise and target categories to inform their inference. The undergraduates tended to base all their inferences on similarity. However, while such studies illustrate that people vary in the sophistication of the structural representations they have across different domains, the underlying mental processes that prompt people to draw on these or instead fall back on simple similarity during the reasoning process remain unclear.

## Two Types of Reasoning?

One possibility is that drawing on structural representations is an effortful process, whereas the use of simple associations and similarity requires fewer mental resources. The relative importance of each strategy might be determined by domain-general factors, such as available time and mental resources. Support for this position comes from a study looking at reasoning in music experts (composers and musicians) and novices (Baraff \& Coley, 2003; Coley \& Barraff, 2003). Compared to novices, experts tended to use more elaborate context-dependent relational knowledge. However, when the induction task was carried out under time pressure, thus decreasing available cognitive processing time, experts' reasoning was indistinguishable from novice reasoning. This change in expert responding suggests that drawing on structured knowledge representations during reasoning is slow and effortful. Thus, under time pressure, experts had to rely more on associative similarity, the default for novices who lack relevant structural knowledge representations.

A study by Bright and Feeney (2010) lends further support to the suggestion that people reason differently depending upon available mental resources. Thus, when people made speeded inferences, argument strength was predicted by associative strength between the two categories, whereas causal and biological knowledge predicted inference strength when people were not under time pressure.

However, Coley et al. (2005) have argued that some phenomena may be task-specific, especially if people are unaware of the nature of the relation between categories. Most findings are based on experimental paradigms in which people evaluate the strength of an inductive argument (Rabbits have property X, therefore, Foxes have property
X), evaluate a series of conclusions (Rabbits have property X. How likely is that Foxes have property X? Eagles? Hares?), or are forced to choose between two alternative conclusion categories (Rabbits have property X. Is it more likely that Hares or Foxes have property $X$ ?). When people are presented with pre-determined base and conclusion categories, lack of structural knowledge representations that highlight relevant relations between categories might force people into adopting a default associative reasoning strategy that they wouldn't normally use. In contrast, open-ended methodologies allow people to use background knowledge in a more flexible manner. For example, Baker and Coley (Baker \& Coley, 2005; Coley \& Baker, 2004) gave their participants two related category pairs and asked them to make inferences about which other categories might also have a novel property. People tended to make inferences based on complex ecological relations rather than on taxonomic similarity, suggesting that they were recruiting whatever relevant structural knowledge representations were available to them.

In the following experiment, people were told that a base category had a property and were asked to infer which other category was most likely to also have that property. We predicted that people who generated categories under cognitive load would use a strategy that placed less demand on cognitive resources, such as similarity or strength of association. In contrast, we expected people to make use of diverse structural knowledge representations when they were not under cognitive load. Previous work using a speeded response paradigm (Shafto, Coley \& Baldwin, 2007) has suggested that taxonomic knowledge is more available to reasoning processes than is ecological knowledge. When they have sufficient time, people tend to bring taxonomic knowledge to bear when reasoning about intrinsic properties such as cells and ecological knowledge to bear when reasoning about extrinsic properties such as diseases (see Shafto et al., 2007). So that we could attempt to replicate Shafto et al's finding that taxonomic knowledge is more available to reasoning processes, we asked people to reason about cell and disease properties expecting that only under light load would there be evidence of use of ecological relations when people reasoned about diseases.

## Methods

The experiment had three phases, the induction generation phase 1 , the associative rating phase 2 and the structured relation rating phase 3 .

## Induction Generation Phase

The first phase had a 2 (load: heavy or light) by 2 (property: infection or cells) mixed design, with load as the between-subjects manipulation.

Twenty-three students ( $M$ age $=24.2$ years) from Durham University (the reasoners) were presented with 20 base categories and told that each category had a novel property,
either an infection (e.g. has infection 5 y 5 u ) or cells (e.g. has 3 -yu-cells). There were equal numbers of each property type and the combination of property type and base category was counterbalanced. Participants were then asked to generate ONE other category that they believed was most likely to also have the property. For example, people would read the following generative induction problem:

Weasels have 4Ou-cells / infection 4Ou.
Which other category is most likely to also have 4Oucells/ infection 4OU?

Once people had written down their response, they rated how likely they thought it was that the two categories shared the property on a scale from 1 (very unlikely) to 9 (highly likely).

Preceding each of the induction trials was a secondary memory task. People were presented with a $4 * 4$ dot matrix with 4 randomly placed black dots for 2000 ms . Participants remembered the location of the dots, completed the induction task and then recalled the location of the dots in an empty matrix. The configuration of the dots was different for each of the 20 trials.

In the heavy load condition, the dots were completely randomly placed, with the restriction that they could never appear in a straight or diagonal line. In the light load control condition, the dots always appeared in a straight or diagonal line, placing minimal burden on working memory.

## Association Rating Phase

In the second phase each individual reasoner's 20 category pairs were transcribed onto an association rating sheet and interspersed with 15 weakly associated distracter items. A group of 92 participants (the raters) who had not taken part in the first phase received one of 23 different sheets (approximately 4 participants per sheet) and were asked to rate the strength of association on a scale from 1 (unrelated) to 9 (very highly associated) between the 35 category pairs. They were instructed to respond as fast as possible, based on the first intuitive answer that came to mind.

## Structured Relation Ratings

In order to determine the underlying structural relations between the base and conclusion categories generated by reasoners in phase 1 , the experimenter and a second blind coder rated whether there was a taxonomic and/or interaction-based relationship between the 20 category pairs. Table 1 below contains examples of the different types of relation.

Thus, category pairs were awarded 0 if there was no discernible link between the base and the generated category (e.g. alligator $\rightarrow$ soil), 1 if they were taxonomically related (e.g. zebra $\rightarrow$ horse), 1 if they were related through a causal link or ecological interaction (e.g. hawk $\rightarrow$ mouse) and 2 if there was both a taxonomic and interaction-based relation
between the categories (e.g. cod $\rightarrow$ shark). Concordance rate across the two primary coders was $67 \%$. Disagreements were resolved through discussion with two further colleagues.

## Table 1: Coding Scheme for Structured Relations

| Taxonomic Relationship |  |
| :--- | :--- |
| Category <br> Membership | Both categories belong to the same class or <br> category (e.g. carrot \& parsnip) |
| Physiological <br> Similarity | Both categories are similar with respect to <br> specific organs or systems (e.g. bat \& bird) |
| Interaction-Based Relationship |  |
| Similar <br> Habitat | Both categories share similar or the same <br> habitat (e.g. trout \& shrimp) |
| Behavioural <br> Interaction | Both Categories interact via some aspect <br> of behaviour (e.g. monkey \& tree) |
| Food Chain <br> Interaction | Both categories interact with respect to <br> diet or eating, i.e., one category eats or is <br> eaten by the other (e.g. heron \& fish) |

## Results

## Association Ratings

We averaged association ratings made by raters in phase 2 across all 20 category pairs generated by reasoners in phase 1. One rater in phase 2 failed to complete more than $50 \%$ of the association ratings and was excluded from the analysis.
The mean association scores were analyzed with a 2 (load: heavy or light) by 2 (property: cells or infection) mixed-design ANOVA, with load as the between-subjects variable.

There was no main effect of property, $\mathrm{F}_{(1,89)}=1.08, \mathrm{p}=$ .30 , effect size $\mathrm{d}=.22$. People gave a mean association rating of $6.23(\mathrm{SE}=0.12)$ for category pairs which had been generated about shared cells, and a mean association rating of $6.15(\mathrm{SE}=0.13)$ for category pairs generated about infections.

As predicted though, there was a main effect of load, $\mathrm{F}_{(1,}$ ${ }_{89}=4.03, \mathrm{p}=.048$, effect size $\mathrm{d}=.42$, such that categories generated under conditions of heavy load ( $\mathrm{M}=6.42$, SE $=.16$ ) were rated as more strongly associated than categories generated by reasoners whose resources were minimally taxed $(\mathrm{M}=5.96, \mathrm{SE}=.16)$.

Finally, there was no interaction between property and load condition $\mathrm{F}_{(1,89)}=.55, \mathrm{p}=.46$, effect size $\mathrm{f}=0.08$.

## Types of Structured Relations

We summed the taxonomic relationship ratings and the interaction-based relationship ratings across the categories for which reasoners had made inferences about diseases, and likewise across the 10 category pairs that were generated for
shared cells. These were analyzed with a 2 (type of relationship: taxonomic or interaction-based) by 2 (load: heavy or light) by 2 (property: cells or infections) mixeddesign ANOVA, with load as the between subjects variable. The crucial result was a three-way interaction between property, relation and load, $\mathrm{F}_{(1,21)}=5.43, p=.03$, effect size $\mathrm{f}=0.51$, illustrated in Figure 1 below.

Figure 1: Number of interaction-based and taxonomic relations (and standard errors) across the two types of property for heavy and light load conditions

## Heavy Load

In the heavy load condition, there was a main effect of property, $\mathrm{F}_{(1,10)}=26.94, p<.0005, \mathrm{~d}=3.3$. Thus, when people reasoned about cells, the conclusion categories they generated shared more structural relations with the base categories ( $\mathrm{M}=5.50, \mathrm{SE}=0.19$ ) than when they generated categorical inferences about infections $(\mathrm{M}=4.64, \mathrm{SE}=$ $0.18)$.

There was also a significant main effect of type of relation, $\mathrm{F}_{(1,10)}=68.15, p<.0005, \mathrm{~d}=5.3$. Thus, people seemed to generate more taxonomically-related categories $(\mathrm{M}=8.05, \mathrm{SE}=0.41)$ than conclusion categories which were related via an interaction $(M=2.09, S E=0.39)$.

Finally, there was a significant two-way interaction between property and relation $\mathrm{F}_{(1,10)}=8.27, p=.017$, effect size $\mathrm{f}=0.91$. Bonferroni post-hoc tests showed that there were no property effects for interaction-based responses. Interaction-based responses were similarly low when reasoning about cells ( $\mathrm{M}=1.82, \mathrm{SE}=0.38$ ) and infections ( $\mathrm{M}=2.36, \mathrm{SE}=0.53, p=.29$ ). In contrast, property effects arose for taxonomic responses, showing that people gave more taxonomic responses when reasoning about cells ( $\mathrm{M}=$ $9.18, \mathrm{SE}=0.30$ ) than when reasoning about infections ( $\mathrm{M}=$ $6.91, \mathrm{SE}=0.63, p=.002$ ).

## Light Load

The pattern of results was different in the light load condition. Here, the only significant effect was for property, $F_{(1,11)}=33.0, p<.0005$, effect size $\mathrm{d}=3.5$. When people reasoned about cells, the conclusion categories they generated shared more structural relations with the base
categories $(M=6.58, S E=0.20)$ than when they generated categorical inferences about infections $(\mathrm{M}=5.33$, $\mathrm{SE}=$ 0.09 ).

Although the pattern of means suggests that people generate more taxonomically related conclusion categories ( $\mathrm{M}=7.54, \mathrm{SE}=0.77$ ) than interaction-based conclusions categories ( $M=4.38, S E=0.89$ ), this main effect of type of relation was not statistically significant, $\mathrm{F}_{(1,11)}=3.69, p=$ .08 , effect size $\mathrm{d}=0.4$. Finally, the most important difference compared to the heavy load condition was an absence of an interaction between property and type of relation, $\mathrm{F}_{(1,11)}=0.128, p=.73$, effect size $\mathrm{f}=0.38$.

## Generative Inductive Strength Ratings

Inductive strength ratings for the categories the reasoners had generated were analyzed with a 2 (load) by 2 (property) mixed-design ANOVA with load as a between-subjects variable. Inductive strength ratings did not differ between the load conditions, $\mathrm{F}_{(1,21)}<.001, p=.99$, effect size $\mathrm{d}<$ .01. Reasoners under heavy load gave a mean inductive strength rating of 5.55 ( $\mathrm{SE}=.40$ ) whereas those under minimal load rated the strength of their induction at 5.56 ( $\mathrm{SE}=.42$ ).
There was also no main effect of property, $\mathrm{F}_{(1,21)}=2.1, p$ $=.16$, effect size $\mathrm{d}=.63$. Inferences about cells $(\mathrm{M}=5.68$, $\mathrm{SE}=.32$ ) were rated as strong as inferences about infections ( $\mathrm{M}=5.42, \mathrm{SE}=.29$ ).
The interaction between load and property was not statistically significant, $\mathrm{F}_{(1,21)}=2.68, p=.12$, effect size $\mathrm{f}=$ . 35 .

## Relations between Inductive Strength Ratings, Structured Relations and Associative Strength

To explore whether reasoners place different emphasis on associative processes and reasoning based on structured knowledge representation in the two load conditions we used an associative strength measure and the index of structured relations described above to predict their inductive strength ratings.

To create the associative strength measure we averaged the mean strength of association scores attached to each reasoner's 20 category pairs across the four raters from phase 2. We then calculated Cronbach's Alpha for each of the 23 reasoners across the association ratings. The mean Cronbach's Alpha across all reasoners was .71 ( $\mathrm{SD}=.13$ ), showing that the association ratings had good inter-rater reliability.
To create the structured relation measure, the experimenter and a second blind coder assessed in how many ways the generated target could be related to the base. 0 was attached if there was no obvious structured link, 1 if there was either a taxonomic or an interaction-based connection, and 2 if they were related in more than one way.
For each reasoner who had taken part in phase 1, we used the associative strength and structured relation measures to predict his/her inductive strength ratings. The beta weights were then subjected to a 2 (load: heavy or light) by 2 (type
of beta weight: associative versus structured relation) mixed-design ANOVA, with type of beta weight as the repeated-measures variable.

There was no significant main effect of type of beta weight, $\mathrm{F}_{(1,21)}=.068, \mathrm{p}=.80$, effect size $\mathrm{d}=.11$ and no main effect of load, $\mathrm{F}_{(1,21)}=3.22, \mathrm{p}=.09$, effect size $\mathrm{d}=$ .78. However, there was a significant interaction between beta weight type and load, $\mathrm{F}_{(1,21)}=6.53, \mathrm{p}=.018$, effect size $d=1.1$. This is illustrated below in Figure 2.

Figure 2: Beta weights (and standard errors) across the two load conditions

Bonferroni posthoc tests showed that when reasoners were under heavy memory load, the associative strength beta weight ( M beta $=.20, \mathrm{SE}=.07$ ) was larger than the structured relation beta weight $(\mathrm{M}$ beta $=.02, \mathrm{SE}=.02)$, although this difference was not quite statistically significant due to the small number of participants in this condition ( $\mathrm{p}=.065$, effect size $\mathrm{d}=1.2$ ). A one-sample t -test confirmed that associative strength beta weight was significantly above zero, $\mathrm{t}_{(10)}=3.79, p=.004$, but that the structured relation beta weight was not significantly above zero, $\mathrm{t}_{(10)}=0.45, p=.66$.

The pattern was reversed when reasoners were not under a heavy memory load. Thus, the structured relation beta weight ( M beta $=.28, \mathrm{SE}=.05$ ) was slightly but not significantly larger in magnitude than associative strength beta weight $(\mathrm{M}$ beta $=.11, \mathrm{SE}=.07, p=.11$, effect size $\mathrm{d}=$ .62). However, the one-sample t-test showed that whereas the structured relation beta weight was significantly above zero, $\mathrm{t}_{(11)}=5.24, \mathrm{p}<.0005$, the associative strength beta weight was not statistically different from zero, $\mathrm{t}_{(11)}=1.56$, $p=.15$.

Across the two load conditions, the associative strength beta weight was slightly but not significantly larger for reasoners who generated their inferences under load compared to those who were not cognitively compromised ( $p=.44$, effect size $\mathrm{d}=.32$ ). In contrast, the mean structured relation beta weights were significantly larger for reasoners who generated their inferences under minimal cognitive load compared to reasoners who were cognitively burdened
by the complex dot matrix task ( $p=.001$, effect size $\mathrm{d}=$ 1.6).

The results suggest that the reasoning process used to arrive at a particular inference depends to some extent on available cognitive resources. Whereas structured knowledge representations were influential when reasoners were only under minimal cognitive load, associations seemed to be more important to reasoners under a heavy cognitive load.

## Discussion

Our results suggest that the process people adopt to generate category-based inductive inferences depends upon available cognitive resources. Categories produced under heavy load were rated as more strongly associated than categories generated under a light load. Furthermore, under heavy load conditions, those association ratings were better predictors of inductive strength than an index of structured relations. In contrast, in the light load condition the index of structured relations was the better predictor of inductive strength ratings. Furthermore, under heavy cognitive load, people were less likely to generate categories that shared more complex interaction-based relationships, whereas generating taxonomically related categories was unaffected by cognitive load.

The advantage of the open ended paradigm is that we can be sure that participants possess knowledge about structured relations between base and conclusion categories. Despite using this more flexible reasoning paradigm, people who were under cognitive load seemed less able to make use of complex structural representations, and instead relied more strongly on associative processes. This suggests that while people do seem motivated to base their reasoning on domain-specific knowledge representations such as ecological/ causal structures, this comes at a cognitive cost. If necessary, people can shift towards a more associative strategy that might result in an inference that is different to the one that would have been generated through the activation of more complex structural knowledge representations. Sloutsky and colleagues (2008) suggest that structured knowledge can arise from simple associative processes and co-occurrence. Thus, it is conceivable that even once people possess more elaborate knowledge structures, they may use associative strength as a useful heuristic short-cut during reasoning, especially when time and/or cognitive resources are sparse.

Interestingly, we found no differences in people's inductive strength ratings across the two load conditions, suggesting that people were equally confident about inferences generated using associative reasoning or a reasoning strategy based on more complex structural knowledge.

As well as allowing us to disentangle the relative effects of associative and structured knowledge on reasoning, our results replicate Shafto et al's finding that taxonomic knowledge is more available to reasoning processes than is
ecological knowledge. Although our results clearly show that associative knowledge was a better predictor of reasoning when participants were under load, they also show that participants were much more likely to generate conclusion categories that were taxonomically rather than ecologically related to the base category when under load. This was regardless of the property they were asked to reason about. Large numbers of ecologically related conclusion categories were seen only when participants reasoned about disease properties under light load.

## Conclusion

Our results suggest that apparently contradictory theories of category-based inductive reasoning best explain inference strategies under different domain-general processing conditions. People's reasoning might best be explained by associative approaches such as parallel-distributed processing connectionist accounts (Rogers \& McClelland, 2004) and featural similarity (Sloman, 1993) when they do not have time or available mental resources to engage in more elaborate reasoning.. In contrast, people with plenty of time and cognitive capacity might recruit complex structural knowledge representations (e.g. Kemp \& Tenenbaum, 2009) to derive their inferences.

# Motor Asymmetries Predict Neural Organization of Emotion 

Geoffrey Brookshire ${ }^{1}$, Cleve Graver ${ }^{1}$, and Daniel Casasanto ${ }^{1,2}$<br>\{broog731; gravc243; casasand\} @ newschool.edu<br>${ }^{1}$ Department of Psychology, The New School for Social Research, New York<br>${ }^{2}$ Donders Center for Brain, Cognition, and Behaviour, Nijmegen, NL

#### Abstract

According to decades of research in affective neuroscience, approach and avoidance motivation are supported by the left and right hemispheres, respectively. With the Sword and Shield Hypothesis (SSH), we challenge this conclusion, and propose a novel principle underlying the organization of emotion in the brain: the hemispheric lateralization of motivation depends on the neural locus of motor control for the dominant hand (used preferentially for approach actions) and the non-dominant hand (used preferentially for avoidance actions). The SSH predicts that the laterality of approach motivation should vary continuously with the laterality of circuits used for planning and executing approach-related actions. To test this prediction, we measured mood before and after 5 sessions of tDCS applied bilaterally to DLPFC in right- and lefthanders. Results in right-handers show that positive emotions increased after left-excitatory stimulation, but decreased after right-excitatory stimulation. In non-right-handers, however, the opposite pattern was found: Positive emotions decreased after left-excitatory stimulation, but increased after right-excitatory stimulation. These findings reveal continuous covariation between the neural systems for action and emotion, supporting the SSH.

Keywords: Emotion; motivation; motor control; handedness; hemispheric specialization, tDCS.

## Introduction

A cornerstone of cognitive-affective neuroscience is the robust finding that the left hemisphere is specialized for approach motivation and the right hemisphere for avoidance motivation (reviewed in Harmon-Jones, Gable, \& Peterson, 2010). Although temporal and parietal areas have been implicated in affective motivation (Amodio, Master, Yee, \& Taylor, 2008; Brookshire \& Casasanto, 2012), studies suggest that this asymmetry centrally involves dorsolateral prefrontal cortex (DLPFC): Approach motivation recruits left DLPFC, and avoidance motivation recruits right DLPFC (Berkman \& Lieberman, 2010).

Approach/avoidance asymmetries can also be observed in behavior. People tend to perform approach actions with the dominant hand, and avoidance actions with the non-dominant hand (Casasanto, 2009). The dominant hand, for example, is preferred when eating. In contrast, people reflexively protect their faces with the non-dominant hand when startled (Coren, 1992). Sword-fighters in centuries past approached their enemies with a sword held in the dominant hand, and avoided incoming blows with a shield in the non-dominant hand (Harris, 2010).

In right-handers, therefore, the left hemisphere is involved both in approach motivation and in coordinating actions with the hand preferred for approach actions. Casasanto (2009) proposed that this correspondence may result from a functional relationship between affective motivation and manual
motor control for approach and avoidance actions. We call this the Sword and Shield Hypothesis (SSH; Brookshire \& Casasanto, 2012). The SSH suggests that the lateralization of approach/avoidance motivation is functionally linked to the way we use our hands to perform approach and avoidance actions, and offers a new principle to predict and explain the neural organization of emotion.

The SSH predicts that differences in how people use their hands for approach and avoidance actions should correspond to differences in the neural organization of affective motivation. Left-handers tend to perform approach actions with their left hands and avoidance actions with their right hands (Coren, 1992; Harris, 2010). Accordingly, approach motivation in left-handers should be lateralized to the right hemisphere, the reversal of the pattern found in right-handers.

To test this prediction, Brookshire and Casasanto (2012) examined resting activation asymmetries in EEG as a function of manual motor asymmetries and trait approach motivation. As in previous studies (Sutton \& Davidson, 1997), higher approach motivation in right-handers correlated with greater leftward activation asymmetries. This pattern reversed in left-handers, however. Consistent with the SSH, increased approach motivation in left-handers correlated with greater rightward activation asymmetries (Brookshire \& Casasanto, 2012).

## Causal role of frontal asymmetry

Frontal asymmetries are widely believed to play a causal role in determining emotional experience (Harmon-Jones et al., 2010). Supporting this idea, patients with left hemisphere lesions are prone to depression, whereas those with right hemisphere lesions are prone to mania and indifference to their injuries (Robinson, Boston, Starkstein, \& Price, 1988). Similarly, deactivating the right hemisphere with sodium amobarbital causes laughter and elation, whereas deactivating the left hemisphere causes crying and negative affect (Lee, Loring, Meader, \& Brooks, 1990). These data underscore the necessity of the two hemispheres in emotion, but they are limited by low spatial resolution (constrained to the level of hemisphere), and by the extremity of processing disruptions used (completely deactivating a neural area). Would subtler, more spatially restricted manipulations of activation asymmetries influence emotional processing?

Allen, Harmon-Jones, and Cavender (2001) used biofeedback in EEG to train participants to induce rightward or leftward frontal activation asymmetries. Participants trained to produce leftward asymmetries experienced greater positive, approach-oriented emotions than those with rightward train-
ing. However, it is possible that participants used strategies to complete the biofeedback task (e.g. rehearsing approachmotivated memories), complicating inferences about a causal role of frontal activation in producing emotions. Activation asymmetries may have been a consequence-not a cause-of changes in emotional state.

Subsequent work has addressed the causal role of frontal asymmetries using transcranial direct current stimulation (tDCS). In tDCS, a weak, constant electrical current is passed between two conductive electrodes on the scalp. After 5-20 minutes of stimulation, neurons beneath the anodal electrode are transiently excited, and those beneath the cathode are inhibited (Nitsche \& Paulus, 2000).

Several studies have used tDCS to intervene on activation asymmetries in DLPFC, but many of these fail to find support for a causal involvement of frontal asymmetries in emotional experience. Specifically, tDCS applied in a single session to DLPFC had no effect on self-reported mood or trait motivational tendencies (Koenigs, Ukueberuwa, Campion, Grafman, \& Wassermann, 2010; Plazier, Joos, Vanneste, Ost, \& De Ridder, 2011; Nitsche et al., 2012).

Studies of the causal role of frontal asymmetries on more implicit emotional processing have yielded mixed results. Nitsche et al. (2012) found that anodal tDCS over left DLPFC facilitated identification of both positive and negative facial expressions, but that the effect was stronger for positive expressions. Penolazzi et al. (2010) examined memory for emotional pictures after bilateral tDCS over DLPFC. Anodal tDCS almost invariably improves memory performance (for review see Jacobson, Koslowski, \& Lavidor, 2011). Surprisingly, however, left-anodal/right-cathodal stimulation facilitated recall of unpleasant pictures, and right-anodal/leftcathodal stimulation facilitated recall of pleasant pictures. Although this experiment seems to suggest a causal role of frontal asymmetries in emotional memory, the fact that leftexcitatory tDCS improved recall of negative pictures, and right-excitatory of positive pictures, is inconsistent with a great deal of research in right-handers linking positive emotions with the left hemisphere (Harmon-Jones et al., 2010).

Researchers noting the clinical potential of neurostimulation have begun using repeated sessions of tDCS to treat major depressive disorder, with somewhat more consistent results than the single-session studies reviewed above. Left-anodal tDCS often ameliorates symptoms of depression (reviewed in Murphy, Boggio, \& Fregni, 2009). However, these treatment-oriented studies did not include all of the experimental conditions needed to support the conclusion that induced activation asymmetries play a causal role in emotional experience: Researchers delivered only left-excitatory and sham stimulation, but never right-excitatory stimulation. Thus, it is not possible to conclude that increasing activity in the left hemisphere relative to the right was responsible for the positive effects of neurostimulation of mood. Perhaps multiple sessions of tDCS may boost positive mood regardless of stimulation montage. To determine whether frontal
activation asymmetries play a functional role in determining emotional states, experiments must apply both left- and rightexcitatory stimulation. Furthermore, in order for the findings to be generalizable beyond a clinical population, relationships between lateralized stimulation and mood would need to be shown in healthy participants.

## Parametric covariation in brain and behavior

According to the SSH, there is a functional relationship between the neural circuits for motivation and manual motor asymmetries. In addition to predicting a reversal in approach/avoidance lateralization in left-handers, the SSH predicts that parametric variation in manual motor asymmetries should correlate with graded differences in the lateralization of motivation. Strong right-handers, that is, should show stronger left-lateralization of approach motivation than weak right-handers. Previous work has not tested this prediction.

## The present experiment

In this study, we measure mood before and after 5 sessions of tDCS applied bilaterally to DLPFC. We analyze changes in emotional state as a function of participants' manual motor asymmetries, and whether they received left-anodal/rightcathodal or right-anodal/left-cathodal stimulation. In doing so, we test for a causal role of frontal activation asymmetries in determining emotional state. Furthermore, we test for the graded relationship between motor control and the lateralization of affective motivation predicted by the SSH.

## Method

## Participants

Participants $(\mathrm{N}=30)$ were recruited from the New School community, postings to the website www.craigslist.org/, and a database of participants who have taken part in other studies in our lab. To ensure that the sample included participants with the full range of handedness asymmetries, we selectively contacted left-handed and ambidextrous participants from the database. These participants were not aware that they were being contacted based on their handedness.

Several exclusion criteria were followed to ensure participants' safety. Respondents were not included in the study if they indicated that they were pregnant, had ever experienced an epileptic seizure, had ever sustained a stroke or other brain injury, or were taking any psychoactive drugs or medications. Additionally, we did not test anyone who reported ever having been diagnosed with depression, bipolar disorder, anxiety disorder, or schizophrenia.

One participant was canceled during the first session when a low impedance could not be obtained. Four additional participants did not complete the study (Right-excitatory stimulation, $\mathrm{N}=2$; Left-excitatory stimulation, $\mathrm{N}=2$ ), one of whom returned to complete the final day of data collection. Data were analyzed from the remaining 25 participants (Right-handers, EHI $\geq 40: \mathrm{N}=17$; Non-right-handers, EHI $<40: \mathrm{N}=8$ ). Demographics such as age and gender were not collected.

## Procedure

This study took place over five consecutive days (MondayFriday). Informed consent was obtained at the beginning of each session, and participants were payed at the end of every session. On day 1, participants completed an untimed, computerized version of the Positive and Negative Affect Scale (PANAS; Watson \& Clark, 1994). Emotion words appeared on the screen one at a time, and participants rated the degree to which they had experienced that emotion "during the past few days" on a scale of one ("very slightly or not at all") to five ("extremely") by pressing the numbers $1-5$ on a computer keyboard. To assess handedness, participants completed the Edinburgh Handedness Inventory (EHI; Oldfield, 1971). This scale offers a continuous measurement of handedness, in which scores vary from strongly left-handed ( -100 ) to strongly right-handed (100).

On days 2-4, tDCS was applied after ensuring that participants had not experienced any discomfort after the previous sessions. After applying tDCS on day 5, the same tests were performed as on day 1. After the first cohort of 7 participants, we began collecting EHI at day 5. Participants also completed a brief adverse effects questionnaire. Upon completing the study, participants were debriefed and encouraged to contact the experimenter if they had any further questions or experienced any discomfort. ${ }^{1}$

## Transcranial Direct Current Stimulation

Direct current stimulation was delivered using a batterypowered stimulator (Soterix Medical, New York) with two $5 \times 7 \mathrm{~cm}$ saline-soaked sponges covering the electrodes. New sponges were used for each session. In each session, a current was applied at 2 mA for 20 min . To minimize discomfort, the current slowly ramped between 0 and 2 mA when powering on and off. Stimulation was delivered bilaterally above DLPFC at F3-4 in the 10-20 system (DaSilva, Volz, Bikson, \& Fregni, 2011). An experimenter was in the room with the participant at all times to ensure that stimulation remained comfortable.

Stimulation was delivered double-blindly in two betweensubjects conditions. Before beginning the study, a confederate set a polarity-blinding box to either reverse the polarity of the outgoing wires, or leave polarity unchanged, and then sealed the box. This allowed both the experimenter and the participant to remain blind to the stimulation condition. Participants were randomly assigned to one of the two conditions.

In one condition, the anode was placed above F3 and the cathode above F4, exciting left frontal areas while inhibiting right frontal areas (Left-excitatory). In the second condi-

[^23]tion, the anode was placed above F4 and the cathode above F3, exciting right while inhibiting left frontal areas (Rightexcitatory). Stimulation condition remained the same across all 5 sessions. Of the participants retained in the final analysis, $\mathrm{N}=10$ were given right-excitatory stimulation, and $\mathrm{N}=15$ left-excitatory stimulation.

## Results

## Adverse effects

One participant canceled the study due to a persistent headache, and three further participants requested that the intensity be reduced for several minutes in one session. Of the four participants reporting discomfort, two had received leftexcitatory stimulation, and two right-excitatory stimulation. No other subjects reported significant discomfort.

## Manual motor asymmetries

To examine whether tDCS altered manual motor asymmetries, we compared EHI scores before and after stimulation. EHI scores on days 1 and 5 were strongly correlated ( $r=.98$ ). Change in EHI scores did not significantly depend on tDCS polarity (Welch's $t(12.3)=-1.50, p=.16)$.

## Emotional state

PANAS responses were analyzed using linear mixed-effects regressions fit by maximum likelihood in R ( R Core Team, 2012) with the lmer () function in the lme 4 library (Baayen, Davidson, \& Bates, 2008). Change in each emotion (day 5 day 1) was modeled as a function of valence (Positive; Negative), tDCS polarity (Left-excitatory; Right-excitatory), and handedness (entered continuously using EHI score collected on day 1). Random intercepts were included for Subjects and Items (i.e. emotion words). All categorical predictors were entered using deviation coding. Unless otherwise noted, pvalues and 95\% Highest Posterior Density intervals (HPD) of the parameter estimates were estimated using Markov chain Monte Carlo (MCMC) sampling with 20,000 samples using the pvals.fnc () function in the languageR library.

Of primary interest, handedness, valence, and tDCS polarity interacted to predict change in PANAS ratings ( $\beta=$ $-0.015, \mathrm{HPD}=[-0.022,-0.009], p=.0001)$. As evident from Figure 1, this interaction was driven primarily by strong effects of handedness and polarity on positive emotions, but not on negative emotions. Separate mixed-effects regressions with positive and negative items support this conclusion.

Change in negative emotions did not significantly depend on handedness, tDCS polarity, or their interaction (all $p \mathrm{~s}>.5$; Fig. 1a). In contrast, handedness significantly interacted with tDCS polarity to predict change in the intensity of positive emotions $(\beta=-0.016$, HPD $=$ [ $-0.021,-0.010], p=.0001$; Fig. 1b). In participants receiving left-excitatory stimulation, stronger right-handedness correlated with greater increases in positive emotions ( $\beta=$ $0.011, \mathrm{HPD}=[0.0064,0.016], p=.0001)$. In those receiving right-excitatory stimulation, the opposite pattern

Figure 1: Change in (a) negative and (b) positive emotion from day 1 to day 5 as a function of manual motor asymmetries (EHI). Each point illustrates Z-transformed average change across all PANAS items for a single participant. Best-fit lines are plotted for each stimulation condition. Left-excitatory $=$ anode left, cathode right; Right-excitatory $=$ cathode left, anode right.
was observed: stronger right-handedness correlated with decreases in positive emotions $(\beta=-0.0044$, HPD $=$ [ $-0.0080,-0.0006], p=.02$ ).

By defining handedness categorically, we examined differences between right- and non-right-handers in the effects of tDCS on emotional state. For right-handers, left-excitatory tDCS led to more positive emotions than with rightexcitatory tDCS $(\beta=-0.21, \mathrm{HPD}=[-0.41,-0.012], p=$ $.04)$. For non-right-handers, the opposite pattern emerged: left-excitatory tDCS caused decreases in positive emotions compared with right-excitatory tDCS $(\beta=0.55, \mathrm{HPD}=$ [0.19, 0.89], $p=.006$ ).

These regression analyses leave open the question of whether parametric variation in handedness corresponds to graded differences in the hemispheric lateralization of emotion; significant parameter estimates in linear regressions can be caused by either continuous covariation or a stepfunction. Rank-order tests, however, can be used to discriminate between categorical and continuous relationships. A significant Spearman's correlation revealed that stronger right-handedness was continuously related to greater increases in positive emotions in participants who received leftexcitatory stimulation $(\rho(13)=0.71, p=.003)$. In those who received right-excitatory stimulation, this correlation was marginally significant in the opposite direction: stronger right-handedness continuously predicted greater reductions in positive emotions ( $\rho(8)=-0.56, p=.09$ ).

## Discussion

The effects of tDCS on mood depend upon the hemisphere to which excitatory stimulation is applied and the handedness of the participant. In right-handers, five sessions of left-excitatory (left-anodal, right-cathodal) tDCS led to
increased positive emotions, whereas right-excitatory (leftcathodal, right-anodal) tDCS led to decreased positive emotions. Non-right-handers, by contrast, showed the opposite pattern, with right-excitatory tDCS increasing positive emotions and left-excitatory tDCS decreasing them. Furthermore, we find graded, parametric variation between manual motor asymmetries and emotion in the brain. Stronger motor asymmetries correlate with more strongly lateralized circuits for emotion. These results demonstrate a functional relationship between activation asymmetries in the frontal lobes and the experience of positive emotions, and show that the laterality of positive emotion covaries continuously with the laterality of manual motor control.

According to the motivational model of hemispheric specialization for emotion, approach motivation is lateralized to the left hemisphere and avoidance to the right (Harmon-Jones et al., 2010). In conflict with this model, we show that neural regions specializing in approach motivation are co-lateralized with circuits that control the dominant hand. This finding is consistent with the SSH, which proposes a functional relationship between motivation and manual action.

Manual motor asymmetries predict the way approach motivation is distributed across the two hemispheres. For the right-handed majority, this appears as left-lateralized approach motivation. Does this mean that the classic motivational model is mostly correct-that it is right for the approximately $90 \%$ of people who are right-handed, and only wrong for the other $10 \%$ ? We suggest the answer is no: As a field, we have arrived at incorrect generalizations about the cortical basis of emotions. It is not the case that "anterior regions of the left and right hemispheres are specialized for approach and withdrawal processes, respectively" (Davidson, 1992, p. 127). It is only incidentally true that the left hemi-
sphere is specialized for approach motivation in most of the people who have been tested. This specialization is not due to any functional properties of the left hemisphere, per se. It appears that any theory that assigns a privileged role to the left hemisphere in processing approach motivation is incorrect.

These findings may help to elucidate an enduring mystery in affective neuroscience: What role do activation asymmetries play in motivation? Although no clear consensus has emerged, some researchers believe that leftward asymmetries may reflect "expression of approach-related emotions" (Harmon-Jones, 2004, p. 55) or "approach-related, goaldirected action planning" (Davidson, 2004, p. 225). By highlighting the close connection between action and emotion, our findings suggest that leftward asymmetries are closely linked to performance of approach actions.

## Causal links between frontal asymmetries, motivation, and hand action

To our knowledge, these findings provide the first unequivocal evidence that frontal activation asymmetries casually influence emotional experience in healthy participants. However, this study leaves open the question of the causal relationship between neural circuits for motivation and for motor control of the hands. We consider three possibilities.

First, handedness could determine the laterality of motivation. In this case, handedness is assumed to be set by some combination of genetic and environmental influences. If approach actions require greater dexterity than avoidance actions, then habits could develop in which approach actions are performed by the more adept dominant hand. These habits could then stabilize on an evolutionary or a developmental timescale, causing cortical areas involved in planning actions with the dominant hand to specialize in approach actions.

Second, the laterality of motivation could determine handedness. In this case, the laterality of motivation is assumed to be determined by genetic and environmental factors. Manual action circuits ipsilateral to regions specializing in approach motivation may subsequently come to be used preferentially for approach actions. If approach actions are more frequent or require more skill than avoidance actions, then dexterity may be enhanced in the hand used to perform them.

Third, handedness and the laterality of motivation could be determined by a common factor. In this case, there would be no direct causal link between the lateralization of neural circuits of motivation and manual motor control. Any proposed third factor would need to account for the close covariation we observe.

## Valence and motivational direction

We find that positive emotions are strongly modulated by induced frontal activation asymmetries, whereas negative emotions are unaffected. If negative emotions are assumed to be the mirror image of positive emotions, this result seems incongruous. This apparent contradiction resolves when examining the motivational direction of the words in the positive and negative PANAS subscales.

The left and right hemispheres appear to be differentially specialized for motivational direction, not valence (Berkman \& Lieberman, 2010; Harmon-Jones et al., 2010). Although these dimensions are highly correlated, they can also be dissociated. Induced frontal asymmetries, then, should alter the motivational direction-but not necessarily the valence-of participants' mood.

The emotions comprising the positive PANAS subscale uniformly involve strong approach motivation (active, alert, attentive, determined, enthusiastic, excited, inspired, interested, proud, strong). The negative subscale, on the other hand, is more varied. Some items seem to involve avoidance motivation (afraid, scared, ashamed), some approach motivation (hostile, irritable), and some do not have any clear motivational direction (nervous, jittery, guilty, upset, distressed).

In summary, we find that an emotion category with a consistent motivational direction (the positive subscale) is influenced by manipulations of frontal activation asymmetries, whereas a more heterogenous emotion category (the negative subscale) is not affected. Further studies must determine if avoidance motivation can be similarly modulated by induced activation asymmetries.

## Clinical implications

Neurostimulation techniques such as tDCS and transcranial magnetic stimulation (TMS) are currently in use as treatments of major depressive disorder (Murphy et al., 2009). By increasing activation in left frontal areas, clinicians hope to augment positive, approach-oriented emotions, alleviating depression. This treatment is predicated on the assumption that the left hemisphere is specialized for approach motivation. We provide evidence against this assumption. Hemispheric specialization for motivation reverses in many people, including left-handers (see also Brookshire \& Casasanto, 2012), who are at increased risk for depression (Denny, 2009).

Systematic differences in the neural organization of motivation may have urgent consequences for the success and safety of neurostimulation therapies. We show that positive affect is reduced after anodal tDCS to the hemisphere that controls the non-dominant hand. This result suggests that FDA-approved treatments involving anodal tDCS to leftDLPFC may exacerbate depression in non-right-handers.

## Conclusions

Accepted theories of emotion in the brain hold that the left hemisphere is specialized for approach motivation, and the right for avoidance motivation. We provide evidence against this "motivation model" and in support of the SSH. Hemispheric lateralization for emotion covaries with manual motor asymmetries, consistent with a causal relationship between motivation and motor control. The SSH proposes a principle by which the hemispheres become specialized for approach and avoidance states, and may lead not only to a better understanding of how motivation is organized in the cerebral cortex, but also of why it is organized that way.

# The Effect of Discourse Context on Online Sentence Processing 

Juliane Burmester (juliane.burmester@uni-potsdam.de)<br>Isabell Wartenburger (isabell.wartenburger@uni-potsdam.de)<br>University of Potsdam, Department of Linguistics, Center of Excellence Cognitive Science, Karl-Liebknecht-Str. 24-25, 14476 Potsdam, Germany<br>Katharina Spalek (katharina.spalek@staff.hu-berlin.de)<br>Humboldt-Universität zu Berlin, Department of German Language and Linguistics, Dorotheenstr. 24, 10117 Berlin, Germany

#### Abstract

Information structure describes how the information is packaged within a discourse to optimize information transfer. We addressed the question if and how a discourse context modulates the online processing of German declaratives. Native speakers of German read fictitious stories that depicted a simple action scene of two characters while we recorded event-related brain potentials (ERPs). Two types of discourse contexts (topic vs. neutral) were compared with regard to the processing of declarative canonical subject-before-object (SO) and non-canonical object-before-subject (OS) sentences. The preceding topic context only modulated the processing of OS sentences. This was indicated by a less pronounced positivity around 500 to 900 ms for the topic compared to the neutral context. As supported by previous research we argue that this context-induced effect in the processing of noncanonical sentences reflects reduced processing costs for the integration of the discourse relevant topic information into the current discourse model.

Keywords: information structure; discourse context integration; topic; sentence processing; word order variation; ERP; P600

## Introduction

In our everyday-life communicative utterances are typically linked to the discourse environment of the interlocutors. Previous evidence suggests that contextual information (e.g., from prior discourse) plays a crucial role in sentence comprehension. Information structure is concerned with the question how the information is structured and packaged within a discourse to optimize information transfer (e.g., Chafe, 1976). If and to which degree information structure interacts with syntax and other linguistic domains is still under debate (e.g., Büring, 2007; Fanselow \& Lenertová, 2011)

Information structure research in the domain of syntax (and in particular word order) addressed the question how word order variation might be affected by information structural concepts such as topic-comment, focusbackground, or the given-new distinction (Lambrecht, 1994; Rizzi, 1997). Topic (also aboutness topic) refers to the entity the sentence is about (Gundel, 1988; Reinhart, 1981). Mostly topics are introduced by the previous discourse (e.g., Skopeteas et al., 2006). It has been proposed that topics, independent of their grammatical function, are preferably placed in a specific syntactic position which is sentence-
initial (i.e., prefield) for German main clauses (Büring, 1999; Rosengren, 1993).

German is a language with relatively flexible word order because morphological features such as case marking allow the reordering of constituents without changing the grammatical function of the constituents. ${ }^{1}$ Therefore, German is ideal to study the effect of information structure on word order. In German, subject-before-object (SO) is the canonical word order which is preferred to object-beforesubject (OS) sentences (e.g., Gorrell, 2000). If presented without a felicitous discourse context, OS sentences lead to lower acceptability ratings and longer latencies in reading (e.g., Meng, Bader \& Bayer, 1999) compared to SO sentences. It has been pointed out that the processing of OS sentences might require contextual licensing (e.g., Bornkessel \& Schlesewsky, 2006; Höhle, 1982; Hörnig, Weskott, Kliegl \& Fanselow, 2006). Specific contextual information (e.g., object given in prior discourse or object in contrastive whole-part relation to a referent in the context) has been found to improve acceptability ratings and shorten reading times of OS sentences (Meng et al., 1999; Weskott, Hörnig \& Fanselow, 2009).

However, acceptability ratings and reading times do not tell us which underlying mechanisms of information structure help to optimize information transfer. Eventrelated potentials (ERPs) are a promising tool to shed more light on the effect of context on sentence processing (e.g., Van Berkum, 2008). For instance, a context-induced N400 effect for inferable vs. given referential expressions across different sentence positions was attributed to discourselinking processes (Schumacher \& Hung, 2012). A late positivity was associated with processing costs induced by updating the current discourse model and the integration of a new referent into discourse (e.g., Burkhart, 2007; Schumacher \& Hung, 2012).

Although many studies tested the online processing of OS sentences in isolation and indicated higher processing difficulty compared to SO (Matzke, Mai, Nager, Rüsseler \&

[^24]Münte, 2002; Rösler, Pechmann, Streb, Röder \& Hennighausen, 1998), previous behavioral and neurophysiological research has shown that contextual information (e.g., focus, givenness) is of central relevance for the processing of canonical and non-canonical sentences (e.g., Bornkessel, Schlesewsky \& Friederici, 2003; Schumacher \& Hung, 2012). However, it remains unclear if a topic introduced by the discourse context reveals an immediate processing advantage at the sentence-initial position of OS sentences.

The present ERP experiment aims to characterize the differential effect of a preceding topic context on the processing of German declaratives. We compare if and how a preceding topic context which assigns topic status to one of two characters of a scene modulates the processing of the following topic-first OS or SO sentence. The effect of the topic context is compared to a neutral context which induces a wide scope on the scene and serves as a baseline. Based on previous research we expect that the processing of the canonical SO sentences is not modulated by the preceding context information. Instead, for the non-canonical OS sentences we predict a processing advantage if they are preceded by a topic context as compared to a neutral context such that the topic status of the sentence-initial object leads to a less effortful linking and integration of information into the current discourse model. This type of processing advantage might be reflected in a reduced P600 component (e.g., Burkhart, 2007).

## Methods and Material

## Participants

Twenty-one native speakers of German participated in the present ERP experiment. All participants were right-handed according to the Edinburgh Handedness Inventory (Oldfield, 1971). None of them reported any neurological disorder. All had normal or corrected-to-normal vision. The participants were reimbursed or received course credits for participation. Due to a low behavioral accuracy ( $<60 \%$ correct) in the sentence-picture-verification task (see Procedure) the data of two participants were excluded from further analysis. Thus the ERP analysis is based on 19 participants (11 female, mean age 25 years, age range 19-30 years).

## Material

Each trial consisted of a description of a fictitious scene with two animals. Each animal was both a plausible agent and a plausible patient of the depicted action. Each trial comprised three parts starting with a lead-in context (1) in which both animals were introduced plus the instrument of the action that is going to be performed (see (1) in Table 1 for an example). Thus both referents were discourse-given in terms of information structure (Prince, 1981). The action was inferable from the instrument mentioned. The lead-in context was followed by one of two context types presented in form of a context question (2) that was either neutral indicating a wide scope on the scene ('What exactly is going on?`) or assigned topic status to one of the two animals ('What about the owl?`). The context question was followed by the target sentence (3) in SO or OS order revealing the answer to the context question.

Participants were presented with 80 SO and 80 OS target sentences that were either preceded by a neutral context or a topic context (i.e., 40 trials per condition). The different scenes for the 160 trials were created by combining two of the 40 nouns (animals, monomorphemic, masculine, 1-syllabic $(\mathrm{n}=18)$ to 2 -syllabic $(\mathrm{n}=22)$ ) with one of 10 action verbs (monomorphemic, transitive, 2-syllabic) with its corresponding instrument. The nouns and verbs were controlled for written lemma frequency, type frequency and normalized $\log _{10}$ familiarity values (dlex database: Heister et al., 2011). To avoid lexical-semantic effects of certain nouns in the first and second noun phrase position of the target sentence, each noun occurred once in each of the four conditions at both sentence positions, respectively. Thus each animal served four times as the agent and four times as the patient of the target sentence, respectively, always with a different action. For the lead-in context the first and second mention of the potential agent and patient of the action was counterbalanced across conditions. All animal pairs in the trials always differed in the initial phonemes. The 160 trials were pseudo-randomized such that maximal two consecutive trials were of the same condition or had the same word order in the target sentence to minimize possible effects of structural priming (e.g., Scheepers \& Crocker, 2004). To avoid any preferences of thematic role or topic assignment due to the previous trial at least five trials separated the repetition of an animal and at least two trials the repetition of an action.

## Procedure

Each participant was seated in a sound-attenuated cabin 90 cm in front of a computer screen and a button box (Cedrus response pad model RB-830). The trials were presented visually in the center of the screen by means of the software Presentation (www.neurobs.com). Each trial began with the presentation of a red asterisk for 1000 ms to indicate the beginning of a new scene. Before and after the lead-in context a blank screen was displayed for 200 ms . Lead-in-context and context question were presented as a whole in a self-paced reading manner with a minimum reading time of 3350 ms and 1400 ms , respectively. The participant had to press a button with the left thumb for further reading. The context question was followed by a fixation cross for 500 ms in the center of the screen. Then the target sentence was presented phrase-wise with 500 ms for each determiner phrase (DP) and prepositional phrase (PP) and 450 ms for the verb with an ISI of 100 ms (as used in previous studies, e.g., Bornkessel et al., 2003).

In $20 \%$ of the trials a sentence-picture-verification task followed the target sentence. The pictures depicted the scene of the preceding target sentence with correct or exchanged thematic roles (the owl painting the hedgehog vs. the hedgehog painting the owl). For each of the four conditions there was the same number of matching/mismatching

Table 1: Example of experimental trial for each condition (vertical bars in target sentence indicate phrase-wise presentation, Abb.: NOM = nominative case, $\mathrm{ACC}=$ accusative case, $\mathrm{S}=$ subject, $\mathrm{V}=$ verb, $\mathrm{O}=$ object, $\mathrm{PP}=$ prepositional phrase, $\mathrm{SO}=$ subject-before-object, OS = object-before-subject).

probes. The picture was presented for two seconds before the participant had to press the corresponding button for match (yes) or mismatch (no) within a time window of two seconds.
Participants were instructed to read each scene attentively and silently and to answer the sentence-picture-verification task after some of the scenes as accurately and fast as possible. The assignment of the response buttons to the right fore and middle finger was counterbalanced across participants. Participants were asked to avoid any movements during the time of sentence reading. To become familiar with the procedure participants performed three practice trials. The whole experiment included pauses after each 40 trials and lasted approximately 30 minutes.

## EEG Recording

EEG was recorded by means of a 32 channel active electrode system (Brain Products, Gilching) with a sampling rate of 1000 Hz . The electrode configuration included the following 29 scalp sites according to the international 10-20 system: F7/8, F5/6, F3/4, FC3/4, C5/6, C3/4, CP5/6, P3/4, P7/8, PO3/4, FPz, AFz, Fz, FCz, Cz, CPz, Pz, POz, Oz. To detect blinks and vertical eye movements an electrooculogram was monitored by one electrode under and one electrode above the right eye. The left mastoid served as the reference electrode but the recording was re-referenced to bilateral mastoids offline. The ground electrode was placed at FP1. Impedance was kept below 5 kOhm .

## ERP data analysis

The raw data were filtered by applying the Butterworth zero phase filter with a 0.3 Hz low cutoff and 70 Hz high cutoff (slope: $12 \mathrm{~dB} / \mathrm{oct}$ ) and a Notch Filter of 50 Hz . An automatic artifact rejection was applied to reject blinks and drifts in the time window of -200 to 1700 ms before and after the onset of the target sentence (rejection criteria: max. voltage step of $30 \mu \mathrm{~V} / \mathrm{ms}$, max. $200 \mu \mathrm{~V}$ difference of values in interval). On average $5.43 \%$ of the trials per condition had to be excluded from the analysis. The rejections were equally distributed across the conditions. For the correction of vertical eye movements the algorithm by Gratton, Coles
\& Donchin (1983) was used. Baseline correction was applied for 200 ms before the onset of the target sentence.
Time locked to the onset of the target sentence, mean amplitude values of the ERPs per condition were analyzed within three time windows ( $100-300 \mathrm{~ms}, 300-500 \mathrm{~ms}$ and $500-900 \mathrm{~ms}$ ) based on visual inspection and according to the current literature on language related ERP components (i.e., N400, P600). The following regions of interest (ROIs) were analyzed via mean amplitudes of the three appropriate electrodes: left anterior (F5, F3, FC3), left central (C5, C3, CP5), left posterior (P3, P7, PO3), right anterior (F6, F4, FC4), right central (C6, C4, CP6), right posterior (P4, P8, PO4), anterior midline ( $\mathrm{FPz}, \mathrm{AFz}, \mathrm{Fz}$ ), central midline ( FCz , $\mathrm{Cz}, \mathrm{CPz}$ ), posterior midline ( $\mathrm{Pz}, \mathrm{POz}, \mathrm{Oz}$ ). For statistical ERP analysis a repeated measures ANOVA was applied for the three within-subject factors WORD ORDER (SO, OS), CONTEXT TYPE (TOPIC, NEUTRAL) and ROI (nine levels) using SPSS Statistics (version 21). The correction according to Greenhouse and Geisser (1959) was applied. We report the corrected F - and p -values but the original degrees of freedom. Only significant main effects and interactions ( $\mathrm{p}<.05$ ) including the factors CONTEXT TYPE and/or WORD ORDER are reported and resolved by using paired T-Tests. Note that we only compare context effects on the very same sentence structures, that is, we compare SO with SO sentences and OS with OS sentences, depending on their preceding CONTEXT TYPE (TOPIC vs. NEUTRAL).

## Results

Figure 1 displays the grand average ERPs for the factor CONTEXT TYPE (TOPIC vs. NEUTRAL) at the onset of the SO and OS target sentences. The statistical analysis of the ERPs in three different time windows revealed the following results:

## Time window $100-300 \mathrm{~ms}$

Statistical analysis in the time window 100 to 300 ms after onset of the target sentence revealed a statistically significant main effect of CONTEXT TYPE
$[F(1,18)=5.29, \mathrm{p}<.05]$ reflected by less positive going ERP amplitudes following the topic context relative to the neutral context (see Figure 1, panel A and B).

## Time window 300-500 ms

The ANOVA in the time window of 300 to 500 ms after the onset of the target sentence neither revealed statistically significant main effects nor interactions.

Figure 1: Grand average ERPs of electrode FC4 as an example from the right anterior ROI time-locked to the onset of the target sentences showing the effect of CONTEXT TYPE (TOPIC vs. NEUTRAL) for SO and OS sentences. For presentation purposes the displayed ERP-plots are 7 Hz low-pass filtered. Negativity is plotted upwards.

## Time window 500-900 ms

In the late time window of 500 to 900 ms after the onset of the target sentence the ANOVA revealed a statistically significant interaction of WORD ORDER $x$ ROI $[\mathrm{F}(8,144)=4.09, \mathrm{p} \leq .01]$, WORD ORDER x CONTEXT TYPE $[F(1,18)=4.84, \mathrm{p}<.05]$ as well as of WORD ORDER x CONTEXT TYPE x ROI $[F(8,144)=4.29$, $\mathrm{p} \leq .01]$. Follow-up analysis of the three-way interaction reached significance for OS sentences in the right anterior ROI $[t(18)=-2.20, p=<.05]$ : OS sentences revealed a less
pronounced positivity in case of the preceding TOPIC context compared to the NEUTRAL context. SO sentences did not reveal a statistically significant difference depending on the CONTEXT TYPE in any of the nine ROIs.

## Summary of ERP results

The statistical analysis showed that the factor CONTEXT TYPE significantly interacted with WORD ORDER. In the late time window ( 500 to 900 ms ) the preceding context affected the processing of otherwise identical OS sentences: The topic context lead to a less pronounced positivity as compared to the neutral context. For SO sentences no such difference was induced by the preceding context. Besides, the analysis revealed a main effect of the preceding CONTEXT TYPE in the early time window ( 100 to 300 ms after target sentence onset) such that the topic context induced a reduced positivity compared to the neutral context.

## Discussion

The present ERP experiment addressed the question if and how a preceding topic context modulates the online processing of German declaratives. In line with previous research the preceding topic context did not affect the processing of SO sentences because SO is the canonical word order in German sentences. Importantly, for the processing of OS sentences we found an impact of the topic context reflected in a reduced late positivity ( 500 to 900 ms ) in comparison to a neutral context.

Besides the late positivity, the early positivity (100 to 300 ms ) was modulated by the context type independent of the word order of the target sentence: Sentences following the topic context showed a reduced positivity compared to the neutral context. Note that in the topic context condition the sentence-final noun of the context sentence is repeated in the sentence-initial position of the target sentence, whereas no such repetition occurred in the neutral context condition. As rather early ERP components have commonly been linked to basic visual processes (e.g., Dunn, Dunn, Languis \& Andrews, 1998), the reduced P2-like response in our study might be attributable to a pure word repetition effect (e.g., Van Petten, Kutas, Kluender, Mitchiner \& McIsaac, 1991). Although recent findings report modulations of an early positivity by contextual information in terms of the integration of semantic information (e.g., Federmeier \& Kutas, 2001; Lee, Liu \& Tsai, 2012) or the integration of discourse relevant information comparing a focus vs. neutral context (Bornkessel et al., 2003) such an interpretation of the early positivity in our study is not eligible due to the chosen experimental design.
As expected, the late positivity in the time window of 500 to 900 ms (P600) was reduced only for OS sentences following the topic context relative to the neutral context. In line with recent data this reduced P600 might indicate lower processing efforts for updating the current discourse model (e.g., Burkhart, 2007; Schumacher \& Hung, 2012) or structural re-analysis (as suggested for instance by the
neurocognitive model of sentence processing by Friederici (2002)). Thus, the chosen topic context elicited a processing advantage for the non-canonical OS sentences such that the integration of the sentence-initial object was facilitated compared to the neutral context in which a wide scope on the scene with the discourse-given referents and action was induced.
Our interpretation of the reduced P600 in OS sentences as reflecting lower processing efforts for the sentence-initial topic compared to a preceding neutral context is in line with the results of a follow-up study using the same experimental material and design as in the ERP experiment combined with a categorical judgment task on the comprehensibility of each story instead of the sentence-picture-verification task. Across 28 participants the mean percentage of stories judged as easily comprehensible was $90.71 \%$ for the condition NEUTRAL-SO, 88.93 \% for TOPIC-SO, 34.82 \% for NEUTRAL-OS and 51.79 \% for TOPIC-OS. Statistical analysis using a linear mixed effects model revealed a significant main effect of CONTEXT TYPE ( $z=3.13$, $\mathrm{p}<.01$ ) and WORD ORDER ( $\mathrm{z}=-7.41, \mathrm{p}<.001$ ) and a significant CONTEXT TYPE x WORD ORDER interaction ( $\mathrm{z}=-2.53, \mathrm{p}<.01$ ). Post-hoc comparisons showed that stories containing OS target sentences were significantly more likely to be judged as easily comprehensible if presented together with the topic context ( $\mathrm{z}=3.22, \mathrm{p}<.01$ ), whereas the context type did not affect the comprehensibility of the canonical SO sentences $(z=0.40$, p > .05).

Notably, other than expected we did not see a modulation of the N400 component in our data, neither in SO nor in OS sentences (see e.g., Schumacher \& Hung, 2012). Moreover, the effect of canonicity which was reported in form of a negativity at around 400 ms for OS vs. SO sentences in some (e.g., Matzke et al., 2002) but not in other studies (e.g., Frisch, Schlesewsky, Saddy \& Alpermann, 2002) was not present in our experiment. This might be due to the rather simple sentences used or due to the fact that $50 \%$ of the presented sentences were OS sentences, so the initial preference for SO might have been "overwritten" by our experimental design.

In summary, our findings suggest that the topic assigning contextual information used in the present experiment seemed to play a crucial role just in the processing of noncanonical OS sentences. The processing of OS sentences was modulated in terms of lower processing costs for the integration of discourse relevant information induced by the preceding topic context relative to a preceding neutral context. For the processing of canonical SO sentences that have been known to be felicitous in the absence of a supportive context no impact of the preceding discourse context was found. Hence our data indicate that the online processing of a sentence-initial object is enhanced by a topic assigning contextual discourse through an easier integration of discourse relevant information into the current discourse model.

# Probabilistic reasoning in the two-envelope problem 

Bruce D. Burns (bruce.burns@sydney.edu.au)<br>School of Psychology, The University of Sydney<br>NSW 2006 Australia

#### Abstract

In the two-envelope problem a reasoner is offered two envelopes, one containing exactly twice the money in the other. After observing the amount in one envelope it can be traded for the unseen contents of the other. Until recently it was argued that it did not matter whether the envelope was traded or not, but Abbott, Davis \& Parrondo (2010) showed that gains could be made if trading was a probabilistic function of amount observed. Three experiments varied where the observed and maximum amounts fell in a possible distribution and tested whether this affected choices. Trading was less likely for lower observed amount than higher, but this effect differed depending on the stated distribution. This suggests that participants' trade decisions were affected by where observations fit in the distribution, and thus their probabilities. The modeling tools used here may be applicable to other reasoning phenomena.

Keywords: Probabilistic reasoning, two-envelope problem, mathematical modelling, decision making.

## Introduction

The overwhelming evidence of heuristics and biases affecting people's reasoning has often been seen as evidence of irrationality in human thought (Stanovich, 1999). Stanovich pointed out that this conclusion relies on the apparent gap between normatively correct decisions and actual behaviour. However that such a gap indicates irrationality has been challenged by those suggesting that such norms are inappropriate. For example, Oaksford and Chater (1994) suggested that what is seen as an error in the well-known Wason's 4-card selection task is not an error in terms of information gain if you make appropriate assumptions about the distribution of the relevant variables in the environment. Such probabilistic reasoning approaches have gained increasing acceptance (Oaksford \& Chater, 2007). Setting normative standards against which to judge rationality is especially difficult when formal analysis of a problem is difficult, such as has been the case for the twoenvelope problem (Zabell, 1988). However a recent analysis (Abbott, Davis \& Parrondo, 2010; McDonnell \& Abbott, 2009) supported by simulations suggests that distributions are critical to analysing that problem, so it is reasonable to ask whether people act rationally by showing sensitivity to distributions when faced with what has sometimes been considered a paradox.

## The two-envelope problem

Versions of the two-envelope problem were proposed by Kaitchik (1953, pp. 133-134) and attributed by the mathematician Littlewood to the physicist Erwin Schödinger (Littlewood, 1953/1986, p. 26). Although he
does not claim authorship of it, Zabell (1988) stated a twoenvelope version with the following characteristics: the contents of the two envelopes are $x$ and $2 x$; no distribution or limit is given for $x$; the reasoner is handed an envelope (randomly) and opens it; however then the reasoner is given a choice: keep the amount observed, or trade it for the contents of the other envelope. Before the envelope is opened the expected outcome is:

$$
\begin{equation*}
\mathrm{E}=1 / 2(x+2 x)=3 x / 2 \tag{1}
\end{equation*}
$$

Opening an envelope cannot change the amounts in the envelopes so it should not matter whether you keep or trade envelopes because to trade is equivalent to changing your initial random choice. However, opening an envelope containing $y$ means that trading yields either $2 y$ or $1 / 2 y$. If each is a $50 \%$ possibility then trading appears to result in an expected outcome equal to $5 y / 4$. Worse, if the two envelopes were held by two different people (as Zabell proposed), then after opening their own envelopes both would expect to gain from trading. This cannot be true so the problem has sometimes been called a paradox. As Zabell and others have pointed out, the resolution of this paradox is that the envelopes contain two possible pairs of amounts $[2 y, y]$ or $[y, 1 / 2 y]$ but they are not equally likely. The $p(y \mid$ pair ) is not equal to $p$ (pair|y); the first probability is known but it is the second that the reasoner needs. Analyzing what that probability is, and thus what the reasoner should do, has defied a satisfactory mathematical solution (Albers, Kooi, \& Schaafsma, 2005). So the paradox was resolved but the problem of whether to trade remained.

McDonnell and Abbott (2009) point out that the envelope problem has attracted wide interest in game theory and probability theory, and that it is paradigmatic of recent problems in physics, engineering and economics which involve probabilistic switching between two states. For example, it has been shown in stochastic control theory that random switching between two unstable states can result in a stable state (Allison \& Abbott, 2001). Maslov and Zhang (1998) modelled how switching between volatile assets and non-performing cash reserves can produce a net gain.

There is only one published paper on how people respond to the envelope problem. Butler and Nickerson (2008) presented participants with six different versions of the problem. They were told that Envelope 1 (E1) contained a random amount between $\$ 1$ and $\$ 100$, and Envelope 2 (E2) contained either twice or half that amount depending on the result of a coin toss. They varied whether the participant was given E1 or E2, whether the participant knew which it was, and whether they opened the envelope. If participants

Figure 1: Markov model based on Abbott el al's (2010) analysis. $P(x)$ representing the probability of trading if the value in the opened envelope is $x$, and $P(2 x)$ representing the probability of trading if the observed value is $2 x$.
observed the amount then Butler and Nickerson asked them what they would do if it had various values (\$1, \$20, \$40, $\$ 60, \$ 80, \$ 100$ ). Nickerson and Falk's (2006) analysis of these different versions showed whether it was optimal to always trade, trade depending on the observation, always keep, or to be indifferent. For example, if you know you have been given E1 then it is optimal to trade because E2 was generated from E1 with a 50\% chance of two outcomes. They found that if participants observed the amount then there was a tendency towards trading when the amount was less than $\$ 50$ and keeping when it was above $\$ 50$, but this was irrespective of whether the conditions should influence their decision. Consistent optimal decision making was rare, so Butler and Nickerson concluded that participants were largely insensitive to the logical structure of the problem; instead they applied simple heuristics or folk wisdom.

## A general mathematical solution

Different predictions regarding human performance in the two-envelope problem may arise if there was an accepted mathematical analysis of it. Recently McDonnell and Abbott (2009) and Abbott, et al (2010) propose a strategy that can increase the expected outcome above that in Equation 1. The key to their approach is to recognize that once an envelope is opened the information of what it contains breaks the symmetry that leads to Equation 1. Their
starting point was Cover’s (1987) switching function used to solve the pick the largest number problem and the analysis of Parrondo's games in which two losing strategies can be combined to produce a winning strategy if the current state of the problem is used as a criterion (Harmer \& Abbott, 1999). Solving these types of problems requires probabilistic switching between states.
Abbott et al (2010) supposed that opening the envelope reveals $y$ dollars, and the player then trades envelopes with a probability $\mathrm{P}(y) \in[0,1]$. Figure 1 converts their analysis to a Markov model. From the model it can be seen that the expected return (E) when $x$ represents the smaller of the two amounts and $2 x$ the larger, will be:

$$
\begin{align*}
\mathrm{E}=1 / 2[2 x & \mathrm{P}(x)+x[1-\mathrm{P}(x)]+x \mathrm{P}(2 x)+2 x[1-\mathrm{P}(2 x)]]  \tag{2}\\
& =1 / 2[3 x+x \mathrm{P}(x)-x \mathrm{P}(2 x)] \\
& =3 x / 2+x / 2[\mathrm{P}(x)-\mathrm{P}(2 x)]
\end{align*}
$$

Equation 2 shows that probabilistic trading as a function of $x$ can raise the expected value above that expected from either trading or keeping regardless of the observed amount (i.e., Equation 1). Returns can be only be improved if $\mathrm{P}(x)>$ $\mathrm{P}(2 x)$, that is, when the trading function is such that trading is less likely the higher the observed amount is (i.e., the more likely it is to be $2 x$ rather than $x$ ). Abbott et al (2010) show that a monotonically decreasing function will increase
the expected outcome, and that this does not presuppose any particular probability density function for $x$. Calculating the optimal trading function requires knowing the probability density function, but their analysis demonstrates that a simple negative monotonic tendency to trade as a function of observed amount can increase expected outcomes.

## Goals

Abbott et al's (2010) model shows that the higher an observed amount sits within the distribution of amounts, the less likely trading should be. Thus adaptive behavior for people faced with the two-envelope problem would be to be less likely to trade the higher the observed is within the distribution of possibilities. This prediction was tested in two experiments. A third tested whether the distribution itself was critical. Participants may be acting more rationally than Butler and Nickerson (2008) suggested.

## Experiment 1

Where the observed contents of an envelope sit in a distribution of possible amounts depends both on what the amount is and what are the upper and lower limits of possible amounts. So in Experiment 1 both the observed amount ( $\$ 10$ or $\$ 100$ ) and the limit ( $\$ 200$ or no limit) were manipulated. It was predicted that trading rates would be affected by the interaction of the observed and limit factors, such that they would be least likely to trade when the observed was $\$ 100$ and the upper limit was $\$ 200$.

## Method

Participants. A total of 160 senior psychology students at the University of Sydney participated during a practical class focused on reasoning.
Materials and Procedure. Participants read and responded to the following scenario on paper (the italicized text in the squared brackets replaced the underlined text in the relevant condition):
Imagine that you given a choice between two envelopes each containing a sum of money. You are told that neither envelope could hold more than $\$ 200$ [You are told that the envelopes could contain any amount of money], but one envelope contains exactly twice as much money as the other. You randomly choose one of the envelopes and open it, revealing that it contains $\$ 100$ [ $\$ 10]$. You are told that you can either keep the $\$ 100$ [\$10] or take whatever is in the other envelope. What would you do?
Participants circled whether they would keep the $\$ 100$ [\$10] or trade it for whatever was in the other envelope.

## Results \& Discussion

Table 1 presents the proportion of participants choosing to trade in each condition. A logistic regression analysis (using the "Logistic Regression" procedure in SPSS) was performed on choice ( $0=$ keep, $1=$ trade) entering the factors of limit, observed amount, and their interaction. This yielded the following equation for trading:
$\log ($ odds $)=1.355+-0.385 *$ limit $+-2.128 *$ observed + 1.39*limit*observed

The parameter for limit was not significant, Wald $\chi 2(1)=$ $0.525, p=.469$, but that for observed was, Wald $\chi 2(1)=$ $16.224, p<.001$, and so was the interaction, Wald $\chi 2(1)=$ 3.885, $p=.049$.

As predicted, these results showed that participants' choices were affected by the observed contents of the envelope, in that overall there was a strong effect of observed amount. However there was also a significant interaction in that trading was least likely if the highest and observed amounts were such that the largest amount possible was at the limit. This suggests that people's responses were affected by where they saw the possible amounts as falling in the distribution of amounts.

Table 1: Proportion of participants in each condition of Experiment 1 choosing to trade (with sample sizes).

|  | \$10 in opened <br> envelope | \$100 in opened <br> envelope |
| :--- | :---: | :---: |
| $\$ 200$ limit | $.80(\mathrm{n}=39)$ | $.32(\mathrm{n}=38)$ |
| unlimited | $.73(\mathrm{n}=40)$ | $.56(\mathrm{n}=43)$ |

## Experiment 2

An alternative explanation for the interaction between observed amount and limit in Experiment 1 could be that the observed is perceived as worth less in the context of a limit that it is close to. Butler and Nickerson (2008) alluded to such a context effect. So in Experiment 2 participants were directly asked to judge the prior probability of the amount in the envelope. These probabilities should also be lower when the observed amount is half the limit, but such a pattern could not be due to perceptions of monetary value.

Other changes were also made to help generalize the results of Experiment 1. Having a definite limit changes some analyses of the two-envelope problem, so instead of "no limit" a large limit $(\$ 10,000)$ was used. It is unlikely this makes much difference to participants but it removes a potential difference between the two limit conditions. Another possibility is that using such a small amount (\$10) for the lower observed amount may have led to trading because it was perceived as a trivial amount. So in Experiment 2 the lower observed amount was set to $\$ 50$.

The $2 x 2$ design of Experiment 2 was the similar to that for Experiment 1, with factors for limit ( $\$ 200$ or $\$ 10,000$ ) and observed ( $\$ 50$ or $\$ 100$ ). Again I predicted an interaction between trading and observed such the lowest rate should be when the observed amount was close to the limit.

## Method

Participants. A total of 235 senior psychology students participated during practical classes focused on reasoning.
Materials and Procedure. Unlike Experiment 1, the task was presented on a computer. Participants read on-screen instructions that were the same as in Experiment 1 (with appropriate variations for the condition) except that now the
envelope they opened was referred to as "Envelope A" and the unopened as "Envelope B".

Participants were asked the following four questions (\$50 replaces $\$ 100$ in the appropriate condition):

QUESTION 1. First, to check if you understand the instructions correctly, can you type what is the MAXIMUM dollars that Envelope B could contain: \$

QUESTION 2. What would you do? (click one)
Keep the $\$ 100$ [\$50] in Envelope A
Take whatever is in Envelope B
QUESTION 3. Approximately what do you think is the percentage chance that Envelope A (the one you FIRST opened) contains the LARGER amount of money?
$\qquad$ \%

QUESTION 4. In this situation, before any envelopes had been opened, what do you think would have been the probability that the first envelope opened contained $\$ 100$ [\$50] or more? $\qquad$ \%

## Results \& Discussion

Question 1 was designed to check that participants had correctly understood the problem. Most participants (84.3\%) gave the correct answer (either $\$ 100$ or $\$ 200$, depending on condition), but rates of correctness were not affected by condition. It was decided that participants who did not answer this question correctly either misinterpreted the instructions or were not paying attention. Either way their responses could not be relied on, so only the 198 participants who answered correctly were analysed.

Table 2: Proportion of participants in each condition of Experiment 2 choosing to trade. Samples sizes are in parentheses.

|  | $\$ 50$ in opened <br> envelope | $\$ 100$ in opened <br> envelope |
| :--- | :---: | :---: |
| $\$ 200$ limit | $.65(\mathrm{n}=51)$ | $.30(\mathrm{n}=61)$ |
| $\$ 10,000$ limit | $.55(\mathrm{n}=38)$ | $.60(\mathrm{n}=48)$ |

Table 2 shows the proportion of participants in each condition choosing to trade envelopes in response to Question 2. (Sample sizes varied because participants were randomly assigned to a condition by their individual computer.) A logistic regression analysis was performed on choice ( $0=$ keep, $1=$ trade) entering the factors limit, observed amount, and their interaction. This yielded the following equation for trading:

```
Log(odds) = 0.534 + -0.483*limit + -1.374*observed +
1.728*limit*observed
```

The parameter for limit was not significant, Wald $\chi 2(1)=$ 1.190, $p=.275$, but that for observed was, Wald $\chi 2(1)=$ $11.190, p=.001$, and so was the interaction, Wald $\chi 2(1)=$
$8.420, p=.004$. So the Experiment 1 interaction pattern was replicated despite changing the lower observed amount, the specification of the higher limit, and mode of presentation.

In response to Question 3 most participants (92.2\%) thought there was exactly a $50 \%$ chance that the other envelope would contain more money. The overall mean response was $49.49 \%$, and there were no effects of condition. Thus, despite choosing to keep or trade their envelope, very few participants seemed to think the odds of the other envelope containing more was other than $50 \%$. Even if participants act as though sensitive to a distribution, this does not necessarily mean they are aware of it (e.g., Bargh \& Ferguson, 2000).

Table 3: Mean judgments (with standard deviations) of prior probabilities (percentages) for each condition.

|  | \$50 in opened <br> envelope | \$100 in opened <br> envelope |
| :--- | :---: | :---: |
| \$200 limit | $57.25(\mathrm{sd}=17.3)$ | $46.70(\mathrm{sd}=14.1)$ |
| $\$ 10,000$ limit | $54.41(\mathrm{sd}=29.1)$ | $58.22(\mathrm{sd}=25.5)$ |

In response to Question 4 most participants thought that there was about a $50 \%$ probability that their envelope could have contained an equal or higher amount before it was observed, but Table 3 shows that this varied with condition. A $2 x 2$ ANOVA found no main effects of limit, $F(1,194)=$ $1.980, p=.161$, no effect of amount observed, $F(1,194)=$ 1.190, $p=.277$, but a significant interaction, $F(1,194)=$ 5.409, $p=.021$. Thus consistent with the observed $\$ 100$ and limit $\$ 200$ condition being the one least likely to lead participants to favour trading envelopes, participants in this condition were also least likely to think that their envelope could have contained more a priori. Why Question 4 but not 3 showed a difference may be because it does not so starkly ask participants to contradict their intuition that two coinflip like choices should mean $50 \%$ each.

By replicating the interaction found in Experiment 1, Experiment 2 further supported the hypothesis that participants are less likely to trade when the higher amount would be at the end of the distribution. Adding support to the claim that this was because of where they felt the observed amount fell in the distribution the manipulations had a similar effect on a direct measure of how likely they thought that the observed amount could have been higher.

## Experiment 3

Abbott et al's (2010) solution suggests that people may be less likely to trade when the observed amount is higher in the distribution, but working out the optimal trading strategy would depend on knowing the details of the distribution of amounts. If people act consistent with this analysis, then people’s tendency to trade should be affected by what they believe about the distribution. So far the results suggest that that people's responses reflect a sensitivity to the distribution of amounts, so explicitly stating a different distribution could affect their choices.

In Experiment 3 participants were told that the envelope amounts had either a flat or a bimodal distribution. It is likely that many participants assumed an essentially flat distribution in the previous experiments, in which case explicitly stating that the distribution is flat should produce similar results to Experiments 1 and 2. However explicitly stating that there was a bimodal distribution could lead to a different pattern of results. By increasing the chances of high amounts in envelopes this distribution should increase trading when the other envelope potentially contains an amount at the top of the distribution. A 2 x 2 design was used with factors for distribution (flat or bimodal) and observed ( $\$ 50$ or $\$ 100$ ). The limit was always $\$ 200$.

Figure 2: Diagrams accompanying the instructions for the bimodal (Panel A) and flat (Panel B) distributions.

## Method

Participants. One hundred and three first-year psychology students completed the experiment for partial course credit.

Materials and procedure. Materials and procedure were identical to Experiment 2 except for the addition of the distribution manipulation. In the flat condition participants read that "the probability of any amount is equal to any other" and saw the graph in Panel B of Figure 2. In the bimodal condition they read "the probability of any amount is not equal, in that amounts closer to the minimum or maximum amounts are more likely" and saw the graph in Panel A of Figure 2. These graphs were intentionally vague in order to give a general shape to the distribution rather than provide a precise way to calculate the probabilities.

The observed amount in the opened envelope was either \$50 or $\$ 100$, but the maximum possible was always $\$ 200$.

## Results \& Discussion

Most (83.5\%) participants correctly identified the maximum amount the unopened envelope could contain, but as in Experiment 2 only these 86 were analysed. The proportion in each condition choosing to trade is presented in Table 4.

Table 4: Proportion of participants in Experiment 3 choosing to trade. Maximum amount was always $\$ 200$.

|  | \$50 in opened <br> envelope | \$100 in opened <br> envelope |
| :--- | :---: | :---: |
| Bimodal distribution | $.25(\mathrm{n}=20)$ | $.42(\mathrm{n}=24)$ |
| Flat distribution | $.58(\mathrm{n}=19)$ | $.26(\mathrm{n}=23)$ |

For the flat distribution the trading proportions were similar to the same conditions in Experiment 2 in which no distribution was specified, with more trading when the observed amount was $\$ 50$ than when $\$ 100, \chi 2(1)=4.37, p$ $=.037$. In the bimodal condition, the direction of the effect of revealed amount was the opposite, but this effect was not significant, $\chi 2(1)=1.35, p=.246$. A logistic regression analysis was performed on choice entering the factors distribution ( $0=$ bimodal, $1=$ flat), revealed amount, and their interaction. This yielded the following equation for trading:

Log(odds) $=-1.099+1.417 *$ distribution $+0.762 *$ observed + -2.122*distribution*observed

The parameter for distribution was significant, Wald $\chi 2(1)$ $=4.161, p=.041$, but not that for observed, Wald $\chi 2(1)=$ 1.326, $p=.250$. The interaction parameter was significant, Wald $\chi 2(1)=5.120, p=.024$.

These results indicated that people were sensitive to the distributions of amounts when deciding whether to trade. For the same amount with the same limit their propensity to trade was influenced by what they were told about the distribution of amounts. When the distribution was flat they responded similarly to how they did in Experiment 2, suggesting that participants had previously assumed a flat distribution. However a bimodal distribution changed the pattern of their responses implying that they took into account the prior probabilities of different amounts.

It should be noted that the Figure 2 distributions are only possible for either the higher or the lower amounts, not the sum of their distributions. Given that participants do not know if they observe the higher or the lower amount they may have been confused as to what exactly was the distribution represented by their diagram. However the main point of the experiment was to test whether the distribution plays a role in participants' choices, and confusion about the distribution should not affect their choices unless they see the distribution as important.

## General Discussion

Abbott et al's (2010) analysis suggests that a probabilistic strategy for trading can lead to gains in the two-envelope problem unobtainable by a pure strategy. In general, such a probabilistic strategy can increase expected outcome over an absolute strategy if the probability of trading is a monotically decreasing function of the observed amount. This suggests that people given the two envelope problem may have a tendency to trade that is sensitive to the distribution of amounts. The results of Experiments 1-3 support the claim that people do this when faced with the two-envelope problem. Participants were consistently least likely to trade when the higher alternative would be at the top of the distribution, except in Experiment 3 when the bimodal distribution increased the likelihood of such an amount. Furthermore, in Experiment 2 it was found that participants' assessments of the prior probabilities of amounts had the same pattern. Thus the results suggest that people are consistent with what Abbott et al's model suggests optimizes responses to the two-envelope problem: trading as a function of the observed amount and being sensitive to the distributions. Experiment 3 is critical in showing that not just the size of the observed amounts but their perceived distribution affected choices. However this conclusion is weakened by possible limitations of its methodology, therefore more research is required.

These experiments did not systematically manipulate the amount in the revealed envelope to see what shape there might be to any monotonic function to trade. Inspection of Butler and Nickerson's (2008) data suggests that there is a trend within the large effect of greater/lesser than \$50 towards less trading as observed amounts increase. However their sample size is not large enough to expect a post-hoc analysis to show a significant effect. Overall, the results do not dispute Butler and Nickerson's finding that participants often make fundamental errors in analysing the twoenvelope problem. The errors they revealed were in understanding the logical implications of the details of different versions, and in this way they are analogous to Wason's (1968) finding that people were poor at understanding the logical implications of his selection task. However Oaksford and Chater's (1994) analysis showed that people's responses may make sense if seen in terms of how information is distributed in the world. Thus my results fit with a more general trend of finding that people are poor at applying formal logic but can be sensitive to the implications of probability distributions. Applying probabilistic inference may be seen as the computational goal of cognition.

McDonnell and Abbott (2009) saw the two-envelope problem as interesting because it embodies a phenomenon that comes up in many domains, that of probabilistic switching between two states. Their analysis demonstrates that an appropriate probabilistic function may improve outcomes even when important characteristics of the distributions are unknown. A number of decision making tasks require a choice between functions whose properties
are uncertain, for example, choices between different market options. The demonstration here that the mathematical analysis of such choices can lead to supportable behavioural predictions suggests that these mathematical tools may have value for analysing other types of decisions.

#### Abstract

Evaluating whether information is generalizable, essential knowledge about a novel category is a critical component of conceptual development. In previous work (Butler \& Markman, 2012) 4-year-old children were able to use their understanding of whether information was explicitly communicated for their benefit to guide such reasoning, while 3-year-olds were not. In two experiments, we further investigate this finding. Four-year-olds were adept at navigating pedagogical interactions, judiciously identifying which specific actions in an ongoing interaction were meant as communicative demonstrations for their benefit, while 3-year-olds did not distinguish between the manners of demonstration even in a simpler context. Taken together, these experiments illustrate that this powerful learning mechanism for facilitating children's conceptual development is under construction during the preschool years.

Keywords: Social cognition; inductive inference; generalization; pedagogy; communication.

## Introduction

A foundational developmental process is the acquisition of generic knowledge about kinds and categories that supports the construction of a coherent conceptual understanding of the world (Gelman, 2003; Gelman \& Wellman, 1991; Keil, 1989; Markman, 1989). But acquiring such knowledge often requires making inductive inferences on the basis of limited information. For example, imagine that a person learns a new fact about an individual animal, say that a bird has a particular shape of feather. Should this person infer that all birds of this kind have similar feathers? That all birds have similar feathers? Or alternatively, that these feathers are unusual and idiosyncratic to only this individual, or to a limited set of related birds? One could arguably make each of these generalizations with equal legitimacy based on the given evidence (cf., Goodman, 1965).

Determining the scope of a generalization is a challenge for young children, who experience a flood of new information and must rapidly construct a conceptual framework for understanding the world (Lopez, Gelman, Gutheil, \& Smith, 1992). Although in many cases children can tackle this problem by relying on linguistic cues that mark generic knowledge (e.g., Cimpian \& Markman, 2009,

2011; Gelman, Star, and Flukes 2002; Hollander, Gelman, \& Raman, 2009), there are many potential non-linguistic contexts in which children observe others' actions and must evaluate whether the information those actions produce is generic. How do children carry out this process?

Previous research with infants suggests that even infants are sensitive to cues that someone is deliberately communicating information for their benefit (see Cisbra, 2010), and that this sensitivity appears to change how infants process that information. Specifically, they appear to encode information conveyed communicatively as more kind-relevant and stable than information produced noncommunicatively (Gergely, Egyed, \& Király, 2007; Futó, Téglás, Csibra, \& Gergely, 2010; Yoon, Johnson, and Csibra, 2008). Does this early sensitivity to communicative cues also play a role in older children's ability to assess whether information is generic?

In recent research, Butler and Markman (2012) demonstrated that by age 4 children utilize cues that someone is deliberately communicating information for their benefit to guide such inductive inferences. Three- and 4-year- old children were first taught a label ("blicket") for a novel object. Children then observed perceptually identical evidence that this object was magnetic, but produced with subtly different actions: the experimenter accidentally used the object as a magnet; did so intentionally; or did so while conveying that they were acting communicatively and pedagogically for the child's benefit.

Importantly, after being taught the object's name, children engaged in a short, unrelated distractor task. This was done in an attempt to create a clear break between the pedagogical word-learning phase and the experimental manipulation so that children would not interpret every action as meant "for them," simply because the adult had previously been teaching them something about this kind.

After seeing this evidence, children were given 10 additional blickets that were identical, but which upon exploration turned out not to be magnetic. To assess the strength of children's inductive inferences, we measured their continued exploration of the inert objects when they discovered that they failed to have the novel property (after Schulz, Standing, \& Bonawitz, 2008): specifically how long and how many attempts children made to try get the inert
blickets to pick up paperclips. This persistence in the face of such negative evidence is an index of how strongly children inferred that the property should generalize.

Four-year-olds showed significantly more such exploration in the pedagogical condition, suggesting they made stronger inductive generalizations about the property when it was demonstrated communicatively. So by age 4 preschoolers are able to use communicative cues to guide their reasoning about whether information represents generic knowledge about a kind. Interestingly, 3-year-olds also based their inferences on the intentions of the adult, but did so purely on the basis of whether the evidence was produced intentionally rather than accidentally. That is, 3 year olds treated intentional and pedagogical actions as warranting similarly strong inferences, more so than an accidental action. Thus there appears to be a developmental difference in how children identify and make use of communicative acts in guiding their inductive inferences.

This developmental difference is intriguing. It seems unlikely that 3 -year-old children fail to recognize the communicative cues that signal that an action is meant for their benefit. Indeed, infants as young as 10 months appear to recognize such cues, and having information conveyed with those communicative cues does appear to impact how they treat new information. (Csibra, 2010; Csibra \& Gergely, 2009). The hypothesis we consider here is whether there may be a developmental difference in the ability to assess, in real time, which actions within a given context are pedagogical. Even within a pedagogical interaction adults may perform a number of actions that are not meant to carry meaningful information, but which could potentially be misinterpreted as acts of teaching. Imagine that a child is watching her mother or father preparing a snack. The adult is interacting with a number of kitchen tools, occasionally interrupting an action to attend to a forgotten item or ingredient, and then returning to the task at hand. In such a dynamic, flowing context, if a child is going to utilize her sensitivity to whether or not an action is meant for her, she needs to be able to identify which actions are truly meant as demonstrations, and which are merely incidental, unnecessary, or part of a different embedded event.

The current research aims to shed initial light on this issue, taking two complementary approaches. First, we ask what factors might play a role in driving the effect seen previously in older children. How best can we characterize 4 year olds' use of communicative cues to guide their inferences, and how nuanced is this learning mechanism? Second, what might be preventing younger children from using this distinction to guide their inferences? Does a manipulation that might make it easier for children to draw the distinction between the conditions reveal a similar pattern of inferences at a younger age?

## Experiment 1

In utilizing their sensitivity to communicative cues to guide their inductive inference, children need to be able to do so while navigating ongoing interactions with adults,
discriminating those actions that are truly meant for their learning benefit from those that are not.

As discussed earlier, in Butler and Markman's (2012) task, in which children learned that an object was called a "blicket," and then saw that it was magnetic, they were given an unrelated distractor task between the word learning and evidence phases, in an attempt to distance the pedagogical teaching of the word from the experimental manipulation of how the key evidence was produced. Thus the distractor task was meant to provide a clear interruption of the ongoing pedagogical interaction, potentially implying that the subsequent actions were not necessarily meant for the child's benefit, unless they were clearly marked as communicative acts. This opens up a question about the nature of 4-year-olds' ability to selectively use communicative cues to guide their inferences about novel information. How adept are they at identifying an action meant for their benefit when the target action is embedded within a still-continuing pedagogical interaction?

## Method

The procedure for Experiment 1 was closely modeled after Butler and Markman (2012), in which children were presented with evidence that a novel object had a novel function, in one of three subtly different ways: communicatively, intentionally, or accidentally. In order to directly address the question of how adept 4 -year-olds are at applying their sensitivity to communicative cues in an ongoing context, we manipulated the the position of the distractor task within the continuous stream of events (see Figure 1), thus varying whether or not the ongoing pedagogical interaction was clearly interrupted prior to the evidence phase. If 4 -year-olds are truly conducting a nuanced, moment-by-moment analysis of an adult's communicative intentions at each particular point in time, they may distinguish between pedagogical and intentional actions even within an ongoing pedagogical interaction, regardless of the position of the distractor task.

Materials The materials in Experiment 1 were 11 PVC pipes, 5 cm in diameter and 7.5 cm tall. The active object had a noisemaker inside that made an animal noise when it was flipped upside down. The 10 inert objects had several pebbles taped to the inside of the PVC piping in order to give them an equivalent weight and feel as the active object. All 11 objects were covered with blue duct tape, on one end and around the sides, and had yellow duct tape covering one end. The objects were perceptually indistinguishable.

Participants The participants were 96 children from a university preschool ( $M_{\text {age }}=4$ years, 8 months). An additional 9 children were excluded because of experimenter error, or because they did not attend to or finish the procedure. Participants were randomly assigned to one of two orders and three experimental conditions, with the constraint that all six condition-order groups were matched for gender and age.

Procedure The procedure was modeled after that used in Butler and Markman (2012) and described above, but the order of the procedure was manipulated (see Figure 1). In the interruption order, the sequence of events was identical to that used previously. The experimenter brought out the target object and four distractor objects, and proceeded to teach the child a novel word ("femo") for the target object. All children successfully picked out the target object when asked for it by name on two successive trials. The experimenter then said, "Now let's do something really fun! We can make a boat out of colored paper!" and then proceeded with the distractor task. In the no interruption order, the placement of the word learning and distractor phases was switched. Children first participated in the boatmaking task as a warm-up game. The experimenter then brought out the target object and the four distractors and conducted the word learning procedure. In both orders, after the second phase of the procedure the experimenter then said, "I'm going to put a few of my things away" and proceeded to put away each of the distractor objects, finally picking up the target object.

In the evidence phase, the experimenter moved the object from one hand into the other, flipping it upside down in the process and placing it yellow-side-down on the table, all in one continuous action. This action was identical in the pedagogical and intentional conditions, except that in the pedagogical condition the experimenter made eye contact with the child and said, "Look, watch this." The action in the accidental condition was nearly identical, but the experimenter appeared to lose her grip on the object as she was picking it up and moving it, saying, "Oops!" and then appeared to catch it with her other hand and place it on the table. In all three conditions the experimenter then said, "Wow!" after placing the object on the table.

Figure 1: Overview of task structure in the two orders of Experiment 1.

Coding \& Data Analysis Two independent judges watched only the exploration phase of each video, and coded both the
amount of time children spent exploring the inert objects, and how many times they attempted to elicit the property from those inert objects.

Children's exploration violated assumptions of normality and homogeneity of variance. Thus we used non-parametric Mann-Whitney tests to conduct pairwise comparisons between conditions, and ordinal logistic regressions (see Cimpian \& Cadena, 2010; Cimpian \& Markman, 2009) to assess the overall impact of condition and order.

## Results

In order to assess the overall impact of condition and order on children's exploration, we conducted ordinal logistic regressions (OLR) on our two principal measures exploration (number of attempts to elicit the property from the inert objects and time exploring the inert objects), with condition and order as predictors. There was a significant effect of condition on both number of attempts (Wald $\chi^{2}=$ 16.06, $p<0.001$ ) and time exploring (Wald $\chi^{2}=16.67, p<$ 0.001 ). There was no effect of order of the distractor task on number of attempts (Wald $\chi^{2}=.064, p=.801$ ), nor was their an interaction between order and condition (Wald $\chi^{2}=$ $.345, p=.841)$. There was a marginal effect of order on time exploring (Wald $\chi^{2}=3.52, p=.061$ ), but there was no interaction between order and condition (Wald $\chi^{2}=.255, p$ $=.880$ ). Overall, these analyses suggest that the experimental condition (pedagogical, intentional, or accidental) had a significant effect on 4 year olds' exploration, and that while the order might have had an effect, it did not alter the effect of condition. To explore these results further, we now compare the results across condition for each order.

Interruption Order The patterns of exploration across conditions in the interruption order clearly replicated the findings of Butler and Markman (2012).

Four-year-olds made significantly more attempts to elicit the property from the inert objects in the pedagogical condition $\left(M_{\text {pedagogical }}=9.37, \mathrm{SD}=7.20\right)$ than in either the intentional $\left(M_{\text {intentional }}=2.69, \mathrm{SD}=3.77\right.$; Mann-Whitney $Z=$ 3.07, $p=.002$ ) or accidental $\left(M_{\text {accidental }}=3.94, \mathrm{SD}=5.20\right.$; Mann-Whitney $Z=2.38, p=.017$ ) conditions (see Figure 2). There was no difference between the intentional and accidental conditions (Mann-Whitney $Z=.218, p=.828$ ).

Figure 2: Mean number of attempts in each condition in the interruption order of Experiment $1 . N=64$ (16 per condition). Error bars represent $+/-1$ SEM.

Four-year-olds also spent significantly longer exploring the inert objects in the pedagogical condition $\left(M_{\text {pedagogical }}=\right.$ $13.94 \mathrm{~s}, \mathrm{SD}=10.54$ ) than in either the intentional ( $M_{\text {intentional }}$ $=3.87 \mathrm{~s}, \mathrm{SD}=5.05$; Mann-Whitney $Z=2.97, p=.003$ ) or accidental $\left(M_{\text {accidental }}=5.44 \mathrm{~s}, \mathrm{SD}=9.03\right.$; Mann-Whitney $Z$ $=2.59, p=.010)$ conditions. There was no difference between the intentional and accidental conditions (MannWhitney $Z=.276, p=.783$ ).

No-Interruption Order Despite the marginal overall effect of order on time exploring seen in the OLR analyses, the patterns of exploration by children who saw the distractor first, and then learned the word, followed immediately by the evidence phase with no interruption, were nearly identical to those who saw a clear interruption between these phases.

Four-year-olds made significantly more attempts to elicit the property from the inert blickets in the pedagogical condition ( $M_{\text {pedagogical }}=10.37, \mathrm{SD}=10.12$ ) than in either the intentional $\left(M_{\text {intentional }}=3.94, \mathrm{SD}=4.22\right.$; Mann-Whitney $Z=$ 1.97, $p=.048)$ or accidental $\left(M_{\text {accidental }}=3.67, \mathrm{SD}=4.98\right.$; Mann-Whitney $Z=2.07, p=.038$ ) conditions (see Figure 3 ). There was no difference between the intentional and accidental conditions (Mann-Whitney $Z=.270, p=.787$ ).

Figure 3: Mean number of attempts in each condition in the no interruption order of Experiment $1 . N=64$ (16 per condition). Error bars represent $+/-1$ SEM.

Four-year-olds also spent significantly longer exploring the inert blickets in the pedagogical condition $\left(M_{\text {pedagogical }}=\right.$ $24.50 \mathrm{~s}, \mathrm{SD}=20.65)$ than in either the intentional $\left(M_{\text {intentional }}\right.$ $=10.31 \mathrm{~s}, \mathrm{SD}=11.72$; Mann-Whitney $Z=2.11, p=.035$ ) or accidental $\left(M_{\text {accidental }}=8.07 \mathrm{~s}, \mathrm{SD}=9.92\right.$; Mann-Whitney $Z$ $=2.35, p=.019$ ) conditions. There was no difference between the intentional and accidental conditions (MannWhitney $Z=.353, p=.724$ ).

## Discussion

The results of Experiment 1 help clarify how older preschoolers use communicative cues to guide their inductive inferences. Regardless of whether or not they were given a clear interruption in the overarching pedagogical interaction, a deliberate break between engaging in an overarching pedagogical interaction and seeing the target action producing the evidence, children selectively
modulated the strength of their inductive generalizations on the basis of whether or not the experimenter explicitly demonstrated that action for their benefit. This suggests that 4-year-olds' inferences are driven a moment-by-moment analysis of whether or not each individual action or series of actions is meant for them.

A judicious application of this learning mechanism is important for the accuracy of young children's developing conceptual representations. If children simply made a broad inference about whether an adult is currently teaching them or not, they might be misled about the importance of various pieces of information that they might witness in such contexts. If children did not engage in a moment-bymoment analysis of which actions were deliberately meant for them, they might mistakenly generalize even an incidental action action as what one does with this kind of object, even though in fact this is an idiosyncratic, unusual way to use this kind of object. Simply put, it is helpful for children to use their understanding of others' communicative intentions to guide the inferences if they can do so selectively. The results of this experiment suggest that, at least by age 4, children appear to be capable of using communicative cues to guard against such over interpretation, ensuring that the information that does make it into their representations is likely to be important, generic information about the kind.

## Experiment 2

The results of Experiment 1 shed light on the sophistication of 4-year-olds' ability to navigate ongoing interactions in order to identify which actions are meant as communicative acts for their benefit, and thus what information ought to be taken as important and generalizable. Even when children have to conduct a more nuanced moment-by-moment analysis of the interaction, 4-year-olds show a consistent pattern of making stronger inferences about evidence that is demonstrated communicatively for their benefit.

This contrasts with the findings with 3-year-olds from Butler and Markman (2012). In three experiments, 3-yearolds consistently showed an analogous effect for pedagogical demonstration compared to seeing the same action done accidentally. However, 3-year-olds did not distinguish between the pedagogical and intentional actions, making similarly strong inferences in both conditions. What might account for this developmental difference? Moreover, as we have suggested this inference requires that children not only recognize that an action is for them, but have to be able to navigate an ongoing interaction, assessing moment-by-moment whether or not particular actions are indeed meant for them, even when they occur within a communicative context. If younger children struggle with identifying individual pedagogical actions within an overarching stream of actions, it might take a more explicit demarcation of the specific actions that produce the relevant evidence in order to elicit the pattern of reasoning seen in older children.

In Experiment 2, we take a first step at asking whether presenting this manipulation in a context that might make it easier for children to navigate the ongoing interaction and identify which actions are truly made for their benefit, might lead 3-year-olds to be more successful at selectively using communicative cues to guide their inferences.

## Method

Recall that in Experiment 1, we investigated the importance of the distractor task in potentially facilitating children's ability to navigate the ongoing interaction and identify which actions were and were not meant for them. For older children this did not seem to have any tangible impacteven without any clear interruption between the word learning and evidence phases, 4-year-olds were readily able to selectively use the communicatively demonstrated evidence to make a stronger inference about the novel property. But this interruption seems like a logical place to start in asking whether manipulating the complexity of the context might help facilitate 3 -year-olds' ability to engage in the same inference process.

In Experiment 2, we attempted to boost the clarity of the break provided by the distractor task by making it clearly non-pedagogical, non-communicative, and even noninteractive. We hypothesized that 3 -year-olds have a more global sense of whether or not they are engaged in a pedagogical interaction, and that this may be leading them to over interpret everything that occurs in this context as likely pedagogical unless otherwise marked. If so, then establishing a clearer break between the pedagogical word learning and the evidence phase might help them distinguish between the pedagogical and intentional actions.

Materials Having established in Experiment 1 that previous findings were not an artifact of the materials used in those studies, in Experiment 2 we returned to using materials identical to those used in Butler and Markman (2012): 1 target magnetic object, 10 identical inert objects, and metal paperclips.

Participants The participants were an additional 24 children from a university preschool ( $M_{\text {age }}=3$ years, 5 months). Participants were randomly assigned to one of two experimental conditions (Pedagogical or Intentional), with the constraint that the conditions be equated for gender and age.

Procedure As in Butler \& Markman (2012) and the Interruption order of Experiment 1, children were first explicitly taught a label for the target object. After children were taught the novel word and had successfully indicated the target object on two successive trials, the experimenter brought out the paperclips, colored pencils, and a sheet of paper with a simple triangle outline on it, and said, ""And here's a picture to color! Why don't pick out your favorite color to color the triangle with, and then I can write your name on your picture!" The experimenter then let the child
color for 60 s while she pretended to write something down, not making eye contact or otherwise engaging with the child during this distractor task. The experimenter then said "I'm going to put these away" and began to clean up each of the distractor objects, finally picking up the target object and using the object to magnetically pick up the paperclips. This evidence was produced one of two three subtly different ways, as in Experiment 1: pedagogically or intentionally (but non-communicatively). As our main interest was in whether these younger children would distinguish between the pedagogical and intentional conditions (and not whether patterns of exploration in these two conditions would differ from the accidental condition), only these two conditions were run..

The key change from previous studies was the use of this non-interactive distractor task. This was done as an attempt to provide children with a clearer interruption in the ongoing pedagogical interaction. If 3-year-olds' failure to distinguish between the intentional and pedagogical conditions in previous studies was due to an overall sense of being in a pedagogical interaction, this change might help them disengage from this and discriminate whether or not the target action is truly meant as an act of communication.

## Results

Replicating the findings from Butler \& Markman (2012), 3-year-olds did not appear to make any distinction between the pedagogical and intentional conditions. Children were equally likely to explore the inert objects in both the pedagogical ( 8 children, $75 \%$ ) and intentional ( 7 children, $58 \%$ ). Moreover, children made similar numbers of attempts to elicit the property form the inert objects in both the pedagogical $\left(M_{\text {pedagogical }}=3.17, \mathrm{SD}=3.49\right)$ and intentional $\left(M_{\text {intentional }}=4.08, \mathrm{SD}=4.80\right.$, Mann Whitney $\mathrm{Z}=.240, p=$ .810). Children also spent a similar amount of time exploring the inert objects in both the pedagogical ( $M_{\text {pedagogical }}=8.67 \mathrm{~s}, \mathrm{SD}=10.31$ ) and intentional ( $M_{\text {intentional }}$ $=8.42 \mathrm{~s}, \mathrm{SD}=11.76$, Mann Whitney $\mathrm{Z}=.090, p=.928$ ).

## Discussion

Providing younger children with a clearer break between the pedagogical word learning and evidence phases did not facilitate their ability to selectively use communicative cues to guide their inferences. Even when we had a 60 s break in which the experimenter did not interact with the children, these children still failed to distinguish the pedagogical demonstration and the intentional, but non-pedagogical, action, making similarly strong inferences in both cases. Although we cannot compare children's inferences in these conditions to an accidental condition, across three studies in Butler \& Markman (2012), 3-year-olds consistently distinguished between intentional or pedagogical and accidental conditions, and there is little reason to expect them not to do so in this experiment. Moreover, the key point for our conclusion is that children failed to distinguish between a pedagogical and identical, but non-pedagogical, action, even given a clearer break.

However, it should be noted that there was still an overarching pedagogical context. That is, children still came to the room with a knowledgeable adult and engaged in a brief pedagogical interaction with them. If the distinction between pedagogical and intentional is more global for these younger children, happening on the level of the overarching context rather than moment-by-moment actions, this may explain why having the ongoing pedagogical interaction interrupted by a clearly noncommunicative, non-interactive distractor task was not enough to enable them to fully disengage from the pedagogical expectation and evaluate whether the individual instrumental action was deliberately done for their benefit.

## General Discussion

To return to our original research question, how best to we characterize preschoolers' ability to use communicative cues to guide their inductive inferences? Our perspective is that although younger children most certainly are capable of recognizing communicative cues (Cisbra, 2010), they may be less adept at navigating pedagogical interactions in order to identify which actions are meant for their benefit. On this account, younger children may have a more global sense of whether or not they are currently engaged in a pedagogical interaction with a knowledgeable adult, and may interpret, or even over-interpret, a variety of intentional actions as for them, even if they are not clearly meant as such, and only disengage from this interpretation when an action is clearly marked otherwise, for example as accidental.

The results of these experiments are consistent with this interpretation. Although 4-year-olds judiciously identified which actions were meant for them even when embedded in an ongoing pedagogical interaction, even when 3-year-olds were given a clear break between being taught the word and seeing the evidence produced either communicatively or non-communicatively, they did not use that distinction to guide their inferences. Thus simply interrupting the pedagogical interaction does not seem to be enough to disengage children's overall pedagogical interpretation of the situation.

More broadly, the learning mechanism explored in this paper clearly has powerful implications. Preschoolers are highly sensitive to communicative cues that indicate a particular action is meant for their benefit, and use this to guide stronger and inferences about novel information. But important questions remain about how best to characterize this learning mechanism, what inferential processes are children engaged in, and how this develops over the preschool years.

## Acknowledgments

This research was based on a doctoral dissertation submitted to Stanford University, and was supported by a NSF Graduate Research Fellowship.. Special thanks to the parents, children, teachers, and staff at the Bing Nursery School. We also thank Kimmy Scheible for assistance with data collection and coding, and Andrei Cimpian and
members of the Markman Lab for helpful discussion of this work.

# A Computational Model of General Rule Learning with Unnatural Classes 

Shira Calamaro (shira.calamaro@ yale.edu)<br>Department of Linguistics, 370 Temple Street<br>New Haven, CT 06511 USA

#### Abstract

This paper presents the results of a computational model of generalized phonological rule learning (Calamaro and Jarosz, 2012), which is used to model experimental studies on the learning of phonotactic patterns governed by natural and unnatural classes. I focus on two papers with conflicting results on the learnability of natural and unnatural rules. Saffran and Thiessen (2003) find that a phonotactic pattern of positional voicing restrictions governed by a natural class of segments is learned by infants, but a similar pattern governed by an unnatural class is not learned. In contrast, Chambers, Onishi, and Fisher (2003) find that infants can learn a phonotactic pattern governed by an unnatural class of segments. The computational model presented in this paper is able to account for these seemingly conflicting results, explaining both the learnability and unlearnability of rules governed by unnatural classes.

Keywords: Linguistics; Phonology; Language Acquisition; Computational Model; Statistical Learning

## Introduction

Many artificial-language experiments have explored the learnability of sound patterns in acquisition and how these may reflect biases in the phonology. The interpretation of experimental results can often be attributed to a number of different theoretical models. In this paper, I explore the results of experimental studies on the learnability of unnatural rules and provide an analysis in a computational model.

Experiments in language acquisition have found conflicting results in the learnability of unnatural sound patterns. In one study, Saffran and Thiessen (2003) found that infants were able to learn phonotactic voicing restrictions governed by a natural class of segments, but were unable to learn the same pattern when governed by an unnatural class. In contrast, Chambers, Onishi, and Fisher (2003) have shown that phonotactic patterns governed by unnatural classes may be learnable.

In this paper, I present a computational model of generalized rule learning (Calamaro and Jarosz, 2012), which offers an account of the results found by Saffran and Thiessen (2003) and Chambers et al. (2003). This model uses statistical regularities in the input, as well as linguistic filters, to learn phonological alternations. It encodes these patterns as generalized rules over natural classes of segments, which can explain the inability to generalize certain patterns that do not fall into a natural class.

The results of these computational experiments will help to further clarify the nature of the results of the acquisition studies. The preference for patterns governed by natural
classes over unnatural classes may be explained by the inability to generalize over certain classes of segments. This preference is realized in the model through a generalization bias, or preference for general rules. The learnability of some types of unnatural rules is also explained by the model, which can identify the robust patterns present in the data and distinguish between them through the interaction of complexity and competition.

## Background

In their artificial-language experiments on phonological acquisition, Saffran and Thiessen (2003) attempt to find the types of patterns that are learnable by infants and identify the types of pattern that are more difficult to learn. 9-monthold infants were trained on a set of language data exhibiting the specified pattern. They were then tested using the headturn preference procedure, in which listening times for familiar and novel words were measured. A significant difference in listening times would indicate which patterns had been learned by the infants after a brief training period.

In one experiment, they looked at the learning of voicing restrictions in different positions of a syllable. Using two conditions, they restricted the types of consonants that could appear in the onset, the position preceding the vowel, and the coda, the position following the vowel. In one condition, the onset position was restricted to the set of voiceless stops $[\mathrm{p}, \mathrm{t}, \mathrm{k}]$, while the coda was restricted to voiced stops $[\mathrm{b}, \mathrm{d}, \mathrm{g}]$. For example, words of the form pibtad were permitted, but not *bipdat. In the second condition, the restrictions were reversed, with voiced stops in the onset and voiceless stops in the coda. The sets $[p, t, k]$ and $[b, d, g]$ each form a natural class of stop consonants because they can be distinguished using a single feature, [voice]. The results showed that infants were indeed capable of learning this distinction, with a significant difference in looking times between familiar and novel words. In this experiment, the infants were able to learn a phonotactic pattern governed by a natural class of segments.

The next experiment investigated the learning of voicing restrictions of unnatural classes in different prosodic positions. Unlike the previous experiment, in which the sets $[\mathrm{p}, \mathrm{t}, \mathrm{k}]$ and $[\mathrm{b}, \mathrm{d}, \mathrm{g}]$ could be distinguished by the [voice] feature, the sets used in the second experiment cannot be distinguished by any feature, making them unnatural. In one condition, [p,d,k] appeared in the onset while $[b, t, g]$ appeared in the coda. The reverse was true in the second condition, with $[\mathrm{b}, \mathrm{t}, \mathrm{g}]$ appearing in the onset and $[\mathrm{p}, \mathrm{d}, \mathrm{k}]$ occurring in the coda. The experimental results differed, with no significant difference in looking times between the familiar and novel words. In the experiment, the infants
failed to learn a phonotactic pattern governed by an unnatural class of segments.

Overall, the Saffran and Thiessen (2003) results show that infants are capable of learning patterns over a set of segments that form a natural class and can be described by a minimal number of features, and it is more difficult to learn a pattern over an unnatural class of segments which cannot be described by any set of features.

In contrast, Chambers et al. (2003) have shown that infants are capable of learning phonotactic patterns governed by an unnatural class of segments. In this experiment, 16.5 -month-old infants were tested using a head-turn preference test. The training data consisted of artificial CVC words in which the set of segments [b, k, m, $\mathrm{t}, \mathrm{f}]$ and $[\mathrm{p}, \mathrm{g}, \mathrm{n}, \mathrm{t}$, s] were restricted by position, appearing in either the onset or coda. There is no combination of features that can be used to define these segments, so these sets of segments constitute an unnatural class. In the testing phase of the experiment, infants were able to distinguish between legal and illegal words, meaning they had learned the phonotactic pattern they had been trained on.

The results found by Chambers et al. (2003) seem to be in conflict with the results found by Saffran and Thiessen (2003) on the learnability on rules governed by unnatural classes. In addition to the distinction between natural and unnatural classes, a learning model should also be able to account for these different results on the learnability of unnatural classes. In the next section, I present such a model to account for these results.

## Generalized Rule Learning Model

The Generalized Rule Learning model (GRL: Calamaro and Jarosz 2012) presented here is used to test the learning of the acquisition data in a computational setting. The GRL is a statistical model with linguistic constraints and generalized rule learning. The generalization component of the model is motivated by experimental evidence showing that infants are able to generalize rules using features (Maye, Weiss, and Aslin 2008; Cristiá and Seidl 2008). Given a set of segmented data, the model learns general rules for alternations in the data at the contexts in which they occur, as well as a score reflecting the strength of the rule. The original goal of the GRL model was the learning of alternations, such as word-final devoicing in Dutch, but in this paper it is applied to static phonotactic patterns. The GRL model is based on an earlier model (PLND: Peperkamp, Le Calvez, Nadal, and Dupoux, 2006) for learning pairs of alternating segments by calculating their statistical distribution in the data with an application of KLdivergence (Kullback and Leibler, 1951) and linguistic filters.

The GRL model maintains the use of the two linguistic filters ${ }^{1}$ from PLND, which remove spurious pairs that should not be considered as alternating segments for linguistic reasons. The first filter removes pairs which have

[^25]an intervening segment in the phonetic space based on their features, which are represented by a vector with values for place, sonority, voicing, nasality, rounding, and vocalic. ${ }^{2}$ The second filter removes pairs in which the allophone is not more similar to its context than the default segment. Overall, these filters are able to introduce phonological knowledge not available to a purely statistical model.
The GRL model also maintains use of KL-divergence, though the formulation is somewhat changed, with the new calculation shown in (1) :
(1) $\operatorname{Score}_{(\mathrm{c}, \mathrm{s} 1, \mathrm{~s} \mathbf{2})}=D\left(c, s_{1}, s_{2}\right) * \mathbf{Z}^{2}$
\[

$$
\begin{aligned}
& \text { Where: } \\
& D\left(c, s_{1}, s_{2}\right)=P\left(c \mid s_{1}\right) \log \frac{P\left(c \mid s_{1}\right)}{P\left(c \mid s_{2}\right)}+P\left(c \mid s_{2}\right) \log \frac{P\left(c \mid s_{2}\right)}{P\left(c \mid s_{1}\right)} \\
& \text { and } Z=\frac{K L\left(c, s_{1}, s_{2}\right)-\mu}{\sigma}
\end{aligned}
$$
\]

The equation in (1) is used to calculate scores for pairs of alternating pairs of segments at a context $c$, defined as the following segment. The use of KL-divergence to find alternating pairs captures the intuition that segments which have highly distinct distributions in the data are likely to governed by some phonological or phonotactic rule.
The model creates general rules by merging alternating pairs which undergo an identical structural change, as represented by a feature vector. For example, the alternating pair ( $\mathrm{d}, \mathrm{t}$ ) has a structural change of $[0,-1,-1,0,0,0]$, calculated as the difference between the feature vector of segments $t$ : $[4,1,0,0,0,0]$ and $d:[4,2,1,0,0,0]$. This difference vector represents the devoicing pattern of the ( $\mathrm{d}, \mathrm{t}$ ) pair.
The scores of alternating pairs as calculated in (1) are summed for all pairs whose change in features is the same, giving a contextualized rule score. Each contextualized rule is represented by a structural change vector, the context in which it occurs, and a rule measuring its strength. The calculation of contextualized rule scores is shown in (2):
(2)

$$
\operatorname{Score}_{(c, \vec{f})}=\sum_{(s 1, s 2)} \operatorname{Score}_{(c, s 1, s 2)}
$$

The output of the formula in (2) is a set of rules which each apply at a single context. Many phonological rules apply at multiple, related contexts, such as a vowel nasalization rule that applies in the context of all nasal segments. The contextualized rule scores can be further generalized, by merging rules whose contexts are phonologically related to each other and the change undergone by the rule. The formal calculation of the rule merging is defined in (3):
(3)

$$
\text { Score }_{(\{C\}, \vec{f})}=\sum_{\mathbf{c} \in \mathrm{C} \text { where SCC and SvC hold }} \text { Score }_{(\mathrm{c}, \vec{f})}
$$

[^26]Shared Change Condition (SCC): To merge, contexts must share feature values for any non-zero values in $\overrightarrow{\boldsymbol{f}}$.

Shared Values Condition (SVC): To merge, contexts must not differ along more than one feature.

The formula in (3) is used to calculate the score of a generalized rule as the sum of all rules whose contexts meet two conditions: the Shared Change Condition (SCC) and the Shared Values Condition (SVC). Like the linguistic filters from Peperkamp et al (2006), the merging conditions provide linguistic information in assigning classes of sounds that pattern together. The SCC requires that contexts must be related to the rule change in the same way by restricting merging to contexts which share non-zero values of the rule vector. The SVC requires that contexts be related to each other by restricting merging to contexts which only differ along a single feature dimension, thus approximating a natural class. The merging of contextualized rules into generalized rules can capture generalizations about the data as well as assign increased scores to more robust rules occurring in a set of related contexts.

This model learns generalized rules as a difference vector of features, a set of contexts of application, and a score indicating the goodness of the rule. The rules learned by the model will need to be interpreted somewhat differently from the results of the Saffran and Thiessen (2003) and Chambers et al. (2003) experiments, which measured successful learning by significant differences in looking times in a head-turn test. Instead, this model will need to look for rules which reflect the regularities found in the training data. Additionally, the model looks at alternations conditioned by contexts defined as following segments and does not have access to syllabic structure. Due to these limitations of the model, this discussion will focus on the results as they relate to the learning of the pattern in coda position, which is defined by the following segment. With these restrictions in mind, successful replication of results in the model will mean the learning of a word-medial and word-final voicing/devoicing rule in Experiment 1, no successful learning of any such a rule in Experiment 2, and the learning of meaningful rules in Experiment 3.

## Experiment 1: Learning rules governed by natural classes

In Experiment 1, I replicate the results of an experiment by Saffran and Thiessen (2003), in which infants were able to learn voicing restrictions by position.

## Method

The Generalized Rule Learning Model, as described in the previous section, was used.

## Data

The same training data from Saffran and Thiessen (2003) was used. Each condition in the training data consisted of 30 unique CVCCVC words for each condition, made from an
alphabet with four vowels $[\mathrm{a}, \mathrm{i}, \mathrm{o}, \mathrm{u}]$, three voiceless stops $[\mathrm{p}, \mathrm{t}, \mathrm{k}]$, and three voiced stops [b, d, g]. In condition a, voiced stops were restricted to coda position and voiceless stops were restricted to onset position. The opposite was true for condition $b$, with voiceless stops occurring in coda position and voiceless stops occurring in onset position.

While the model does not specifically reference syllable structure, successful learning of this data would find a rule of voicing/devoicing in the word-final context and before voiceless/voiced consonants.

## Results

The results from experiment 1 are shown in Figure 1, reflecting the highest scoring rules found by the model.

Figure 1: Exp. 1 results
Each bar in Figure 1 shows the score of a generalized rule. In Condition a, the highest scoring rule is the wordfinal voicing rule, (\# [0, 1, 1,0,0,0]), where \# represents the word-final context and $[0,1,1,0,0,0]$ represents the structural change vector. The two non-zero values in the vector indicate a change in the sonority and voicing features in pairs such as $(\mathrm{t}, \mathrm{d}) .{ }^{3}$ The reverse rule is found in Condition b, with a structural change vector $[0,-1,-1,0,0,0]$ indicating devoicing in pairs such as $(\mathrm{d}, \mathrm{t})$.

In each of the two conditions, the highest scoring rule is the desired voicing or devoicing rule. This rule reflects the change in voicing of the stops in coda position in the training data. The voicing/devoicing rule is quite robust in each of the two conditions, scoring much higher than the next highest scoring rule. A similar rule for word-medial codas is also found, which is the voicing/devoicing rule occurring in $\{\mathrm{p}, \mathrm{t}, \mathrm{k}\}$ or $\{\mathrm{b}, \mathrm{d}, \mathrm{g}\}$ contexts.

A number of spurious rules were also found by the model. These rules reflect a change in place of articulation, shown as fronting and backing rules. While these rules are not desired, they do reflect a generalization in the data, namely, a possible alternation between pairs like [ $\mathrm{p}, \mathrm{t}]$ or $[\mathrm{t}, \mathrm{k}]$, in which the segments differ only in place of articulation. These spurious rules are likely an artifact of the small

[^27]segment inventory, making a minor statistical regularity appear to reflect a possible alternation. In artificial language learning, these types of spurious statistical regularities have the potential to affect the results to a greater extent than in natural language learning, as will be seen in Experiment 3.

Overall, the results in Experiment 1 show learning of the phonotactic pattern, aligning with the results found by Saffran and Thiessen (2003). The model successfully learned the voicing restrictions when they were governed by a natural class of segments.

## Experiment 2: Failure to learn rules governed by unnatural classes

In experiment 2, I replicate the results of a second experiment from Saffran and Thiessen (2003), in which infants were not able to learn phonotactic restrictions of unnatural classes of segments which are specified by voice and place of articulation.

## Method

The Generalized Rule Learning Model, as used in the previous experiment.

## Data

The same training data from the Saffran and Thiessen (2003) experiment was used. The training data consisted of 30 CVCCVC words in each condition with the same alphabet as experiment 1 . In condition a, the set of coda consonants was $[\mathrm{b}, \mathrm{t}, \mathrm{g}]$ and the set of onset consonants were [ $\mathrm{p}, \mathrm{d}, \mathrm{k}]$. In condition b the voicing specifications were reversed, with codas [p, d, k] and onsets [b, t, k].

## Results

In Exp. 2, the model failed to learn voicing restrictions governed by unnatural classes. These results are shown in Figure 2, with the highest scoring rules represented.

Figure 2: Exp. 2 results
The voicing and devoicing rules are no longer learned as the highest scoring rules, as seen in Figure 2. The highest scoring rule is now a spurious rule reflecting a change in the
place of articulation. This rule would account for a possible alternation between pairs such as ( $\mathrm{p}, \mathrm{t}$ ) or ( $\mathrm{d}, \mathrm{g}$ ), which can be generalized from statistical regularities in the data.

The desired rules of voice alternations receive lower scores than some of the spurious rules. The overall strength of these desired rules has decreased, with the weight of each voicing/devoicing rule being split into two lower weighted rules. The reason for this decrease in the score is that the patterns cannot be fully generalized because they belong to an unnatural class. In experiment 1 , the desired voicing rules were supported by three pairs of segments, one for each place of articulation. In this experiment, the scores were split between two separate rules, each supported by one or two pairs of segments, $(\mathrm{t}, \mathrm{d})$ or $(\mathrm{b}, \mathrm{p})$ and $(\mathrm{g}, \mathrm{k})$.

Both factors of decrease in rule rank and loss of rule strength contribute to the increased difficulty of learning the phonotactic pattern in experiment 2 . This difficulty in learning is a desired result because infants failed to learn this same pattern in an experimental setting (Saffran and Thiessen 2003).

In this case, the unnatural voicing pattern was not the most robust pattern in the data. The model found other patterns which were generalizable from the given data, obscuring the desired patterns. From this result, a prediction of the model is that it would be able to learn a rule governed by unnatural classes, if the data did not contain any other patterns which could be inferred. Such a case is used by Chambers et al. (2003), which will be shown in the following experiment.

## Experiment 3: Learning rules governed by unnatural classes

In a final experiment, I run the GRL model on the data from Chambers et al. (2003), in which infants were able to learn phonotactic patterns governed by an unnatural class of segments.

## Method

The Generalized Rule Learning Model, as used in the previous experiments.

## Data

The data used in this experiment were replicated from Chambers et al. (2003). A set of CVC words were creating using two groups of consonants belonging to an unnatural class: $[\mathrm{b}, \mathrm{k}, \mathrm{m}, \mathrm{t}, \mathrm{f}]$ and $[\mathrm{p}, \mathrm{g}, \mathrm{n}, \mathfrak{t}, \mathrm{s}]$. The onsets were drawn from one group and codas from another, creating a phonotactic pattern governed by an unnatural class of segments.

## Results

While the data could not be generalized, the patterns were learnable as separate rules, as shown in Figure 3:

Figure 3: Exp. 3 results
The rules shown in Figure 3 are striking due to the uniformity of the data. While the segments could not be generalized by position, the model was able to find relationships among between-group segments. For example, the ( $\mathrm{b}, \mathrm{p}$ ) pair is reflected by the word-final devoicing rule (\# $[0,-1,-1,0,0,0]$ ), while the ( $k, \mathrm{~g}$ ) pair is reflected by the word-final voicing rule (\# [0,1,1,0,0,0]).

With a one-to-one mapping of segments to learned rules, we would expect five rules, but instead find eight. While each segment belongs to at least one rule, some segments are learned as multiple rules. For example, ' $p$ ' is found in both the devoicing rule (\# [0,-1,-1,0,0,0]) with the pair (b,p), but also in the fortition rule (\# [-1,-2,0,0,0,0]) with (f,p).

While some of these are the same rules which were unlearnable in Experiment 2, namely voicing and devoicing, a potential difference here is the lack of interference from spurious rules. While in the case demonstrating unlearnability, the desired rules were dominated by spurious rules. In this experiment, the desired rules were the highest scoring rules.

## Discussion

The computational experiments presented in this paper seek to address two fundamental questions about the learnability of phonotactic patterns: Why are patterns governed by natural classes easier to learn than those governed by unnatural ones? How can we explain results in which unnatural patterns are learnable? The first question is addressed by comparing the results of Experiments 1 and 2, and the second by comparing the results of Experiments 2 and 3.

## Natural vs. Unnatural Classes

In Experiments 1 and 2, the GRL replicated the results found by Saffran and Thiessen (2003), that a phonotactic pattern governed by a natural class is learned, while one
governed by an unnatural class is not. Specifically, infants can learn patterns which occur over a set of segments that all agree in voicing and differ in place, they cannot learn patterns which occur over a set of segments that differ in both place and voicing.

The GRL finds an asymmetry in the learning of natural and unnatural classes due to an inherent bias in the generalization mechanism. Generalized rules receive higher scores from the model because they have support from more pairs of segments. The strength of general rules is computed by summing the scores of rules governing alternations between a single pair. Therefore, the more pairs of segments contributing to a general rule, the higher its score will be. In the case of the Saffran and Thiessen (2003) data, the rules governed by natural classes are supported by more segments than the unnatural ones. This inherent generalization bias assigns higher scores to the natural rules in Exp. 1 than the unnatural rules in Exp. 2.

The asymmetry in the learning of natural and unnatural rules has previously been explained by a Complexity Bias (Moreton and Pater, 2011). Under this account, the more complex set of features needed to describe unnatural classes makes the learning of unnatural patterns more difficult. Natural classes, which can be described with fewer features, can be learned more easily.

The generalization mechanism in the GRL accounts for the same patterns as the Complexity Bias, but for a different reason. While the Complexity Bias asserts that unnatural rules are more difficult to learn because they require the encoding of additional feature values, the GRL attributes this asymmetry to weaker statistical regularities due to the more complex data. This prediction of the GRL can be seen by the difference in rules scores in Exp. 1 versus Exp. 2.

The GRL model has an additional property that interacts with complexity: competition. In the results from Exp.1, the desired pattern was learned because of the high score relative to other rules. In Exp. 2, the lower scoring unnatural rules were dominated by competing spurious rules, interfering with their learnability. This interaction between complexity and competition allows the GRL to make additional predictions beyond complexity alone, which will play a role in the learning of different types of unnatural classes.

## Unnatural vs. Unnatural Classes

In Experiments 2 and 3, the learning data contained phonotactic patterns governed by unnatural classes. In the original experimental setting, infants did not learn the unnatural pattern in Experiment 2 (Saffran and Thiessen 2003), but did learn the pattern in Experiment 3 (Chambers, et al. 2003). Likewise, the GRL found a similar difference in the learnability of the two unnatural patterns, as shown in this paper. The distinction to be made between these two unnatural patterns lies in the nature of the data.

Both experiments presented artificial data in which syllable positions were restricted to a specific set of consonants. In Saffran and Thiessen (2003) the sets were [p,
$\mathrm{d}, \mathrm{k}]$ and $[\mathrm{b}, \mathrm{t}, \mathrm{g}]$; in Chambers et al. (2003) they were [b, k, $\mathrm{m}, \mathrm{t}, \mathrm{f}]$ and $[\mathrm{p}, \mathrm{g}, \mathrm{n}, \mathrm{t}$, s]. While both sets of data are unnatural to some extent, there is a striking difference in the segment inventories of the two experiments.

While the pattern presented in Saffran and Thiessen (2003) is unnatural, the segment inventory is well-balanced among the feature set it uses, with a voicing distinction present for each place of articulation. In contrast, the segment inventory of Chambers et al. (2003) is not as balanced, with a mix of voicing, place and sonority distinctions that do not apply across all pairs of segments. For example, there is a voicing distinction for the pairs ( $\mathrm{p}, \mathrm{b}$ ) and ( $\mathrm{k}, \mathrm{g}$ ), but there exists no pair ( $\mathrm{t}, \mathrm{d}$ ).

The effects of the overall naturalness of the data are seen directly in the computational results of Experiments 2 and 3. In Experiment 2, the more balanced data allowed the GRL to make a number of spurious generalizations, obscuring the robustness of the desired unnatural rules. In Experiment 3, the less balanced data could not be generalized by the model, leaving the set of desired unnatural rules as the most robust in the data.

In the distinction between these two sets of unnatural patterns, the GRL is better able to predict these results than a model using complexity alone. The Complexity Bias (Moreton and Pater 2011) predicts difficulty in the learning of both types of unnatural patterns, but would predict even greater difficulty in Exp. 3 due to the greater number of features needed to describe the unrelated set of segments. However, the experimental evidence shows the opposite is true, with the data in Exp. 3 being learned more easily. The predictions of the GRL align with the experimental evidence due to the interaction of competition and complexity in the model. The unnatural pattern in Exp. 3 is learned more easily than that in Exp. 2 because the desired rules are not in competition with any high scoring spurious rules as is the case in Exp. 2.

## Conclusion

The GRL is able to model the results of experimental data showing the learning of phonotactic patterns by infants. It can account for the preference for learning natural rules over unnatural ones, as well as the distinction between the learnability of different patterns of unnatural classes. This preference for natural classes is an inherent property of the model, due to the rule generalization component. While the generalization component of the model does facilitate the learning of natural rules, it does not exclude the learning of rules governed by unnatural classes. Indeed, rules governed by unnatural classes were learned by the model, when there were no other more robust rules in the data.

These experiments provide some promising results for the GRL model, with its ability to account for attested cases of phonological learning. While there remains a possibility that differences in infant learning can be attributed to differences in experimental methodologies, these results show compelling evidence for further exploration of this topic.

Future work will explore other predictions made by the model and extensions needed to account for additional data.

## Appendix

## Linguistic filters (Peperkamp et al. 2006)

Allophonic distributions of $\mathrm{s}_{\mathrm{a}}$ and $\mathrm{s}_{\mathrm{d}}$ are spurious if:

$$
\exists s\left[\begin{array}{c}
\forall i \in\{1, \ldots, 5\}, v_{i}\left(s_{a}\right) \leq v_{i}(s) \leq v_{i}\left(s_{d}\right) \\
\operatorname{or} v_{i}\left(s_{d}\right) \leq v_{i}(s) \leq v_{i}\left(s_{a}\right)
\end{array}\right]
$$

With $v_{i}(s)$ the ith component of the vector representation of s.

Allophonic distributions of $\mathrm{s}_{\mathrm{a}}$ and $\mathrm{s}_{\mathrm{d}}$ are spurious if:

$$
\exists i \in\{1, \ldots, 5\},\left|\sum_{s \in C\left[s_{a}\right]}\left(v_{i}\left(s_{a}\right)-v_{i}(s)\right)\right|>\left|\sum_{s \in C\left[s_{a}\right]}\left(v_{i}\left(s_{d}\right)-v_{i}(s)\right)\right|
$$

## Feature values

Segments are represented as feature vectors with the following values:

Place: bilabial 1, labio-dental 2, dental 3, alveolar 4, postalveolar 5, palatal 6, velar 7, uvular 8, glottal 9

Sonority: voiceless stop 1, voiced stop 2, voiceless fricative 3, voiced fricative 4 , nasal 5, lateral 6 , rhotic 7 , glide 8 , high vowel 9 , mid vowel 10, low vowel 11

Voicing: voiceless 0 , voiced 1
Nasality: oral 0, nasal 1
Rounding: unrounded 0, rounded 1
Vocalic: non-vowel 0, vowel 1

## Acknowledgments

Many thanks for feedback from Gaja Jarosz, CLAY Lab, audiences at LSA 2013, and an anonymous reviewer.

#### Abstract

The aim of this paper is to highlight the role of the social factors among the different forces which influence natural selection. To do this, we'll start analyzing an example of highly complex society, like that of the baboons, in order to show that the building-up of a society depends on extremely flexible and continually negotiated social relationships, rather than on features that are genetically determined. However, in our view, when we shift from animal societies to the human ones, we have to recognize the central role of language. In fact, even if the role of social influence appears to be relevant in other animal species, in humans it was language that provided the way to make this social influence much more important, to redefine the roles, to reverse the genetic dominances even more, and to make human cooperation something unique.

Keywords: cooperation; social influence; evolution; language.

## Introduction

The concept of cooperation can be particularly useful to throw a new light into the building-up of societies both in animals and humans. A more in-depth analysis of the ways in which cooperation works in different animal societies, can allow us to assign the right role, in the evolutionary perspective, to social influences and non-deterministic factors like chance, history and the single choices of the individuals belonging to one group. Our framework is the one suggested by Weiss and Buchanan, which provides "an alternative view of natural selection in which there is more slippage and tolerance, multiple solutions with larger acceptability spaces, and the possibility that an adaptive fit will be 'good enough' rather than seamless" (Weiss and Buchanan 2009, p. 305). In this perspective, we'll start analyzing an example of highly complex society, like that of the baboons, in order to show that the buildingup of a society depends on extremely flexible and continually negotiated social relations, rather than on features that are genetically determined. Baboons' society seems to be a good example of the way
cooperation can modify, and even reverse, the genetic dominances. Our examination of the role played by social influence in these non human primates will bring us to look to the interaction between society and biology in a different way, both in animals and humans.

## The survival of the fittest. Or not?

The law of evolution is that the strongest survives. This seems to be what Darwin (1859) has taught us. The fittest do survive, and produce offspring, the others simply don't. At first glance, baboon males, with their aggressive anatomy, seem to be the perfect image of the law of the strongest, and the perfect match between anatomy and behavior (Washburn and DeVore, 1961; DeVore and Hall, 1965): remarkable canines, big mantle of hair, large body size, all seem to suggest that the social rank, and therefore the reproductive success, is determined by the males' fighting ability. But then, why, on a closer inspection, the social structure turns up to be matrilinear, where females have political functions (besides motherhood) that are not defined in terms of their relationships with males? Why the male hierarchies, based on the physical structure, can't predict the priority of access to resources (including the females), and not even the winner in a fight?
Clearly, in Darwinian (and also in NeoDarwinian) terms fittest is not necessarily the strongest, but often the smartest, the swiftest, the most patient, and so on. Darwin would agree that not always the strongest survives (as claimed by hyperdarwinism). Various authors recently focus on a more general "multilevel selection" theory, and on the compatibility between individual selection, kin selection and group selection (Pievani in press). They identify the level of the population structure as the key factor, offering a
pluralistic perspective within the theory of evolution. Here, we suggest to focus on the relationship among individuals (including the echological constraints) rather than on the single member of a species. And, in the case in question, if we want not to miss these factors, we must take into account something else, apart from the role of competition; we have to refer to the role played by cooperation if we want to have a clearer idea of the way the baboons' society works. Baboons have some alternatives to aggression, social strategies that are less risky and that settle competition and defense. These alternatives are based on "special relationships". For example, a potential loser can come back to the aggressor with a baby on his belly, and thus leading the aggressor to back off. In order to be successful, however, a special relationship between the male and the baby is needed, and this relation must be grounded on trust. Thanks to this special relationship, thus, the infant will start screaming when becoming closer to the aggressor, making him the object of mobbing by the group. But without trust, the infant could scream at "the false friend" rather than at the opponent, and the male could run the risk of himself becoming the object of mobbing.
Baboons use their social abilities in other different ways. For example, an older baboon can get copulation thanks to his social skills; he can monitor a male from a distance, manipulate aggression between this male and his closer followers, and then, while he's engaged on a fight, he can dash to his consort, copulate with her and become her new partner. In general, one can notice the same trajectory through a male's life history, "from socially unskilled maturing male with growing physical powers (using aggressive strategies) to the socially skillful mature male whose success depends entirely on social expertise when he is old (using social strategies of competition and defense)" (Strum 2012, p. 6). The possibility to use different alternatives to aggression makes baboons' society more complex and less predictable. Among baboons, it is not always that the strongest wins.

## Evolution in action

Strum (1987; 2012) had the opportunity to "test" natural selection. Because of the increasing encounters with humans, Strum and his colleagues had to translocate three groups of baboons to the arid savanna of Eastern Laikipia Plateau. This was a unique opportunity to test the baboons' adaptability and to look at the moment where a behavior becomes crucial for survival and reproductive success, rather than infer it ex-post, as scientists usually do. Strum notes that "if
ever there was a situation where survival of the fittest should operate, where competition should have had an upper hand, this was it. Instead [...] the translocation, pointed out how evolutionary principles get embedded in a specific time and place and why context matters. Each group's 'natural history' illustrated a variety of different paths" (Strum 2012, p. 8).
The process of adaptation was actually much more complicated than expected, and chance and individuals' social abilities played an important role. Relationships between the immigrants and the indigenous troops were also crucial for survival, for examples an immigrant baboon could follow an indigenous one in order to "adjust" his diet or to find water.
The possibility to observe the process of adaptation in action allows us to take a hard look at the natural selection, which can't be reduced to the survival of the fittest. More precisely, when observing the behavior of a group, one can notice the large amount of flexibility (including the possibility of mistakes that don't lead to extinction) depending on the group's social complexity. Thus, we agree with Strum, when she claims that "evolutionary time speculations of cause and effect assume rather than clarify how evolutionary principles are situated by chance, contingency, and history. This is because they either lack the information or ignore the importance of context and 'black-box' the relationships between real behaviors and evolutionary outcomes" (Strum 2012, p. 10).

## Natural selection is not enough

The idea according to which the survival of the fittest is not the unique force to guide evolution is not a new one. There are in fact many elements, coming from different fields of studies, which contribute to "soften" the adaptationist aspect that Darwin's theory (especially in some of its contemporary versions) risk to endorse.
For example, the evo-devo researchers highlighted the role of structural constraints. As a matter of fact, some forms are not present in nature even if their absence can't be explained through natural selection, because they seem to be very small variations of other forms that are actually produced. These unexpected absences seem to suggest that natural selection can't help but choose among the possible variations, for it can't interfere with the fixed ways that are prescribed by the laws of development (Minelli 2009). The modern molecular biology, from its corner, seems to confirm the fundamental role played by the constraints, because the properties of very different living beings
are grounded on the same mechanism of molecular conservation. Genes involved in behavior are highly conserved during evolution (Gehring and Ikeo 1999, Carroll 2000) and one can find genetic and behavioral homologies even between traits that evolved convergentely (i.e. not from an immediate common ancestor, cf. Shubin et al. 1997). As claimed by Gould (1997, p. 36) "most biologists feel that such stability acts primarily as a constraint upon the range and potentiality of adaptation, for if organisms of such different function and ecology must build bodies along the same basic pathways, then limitation of possibilities rather than adaptive honing to perfection becomes a dominant theme in evolution. At a minimum, in explaining evolutionary pathways through time, the constraints imposed by history rise to equal prominence with the immediate advantages of adaptation".
Moreover, we must look at the role of adaptations from the perspective of long-term evolutionary trends. These trends show that evolution can't be described as a gradual accumulation of adaptations within a population. The actual picture is much more similar to the punctuated equilibrium described by Gould and Eldredge (1977), long periods of stability (even million years of stasis) punctuated by the brunching of new species, that only in limited cases can be described as adaptative improvements of some individuals within a species.
In this long-term perspective, the adaptations with immediate effect can even play no role in survival. In the North American Pleistocene megafauna extinctions the species that went extinct did not have characteristics that set them apart from those that survived; so these processes are not deterministic but they are contingent and complex because the individual's behavioral responses are often unpredictable (cf. Gilbert and Epel, 2009 and their eco-evo-devo).
But what we want to stress here is that, among the different forces which influence natural selection, the social factors have to be taken into account. Thus, to come back to this influence, we have to mention another kind of selection, the sexual one.
The idea that the stronger the male is, the more reproductive success he has, comes from Darwin's theory of sexual selection. According to this theory, males and females obey to different behavioral patterns: the former would be passionate, the latter coy. "Males of almost all animals have stronger passions than females [...] The female, on the other hand, with the rarest exception is less eager than the
male" (Darwin, 1871, pp. 272-3). Males would fight over the possession of females, and females would be agents of selection, choosing only the most virile and showy males, because these features would guarantee many healthy descendants.
Evolutionary psychology, that applies sexual selection also to humans, gave us a very simplified (and quite grotesque) picture of the relationship between male and female (and therefore between man and woman). Males would be more promiscuous because sperm are supposed to be cheap and they would therefore spend all the time looking for females to fertilize. Females, on the other hand, would be more "choosy" because pregnancy is expensive and they would have to guard themselves from wrong investments into "bad" genes. But, as explained by Roughgarden in her book Rainbow (2004), what actually happens in nature proves these theories wrong. Males are not always passionate and females are far from being always coy. Once again, baboons' society shows us that females often present to males, but are refused by them. Why should males refuse females in heat when sperm is supposed to be cheap? Moreover, females don't select always the best genes. They can prefer mating with males who turn out to be good fathers (e.g., in protecting the eggs) rather than males that are dominant in competition with other males. For example, whether a male of sand gobies is dominant in competition for nests does not correlate with whether he is a good father in protecting the eggs. And the goby female knows it; in fact, an experiment reported by Roughgarden (2004) showed that the females of this species regularly select the males that would protect the eggs, and that they don't care if the male they preferred won some fights against other males. These cases show us that male success rests on more than the male dominance hierarchy, and that it depends on different factors, including the relationships based on collaboration that he is able to build (as baboons have taught us). So, it seems that, as Strum says in her paper (2012, p. 15): "there are multiple ways for individuals to succeed, not just one optimal evolutionary path".

## From a complex society to a complicated one. Language and cooperation

Nature provides us with various examples of strongest males that are not successful. But we would like to stress above all that it provides us also with examples of extremely complex societies, with constant negotiations about roles, where the strongest doesn't always win over the weaker, and where a large amount
of intertwined relationships reverses the genetic hierarchy. These data show that society is nature, and that there's no opposition between the two terms.
But there is no difference in complexity between the baboon's society and the human one, then? We could say that baboons are pretty much human? It is evident that we won't find, in the animal kingdom, something that compares to the social and technological complexity of Homo sapiens. Nevertheless, baboons' society reveals the shared roots of social complexity which, in our continuistic framework, found our society, too. But what made human sociality all the more complex than baboons' one?
We believe that what makes our sociality so complex is the presence of language. First of all, the faculty of language seems to be one of the variables that allowed that jump which 40.000 years ago gave rise to the first symbolic uses and to the sudden and explosive variation of human tools. As claimed by Spelke (2009), the technological abilities specific to humans probably descend from the possibility to combine representations of objects and representation of actions in a rapid and flexible way, and this ability depends on the combinatoriality typical of human language.
Moreover, language gave us the opportunity to shift from a linear transmission to a cumulative one. Horner and coll. (2006) described in an experiment that chimpanzees are able to spread learned techniques in a linear way. The authors examined a diffusion chain paradigm, whereby a behavior is passed from one individual to the next in a linear sequence: different methods used to obtain food were accurately transmitted along two chains of chimpanzees, with a remarkable fidelity of transmission within each chain. Faithful transmission is not therefore a distinctive feature of human species. But there is a significant difference between linear and cumulative transmission (Tomasello, 1999; Richerson and Boyd, 2008). If humans had only the possibility to faithfully spread a technique across multiple generations, the different practices of tool making would have been almost unchanged through the hominids' evolution. Humans, on the contrary, are able to refine the acquired techniques and to transmit these improvements, so that we won't have to start all over each time. According to our vision the cumulative transmission, which is possible thanks to the cognitive abilities specific to humans, changed its nature with the emergence of language. And this doesn't mean that language simply "helped" to transmit the traditions and made this transmission more rapid. The simple fact that, thanks to language, it is possible to learn how to use a tool in
its absence, inaugurated a completely new way to transmit knowledge. Moreover, a real technology implies the ability to plan and design combination of tools that are more and more complex, and it is also language that develops and improves this planning ability in a significant way.
At the end of her paper, Strum asked herself what would happen to baboons' society if they wore hats (Strum 2012). If they had the possibility to symbolize their roles this way, these roles would be stable in time and space and baboons wouldn't need to point them out or continually negotiate them. But baboons don't use these kinds of symbols, and therefore they can't simplify their negotiations and they have to spend a lot of time making them evident and visible. In other words, they can't manage more complexity and they can't build a complicated large-scale society, which we sapiens can do thanks to language.
But, in our view, language isn't just a set of labels that gave us the opportunity to spare time. Or, in other words, it is not just a tool of communication, as claimed by the vast majority of evolutionary linguistic theories (cf. e.g. Dunbar 1998, Bickerton 1990). Language is a kind of technology, that manages the manipulation of perceived elements into representations and can conversely express inner needs by linking them to the external world (Pennisi and Falzone, 2011). Language is species-specific to sapiens for it is an auditory-vocal technology (speech making) applied to symbolic needs and highly specialized, just like the manual technology (tool making). We don't need to refer to a human specialty or uniqueness: the auditory-vocal technology relies on the evolution of structures and functions which come from a long evolutionary history, but that in nonhuman primates acquired an adaptive role thanks to the social organization (and to other aspects like passage to bipedalism, parental care or social learning).
The thesis according to which language is a modality to represent the world rather than just a tool of communication doesn't belong only to the philosophical and phenomenological framework today. PET and ERP studies showed that language is heavily involved in the building-up of our knowledge about the world, that kind of knowledge which we build because we belong to a social and linguistic specific community. Hagoort (2005) found in the Broca's area the neural locus where the "checking" between linguistic expressions and social reality would occur. These data seem to confirm our hypothesis according to which language is a technology that serves to
represent reality.
Since we have language, it's not possible for us to choose another technological modality to express our symbolic needs, apart from the auditory-vocal technology. Humans can't help but use language to represent the world. So the possibilities that modern sapiens' biological features gave us granted the development and use of a function which worked as a catalyst for the others that were already present and phylogenetically inherited. These abilities have been improved thanks to the interaction with the possibilities of segmentation which language gave us. Finally, language provides a cue to social preferences, which in turn have an effect on cooperation. Experiments with children from five months to five years provided evidence for an early developing social preference for members of one's native language group; even infants who have not begun to produce or understand speech show this preference. This implies that children prefer to play or work together with people of their native language, and that "infants and young children are selective social learners and cooperators, and language provides one basis for this selectivity" (Kinzler et al., 2012, p. 2). Thus, language isn't simple a way to improve communication skills, but it conditions the way we perceive the others (familiar or not, friend or not) and the possibility to collaborate with them. This is a clear example of how language can have a cognitive function in humans, rather than simply a communicative one. In our view, this cognitive role is linked to the articulated nature (speech-making technology) of our language (Pennisi, in press).
Moreover, linguistic development seems to have an effect on the ability to cooperate with peers: children who are more skilled in talking about their own and others' actions and internal states and who refer to themselves and others using personal pronouns are also better at cooperating with their peers (Brownell et al. 2006).
Thus, language seems to be the key factor of human sociality. Even if we can't underestimate the role of social influence in other animal species, because it appears to be huge also without language, we have to consider that, in our species, language provided the way to make this social influence much more important, to redefine the roles, to reverse the genetic dominances even more, to create societies grounded on values, like money or institutions, which have been negotiated once for all, and, finally, it was language that made human cooperation something unique.

#### Abstract

The current paper examines spatial descriptions provided by older adults in the context of a fetch task in a virtual house environment that mimics an eldercare setting. Sixty-four older adults provided directions for how to find a target or where to find a target to a robot or human (named Brian) avatar. There were systematic differences in the form and structure of the descriptions based on the communicative task. Specifically, how descriptions were longer, contained more detail, and were dynamically structured as compared to where descriptions. However, where descriptions were found to be more effective in conveying the target location, as assessed with a subsequent target selection task. Implications for the development of robot algorithms for the comprehension of naturalistic spatial language across these two communicative tasks are discussed.

Keywords: Human-robot interaction (HRI); spatial language; dynamic and static; how and where; effectiveness; fetch task; assistive robotics; eldercare.

## Introduction

An emerging line of research in human-robot interaction involves the development of assistive devices for use in eldercare settings, either as social companions (e.g., Heerink et al., 2008; Kidd, Taggart, \& Turkle, 2006; Libin \& CohenMansfield, 2004; Shibata, Kawaguchi, \& Wada, 2011; Wada et al., 2003) or as task-oriented robots assisting with navigation (Montemerlo et al., 2002), managing medication (Tiwari et al., 2011)], and providing reminders (Pollack et al., 2002). Older adults also report wanting help with tasks such as cleaning, heavy lifting, and fetching objects (Beers et al., 2012). They also prefer to speak naturally to these assistive devices, rather than use a more constrained interface (Scopelliti, Guiliani, \& Fornara, 2005).

To accommodate these preferences, recently we gathered a corpus of spatial descriptions from older adults who interacted with an avatar within a virtual house setting in the context of a fetch task. Our primary goal in this project is to develop robot algorithms for the online comprehension of these natural language spatial descriptions and to test these algorithms in an analogous physical environment with a physical robot. In working toward this goal, on the basis of the corpus, we have identified key components that need to be developed for the robot including speech recognition for
older adults (Alexenko et al., 2013), parsing the natural language descriptions and coding them into chunks that can be converted into robot commands, recognizing key furniture items within a cluttered environment that are included in the descriptions, and identifying spatial relations within the horizontal plane (e.g., behind the couch) and the vertical plane (e.g., on top of the table) (Skubic et al, 2012).

Given that the robot algorithms are driven by the properties of the spatial descriptions, in the current paper we examine how the communicative task of the speaker impacts the features of the descriptions, and present data that reflect the effectiveness of the descriptions.

## Spatial Directions and Spatial Descriptions

A fetch task is one in which a speaker specifies the location of a desired target for an addressee whose goal is to retrieve the target. There are two ways in which the location can be indicated by the speaker. The speaker could provide directions that tell how to get to the target location or the speaker could provide descriptions that specify information about where a given target location is. Research has shown systematic differences in the type and structure of the language that is used for each of these communicative tasks. For example, Plumert et al. (1995) found that written directions on how to find a target in a hierarchically organized doll-house environment were more likely to provide more detailed messages and contain more spatial units that tended to be organized in a descending sequence (floor $\rightarrow$ room $\rightarrow$ reference object. e.g., The keys are on the first floor in the living room on the table.) as compared to written descriptions of where to find a target that were less detailed and organized in an ascending sequence (reference object $\rightarrow$ room $\rightarrow$ floor, e.g., The keys are on the table in the living room on the first floor).

This distinction between how and where has also been characterized as dynamic and static (Wahlster. 1995, Fasola and Mataric 2012) spatial language, respectively, with dynamic stepping the addressee through the environment in a point by point fashion and static offering spatial information that does not embed the addressee in the environment. Dynamic spatial directions are also inherently sequential, while static descriptions are not. Nevertheless, static descriptions are often overlooked or treated the same
as dynamic directions by other researchers (Tellex et al, 2011), perhaps due to the focus on two-dimensional route instructions or the assumption that dynamic descriptions are better or more prevalent (Kollar et al., 2010, MacMahon et al., 2006, Vogel and Jurafsky 2010, Shimizu and Haas 2009).

In the current work, we assess two questions related to this how/where distinction: First, we ask whether there are consistent differences in the type and form of the spoken spatial language that is produced by older adults in response to how and where instructions that might echo Plumert et al's (1995) findings with written spatial language. We focus on the type of language included in the descriptions, and the amount of detail, and ignore the hierarchical sequencing that Plumert et al. (1995) measured, because our environment consists of a single floor, as intended for mimicking an eldercare setting. Second, we ask whether these differences are associated with differences in the relative effectiveness of the descriptions.

## Corpus of descriptions from older adults in a virtual fetch task

Our corpus consists of 512 spatial descriptions collected from 64 older adults (mean age $=76$ years) who specified the location of 8 targets embedded in the virtual house environment shown in Figure 1. Targets were placed in the living room (on the left in Figure 1) and bedroom (on the right in Figure 1) on tables that also contained two other objects that could potentially serve as reference objects. On each trial, older adults explored the virtual house with the assistance of an experimenter and found a designated target. They were then positioned in the central hallway (marked by "Start" in Figure 1), and provided a description

Figure 1: Overview and screen shots of the virtual house
of the target location to either a robot or human avatar (named Brian) who faced them (as indicated by the arrow in Figure 1), such that their perspectives were misaligned by 180 degrees. Previous research has shown a preference for speakers to use an addressee perspective when perspectives between speaker and addressee are misaligned (Mainwaring et al., 2003; Schober, 1993), with such preference also observed for robot addressees (Tenbrink et al., 2002). However, given that older adults have shown negative emotional responses to robots (Scopelliti et al, 2005), we included the addressee manipulation to assess whether older adults in particular would be more likely to adopt their own perspective rather than the perspective of the robot. These perspective results are presented in Carlson et al. (2013). A second manipulation was related to the task instructions. Specifically, older adults were instructed to either provide directions for how to find the target or to provide descriptions of where the target was located. Both the addressee manipulation (robot or Brian) and the task instruction manipulation (how or where) were between subject manipulations, with the consequence that 16 older adults each provided 8 descriptions (128) for each of the 4 addressee X instruction combination (128 X $4=512$ descriptions in total).

A full report of the older adult corpus can be found in Carlson et al. (2013). We focus here on the how versus where differences. Figure 2 provides the task instructions (adapted from Plumert et al., 1995), and examples from the corpus.

|  | How | Where |
| :--- | :--- | :--- |
| $\begin{array}{c}\text { Instructions to } \\ \text { participants }\end{array}$ | $\begin{array}{l}\text { Please tell the Brian/the robot how to } \\ \text { find the target. }\end{array}$ | $\begin{array}{c}\text { Please tell Brian/the robot } \\ \text { where the target is. }\end{array}$ |
| $\begin{array}{l}\text { Addressee: Brian } \\ \text { Target 1 = Book }\end{array}$ | $\begin{array}{l}\text { Brian turn to your right. Go to the room } \\ \text { on your right and go straight ahead and } \\ \text { the book is right there before you. } \\ \text { Trian please take 1 or 2 steps forward } \\ \text { Target 2 = Cell phoner the room on your left. Upon } \\ \text { entering the room take about 3 steps } \\ \text { forward and you'll see a small brown } \\ \text { table with a black top. The cell phone } \\ \text { that you are looking for is on that table. }\end{array}$ | $\begin{array}{l}\text { Brian the book is in the room to } \\ \text { your right and its on a table at } \\ \text { the far side of the room. }\end{array}$ |
| The cell phone is in the bedroom |  |  |
| on the bedside table. |  |  |$\}$

Figure 2: Instructions and sample descriptions by how/where and addressee

As shown in Table 1, how descriptions contained more words overall per description, and included more spatial terms (such as "on", "to" and "right") and more hedges (such as "immediately" and "slightly"). In contrast, where descriptions contained more house units (such "room", "door" and "wall"). Descriptions often contained large furniture items in the rooms (such as "bed" and "couch"), and rarely contained reference objects that were collocated
on the tables (such as "lamp"), with the incidence of these categories not varying across how and where descriptions. Finally, how descriptions were more likely to have a dynamic form than the where descriptions.

|  | How | Where |
| :--- | :--- | :--- |
| Words per description | $\mathrm{M}=27.0, \mathrm{SE}=1.8$ | $\mathrm{M}=19.4, \mathrm{SE}=1.5$ |
| Spatial terms per description | $\mathrm{M}=4.1, \mathrm{SE}=.26$ | $\mathrm{M}=2.3, \mathrm{SE}=.29$ |
| House units per description | $\mathrm{M}=1.1, \mathrm{SE}=.10$ | $\mathrm{M}=1.4, \mathrm{SE}=.12$ |
| Hedges per description | $\mathrm{M}=.22, \mathrm{SE}=.05$ | $\mathrm{M}=.09, \mathrm{SE}=.02$ |
| \% dynamic descriptions | $\mathrm{M}=95.3, \mathrm{SE}=3.3$ | $\mathrm{M}=35.8, \mathrm{SE}=7.9$ |

Table 1: Significant differences between how and where older adult descriptions

These results are consistent with Plumert et al. (1995) who also found that how descriptions contained more spatial units and were more detailed than where descriptions. What remains unclear is whether these differences are associated with any differences in effectiveness. That is, these descriptions were all collected by older adult speakers in the context of a fetch task in which accurately specifying the location of the target is critical for the success of the task. We ask next whether how or where descriptions are more effective in identifying the location of the target.

## Differences in how vs. where effectiveness

To assess effectiveness, we randomly selected from the corpus of older adult descriptions two from each speaker's set of 8 descriptions (with half of the speakers addressing Brian and half the robot), with the constraint that the location of each target was specified an equal number of times across the set of descriptions that we were assessing. These descriptions were then provided to sixtyfour younger adults to assess effectiveness. Their task was to listen to a description without the target, navigate through the house in accordance with the description, and then guess the identity of the target. 4 targets were placed on tables in the living room and 4 targets were placed on tables in the bedroom. Each table contained a target and two distractor objects. Each participant performed two trials (one in the living room and one in the bedroom). Before the trials began, the younger adults were shown a video tour of the house that did not include the targets. This was to familiarize them with the house environment and the relative locations of the rooms and their contents. On each trial, participants started in the hallway of the house, standing in the location and at the orientation of the avatar, as specified by the label "robot or avatar" shown in Figure 1 , and facing the original speaker's location (which is marked in Figure 1 with the label "Start" and with an orientation specified by the arrow). They were therefore facing the position of the participants from which the descriptions were gathered. A participant was given a description from the corpus with the target item removed, and they navigated through the house until they thought
they found the target, and then named it. The key dependent measure was their accuracy in selecting the target.

As shown in Figure 3, we examined two indicators of this accuracy: selection of the correct target, and selection of the correct table on which the target appeared. This latter measure is important because two potential reference objects appeared on the tables next to the targets, and often the descriptions did not provide enough information to identify which object on the table was the target (see example descriptions in Figure 2). The infrequent use of the reference objects that appeared next to the target is consistent with Plumert et al. (1995) who found that such reference objects were only consistently used when the target was located on the reference object as opposed to beside it.

Figure 3: Selection accuracy for correct table (top) and correct target (bottom) as a function of how/where and addressee. Dotted line indicates chance selection.

With respect to selection of the correct table, performance in all conditions was significantly above chance performance of 12.5 , based on 8 possible tables in the environment. In addition, significantly better performance was observed for "where" descriptions $(M=61 \%)$ than for "how" descriptions $(\mathrm{M}=42 \%), \mathrm{F}(1,60)=4.51, \mathrm{p}<.05$. In addition, there was a significant effect of addressee, with more accurate performance for descriptions provided to Brian $(M=67 \%)$ than to the robot $(M=36 \%), F(1,60)=$
$12.55, \mathrm{p}<.01$. The interaction between instruction and addressee was marginal, $\mathrm{F}(1,60)=3.13, \mathrm{p}=.08$.

With respect to the selection of the correct object, performance in all conditions was significantly above chance performance of 4.2 (based on 24 possible targets in the environment ( 3 on each of 8 tables)). For this analysis, there was only a main effect of addressee: $F(1,60)=7.10$, $p$ $<.05$; the effect of instruction and the interaction were not significant ( $\mathrm{Fs}<1.6$, $\mathrm{ps}<.21$ ).

For the object selection measure, we also assessed how likely it was that participants selected the correct object, given that they selected the correct table. Chance performance in this case is $33 \%$, given that there are three objects (target and two reference objects on each table).

Figure 4 shows that in all conditions, accuracy was significantly above chance. We expect that this is because the target objects were generally smaller than the reference objects on the tables. Clark, Schreuder and Buttrick (1983) argue that when a reference is under-determined by a speaker, the addressee will select an object from a group of

Figure 4: Selection accuracy for the correct object, conditional on correct table selection. Dotted line indicates chance selection.
objects that offers the most contrast from the others along a given dimension. For example, imagine a speaker tells an addressee to pick up a ball and refers to a collection of three balls (a golf ball, a squash ball and a basketball) that are placed on a table in front of them. Clark et al. argue that it is likely that the addressee will select the basketball because it is the most unique item in the set, standing out in terms of size.

Finally, we also examined whether there were differences in accuracy for the individual targets. Given that each of the targets appeared in a given location (and location was not counterbalanced across targets), this serves an indicator as to whether any of the target locations were particularly difficult to describe and find. Figure 5 shows accuracy as a function of the targets, both as indicated by the correct selection of the table and correct selection of the object.

Figure 5: Selection accuracy for table and target selection as a function of target. Dotted lines indicate chance selection.

Chi-square analyses revealed no significant differences among targets, for either the correct table accuracy or the correct target accuracy. This indicates that there were not any targets or locations that were particularly difficult to describe and/or find. This is likely due to the simple layout and relatively impoverished contents of the rooms in the virtual house.

Overall, the results for the assessment of the older adults spatial descriptions indicate that the where descriptions allowed participants to more easily select the target and its table than the how descriptions. We suspect that the differences in accuracy for table selection as a function of addressee that were observed are likely due to other properties of the descriptions, such as the perspective adopted by the speaker. For a full report of the older adult corpus, see Carlson et al. (2013).

## Conclusions

Together, the detailed analysis of the corpus and the results of the experiment assessing the effectiveness of the descriptions point to an interesting contrast. On the one hand, the corpus analysis reveals that how descriptions are longer, offer more detail, include more spatial terms, and are dynamic, as compared to the where descriptions that are shorter, include more references to house structures, and are often static. On the other hand, these same how descriptions are not as effective in communicating the location of the target, as assessed by the accuracy for selecting the target and its table. We are currently comparing the effectiveness of these older descriptions with the effectiveness of a corpus of descriptions collected from younger adults within the same virtual environment. Moreover, we are also recording the paths that participants take to the target in response to these descriptions, with the idea that the paths may offer an additional online measure of effectiveness. Metrics we are
examining include path length, navigation speed, number of pauses, and changes in heading.

These results also have several interesting implications for the development of robot algorithms in this task. For example, it may be beneficial for the robot algorithm to initially classify a description as one that is conveying directions or one that is conveying location, given that the form and content of the descriptions vary as a function of communicative task. In a natural setting, of course, the speaker may not be explicit about whether he or she is providing directions or specifying location (that is, the speaker is not assigned a how or where task per se, as in our current work). This classification would need to be based on the properties of the descriptions themselves.

In addition, the robot algorithms will need to take into account the differential effectiveness of the two types of descriptions. The "how" descriptions may provide a more explicit approach to allow direct translation into robot commands; however, varying viewing perspectives will complicate the interpretation. To follow the directions of the "how" descriptions, a robot does not rely as much on perception, which may improve the efficiency of the fetch navigation in some static environments but not necessarily the effectiveness. In contrast, the "where" descriptions provide more hints using reference structures and objects so that the robot can navigate to the target using perception. The "how" descriptions may be easier to interpret but have a lower probability to navigate the robot to the specified target, especially given a dynamic environment in which reference furniture items have been moved. The "where" descriptions require the challenge of translating them into navigation commands but may provide more reliable fetch results, even in the case of moved reference items.

## Acknowledgments

This research was supported with funding by the National Science Foundation Grant IIS-1017097. We thank Xiao Ou Li for constructing the virtual house environment and Erin Gibson, Oscar Gonzalez, Diane Garritson, Ashley Herrmann, Mary Johnson, Kevin Kimberly, Kathleen Loftus, Angelique Laboy-Capparopa, Elliott Mitchem, and Joe Wernke for help collecting and coding the data.

# Hypothesis Space Checking in Intuitive Reasoning 

Christopher D. Carroll (cdcarroll@gmail.com)<br>Department of Psychology, Carnegie Mellon University<br>5000 Forbes Ave., Pittsburgh, PA 15213<br>Charles Kemp (ckemp@cmu.edu)<br>Department of Psychology, Carnegie Mellon University<br>5000 Forbes Ave., Pittsburgh, PA 15213

#### Abstract

The process of generating a new hypothesis often begins with the recognition that all of the hypotheses currently under consideration are wrong. While this sort of falsification is straightforward when the observations are incompatible with each of the hypotheses, an interesting situation arises when the observations are implausible under the hypotheses but not incompatible with them. We propose a formal account, inspired by statistical model checking, as an explanation for how people reason about these probabilistic falsifications. We contrast this account with approaches such as Bayesian inference that account for hypothesis comparison but do not explain how a reasoner might decide that the hypothesis space needs to be expanded.

Keywords: hypothesis testing; model checking; surprise

## Introduction

Many modern scientific disciplines are characterized by strange and unintuitive theories that previous generations of scientists never would have imagined. On a less dramatic scale, people often generate inventive explanations in their everyday lives. The existence of these unintuitive theories and inventive explanations raises an interesting question: how are these new theories and explanations discovered?

In many cases, the process of generating a new hypothesis starts when the reasoner decides that all of the hypotheses currently under consideration are wrong. In some cases, the available evidence is incompatible with every hypothesis under consideration, and this decision is straightforward. In other cases, however, the available evidence is implausible under, but not strictly incompatible with, the hypotheses. In cases like these, a reasoner may engage in hypothesis space checking to decide whether the hypothesis space is adequate or needs to be expanded.

Although psychologists have explored many approaches to hypothesis testing, most of these approaches are unable to account for hypothesis space checking. Bayesian accounts, for instance, are able to specify the relative strength of a hypothesis within the hypothesis space, but they do not provide criteria for evaluating the hypothesis space itself.

Statisticians, however, have developed various measures that quantify the extent to which observations are surprising under a given hypothesis or hypothesis space. In this paper, we investigate the possibility that formal measures of this kind can help to explain how people decide that all of the hypotheses in their current hypothesis space are probably wrong.

## Hypothesis space checking

Figure 1 illustrates the kind of situation where hypothesis space checking may be required. There is a universe $U$ of possible explanations for the given observations, but the hypotheses available to the reasoner fall within a hypothesis space $H$ that is a proper subset of $U$. It is possible, of course, that the true explanation is not in $H$; the ability to determine whether this is the case would be useful.

U

Figure 1: The universe $U$ includes all possible hypotheses, and hypothesis $H$ is the subset of these hypotheses that are currently available to the reasoner.

In principle, the adequacy of $H$ could be evaluated by computing whether the available observations are better explained by hypotheses that lie within or outside $H$. Bayesian inference provides one way to formalize this sort of comparative hypothesis testing. Bayes' theorem establishes that given the observed data $d$, the odds that $H$ contains the true explanation are:

$$
\begin{equation*}
\frac{P(H \mid d)}{P(\bar{H} \mid d)}=\frac{P(d \mid H) P(H)}{P(d \mid \bar{H}) P(\bar{H})} \tag{1}
\end{equation*}
$$

Equation 1 shows that the probability that $H$ contains the true explanation depends on (1) the relative probabilities of the data under $H$ and under its complement $\bar{H}$ and (2) the relative prior probabilities of $H$ and $\bar{H}$.

Although Equation 1 is appealing in principle, it is impossible to apply. Given that $\bar{H}$ consists of hypotheses that are unavailable to the reasoner, the term $P(d \mid \bar{H})$ will be impossible to compute (Earman, 1990, Ch. 7; Salmon, 1990). Consider the problem faced by a Newtonian physicist attempting to explain the anomalous precession of Mercury's perihelion. Although the physicist might be able to estimate $P(d \mid H)$ by considering various Newtonian explanations, estimating $P(d \mid \bar{H})$ has a paradoxical flavor:
how would the physicist compute probabilities with respect to theories he cannot currently imagine?

The paradox just described applies to any account (Bayesian or otherwise) that uses comparative hypothesis testing to address the problem defined by Figure 1. We therefore propose that this problem can only be addressed by non-comparative accounts of hypothesis testing in which the current hypothesis space is evaluated not in relation to specific competitors but on its own merits. In statistical practice, this sort of evaluation is often referred to as model checking or goodness-of-fit testing, and it typically involves comparing the actual observations to the expected distribution of the observations given the current hypothesis space. To the extent that the actual observations seem surprising in this context, there is an incentive to search for new hypotheses.

Comparative and non-comparative hypothesis testing seem to address distinct problems in that comparative hypothesis testing seems most useful for selecting among the hypotheses in $H$ and non-comparative hypothesis testing seems most useful for checking $H$ itself (for similar proposals, see Bayarri \& Berger, 1999; Gelman \& Shalizi, 2013; Gillies, 2007). We propose that both kinds of hypothesis testing are represented among people's intuitive inferences, but in this paper we deliberately focus on a situation that calls for non-comparative hypothesis testing.

## A model of non-comparative hypothesis testing

We propose that intuitive hypothesis space checking resembles the process specified in Figure 2. Specifically, we propose that people extract the salient or important features of the available observations, assess the extent to which those individual features are surprising under $H$, and then compute a global measure of surprise. This global measure of surprise provides a criterion for deciding whether to initiate the search for new hypotheses.

Figure 2: The reasoner extracts the salient features of the observations $d$, calculates a measure of surprise for each feature, and combines the surprise values into a global measure $S_{H}$ that captures the extent to which the data are surprising given the current hypothesis space $H$.

Statisticians have proposed various measures of surprise (e.g., Bayarri \& Berger, 1998; Weaver, 1948), but we focus on statistical null hypothesis testing, which is the bestknown statistical procedure that can be used for hypothesis space checking. To investigate null hypothesis testing in the simplest possible setting, we focus on situations where the
hypothesis space contains a single focal hypothesis $h$ (i.e., where $H=\{h\}$ ), but various generalizations of our approach are applicable to composite hypothesis spaces (e.g., Bayarri \& Berger, 1999; Gelman, Meng, \& Stern, 1996). In null hypothesis testing, the statistician first defines a real-valued test statistic $T(d)$ that measures some property of the data; this test statistic can be viewed as one of the features in Figure 2. To evaluate the surprise of the observed value of the test statistic, the statistician then considers the expected distribution of $P\left(d^{\text {rep }}\right)$ given $h$, where $d^{\text {rep }}$ is a random variable representing the data that might be observed if one were to replicate the "experiment" that produced the data. By comparing the observed value of $T(d)$ to the expected distribution of $T\left(d^{\text {rep }}\right)$ under $h$, the statistician can assess whether $T(d)$ is surprising under $h$. If the test statistic is defined such that greater values represent greater deviations from $h$, the surprise of $T(d)$ can be summarized by a $p$-value:

$$
\begin{equation*}
p_{T}(d)=P\left[T\left(d^{\text {rep }}\right) \geq T(d) \mid h\right] . \tag{2}
\end{equation*}
$$

Intuitively, the p-value represents the probability that the test statistic in the imagined replications would be at least as extreme as what was actually observed. Small p-values correspond to surprising results where the observations are unusually extreme.

In the final step of Figure 2, the reasoner combines the surprise measures for each feature into a global measure of surprise. To avoid making assumptions about how people integrate surprise ratings across different features, we focus on situations where there is a single surprising feature. In such situations, it seems reasonable to adopt the surprise value for that feature as the global measure of surprise.

## Method

To evaluate our proposed model of non-comparative hypothesis testing, we conducted an experiment in which participants learned about the ancient burial sites found on a remote island chain. The burial sites were marked by "cairns" (rock piles), and each island had been occupied by one of two cultures that constructed the cairns using different procedures: the "Chaotics" placed a random number of boulders in each cairn and the "Numerologists" placed a number of boulders in accordance with a mathematical function. The instructions explained that the Numerologists used different mathematical functions on different islands but that the mathematical function was always based on the number of people buried at the site. The participants were asked to infer which cultural group occupied an island from information about the burial sites on the island.

Because the number of possible mathematical functions is infinite, we expected that participants would not be able to assess every possible explanation for the observations. We expected that when faced with this impossible task, participants would consider the hypothesis that the Chaotics occupied the island as well as various hypotheses where the

Numerologists occupied the island and used some simple mathematical function. Because the materials were designed so that no simple mathematical function would explain the observed number of boulders at the burial sites, we expected that most participants would end up with a hypothesis space that contained a single viable hypothesis: the hypothesis that the Chaotics occupied the island. We expected that participants would check this hypothesis through a procedure resembling the one depicted in Figure 2. We predicted that when the observations were sufficiently surprising, participants would be willing to attribute occupancy to the Numerologists. Critically, we expected that participants would sometimes make this attribution even when they could not identify a single mathematical function that the Numerologists might have used. As we discuss later, this finding would be difficult to explain as a consequence of comparative hypothesis testing.

The experimental materials were based on three "test statistics" that reflected the salient numerical concepts of equality and magnitude (see Table 1). The equality test statistic, for example, was defined as the count of the burial sites that had the same number of people and boulders, and we expected participants to be surprised when many of the burial sites had the same number of people and boulders.

Table 1: Test statistics

| Name | Definition |
| :--- | :--- |
| Equality | number of burial sites where $b=p$ |
| Minimum | smallest observed value of $b$ |
| Repetition | frequency count for the most frequent $b$ |

Note. $p=$ the number of people at a burial site; $b=$ the number of boulders at a burial site.

## Participants

Sixty-one undergraduates participated in the experiment for course credit.

## Materials

Table 2 displays the observations presented to the participants. In the table and in the rest of the paper, we represent burial sites by two numbers separated by a dash, with the first and second numbers representing the number of people buried and boulders, respectively. Each row of the table corresponds to a different island. Twelve of the islands were designed to be surprising according to exactly one of the test statistics in Table 1 and four additional islands were designed to have no surprising features (the "None" islands). All of the islands contained either three or six burial sites, and the surprising islands were designed so that the coincidence involving the test statistic would be either moderately (. $01<p<.15$ ) or highly ( $p<.01$ ) surprising, as calculated from Equation 2.

The rightmost column shows the p -values for each island; these p -values summarize how surprising the observations would be if the Chaotics occupied the island. The p-values were calculated under the assumption that the number of boulders at a burial site could range from 1 to 100 (the
instructions informed participants that this was the case). To illustrate, consider the calculation of the p-value for the first island. The observed value of the equality test statistic for this island was one: there was exactly one burial site that had the same number of people and boulders. If the Chaotics occupied the island, then the equality test statistic would follow a binomial distribution with a probability parameter of .01 . Consequently, the probability that at least one of the burial sites on a three-site island has the same number of people and boulders is approximately .0297.

For the equality and minimum statistics, the four islands represented the four possible combinations of surprise condition and island size. For the repetition test statistic, we did not include a high-surprise island with three burial sites; instead, we included two moderate surprise islands with three burial sites. The reason for this was that creating a high-surprise "repetition" island with three burial sites necessitated selecting an island where each burial site had the same number of boulders. Because we were interested in situations where the participants would not be able to find a mathematical function to explain the observations, we chose not to present such an island.

Table 2: Experimental materials

| Feature | Srprs. | Sz. | Burial sites | $p$-value |
| :---: | :---: | :---: | :---: | :---: |
| Equality | M | 3 | 20-94, 39-39, 85-78 | . 0297 |
| Equality | H | 3 | 16-16, 65-65, 49-12 | . 0003 |
| Equality | M | 6 | $\begin{aligned} & 7-62,33-85,40-1, \\ & 53-26,59-59,94-18 \end{aligned}$ | . 0585 |
| Equality | H | 6 | $\begin{aligned} & 12-100,19-42,21-21, \\ & 32-14,75-75,93-56 \end{aligned}$ | . 0015 |
| Minimum | M | 3 | 15-86, 63-98, 84-75 | . 0176 |
| Minimum | H | 3 | 16-92, 42-97, 93-90 | . 0013 |
| Minimum | M | 6 | $\begin{aligned} & 5-67,24-81,35-72, \\ & 52-68,57-93,83-54 \end{aligned}$ | . 0108 |
| Minimum | H | 6 | $\begin{aligned} & 13-75,32-95,35-98 \\ & 37-80,72-85,96-94 \end{aligned}$ | . 0003 |
| Repetition | M | 3 | 3-19, 27-84, 74-19 | . 0299 |
| Repetition | M | 3 | 11-75, 39-28, 80-75 | . 0299 |
| Repetition | M | 6 | $\begin{aligned} & 2-5,6-97,31-69 \\ & 59-38,62-52,75-52 \end{aligned}$ | . 1404 |
| Repetition | H | 6 | $\begin{aligned} & 12-98,15-98,26-4 \\ & 45-73,60-53,77-98 \end{aligned}$ | . 0020 |
| None | - | 3 | 23-18, 40-69, 93-55 | - |
| None | - | 3 | 31-46, 80-24, 94-87 | - |
| None | - | 6 | $\begin{aligned} & 1-78,43-61,45-12 \\ & 52-35,83-87,91-46 \end{aligned}$ | - |
| None | - | 6 | $\begin{aligned} & 1-26,8-92,14-36 \\ & 35-20,40-11,63-45 \end{aligned}$ | - |

Note. Srprs. = surprise condition; Sz. = island size; M = moderate surprise; $\mathrm{H}=$ high surprise .

All of the observations were designed so that at most one of the test statistics in Table 1 would be surprising at a level greater than $p=.30$. In addition, we controlled for the distribution of even and odd numbers and for the correlation between the number of people and number of boulders.

## Procedure

Participants were provided with a cover story that described their task and the Chaotics and Numerologists. Participants then completed a familiarization trial. On both the familiarization and experimental trials, the burial sites were represented by "cards" on a computerized display. Each card listed one number next to a stick figure and another number next to an illustration of a boulder pile. These numbers represented the number of people buried at the site and the number of boulders in the cairn, respectively. Participants were encouraged to re-arrange the cards by clicking and dragging them. The interface also provided buttons to automatically sort the cards according to either the number of people buried or the number of boulders. For the practice trial, the three burial sites were 31-1, 48-5, and $90-4$, and participants were told that the island was occupied by Numerologists who placed a number of boulders equal to the number of prime factors of the number of people buried at the site (e.g., because $48=3 * 2 * 2 * 2 * 2$, the burial site with 48 people had 5 boulders). This rule was intended to establish that the Numerologists were sophisticated mathematicians who had access to a wide variety of mathematical properties and rules. In doing so, our goal was to establish a universe of possible explanations that would be too large to consider in full.

Participants reported their inferences about which cultural group had occupied the island using a seven-point rating scale where the leftmost point was labeled "definitely Chaotics", the rightmost point was labeled "definitely Numerologists", and the middle point was labeled "not sure". Responses were coded from -3 ("definitely Chaotics") to 3 ("definitely Numerologists"). Participants who indicated that the Numerologists were more likely to have occupied the island than the Chaotics were also asked to indicate whether they had "discovered ANY function that the Numerologists might have used to determine the number of boulders." Participants answering affirmatively were asked to describe the function. Finally, at the end of each trial, participants were asked to list "any features, coincidences, or patterns in the burial sites that would have been surprising if the Chaotics occupied the island." Participants were provided with three text input fields and could identify up to three features, coincidences, or patterns. The responses to this prompt were intended to measure whether participants noticed the relevant features or any other features of the observations.

After completing the familiarization trial, the participants completed experimental trials for each of the 16 islands listed in Table 2. The presentation order was randomized.

## Results

A preliminary analysis confirmed that participants frequently noticed the relevant features. For each feature, a majority of the participants listed the feature as surprising on at least one of the relevant trials; the proportions were .59 for the minimum feature, .72 for the equality feature and .66 for the repetition feature. A second preliminary analysis
confirmed that the islands did not contain many surprising features other than the intended relevant features. Participants listed other features on only $16.8 \%$ of the experimental trials. The proportion of participants listing other features was similar across the experimental conditions: a logistic regression with categorical predictors corresponding to the surprise conditions, the relevant features, and the island sizes did not explain a significant proportion of the variance in the probability that participants noticed other features, $R^{2}=.26, F(5,8)=0.55, p=.74$.

To evaluate our formal approach we compared the modelderived p-values and the mean culture ratings. Because people often evaluate probabilities on a logarithmic scale (e.g., Gonzalez \& Wu, 1999), we adopted the logit (i.e., the log-odds) of the island p-values as the model's measure of surprise (lesser values corresponded to greater surprise). When calculating the mean culture ratings for each condition, we excluded any culture ratings for which the participant who provided the rating failed to identify the relevant feature as surprising at any point during the experiment. The rationale for this exclusion is that a participant who did not notice the relevant feature could not have been surprised by it.

Figure 3: The culture rating as a function of the logit of the p-value. Different features are represented by different marker shapes, different island sizes are represented by different marker sizes (large markers correspond to islands with six burial sites), and different surprise conditions are represented by different shadings (black markers correspond to high-surprise islands).

Figure 3 shows the comparison of the p -values and the mean culture ratings. A linear regression confirmed that the logit of the p-values explained a significant proportion of the variance in the ratings, $R^{2}=.82, F(1,10)=44.2, p<$ .001. This relationship was essentially unchanged even when culture ratings were included for participants who failed to notice the relevant features, $R^{2}=.77, F(1,10)=$ $33.83, p<.001$. Inspection of Figure 3 also suggests that the islands with six burial sites may have been viewed as less surprising than the islands with three burial sites. The statistical significance of this finding was confirmed by a multistep regression that showed that island size predicts variance in the culture ratings above and beyond the variance explained by the logit of the p -values, $\Delta R^{2}=.14$,
$F(1,9)=25.7, p=.001$. This finding may reflect a general tendency to underestimate the extent to which deviations from the mean become increasingly surprising for larger samples (Kahneman \& Tversky, 1972).

Although our participants compared hypotheses in the sense that they reported whether the Chaotics or Numerologists occupied an island, it seems difficult to explain their inferences as the product of what we have called comparative hypothesis testing. Consider, for example, the difficulties that arise in explaining the culture ratings by appealing to Equation 1, which in the context of our experiment involves the comparison of $P(d \mid$ Chaotics $)$ and $\quad P(d \mid$ Numerologists $)$. Note that $\quad P(d \mid$ Chaotics $)$ depends only on the number of burial sites on the island: for any island with three burial sites, for example, $P(d \mid$ Chaotics $)$ is $(1 / 100)^{3}$. Thus, if the participants' inferences were indeed based on Equation 1, then the differences in the culture ratings must have arisen primarily because of differences in $P(d \mid$ Numerologists $)$.

If $P(f \mid$ Numerologists $)$ is a prior distribution over specific functions $f$, then

$$
\begin{equation*}
P(d \mid \text { Numerologists })=\int_{f}(d \mid f) P(f \mid \text { Numerologists }) \tag{3}
\end{equation*}
$$

The integral in Equation 3 will be large to the extent that there are many functions that are plausible a priori ( $P(f \mid$ Numerologists $)$ is high) and consistent with the data $(P(d \mid f)>0)$. Approximating this integral using sampling or some other standard method would involve identifying one or more functions $f$ for which $P(d \mid f)>0$. Our participants, however, rarely identified even a single function $f$ for which $P(d \mid f)>0$. Recall that participants who claimed that the Numerologists occupied an island were asked whether they had found any mathematical function to explain the observations. Participants reported finding a function on only $15.5 \%$ of these occasions. Furthermore, the "functions" that these participants reported were often not fully specified functions at all. One representative participant claimed to have found a function but then wrote that "I don't have a function, but when put roughly on a graph it almost-kinda-sorta forms a wave." Summarizing his inference, the same participant later added, "I'm grasping at straws though." Figure 4, furthermore, shows that the relationship between function finding and the culture ratings is weak and, according to a linear regression, non-significant, $R^{2}=.016, F(1,12)=.19, p=.67$.

Could participants have estimated $P(d \mid$ Numerologists $)$ without identifying a single specific function $f$ that might have been used by the Numerologists? Might participants, for example, have used some computational procedure that approximates the integral in Equation 3 without actually identifying any specific functions? We cannot exclude this possibility, but we do not know of any such procedure. In the absence of a known procedure that approximates the integral in Equation 3 given some plausible specification of the prior, it seems reasonable to conclude that our participants did not rely on comparative hypothesis testing.

Figure 4: The mean culture ratings as a function of the proportion of participants who claimed to have identified a mathematical function that explained the observations.

As a final test of our model, we investigated whether the model-derived surprise predicted the culture ratings even after excluding trials in which participants claimed to have found a mathematical function. To do so, we recalculated the mean culture ratings while excluding any culture rating where either (1) the participant reported finding a mathematical function or (2) the participant never noticed the relevant feature (as in previous analyses). A linear regression on these recalculated culture ratings confirmed that the logit of the p-values remained strongly predictive of the culture ratings, $R^{2}=.87, F(1,10)=69.43, p<.001$.

Figure 5: Culture ratings as a function of surprise condition and the number of burial sites. The error bars show standard errors.

Our analyses so far have focused on the islands that were designed to be of "moderate" or "high" surprise. We compared these islands to the unsurprising "None" islands by analyzing the mean culture ratings as a function of surprise condition. Figure 5 shows that participants were much more willing to attribute island occupancy to the Numerologists in the high-surprise condition. The similarity between the culture ratings for the unsurprising and moderately-surprising condition was not expected, but it may be that the culture ratings are only influenced by observations once the surprise exceeds a certain threshold. Figure 5 also suggests that island size might have influenced
the culture ratings, either on its own or in an interaction with the surprise condition. A within-subjects ANOVA showed that the culture ratings were influenced by both surprise condition, $F(2,100)=27.80, p<.001$, and island size, $F(1$, $50)=6.89, p=.01$; the interaction between surprise condition and island size was marginally significant, $F(2$, 100) $=2.89, p=.06$. In post-hoc analyses, we confirmed that the culture ratings in the unsurprising and moderatelysurprising conditions were not significantly different, $t(50)$ $=.80, p=.43$, and that the culture ratings in the highsurprise condition were significantly different from those in the unsurprising, $t(50)=5.66, p<.001$, and moderatelysurprising, $t(50)=6.74, p<.001$, conditions.

## Discussion

The experimental findings suggest that people perform hypothesis space checking using an intuitive version of noncomparative hypothesis testing. The findings are not naturally explained by comparative hypothesis testing. This is not to say that comparative hypothesis testing is never useful: recall that our experiment was deliberately designed so that comparative hypothesis testing would be of limited relevance, and comparative hypothesis testing undoubtedly plays an important role in other settings. Moreover, although comparative hypothesis testing cannot explain our main experimental findings, there are reasons to believe that it influenced our participants' thinking to some extent. Participants were often reluctant to fully commit to the idea that the Numerologists occupied the island even after observing very surprising observations: even in the most surprising condition ( $p \approx .0001$ ), the mean culture rating was only 0.73 . One interpretation of this finding is that people are often unwilling to fully reject a hypothesis space until a better explanation is discovered (see also Griffiths \& Tenenbaum, 2007).

Other researchers have proposed that people employ methods such as sampling to approximate Bayesian inference in situations where it is impossible for them to evaluate the entire hypothesis space (e.g., Sanborn, Griffiths, \& Navarro, 2010). These methods, however, do not address the problem posed by Figure 1. Sampling from $H$ may be useful if this hypothesis space is large, but this approach does not explain how a reasoner might decide that the true hypothesis lies outside $H$. Supporters of sampling might respond that the problem of hypothesis space checking never arises because the space of available hypotheses is always equivalent to $U$. This position, however, seems incompatible with the intuition that scientists and others are sometimes able to generate hypotheses and explanations that are genuinely new.

The justifications for comparative and non-comparative testing remain controversial among statisticians and philosophers (e.g., Howson \& Urbach, 1989/1996; Mayo, 1996; see also Gigerenzer et al., 1990, Chapter 3), but both kinds of hypothesis testing seem necessary to account for the inferences that people make. Non-comparative hypothesis testing is especially notable for the role it plays
in the discovery of new hypotheses. These discovery processes, while often mysterious and difficult to explain, are involved in many of the most interesting inferences that people make. Statistical model checking does not explain where new hypotheses come from, but it can explain why people initiate the search for new hypotheses.

# Individuals recapitulate the proposed evolutionary development of spatial lexicons 

Alexandra Carstensen (abc@berkeley.edu)<br>Department of Psychology, University of California, Berkeley, CA 94720 USA<br>Terry Regier (terry.regier@berkeley.edu)<br>Department of Linguistics, Cognitive Science Program, University of California, Berkeley, CA 94720 USA

#### Abstract

When English speakers successively pile-sort colors, their sorting recapitulates an independently proposed hierarchy of color category evolution during language change (Boster, 1986). Here we extend that finding to the semantic domain of spatial relations. Levinson et al. (2003) have proposed a hierarchy of spatial category evolution, and we show that English speakers successively pile-sort spatial scenes in a manner that recapitulates that proposed evolutionary hierarchy. Thus, in the spatial domain, as in color, proposed universal patterns of language change based on crosslanguage observations appear to reflect general cognitive forces that are available in the minds of speakers of a single language.

Keywords: Language and thought; spatial cognition; color naming; semantic universals.

## Language as a mirror of the mind

A core question in cognitive science is whether the structure of language reflects the structure of the human mind. Languages vary widely, both in their formal structure and in their semantic categorization of the experienced world (Evans \& Levinson, 2009). At the same time, similar structures and categories appear in unrelated languages, and many logically possible linguistic structures and categories are not attested. A natural question is whether this constrained variation in language reflects universals of human cognition.

One means of pursuing this question concerns language change. One may observe or infer general patterns in the ways languages evolve over historical time, and ask whether these patterns of change, based on observation across languages and across time, are also evident at a given moment in the minds of individuals who speak a single language.

Such a demonstration has already been made in the semantic domain of color (Boster, 1986), and here we present an analogous demonstration in the semantic domain of spatial relations. In what follows, we first describe the Boster (1986) study on color. We then describe recent work on spatial language (Levinson et al., 2003) that proposes a hierarchy for the evolution of spatial categories over historical time. We next present our study, which closely follows Boster's in design. Our central finding is that English speakers successively pile-sort spatial scenes in accordance with Levinson et al.'s (2003) proposed evolutionary hierarchy. We conclude from this finding that generalizations concerning language change may reflect
cognitive forces in the mind of speakers of a single language, in the domain of space as well as in that of color.

## Color categories in language and cognition

Boster (1986) asked speakers of English to successively pile-sort colors. He initially instructed participants to sort a set of eight colors into two "natural groupings" on the basis of similarity, imagining that they spoke a language with only two color terms. He then asked them to subdivide either of those two groups, making three groups total-and so on until each color was in a group by itself. Finally, he tested whether these hierarchical pile-sorts matched a linguistic hierarchy that had been proposed to represent the historical evolution of color categories across languages (Kay \& McDaniel, 1978, elaborating a proposal by Berlin \& Kay, 1969). That hierarchy of color term evolution is shown in Figure 1. ${ }^{1}$ The top split of this hierarchy represents the claim that a two-term color naming system will tend to group BLUE, PURPLE, GREEN, and BLACK into one category, while grouping white, red, orange, and yellow into the other-as in the language Dani (Heider, 1972). Splits lower in the tree represent claims about finer-grained linguistic divisions, which also tend to match cross-language synchronic and diachronic data (e.g. Dougherty, 1977; Kay, 1975).

Figure 1: Kay and McDaniel's (1978) proposed evolutionary hierarchy of color terms.

Boster (1986) found that there was a significant tendency for successive pile-sorts by English speakers to follow the "successive differentiation" (Kay \& McDaniel, 1978: 640)

[^28]of this linguistic evolutionary hierarchy. This finding suggests that, at least in the semantic domain of color, the forces that produce language change over time may be present in the mind of an individual at a given moment.

## An evolutionary hierarchy for spatial language

We wished to further test this claim in a different semantic domain: spatial relations. For this, we required an evolutionary hierarchy of spatial terms, to play the same role in our analysis that Kay and McDaniel's (1978) color hierarchy played in Boster's. Levinson et al. (2003) have suggested such a spatial hierarchy, based on cross-language observations of spatial systems, and drawing an explicit analogy with the above-cited work on color. ${ }^{2}$ They hypothesized that spatial topological categories in the world's languages evolve such that "large categories will tend...to be split into [smaller] categories over time under particular functional pressures" (Levinson et al., 2003: 512), as shown below in Figure 2, to be interpreted as the color hierarchy in Figure 1 was interpreted. ${ }^{3}$

Figure 2: Levinson et al.’s (2003) proposed evolutionary hierarchy of topological spatial concepts.

## The present study

The present study examines successive pile-sorting of spatial scenes by speakers of English, and asks whether these pile-sorts recapitulate the evolutionary spatial category hierarchy proposed by Levinson et al. (2003). If so, that result would generalize the central claim of Boster (1986) to a new semantic domain.

[^29]
## Methods

Following Boster (1986), we performed an experiment with two conditions in which participants sorted spatial stimuli. In both conditions, participants were instructed to sequentially subdivide the eight stimuli-either the line drawings of Figure 3 (scene sorting condition) or corresponding verbal labels (label sorting condition)-into partitions with $2,3,4,5,6$, and finally 7 groups, at which point there were no further decisions to make about which group to split next.

## Participants

A total of 60 participants took part in the two conditions, with 30 participants in each. The population in our study was a convenience sample of the UC Berkeley community; the majority were undergraduate or graduate students, and received either course credit or monetary compensation for their participation. Of the 60 people who completed the task, data from 15 participants were excluded from analysis: 10 due to missing data or failure to follow instructions, 3 because they were not native speakers of English, and 2 who reported familiarity with the color or spatial relational hierarchies proposed by Berlin and Kay (1969), Kay and McDaniel (1978), and/or Levinson et al. (2003). Data from the remaining participants were included in all analyses. Accordingly, 24 participants were included in the scene sorting condition ( 5 female, mean age $=25.6$ ) and 21 participants in the label sorting condition ( 12 female, mean age $=21.3$ ), all of whom had learned English by age 4 (although a number were bilingual), and were naïve to the research hypothesis and related findings.

## Spatial scene sorting

Participants were presented with eight scenes from Bowerman and Pederson's Topological Relations Picture Series (TRPS; 1992). The scenes were arranged linearly on a tabletop in a randomly shuffled order and participants were instructed to successively divide them based on the similarity of the depicted spatial relationships. Each of the eight scenes-shown in Figure 3-depicts an orange figure object located relative to a black background, representing the following spatial relations: NEAR (TRPS scene 37), ON (59), IN (60), ATTACHED (38), UNDER (31), INSIDE (54), ON TOP (34), and OVER (36). These particular scenes were chosen to represent focal "attractors" in spatial semantics (Levinson et al., 2003), analogous to the focal colors proposed by Berlin and Kay (1969) and used in Boster's (1986) color chip sorting task. Each focal spatial scene was selected based on (1) consistency with Levinson et al.'s (2003) characterization of focal attractors within the core spatial categories named above, and (2) the preferences of native English speakers in a pilot study.

Instructions were adapted from Boster (1986) and asked participants to imagine they spoke a language with only two spatial words, and accordingly, to divide up the relations shown in the scenes to make two natural groupings. After participants initially split the eight scenes into two groups,
they were instructed to successively subdivide their categories until all scenes were separated, and each subdivision was recorded to create a full ordered hierarchy of divisions for each participant (see Figure 4 below for an example).

Figure 3: Focal scenes from the Topological Relations Picture Series used in the sorting tasks.

## Spatial label sorting

The spatial label sorting task was identical to spatial scene sorting, except that in this task, participants were presented with the written English spatial expressions NEAR, ON, IN, ATTACHED, UNDER, INSIDE, ON TOP, and OVER. The labels were presented on paper in a randomly shuffled order, and again, participants were instructed to successively divide the stimuli based on the similarity of the spatial relations they describe. As in Boster (1986), the images from the visual sorting task were made available to participants for reference, although they were instructed to base their partitions on the meanings of the spatial phrases themselves, rather than any specific components of the reference scenes.

Figure 4: Example hierarchy from a participant in the scene sorting condition.

## Analysis

Following Boster (1986), we first measured the similarity between Levinson et al.'s (2003) hierarchy (which we refer to as the model) and the empirical data. We then compared this observed similarity to that between the model and random permutations of the empirical data, to determine whether the observed similarity was significant. Finally, we asked whether there was a significant amount of residual data left unaccounted for by the model.

## Similarity metric

In order to compare the empirical color hierarchies made by participants in his experiment to Kay and McDaniel's (1978) theoretical hierarchy representing the diachronic stages of color lexicon evolution, Boster (1986) converted each hierarchy to a similarity matrix. For each pair of colors, he determined the earliest stage in the hierarchy at which those two colors were separated into different groups, and took this to be the similarity between them. Thus, each non-identical pair had a minimal similarity of 1 , meaning they were grouped together only when all eight colors were grouped together, and a maximal similarity of 7, meaning that they were the last pair to be separated, only after the other 6 colors were fully partitioned into groups of 1 each.

We applied the same analysis to the spatial hierarchies produced in this experiment, creating an $8 \times 8$ matrix representing the similarities across all pairs of spatial relations for each participant. Following Boster (1986), we then averaged across corresponding cells in the matrices from all participants in a given condition to create two group similarity matrices-one based on scene sorting and the other on label sorting. As in the color study, we used Pearson correlations to measure the similarity between matrices, where correlations were calculated based on all corresponding pairs of off-diagonal cells.

## Model comparison

Given the empirical similarity matrices from each condition and Pearson correlations as a metric of similarity between such matrices, we ask whether the English speakers in our experiment created hierarchies that were systematically consistent with the cross-linguistic evolution of spatial lexicons as hypothesized by Levinson et al. (2003).

As with the empirical hierarchies, we created similarity matrices based on the Levinson et al. hierarchy which models "successive fractionation of composite concepts." ${ }^{4}$ Like the Kay and McDaniel model (1978), Levinson et al.'s hierarchy includes some variability in the relative order with which certain categories emerge. For instance, the authors leave intentional variability in whether UNDER or a cluster of ON-like relations (i.e. ON, ON TOP, ATTACHED, OVER) are

[^30]split from a more general composite locative concept first. In keeping with Boster's treatment of such variability in the Kay and McDaniel model, we created two model-consistent hierarchies expressing both alternatives (one of which is shown in Figure 2). ${ }^{5}$ Thus, the similarity matrix representing the Levinson et al. model was created by averaging the similarities derived from these two model-consistent hierarchies.

We assessed the alignment of our empirical and model similarity matrices using Pearson correlations, so in order to determine whether these observed correlations were significantly greater than expected by chance, we used Monte Carlo simulations to create a distribution of comparison correlations. To do this, we randomly permuted the labels on our empirical similarity matrices, creating 1,000 permuted variants of each. Each permuted variant was comparable to the original in that all similarity values were preserved in the matrix, but simply re-assigned to different pairings of spatial foci. We then measured the correlation between each of these permuted matrices and the model matrix to determine whether the correlation between the model and the actual empirical data was greater than chance, i.e. that the actual data was more strongly correlated with the model than $95 \%$ of random permutations derived from it.

## Residual analysis

Because our model comparison was based on correlations, it is difficult to assess how well the model explains the observed data beyond testing whether it does so to a significant degree. To this end-and again following Boster's (1986) methods-we employed an analysis designed to determine whether a significant portion of the observed similarity matrix data was left unexplained by the model (Hubert \& Golledge, 1981). The model similarity matrix and two empirical similarity matrices were standardized by subtracting the mean of all values for each matrix from each cell in that matrix, and dividing the result by the standard deviation of the original values in that matrix. The values in each cell of the now standardized model matrix were then subtracted from corresponding cells in the standardized empirical matrices to determine the residual empirical data left unexplained by the model. We measured the Pearson correlations between these residual matrices and their corresponding empirical counterparts.

If the residual matrices no longer bear significant similarity to their full empirical counterparts, we take that to

[^31]mean that the Levinson et al. (2003) model has accounted for the explainable empirical variation. In order to test the significance of the correlation between the residual and observed data, we again create a set of 1,000 simulated matrices by randomly permuting the labels on each of the residual matrices. We measure the correlations between these permuted simulations of the residual matrices and the original empirical matrix and compare this distribution of correlations to that between the actual residual matrices and their empirical counterparts. As before, we take the observed correlation to be significant only if it is greater than that of $95 \%$ of the randomly permuted variants.

## Results

Our similarity analysis found strong correlations between the Levinson et al. (2003) model matrix and the empirical matrices derived from spatial scene sorting ( $r=$ 0.638 ) and spatial term sorting ( $r=0.664$ ), as well as between the two empirical matrices themselves ( $r=0.861$ ). These correlations are presented in Table 1 below alongside the corresponding correlations from Boster (1986). The model and empirical matrices themselves are shown in Tables 2-4.

Table 1: Pearson correlations compared to Boster (1986).

| Correlation | Present study | Boster |
| :--- | :--- | :--- |
| Image sorting vs. model | 0.64 | 0.84 |
| Label sorting vs. model | 0.66 | 0.81 |
| Image vs. label sorting | 0.86 | 0.87 |

| ONTOP | 1.38 | 1.43 | 1.76 | 1.76 | 3.24 | 8.00 | 1.86 | 5.33 |
| ATTACHED | 2.48 | 2.19 | 1.67 | 2.38 | 1.24 | 1.86 | 8.00 | 2.24 |
| ON | 1.57 | 1.38 | 1.52 | 1.67 | 2.67 | 5.33 | 2.24 | 8.00 |

Our permutation analysis found that the randomly permuted variants of the empirical scene matrix were more strongly correlated with the Levinson et al. (2003) model predictions than was the empirical scene matrix itself in only 5 out of 1000 simulations, corresponding to a 1 -tailed $p$-value of .005 . Similarly, only 3 out of 1000 permuted versions of the empirical spatial label matrix were more strongly correlated with the model than was the empirical label matrix itself, corresponding to a 1 -tailed $p$-value of .003. These results (pictured in Figures 5-6) confirm that the observed correlations represent a significant degree of similarity between the empirical matrices and that of the spatial hierarchy model.

Figure 5: Pearson correlations between permuted spatial scene matrices and model matrix.

Figure 6: Pearson correlations between permuted spatial label matrices and model matrix.

The correlation between the empirical scene sorting data and the corresponding residual data after subtracting out the model-explained variation is negligible and not significant ( $r=-0.072$; Monte Carlo 1-tailed $p=0.674$ ). Results are comparable for tests of the correlation between empirical and residual data in the label sorting task $(r=0.073 ; p=$ 0.340 ), which may be interpreted as suggesting that the Levinson et al. (2003) model accounts for all of the explainable observed variation.

## Discussion and conclusions

We find substantial evidence in support of the hypothesis that English speakers synchronically recapitulate Levinson et al.'s (2003) proposed cross-linguistic patterns in the diachronic evolution of spatial lexicons. Our finding in the spatial domain directly parallels that of Boster (1986) in the color domain. Taken together, our finding and his suggest that, at least in these two semantic domains, proposed patterns of language change may be reflected in the minds of individuals at a given moment.

At the same time, there are at least two grounds for caution. First, as we have noted, the Levinson et al. (2003) hierarchy was intended as a tentative diachronic hypothesis, based on synchronic cross-language observation-not as a firm diachronic claim. Direct assessment of that hierarchy using historical data has to our knowledge not yet been conducted, and would be needed before our account can be considered to concern actual, rather than merely proposed, patterns of spatial language change. Second, our analyses, like Boster's (1986), were based on a comparison between model predictions and an aggregate measure of all participants' sorting. When viewed in this way, the evidence does support the recapitulation claim. However, no participants either in Boster's (1986) study or in ours actually recapitulated the model predictions exactly. This may not be surprising given the large number of hierarchical pile-sorts that are possible, some of which are only minimally different from model predictions. Still, in future research it would be informative to analyze such data in a way that separately measures how close each participant came to the model prediction, rather than rely solely on an aggregate measure of all participants' behavior. Such analyses may support a more precise picture of the extent to which individuals recapitulate broad proposed generalizations concerning language change. The present study, like Boster's (1986), has nonetheless demonstrated that such recapitulation is clearly present as a general shared tendency-and that in this sense at least, the character of language change may reflect the structure of the mind.

# The development of predictive processes in children's discourse understanding 

Marisa Casillas<br>middyp@stanford.edu<br>Department of Linguistics<br>Stanford University

Michael C. Frank<br>mcfrank@stanford.edu<br>Department of Psychology<br>Stanford University

#### Abstract

We investigate children's online predictive processing as it occurs naturally, in conversation. We showed 1-7 year-olds short videos of improvised conversation between puppets, controlling for available linguistic information through phonetic manipulation. Even one- and two-year-old children made accurate and spontaneous predictions about when a turn-switch would occur: they gazed at the upcoming speaker before they heard a response begin. This predictive skill relies on both lexical and prosodic information together, and is not tied to either type of information alone. We suggest that children integrate prosodic, lexical, and visual information to effectively predict upcoming linguistic material in conversation.

Keywords: Prediction; online comprehension; turn-taking; timing; child language; prosody; eye-tracking

## Introduction

Conversation is the primary way we use language. It is most often spoken face-to-face with two or more speakers, and is deeply embedded in our current interactional context. Participants in conversation don't just listen; given that inter-turn gaps are so brief, speakers must be simultaneously planning at least part of their response while the current speaker is still talking (Sacks et al., 1974; Stivers et al., 2009). So under normal conditions, listeners deal with critically different processing pressures during conversation than they do in rigidly controlled experiments. For children especially, experience and skill in processing and conversation can be critical to later language development (e.g., Weisleder, 2012). The current study seeks to draw a link between language processing in the lab and language processing in broader contexts by tracing predictive processing during conversation across a broad developmental sample.

Timing is critical in conversation because, in addition to parsing the linguistic signal for its parts and meanings, conversational participants are interested in the upkeep of the ongoing interaction. For example, if someone asks you, "What are your plans for dinner?" you are obligated to do more than just parse the linguistic signal; you must respond. You can't just respond at your convenience either-especially for an implied invitation like this one, a slight hesitation might communicate that you will turn the offer down. This is a substantial cognitive load to bear since speakers must quickly figure out what was said and how to respond. Predictive processes can help maintain the flow of conversation by allowing us to plan for what is likely to happen next in the interaction.

When listening to a single utterance, we make predictions about what the speaker will say next. Many studies have shown that we can use a wide variety of linguistic and nonlinguistic cues to incrementally update our expectations about
what linguistic material will follow (e.g., Altmann \& Kamide, 1999; Ito \& Speer, 2008; Snedeker \& Yuan, 2008).

In multi-utterance contexts, like conversation, speakers must also coordinate their ongoing actions, and so our predictive prowess is even more to our advantage than it is in the lab. There is both naturally-occurring and experimental evidence that adults effortlessly anticipate when a speaker switch will occur during conversation. In order to respond with brief gaps, they need to accurately predict when to begin speaking (Sacks et al., 1974). There is also experimental evidence that adults can anticipate upcoming turn-structurewhen asked to press a button when they think a speaker will finish her turn, adult listeners demonstrate incredible timing accuracy ( $M=168 \mathrm{~ms}$ from the offset of speech; de Ruiter et al., 2006). They also spontaneously track turn-timing and anticipate upcoming speakers with their gaze when watching videos of conversation (Tice \& Henetz, 2011).

Here we ask: do children also make online predictions about conversation? We focus on how children process the multi-utterance speech around them because, as mentioned, children's conversational skill and experience can influence their later language learning.

Children learn language in the context of conversation, and their conversational skills allow them to practice comprehending and using language with others. Children begin to take turns in early infancy, but their coordination of turn-timing with others takes several years to develop. By four months, infants regularly engage in coordinated back-and-forth interactions with their caregivers (Masataka, 1993). Twelve-month-old infants who are watching two-person conversations can (1) track who is speaking, and (2) expect speech to be responded to verbally (Thorgrímsson et al., 2011). Despite this, even at $5 ; 0$, children's timing is significantly delayed compared to adults'-their response delay at $3 ; 0$ is up to 10 times slower (Casillas et al., in prep)—leading some to believe that children can't or don't perform the same predictive processing that adults do (Garvey \& Berninger, 1981). ${ }^{1}$

We propose that, on the contrary, children develop their predictive turn-taking skill early in life, and that their apparent delay is due to the time needed to plan and execute a response. Thus, when children simply observe an ongoing interaction, they show predictive timing similar to adult norms. Casillas and Frank (2012) found that when children and adults watched videos of conversation in a language they didn't speak, they were able to use the available information

[^32](prosodic, temporal, and visual) to track and anticipate the ongoing turn structure with their gaze. Because some linguistic units are more informative than others in predicting turnboundaries (e.g., words > intonation; de Ruiter et al., 2006), we also hypothesize that, like adults, children's online predictions about turn-taking are more heavily influenced by lexical information than they are by prosodic information. By testing these proposals we can (1) track children's development of predictive turn processing during discourse while (2) also beginning to tease apart which linguistic cues children attend to in making their predictions about turn-structure. We measured children's online anticipation about who will speak next in conversation and found that children use multiple linguistic cues to make accurate predictions about what will come next-and they do so even at 1-2 years old.

## Method

We tracked children's eye movements as they watched short videos of conversation to measure their predictive gaze to upcoming speakers at points of speaker-transfer. We controlled the audio signal to limit children's access to either prosodic information or lexical information, making comparisons to their gaze behavior in normal audio conditions and conditions without any linguistic information. We focus here on effects of linguistic information, so we eliminated visual cues to turn-taking by using videos of puppets to replace the original videos of our speakers.

## Participants

We recruited 129 children ages $1 ; 0-7 ; 0$ from the Children's Discovery Museum in San Jose, CA, to participate in the current study. We collected data from 20-23 children for each of the six 1-year age groups. All participants were native English speakers, though some parents reported that their child heard a second (and sometimes third) language at home. ${ }^{2}$

## Materials: Puppet videos

Audio-recordings We recorded six 20-25 second twoperson conversations for use in the puppet videos. Each of the six conversations featured a native English-speaking male and female talker. Talkers were directed to improvise a short conversation on a given topic (one of: 'riding bikes', 'pets', 'breakfast', 'birthday cake', 'rainy days', 'the library'). We asked talkers to talk "as if they were on a children's television show" to establish a child-friendly style. We gave talkers approximately five minutes to work out a basic conversation and then perform it with minimal practice. We edited each conversation to a 20-25 second clip for use in the final video stimuli.

[^33]

Figure 1: The six puppet pairs (and associated audio conditions). Each pair was linked to three distinct conversations from the same condition across the three experiment versions.

Audio Manipulation To control for the linguistic information available in the final puppet videos, we phonetically manipulated the recordings to fall into four conditions: Normal, Words-only, Prosody-only, and No Discernible Speech. Normal videos simply used the 20-25 second audio recording. Words-only videos featured manipulated speech in which intonation was flattened to each talker's average pitch (F0) and every syllable nucleus and coda duration were set to each talker's average nucleus and coda duration. ${ }^{3}$ To do this we used PSOLA resynthesis in Praat (Boersma \& Weenink, 2012). The resulting audio signal was devoid of pitch and durational cues to turn-boundary, so we referred to this audio as 'robot' speech when talking to children. Prosody-only videos also featured manipulated speech, in which the original audio recording was low-pass filtered at 500 Hz with a 50 Hz Hanning window (following de Ruiter et al., 2006). Low-pass filtering removes the phonetic information used to distinguish between phonemes, and so the resulting audio has no identifiable words, but retains the original intonational and rhythmic qualities of the conversation. Low-pass filtered audio sounds muffled, like voices under water, so we referred to this audio as 'merperson' speech. To create Non-discernible speech audio, we overlaid eight different child-oriented conversations (not including the original one) to create multi-talker babble. This is sometimes referred to as 'cocktail party' speech, but we referred to it as 'birthday party' speech. Finally, the Prosody-only audio sounded much quieter than the other conditions because it lacked acoustic energy above 500 Hz , so all other audio conditions were adjusted to match its lower volume.
Video-recordings We then created puppet videorecordings to match the final audio signals. The puppets were designed to be minimally expressive so that the experimenter could only control the opening and closing of their mouths. There were three Normal condition puppet pairs-'red',

[^34]

Figure 2: Proportion gaze to the answerer during the first 333 ms of the answer. Age in years is plotted on the x -axis for each of the four conditions (Question-Answer switches = dark gray; Non-Question-Answer switches = light gray). The vertical bars show the $95 \%$ confidence intervals around each point.

| Condition | Current | Non-current | Elsewhere |
| :--- | :--- | ---: | ---: |
| No discernible speech | 0.51 | 0.15 | 0.35 |
| Prosody only | 0.55 | 0.14 | 0.31 |
| Words only | 0.65 | 0.14 | 0.21 |
| Normal speech | 0.68 | 0.14 | 0.18 |

Table 1: Overall proportion gaze, averaged across all participants, to the current and non-current speakers (and elsewhere) during utterances.
'blue' and 'yellow' ones-and one puppet pair for each of the other conditions: 'robots', 'merpeople', and 'party-goers' (Figure 1). Three conversation topics ('birthday cake', 'pets', and 'breakfast') were used for the Normal conversations, and three ('riding bikes', 'rainy days', and 'the library') were used for the other three conditions. We created three versions of the experiment so that each of the six puppet pairs was associated with at least three different conversation topics. We then hand-aligned the final audio to the puppet video recordings and ensured that half of the videos in each version were female-left-male-right and vice-versa by flipping the video and audio channels as needed. ${ }^{4}$

## Procedure

We seated children in front of a large screen with speakers placed below and at the sides of the screen. Mounted beneath the screen was an SMI 120 Hz remote infrared eye-tracker that continuously recorded their eye movements throughout the experiment. Children then watched a series of short videos comprising six brief puppet conversations and five engaging filler videos (e.g., running puppies and music). The filler videos were inserted between the puppet videos, which were ordered randomly for each participant. The six puppet videos fell into four audio conditions: Normal (3), Words only (1), Prosody only (1), and No Discernible Speech (1). The entire experiment took less than five minutes for most children.

[^35]
## Data analysis

For each participant in the study, we only included data from those video segments in which the participant gazed at the video for more than $75 \%$ of its duration. In prior work (Casillas \& Frank, 2012; Tice \& Henetz, 2011) adults and children $3 ; 0$ and older made anticipatory gaze shifts to upcoming talkers while watching videos of conversation. The shifts sometimes began before the prior turn ended, within the final 300 ms of speech. To determine whether children $1 ; 0-7 ; 0$ in our data made similar anticipatory shifts, we conducted our analyses contingent on looks to the prior listener. Specifically, we only included children who were looking at the prior speaker 333 ms before the prior turn ended. This follows contingent looking analyses in other child language work (Fernald et al., 2008) and guarantees that the children in our analyses were prepared make a gaze switch to the upcoming speaker. We then averaged gaze to the upcoming speaker during the first 333 ms of the answer. ${ }^{5}$ Since each child in our analysis started by looking at the prior speaker, looks to the upcoming speaker at the answer onset will represent the magnitude of children's anticipatory gaze shifts. Because prior work has found that children shift their gaze more quickly after hearing a question than non-question (Casillas \& Frank, 2012), we separated these in our analysis. When gaps are too long they can signal a troubled speaker transition or a disfluency that might need conversational repair (Jefferson, 1974). For this reason we excluded all turn-transitions longer than 550 ms in our stimuli.

## Results

In all conditions, participants were nearly three times more likely to keep their eyes on a talker when that person was speaking, rather than when they were silent (Table 1). Par-

[^36]

Figure 3: Proportion gaze to the answerer during the last 1 second of the prior turn and the first 1 second of the upcoming turn, broken down by participant age and linguistic condition (Question-Answer switches = dark gray; Non-Question-Answer switches $=$ light gray). Error bars indicate the standard error of the mean. The inter-turn gap is represented by the blank area along the trajectory. Included speaker switches had gaps ranging from $3-497 \mathrm{~ms}(M=308 \mathrm{~ms})$. The gap shown above is 300 ms . Gaps in the stimuli varied in length, so looking data during this period isn't plotted.
ticipants looked away from the talkers 18-35\% of the time. This closely matches our prior results (Casillas \& Frank, 2012), though children looked elsewhere more often in the No Discernible Speech and Prosody Only conditions than in the other two. Children's consistent looks to the current, rather than the non-current, talker suggest that the participants were tracking basic turn-taking with their gaze by using information from the audio, video, or (most likely) both. Participants most consistently looked at the current speaker (and looked away least) in the Normal Speech condition.

Children of all ages and in all conditions made anticipatory shifts to upcoming speakers (Figures 2 and 3). Even in the No Discernible Speech condition-in which the children saw puppets mouthing words to unrelated multi-talker babblechildren shifted their gaze toward upcoming speakers by the time the response began. This anticipatory shift was much
smaller in magnitude than what we found for Normal Speech with the same children ( $\sim 25 \%$ vs. $\sim 40 \%$ ).

Perhaps surprisingly, when children only had access to prosodic or lexical information, they performed similarly to when they had no linguistic information at all with slight, if any, improvement with age (Figures 2 and 3). In the Words Only condition, looks to the answerer showed a small, but consistently greater magnitude for Question-Answer turn switches than for non-Question-Answer switches. Switch in gaze to the upcoming speaker was strongest in the Normal Speech condition, in which older children also clearly distinguished their gaze to Question-Answer and non-QuestionAnswer switches.

To test the reliability of the differences in anticipation between conditions and switch types, we fit a linear mixedeffects model (Gelman \& Hill, 2007) to participants' aver-
age gaze at the upcoming speaker during the first 333 ms of the response. We included turn-switches and subjects as random effects, using maximal random effects structure (Barr et al., 2013) to control for variability between participants on the switch type (Question-Answer vs. non-Question-Answer) and linguistic condition. We also included a three-way interaction term for age, switch type, and condition with two-way interaction terms for age and gap duration and condition and gap duration. ${ }^{6}$

Model coefficients suggest that there were two significant effects in the gaze data. First, duration is a significant predictor of anticipation; longer gap durations result in more anticipation $(\beta=0.73$, s.e. $=0.28, t=2.61)$. Second, there is a highly significant three-way interaction between age, switch type, and condition ( $\beta=0.11$, s.e. $=0.03, t=3.16$ ) in predicting anticipation. This derives from the Normal Speech condition, in which children's differential looking behavior for Question-Answer vs. non-Question-Answer switches clearly diverges with age. No other coefficients reached significance.

Are children simply reacting to turn-ends and then looking to the other puppet, or are they instead anticipating the end of the prior speaker's turn and looking early on? To test this we fit a second model on turn-transitions that lasted less than 200 ms. Anticipatory looks in this subset of the data must have been planned before the prior turn ended. Model coefficients suggest anticipation still occurs with 2 two-way interactions between age and condition for Words only and Normal speech ( $\beta=0.07$, s.e. $=0.03, t=2.18$ and $\beta=0.08$, s.e. $=0.06, t=$ 2.31 , respectively). ${ }^{7}$

## General Discussion

Children's looking patterns suggest that they reach at least two developmental benchmarks for predictive processing for discourse. First, children recognize that turn-taking requires immediate responses, and they quickly integrate linguistic and non-linguistic cues to shift their gaze in anticipation of a response. We saw this behavior from all children in our data set. As children grow older, they become more sensitive to linguistic cues, using them to distinguish between different conversational actions (questions vs. non-questions) and make earlier and swifter predictive shifts.

Since children in this age range still appear quite delayed in their own turn-taking, these results are strong evidence that children's apparent delays in everyday conversation are not due to the ability to predict when a turn-switch will occur. We propose that these delays are instead due to the cost of planning a response. Children's turn-timing during conversation is most delayed when they must make a complex response, and so a three-year-old's timing during conversation may appear to be slower than a one-year-old's (Casillas et al., in prep). But in our task, when the cognitive load was lightened so children were only required to perform comprehen-

[^37]sion, we saw that children's skill in predicting turn-structure develops early on and becomes more sensitive to discourse distinctions with age, using linguistic information to distinguish between different conversational acts (e.g., questions).

Children made their earliest and most consistent predictive looks in the condition where they had all linguistic information available to them. These results strengthen claims from previous work that young children spontaneously anticipate what is coming next in conversation (Casillas \& Frank, 2012). By testing a broad age range, we found that children show greater anticipation, with a greater advantage for question- over non-question switches as they get older. Children in our study could effectively make predictions about normal speech by age $1 ; 0$, but that they begin distinguishing between different types of conversational actions (questions vs. non-questions) by the time they are $3 ; 0$ (Figure 3). Question effects are strongest when both prosodic and lexical cues are present, contrary to prior findings with adult listeners that found lexical information sufficient to predict upcoming turnend boundaries (de Ruiter et al., 2006).

Children's performance was significantly downgraded by phonetically controlled stimuli such that their predictive eye movements were comparable to conditions in which they had no linguistic information at all. We suggest that children were able to make anticipatory shifts without linguistic information because they simply waited for one puppet to stop talking before looking to the next. Rather than anticipating the end of the ongoing turn, these children are likely anticipating the start of the next speaker's turn, which explains the significant effect of longer inter-turn gaps. In contrast, anticipation in the Normal Speech and Words only conditions still occurs when gaps are shorter than 200 ms , in which case children do not have time to simply react to the end of the prior turn and make significant shifts by the start of the response-in these cases they must have instead anticipated the end of the prior turn.

One limitation of the current study is that, by using puppets for the visual signal, we removed all visual cues to turn-taking except mouth movement. We did this to focus our analysis on linguistic cues, but visual cues are culturally variable and important indicators of conversational timing and coordination (Kendon, 1967; Stivers et al., 2009). In related work (Casillas \& Frank, 2012), we asked 3-5 year-old children to watch short clips of conversation in languages they didn't speak. We saw larger and earlier-initiated anticipatory shifts in that experiment even though children in that study had no access to lexical information, only non-native prosodic and visual cues. Since children in the current study have smaller shifts, even in the Normal Speech condition, we suspect that visual cues play a large role in helping children guess what will come next, and that children integrate these cues with linguistic information when given the chance. Further work will be required to test this hypothesis. Also, children rarely hear phoneticallycontrolled speech, and may not have been able to process it as efficiently as normal speech, though they still were able to make small anticipatory shifts.

## Conclusion

Just as children must learn to break into the linguistic stream and segment it into words, they must also learn to break into the interactional stream of conversation and segment it into turns. Using children's spontaneous gaze behavior while watching improvised conversations, this study has attempted to link online predictive processes with naturalistic, conversation-based stimuli. We have focused here on children's predictive skill in conversation because children's conversational skills can impact the form of their linguistic input and may be critical to understanding what children hear and how they practice language. Children's turn-taking skills help them become active interactants who have control over the linguistic input and practice they receive.

The implications of conversation-specific skills for language development are likely important (e.g., Weisleder, 2012), but are still largely unknown. Within single- and multi-utterance sequences, children's ability to predict what's coming next can aid in their uptake of new information (Fernald et al., 2008). By being able to predict what upcoming turn-structure will look like and anticipating the type of response needed for different types of actions (e.g., questions vs. non-questions), children are developing conversational skills that affect their input more globally: they can become more successful participants in multi-party interaction. Their skill in prediction within and across utterances then affects the type and quality of linguistic practice that children get during development.

Our findings indicate that rapid turn-timing is one of the earliest properties of organized interaction that children acquire, and that over the first seven years of life, children come to rely on their linguistic knowledge to refine and build on their predictions about what to expect next in conversation. So while children learn about language, they can use their linguistic knowledge online to take turns more effectively, and as children learn to take turns, they can use language more effectively in conversation with others.

# English/Italian Bilinguals Switch Gesture Parameters when they Switch Languages 

Federica Cavicchio (federica.cavicchio@unitn.it)<br>Center for Mind/Brain Science, Corso Bettini 31<br>Rovereto (Tn), 38068 IT<br>and<br>School of Psychology, University of Birmingham<br>Edgbaston, B15 2TT UK<br>Sotaro Kita (kita.s @bham.ac.uk)<br>School of Psychology, University of Birmingham<br>Edgbaston, B15 2TT UK

#### Abstract

We investigated gestural communication in early bilinguals. In particular, we tested which aspects of gestures were "transferred" from a language to another. Though transfer in spoken languages has been studied extensively, transfer in gesture is understudied. Gesture transfer can provide useful information on the cognitive architecture in bilingualism. In this study our focus is on gesture rate and gesture space in Italian/English bilinguals. Contrary to previous findings, we have no evidence of transfer. When bilinguals switch language, their gesture parameters switch accordingly. The switch of gesture (cultural) parameters such as rate and salience show that language and gesture are tightly linked. This suggests that a language and the corresponding gesture parameters might be selected in a high level processing stage at which verbal and nonverbal aspects of communication are planned together.

Keywords: bilingualism; gesture rate; gesture space; linguistic transfer; gesture transfer; lexical access.

## Introduction

Different languages and cultures use gestures differently. For example, Italian is reported as a high gesture frequency language (Barzini, 1964; Kendon, 1992, 1995), as opposed to (British) English, described as a low gesture frequency language (Graham and Argyle, 1975).

It has been claimed that bilinguals' gesture use is linked to their proficiency in the two spoken languages. A common measure of gesture use is gesture rate (the number of gestures performed over the number of words uttered). Sherman and Nicoladis (2004) found no differences between bilinguals' gesture rate when participants have an equal proficiency in both their languages (Canadian English and Spanish, where Spanish is supposed to be a high frequency gesture rate language). Those studies (Nicoladis et al., 1999; Pika, et al., 2006), however, are not very informative about whether or gestural transfer occurs due to the limitation in the design; for example they lack one of the monolingual control groups (see Nicoladis, 2007).

The evidence for gestural transfer in the literature is mixed. In a study on English/French bilingual children in Canada Nicoladis and colleagues (2005) found that bilinguals tend to gestures more than both the two monolingual control groups, but no evidence for gestural
transfer was found. Nicoladis and colleagues explained their results claiming that bilinguals have more "choices" about how to package verbal messages with respect to monolinguals. Therefore, bilinguals gesture more than monolinguals (see also Pika et al., 2006). On the other hand, a study by So (2010) found gesture transfer between American English and Mandarin Chinese in EnglishMandarin bilinguals in Singapore. American English monolinguals gestured significantly more than Mandarin speaking monolinguals. Bilinguals gestured more when speaking Mandarin than the Mandarin monolingual control group, and when speaking English, they gestured at about the same rate as English monolinguals.

Another gesture parameter that varies across cultures is gesture size. Since the seminal study of Efron (1941/1972) comparing Jewish and Italian immigrants' gestures, we know that in different cultures gestures differ in how they are performed in the space. In particular, Efron observed that Italian immigrants' gestures were spatially expansive, moving the entire arm from the shoulder joint, and tended to occupy the lateral (transversal) plane. More recently, Müller (1998) compared the gesture space of native Spanish and German speakers involved in a naturalistic conversation task with a language matching confederate. She found that Spanish speakers produced more gestures in the space above their shoulder than German speakers. Interestingly, Müller did not find difference in gesture rates between German and Spanish. She suggested that the difference in gesture salience create an 'illusion' that Mediterranean region cultures gesture more frequently than north European cultures.

Gesture size is an interesting variable to consider for gesture transfer in bilinguals. First, gesture size varies crossculturally: bigger in Mediterranean cultures than in northern European cultures. Second, gesture size is determined by different psychological processes than gesture rates (Chu, Meyer, Foulkes \& Kita, under review). Thus, gestural transfer or lack of transfer for gesture rates and gesture size may shed light on the relationship between speech and gesture production processes. However, no previous studies have investigated gesture size in bilinguals.

Because the evidence for transfer of gesture rates in the
literature is mixed and there are no studies on transfer of gesture space, we investigate transfer of gesture rates and gesture space in Italian-English bilinguals. We tested two monolingual control groups so that we can properly address the question whether parameters of gesture production transfer in bilinguals and whether bilinguals gesture differently from monolinguals. The two monolingual control groups of English and Italian speakers matched with the bilinguals for gender, age and education background. We focused on highly proficient Italian/English early bilinguals (i.e. they learned both languages before age 6) who had a very similar fluency in both languages. Bilinguals and monolinguals described the exact same stimuli in each language to a confederate language matching speaker. Differently from previous studies using long cartoons that were edited in shorter scenes, our stimuli consisted of 10 single-scene cartoons.

## Method

## Participants

30 participants (10 English native speakers, Females $=8$ Males=2, age mean=22.3 years, recruited at the University of Birmingham; 10 Italian native speakers, Females=8, Males $=2$ age mean $=23.1$, recruited at the University of Trento; and 10 English/Italian bilinguals, Females=8, Males=2; age mean=23.8, recruited at the University of Birmingham and Trento) took part to the experiment. All the participants took a test to assess their linguistic background (Gullberg \& Indefrey, 2003) and the Controlled Word Association Test (COWAT; see Loonstra et al., 2001 for a review) in English and Italian. The COWAT scores ensured that participants were equally fluent in both languages. The mean fluency score for bilinguals was 62.8 words in English and 62.2 words in Italian. The mean fluency score for Italian native speakers was 63.4 words and for English native speakers was 61.7 words.

The bilinguals enrolled in this study started speaking both languages before age 6 , while the native speakers of Italian and English did not learn any other language before age 11 and were not fluent respectively in English or Italian. They were all students enrolled at university bachelor or master degrees.

## Materials

Participants watched 10 Tomato man stimuli (Özyürek, Kita, \& Allen, 2001) depicting two characters (i.e. Tomato man and the green Triangle) performing some actions (Fig. 1, left panel). The goal of these stimuli was eliciting the description of manner and path in the verbal and gesture modality as the participants described Tomato and Triangle actions. The stimuli were presented on a 13 -inch TFT monitor at a resolution of $800 \times 600$. Stimulus presentation was controlled by a PC running Power Point. The participants were audio and video recorded with a Sanyo Xacti HD2000 camera at a medium shot (i.e. they were shot from up their head to their knees, Fig. 1, right panel).

Figure 1: On the left panel, an example of the Tomato man cartoons used to elicit participants' gestures. In this movie Tomato man is "rolling down the hill". On the right panel, a participant describes the cartoon. The two dotted concentric squares define the gesture space: centre (the inner square) and periphery (the outer square).

## Procedure

Participants were seated at approximately 40 cm from the computer screen. An assistant pressed the mouse button to start the experiment. After the participants saw the first stimulus they turned toward a listener sitting near the camera and described what they had just seen. The monolingual participants repeated twice the task in the same language to two listeners who are native speakers of the relevant language. The bilingual participants repeated the task once in Italian, talking to a native speaker of Italian, and once in English to a native speaker of English.

The order of the stimuli was counterbalanced. In particular the stimuli run from clip 1 to clip 10 for the forward order and from 10 to 1 for the backward one. For bilinguals, the order of the task repetition was counterbalanced by language across participants.

## Data Transcription and Analysis

## Transcriptions

Two native speakers of Italian and English transcribed the videotapes following the instruction manual. Disfluencies, repetitions and laughter were transcribed with special fonts. The transcriptions were checked for accuracy by a second fluent speaker. All the transcriptions were reported in Elan 4.3.3 to ensure a correct time alignment with coverbal gestures.

Gesture were transcribed and aligned with videos and transcriptions.

## Gesture Coding

We coded the gestures produced by participants when telling the whole cartoon to the listeners.
In this paper we focus on two main aspect of gesture production:
Gesture Rate was calculated as the number of gesture produced by each participant describing each cartoon over
the number of words produced in each cartoon description (Ngestures/Nwords).
Gesture Salience: Gesture salience was coded for the target gesture performed during the cartoon description (e.g. rolls up, tumble down etc.). To code salience we followed McNeill (1992), who divided the gesture space into sectors using a system of concentric squares. Our annotation coding scheme reflects this notation dividing the gesture space in 2 sectors (see Fig. 1, left panel): "centre" and "periphery". When the gesture stroke was produced in the central sector, the gesture was annotated with 0 (not salient), whereas when the gesture stroke was produced in the periphery sector, the gesture was annotated with 1 (salient).
To ensure the reliability of the adopted coding scheme, a subset of the corpus ( 659 gesture tokens) was annotated by three independent coders. For gesture salience we found a high agreement above the chance level (Kappa $=0.89$ ).

## Results

We analysed our data in a linear (for gesture frequency) and a general (for gesture salience) mixed-effect model, as implemented in the statistical package, R. The analysis was run in R 2.15 using the package lme4, version 0.999999-0 (the function glmer was used for the gesture salience analysis).

## Gesture Rate

A linear mixed model was performed on Gesture Rate (observations $\mathrm{n}=390$ ). We fit the linear mixed model on gesture rate using a "maximum model random slopes" approach, i.e. calculating random (slopes and intercepts) effects for subject and item as well as the following fixed effects: language (Italian vs. English) and language status (bilingual vs. monolingual) and the interaction between language and language status. Because of the high correlation in the random effects (and the consequent danger of over fitting the data), we used a "backward algorithm" to set for the model that best described the variance in the data without over fitting them. Starting from the maximal random slopes and intercepts model, we first tested for the exclusion of random slopes. In this way we set, step by step, for the simpler model that better described the variance of the data. To ensure that the models described the same amount of variance, in each step we confronted the fitting of the simpler model with the previous "more random" ones. The model that better described the variance of the data had random intercepts for subjects, random intercepts for items (cartoons) and Language (Italian or English) varying by subjects random slopes.

We found a significant effect for Language (Est. $=0.06$, S.E. $=0.01, \mathrm{p}<0.001$ ), such that the gesture rate is higher in Italian than in English, but no significant effect for Language Status (monolingual or bilingual; Est.=-0.02, $\mathrm{S} . \mathrm{E}=0.02, \mathrm{p}=0.19$ ). Interaction between the fixed effects (Language status and Language) was investigated but not found ( $\mathrm{Est}=0.007$, S.E. $=0.03, \mathrm{p}=0.84$ ).
p values were calculated from the t values obtained in the
linear mixed effect model output. We treated the $t$ values as they were draw from a normal distribution, using the pnorm function in R. A post hoc power analysis through simulation ( n simulations=1000) revealed that 27 participants per group (81 participants in total) would be needed to obtain statistical power at .80 level.

In Fig. 2 we report the mean values of gesture rate for each group (monolingual or bilingual) in each language (Italian and English).

Figure 2: Mean values of gesture rate for Language Status (Bilingual, dotted line or Monolingual, solid line) in each Language (English and Italian).

## Gesture Salience

A generalized mixed linear model was performed on gesture salience (sample size $n=390$ ). Following the same procedure described for gesture rate, we set for the model that had by items (cartoons) random intercepts, by subjects random intercepts and Language (English or Italian) varying by subjects random slopes. We found a significant effect for both Language ( $\mathrm{Est}=1.85$, S.E. $=0.38$, p $<0.001$ ) and Language Status (Est. $=0.98$,S.E. $=0.39, \mathrm{p}=0.01$ ). Interaction between the fixed effects (Language status and Language) was investigated but not found (Est=0.33, S.E. $=0.76$, $\mathrm{p}=0.66$ ). That is, gestures were more salient in Italian than in English and bilinguals' gestures were more salient than monolinguals'.
p values were automatically calculated from z scores by glmer function. In Fig. 3 we report the probability of producing salient gestures in each Language Status (bilingual and monolingual) and each Language (Italian and English). A post hoc power analysis conducted with data simulation ( n simulations=1000) revealed that 22 participants per group (monolingual English, monolingual Italian, Bilinguals= 66 participants overall) would be needed to obtain statistical power at .80 level.

Figure 3: Probability of producing a salient gesture by Language Status (Bilingual, dotted line or Monolingual, solid line) in each Language (English and Italian).

## Discussion

The aims of this study were to investigate gesture frequency and gesture space in Italian/English bilinguals and the relationship between gesture and language in bilinguals. In addressing this question, the data from a bilingual and two monolingual control groups have been collected and analysed.

A first result was that Italian speakers gestured more frequently and that their gestures were more salient than English speakers. As observed by Kendon (1992) and Efron (1972) Italian is indeed a "high gesture culture". With regard to gesture rate, we found no evidence of transfer when bilinguals switch between Italian and English. With regard to salience, we found, again, no evidence of transfer but, overall, bilinguals' gestures were more salient with respect to the gestures performed by the two control groups. From our results we can conclude that when English/Italian bilinguals switch language, their gesture parameters switch accordingly with the language they talk.

Whether or not one finds gestural transfer in bilinguals may depend upon many variables. First of all, the societal context for bilingualism and the bilingualism level of the participants can affect transfer. Unlike the current study, So (2010) found evidence of transfer for representational gestures only from American English (high gesture rate) to Mandarin-Chinese (lower gesture rate) in Singapore. In Singapore multilingualism is a long established and prominent feature of the society, encouraged by laws. The bilinguals who took part in the present study mostly grew up in non bilingual communities (in Italy or the UK) where one of the two languages was mostly spoken with parents, family members and friends. Although bilingual participants
in this study reported in the Linguistic Background questionnaire that to them it was important to speak well both languages and they equally liked to speak in both, it might be that it is easier for the bilinguals tested in our study to "keep apart" the two linguistic systems.

In contrast, bilinguals in Singapore might have been much more exposed to two or more languages in daily life and it has been documented that transfer of words occurred together with gesture frequency transfer (So, 2010). The bilinguals in this study had some tip-of-the-tongue phenomena but did always choose to talk in the target language. The societal and linguistic context may account for the lack of gestural transfer found in Nicoladis et al. (2005) and for the lack of difference in gesture frequency between the two monolingual control groups. Their EnglishFrench bilingual children were recruited in Alberta, which is an English speaking province of Canada. Thus, just like our English-Italian bilinguals, one of the two languages (French) was mostly spoken with parents, family members and friends. Differently, the French monolingual group was recruited in Quebec, a bilingual area of Canada where French Canadians are highly exposed to English too.

One of the most interesting findings of this study is that bilinguals' gestures were overall more salient than monolinguals' gestures. One possible explanation is that bilinguals may often be in a communicative situation where some people are weak in Italian and others are weak in English. In such situations, bilinguals may make their gestures more salient in order to facilitate communication. This might become a habitual feature of bilinguals' gestures. This speculation though needs to be substantiated by future studies.
Our results indicate that language and gesture, even gesture "cultural" parameters such as frequency and salience, are tightly linked. In addition to that, our results suggest that the selection of those parameters happens at a pre-linguistic level, as these parameters have no strictly communicative meaning. The features specifying a language and the corresponding gesture parameters might be selected at a high level processing stage in which verbal and nonverbal aspects of communication are planned together. This is compatible with the idea that bilinguals specify the language at a conceptual level, as suggested by La Heij's concept selection hypothesis (2005). La Heij stated that the semantic system directly activates target-language lexical nodes over lexical nodes in the non-target language. Thus, the intended language is selected at the conceptual stage after a series of communicative aspects have been taken into account (e.g. who is the interlocutor, in which communicative situation we are etc.).

#### Abstract

Recent studies have shown that the involvement of semantic information in visual lexical decision depends on the nature of nonword foils with semantic effects increased as nonwords become more word-like (Evans, Lambon Ralph \&Woollams, 2012). Given that most models of lexical decision focus on orthographic information (Coltheart, Rastle, Perry, Langdon \& Ziegler, 2001; Grainger \& Jacobs, 1996; Seidenberg \& McClelland, 1989), the role of semantics and its interactions with vision, orthography, and phonology has been overlooked. We developed a recurrent connectionist model of single word reading including visual, orthographic, phonological, and semantic processing. The model differentiated words from nonwords by integrating measures of polarity across four key processing layers. The contribution of semantics depended on the type of nonword foils. The model was more reliant on semantic information when the nonword foils were pseudowords and pseudohomophones rather than consonant strings. The results support the view that semantic involvement in lexical decision is graded by the difficulty of the decision task.

Keywords: semantic effects; lexical decision; reading; computational modelling; visual word recognition.

## Introduction

Lexical decision (LD) has been widely used to study the cognitive processes involved in visual word recognition. Subjects are asked to judge whether a letter string is a word or not. Measures of accuracy and response time are thought to reflect the differences in lexical-semantic processing of words and nonwords. There seems to be consistent evidence that vision, orthography and phonology play roles in visual lexical decision (Coltheart, Davelaar, Jonasson, \& Besner, 1977; Grainger \& Jacobs, 1996; Meyer, Schvanev, \& Ruddy, 1974), however the extent of the involvement of semantics in lexical decision remains debateable (James, 1975; Joordens \& Becker, 1997; Lupker \& Pexman, 2010). James (1975) showed a reliable concreteness effect during lexical decision when using pseudoword and pseudohomophone foils, while the effect disappeared when testing with consonant strings. He suggested subjects might
be able to exploit semantic information to support efficient LD. Although some subsequent studies have found reliable semantic influences on lexical decision under different foil conditions (Joordens \& Becker, 1997), others have failed to find such effect (Lupker \& Pexman, 2010). Evans, Lambon Ralph and Woollams (2012) demonstrated that semantic involvement in lexical decision was graded by the difficulty of the decision task as indexed by the word-likeness of the foil. There were stronger semantic effects with pseudohomophones than with pseudowords, and the effects were stronger with pseudowords than with consonant strings. Apart from the behavioural data, there is also evidence of semantic involvement in lexical decision from neuroimaging studies. Woollams, Silani, Okada, Patterson and Price (2011) revealed that left anterior temporal activation, increased for atypical relative to typical strings when lexical decisions were made more difficult in the context of pseudohomophone foils. The left anterior temporal lobe has been considered as a region for combining various types of sensory and motor information to form amodal semantic representations (Patterson, Nestor, \& Rogers, 2007). The orthographic typicality effect in the left anterior temporal lobe has also been found in a previous electrophysiological (EEG) study. In a speeded lexical decision task, atypical words were found to elicit stronger source currents than did typical words at around 160 msec in the left anterior temporal lobe (Hauk, Patterson, Woollams, et al., 2006). These effects are consistent with what has been observed in the neuropsychological studies of patients with semantic dementia (SD), who have asymmetrically bilateral atrophy degeneration of the anterior temporal lobes. These patients show a progressive degeneration of semantic knowledge (Hodges, Patterson, Oxbury, \& Funnell, 1992). When patients are asked to perform two-alternative forced-choice visual lexical decision, they can correctly choose orthographically typical words from the relatively atypical nonwords but have difficulty in the reverse condition (Rogers, Lambon Ralph, Hodges, \& Patterson, 2004). Taken together, this evidence supports the view that semantic processing is involved in
lexical decision in particular when the words are orthographically atypical and the foils are pseudohomophones.

## Models Based on Localist Views

In the literature, several theories of visual word recognition have been proposed to explain the underlying mechanisms of lexical decision (Coltheart, et al., 1977; Coltheart, et al., 2001; Grainger \& Jacobs, 1996; Plaut, 1997; Seidenberg \& McClelland, 1989). Some researchers argue that lexical decision relies upon the orthographic lexicon (Coltheart, et al., 1977). If there is a match, subjects would give a positive response, otherwise, the negative response is made. On this view, the locus of lexical decision is based on activation within the orthographic lexicon. The involvement of phonology is a relatively late process after the mental lexicon search while the semantic system is generally not involved in the recognition processes unless the discrimination becomes extremely difficult (Coltheart, et al., 2001). This orthographically based approach is shared with Grainger and Jacobs (1996), who developed a computational model of lexical decision. In their multiple read-out model (MROM), a word response could be made either when the particular word unit activation reached a local criterion, $M$, or the overall activity in the word layer reached a global criterion, $\Sigma$, before the temporal deadline as $T$. The RT was based on the earliest moment where either of criteria was met. If neither of the activation criteria was met, a nonword response was given and the RT was the value of the deadline criterion. Grainger and Jacobs (1996) assumed that the $M$ criterion should be fixed as a normal recognition level and was set corresponding to individual word units. While the global criterion $\Sigma$ and the temporal deadline $T$ would vary according to the lexical frequency status of the stimulus. The higher probability the stimulus was a word, the lower global criterion and the longer temporal deadline were used. By this, the MROM model was able to simulate several standard effects seen in lexical decision including the frequency effects, the orthographic neighbourhood size effects, and their interactions (Grainger and Jacobs, 1996). Other models of visual word recognition such as the dual-route cascaded (DRC) model (Coltheart, et al., 2001) and the connectionist dual process (CDP+) model (Perry, Ziegler, \& Zorzi, 2007) share similar decision mechanisms to the MROM model.

## Models Based on Distributed Views

An alternative theory of visual word recognition argues that there is no mental lexicon for the store of word knowledge in the recognition system (Dilkina, McClelland, \& Plaut, 2010; Plaut, 1997; Seidenberg \& McClelland, 1989). On this view, the decision can be made on the basis of the differential activations elicited by familiar words and unfamiliar nonwords. When presenting a word, strong activations are expected because the mappings between the visual or orthographic representation of the word and its phonological and semantic representations have been
learned. Conversely, relatively weaker activations would be expected for a nonword representation as it is a novel stimulus. One important model of lexical decision was developed by Plaut in 1997, who proposed that the measure of how strongly units were activated, called stress or polarity, could be used as a basis for making lexical decisions. He built a feedforward model which consisted of orthographic, phonological and semantic components and demonstrated that words tended to produce higher stress than nonwords at the semantic layer. With the proper decision criteria, over 95 percent of words in the training corpus could be discriminated from nonwords. In addition, the network tended to produce higher semantic stress for pseudohomophones than for pseudowords in line with the behavioural data.

## Accumulated Information for Lexical Decision

There are also other models which have emphasised the use of accumulated information within the system for making decisions. One of these is the diffusion model, developed by Ratcliff, Gomez and Mckoon (2004). The central idea of the diffusion model was that the speed (drift rate) at which information was accumulated over time was affected by the lexical status of the stimuli. They hypothesized that the drift rate had a positive correlation with a measure of how wordlike a stimulus was. In their model, the decision was then made when a random walk process driven by the drift rate reached either a word criterion or nonword criterion. Another model is the Bayesian reader model developed by Norris (2009). The basic premise of this model was to assume subjects would consistently compute the probability of the stimulus being a word or a nonword on the basis of its lexical status. In the simulations conducted in Norris (2009), the recognition of a letter string being a word was made on the basis of the sum of the probabilities of all possible letter strings and this value was expected to be 1.0. Therefore, the nonword likelihood could be computed simply by using 1 minus summed probability of letter strings corresponding to words.

In summary, data from behavioural, neuroimaging and patient studies, all point to the involvement of semantic processing in lexical decision. Previous models either postulate an exclusive role for semantics (Dilkina, McClelland, \& Plaut, 2010; Plaut, 1997) or no role for semantics (Coltheart et al. 2001; Grainger \& Jacobs, 1996; Norris, 2009). Importantly none of the previous models would be able to account for the data from Evans et al. (2012), which indicates that the degree of semantic involvement is flexible and can be modulated by the nature of the nonwords foils. The goal of this paper was to use a novel model of reading to explore to what extent semantics is involved in lexical decision and how it interacts with other processing layers. In addition we aimed to be able to simulate the data from Evans et al. illustrating how changes to the nature of the nonwords foils can bias lexical decision tasks. Based on earlier work (Chang, Furber, \& Welbourne, 2012a), we developed a fully implemented recurrent model
of visual word recognition. The model included a visual processing stage along with the orthographic, phonological and semantic processing stages. Importantly, the orthographic representations were allowed to learn during the training.

## Method

## Network Architecture

The architecture of the model is shown in Figure 1. The model had two separate pathways for recognising words from visual input: a phonological pathway and a semantic pathway. The H0 layer was functionally responsible for visual processing while the OH layer was equivalent to the orthographic layer in the triangle model except that the orthographic representations were learned through the course of training rather than being supplied as inputs. This mimics the situation in human development where orthographic representations emerge to support reading acquisition in children. The word recognition process started from the visual input layer and moved progressively to the orthographic layer, and then progressed in separate pathways to the phonological and semantic layers. The phonological component consisted of 61 phonological units which were all connected to a set of 20 clean up units. These clean up units projected back onto the phonological units, forming an attractor. Similarly, the semantic component consisted of 200 semantic units. These units were all connected to another set of 80 clean up units, which projected back onto the semantic units. The context component consisted of 3 units, which were used to provide additional contextual information for discriminating between homophones. The numbers of hidden units for each layer were determined by pilot trials to ensure the model
was trainable and that the performance of the model was good on the production, comprehension and reading tasks.

There were also control units for each layer except input and output layers. These acted to flexibly inhibit the activation of the layer they were connected to. The control units were important because they allowed the model learn to manage its own temporal dynamics. In particular they allowed the units at the latter layers to be suppressed until the input to them had had time to ramp up to values that reflected the influence of the visual input to the model.

The training corpus consisted of 2,971 words. The visual representations used here were adapted from those used in Chang et al.'s (2012a) study. The network was trained on 12-point lower case words in Arial font. Each word was positioned with its vowel aligned on a fixed slot of the image. Ten slots were used in all and the size of each slot was $16 \times 16$ pixels. The scheme of phonological representations was the same as that used in the Plaut et al.'s (1996) model. The context units were used to differentiate the meanings of homophones, which have same pronunciations but different meanings. For those pronunciations with only one possible word meaning, the context units were all set to zero. For other pronunciations corresponding to more than one word meanings, the context units were all set to 0 for the first meaning; and one of the context units from right to left was set to 1 to represent the second, third and fourth meaning accordingly. The semantic representations were generated using the same scheme as in Chang, Furber, and Welbourne (2012b). The meaning of each word was represented by a 200 -dimensional semantic vector. Each vector had 5 active units in the first half of the vector converted from the top positive attributes and 15 active units in the second half of the vector converted from the top negative attributes.

Figure 1. The architecture of the model. The dashed lines indicate inhibitory connections.

## Training Procedure

The training was separated into two phases. In phase 1 only the phonology-semantics mappings were trained while in phase 2 the full reading model was trained starting from the trained weights obtained in phase 1. In phase 1, the phonology-semantics model was first subdivided into two parts: the production model learning the mappings from semantics to phonology and context, and the comprehension model learning the mappings from phonology and context to semantics. The production and comprehension model were trained separately. The presentation of each example lasted for 6 intervals of time and each interval of time was divided into 3 ticks. In each presentation, the input pattern of a word was clamped onto the input units for the full 6 intervals of time and the task was to produce the correct target representation. For the last 2 intervals, the activations of output units were compared to their targets. Error score, the difference between the units' outputs and their targets, was used to calculate weight changes. No error was recorded if the output unit's activation and target were within 0.1 of each other. At the end of phase 1 the accuracy rates of the production and comprehension model were $99.97 \%$ and $99.43 \%$ for the phonological level and semantic level respectively.

In phase 2, the weights obtained from the end of training the phonology-semantics model were embedded and frozen into the full reading model. The weight connections from the visual layer to both phonological and semantic layers were updated through training. There were local control units for each layer except input and output layers. The initial output of each control unit was set to 1 . The weight connections from its previous layer to each control unit were free to be updated. The weight connections from each control unit to those units that it was controlling were trainable, but the values were limited to between -4 and 0 . The negative boundaries used here were to ensure that the control unit acted to inhibit activation. The model was allowed to update for 30 ticks of time. The visual representation of a word was presented at the input units for all 30 ticks. The task was to produce correct phonological and semantic patterns. For the last 2 intervals, the output units were compared with their corresponding phonological or semantic targets and errors were computed. To encourage more accurate learning, no error was computed when the output unit's activation and target were within 0.001 .The model was trained to produce $99.3 \%$ correct phonological and $97.4 \%$ correct semantic patterns in the word reading task.

## Polarity Measures and Decision Criteria

Plaut (1997) proposed that parallel distributed models can perform the lexical decision task based on the measure of polarity, which is whether the units in the model have learned to adopt a binary representation. To capture this phenomenon, Plaut (1997) introduced a formula to compute the index of unit binarization which was termed unit polarity
as follows:

$$
y=x \cdot \log _{2}(x)+(1-x) \cdot \log _{2}(1-x)+1
$$

where $x$ is the unit activation ranging from 0 to $1 ; \log _{2}(\cdot)$ is the logarithmic function with the base of $2 ; y$ is the polarity measure. When known words are presented, the units tend to become binary, leading to high polarity values. However, when nonwords are presented, the activities of the units tend to be low and closer to 0.5 , resulting in generally low polarities. Two criteria were used for the model to make word-nonword decisions: (1) word boundary: the 3 standard deviation line above the average nonword polarity; (2) nonword boundary: the 3 standard deviation line below the average word polarity. The polarity for an item was computed by combining the measures of polarity for that item at the H 0 (visual processing), OH (orthographic processing), phonological, and semantic layers. If an item polarity crossed over the word boundary the item was classified as a word. By contrast, if the item polarity crossed over the nonword boundary, the item was determined as a nonword. There were, however, a few item polarities that remained between the two boundaries. In this case, responses were made based on which boundary the polarity was closest to at the last time tick. The response time was the time tick when an item polarity first crossed over either word or nonword boundary. In the situation where neither boundary was crossed the response time was taken as 30 ticks.

## Inverse Efficiency

To control for potential differences in speed-accuracy tradeoff caused by the arbitrary selection of standard deviation lines, we adopted a measure of inverse efficiency, which is considered to be a corrected reaction time (Roder, Kusmierek, Spence, \& Schicke, 2007). Inverse efficiency is a combination of both reaction and accuracy (i.e., dividing reaction time by accuracy). The lower the score, the more efficiently the model performed the task.

## Results

## Semantic influences on lexical decision

Evans et al. (2012) suggested that the subjects needed to access semantic information in the lexical decision task particularly when words were tested with more word-like nonwords such as pseudowords and pseudohomophones. They showed a graded imageability effect in lexical decision depending on the difficulty of the task. The imageability effect was larger when words were tested against with pseudohomophones than with pseudowords. The effect disappeared in the context of consonant strings. We tested the model to see whether it could produce the similar pattern as seen in Evans et al.'s data. After removing those words which were not in the training exemplars and their matched nonword items, there were 70 words, consisting of 35 high- and 35 low-imageability words. Their matched nonword pairs for the three different foil conditions, consonant string (CS), pseudoword (PW), and
pseudohomophone ( PH ) were also used in the current test. To compare with Evans et al (2012)'s data, the scores of inverse efficiency were normalised by the value obtained from the low imageability pseudohomophone condition. The same procedure was applied to Evans et al.'s (2012) data. The results are shown in Figure 2. It is clear that the simulation results (Figure 2, left) follow the pattern of Evans et al.'s data (Figure 2, right). A $2 \times 3$ repeated measures ANOVA was conducted with imageability (High/Low) and foil condition (CS/PW/PH) as within subject factors and the scores of inverse efficiency were used as a dependent variable. There was a reliable main effect of imageability, $F(1,19)=9.88, \mathrm{p}<.01$. The main effect of foil condition was also significant, $\mathrm{F}(1.31,24.85)=59.75$, $\mathrm{p}<.001$ (with a Greenhouse-Geisser adjustment).

Importantly, there was a significant interaction between imageability and foil condition, $\mathrm{F}(2,38)=3.60$, $\mathrm{p}<.05$, showing that the size of imageability effect increased along with the word-likeness of the foils. Note that we also ran the statistical tests on the unnormalised scores with the same pattern of results. This is what would be expected based on Evans et al.'s (2012) data. The post-hoc analyses showed that the imageability effect was not significant with consonant strings ( $p>.05$ ) while there were significant imageability effects in the contexts of pseudowords, $\mathrm{F}(1$, $19)=6.76, \mathrm{p}<.05$, and pseudohomophones, $\mathrm{F}(1,19)=15.06$, $\mathrm{p}<.01$. The results were consistent with the findings in Evans et al.’s (2012) study, suggesting semantic effects vary in lexical decision, depending on the foil type.

Figure 2. Data are from simulation (Left) and from Evans et al. (2012). Normalised scores were computed by equating two results based on the low imageability pseudohomophone condition.

## General Discussion

The primary aim of this paper was to develop a large-scale recurrent reading model containing visual, orthographic, phonological, and semantic processing to support lexical decision tasks. The model was used to explore the involvement of semantics in lexical decision with other processing components implemented in the system. This approach is different to most existing models of lexical processing which have focused on activity within a single processing layer. Based on the measure of polarities at four core processing layers ( $\mathrm{H} 0, \mathrm{OH}$, phonology and semantics), the model was able to perform the lexical decision tasks and account for the graded semantic effects found by Evans et al. (2012), as shown in Figure 2. The magnitude of semantic effects increased as nonwords became more word-like, where the semantic effect was stronger with pseudohomophones than with pseudowords and then with consonant strings. This provides evidence supporting the distributed view of lexical decision which proposes that semantic access is important and automatic in lexical decision (Plaut, 1997). The actual use of semantic information is flexible and is largely dependent on the
difficulty of the tasks (Evans, et al., 2012). That is in contrast with the localist view arguing for no or little involvement of semantics in lexical decision (Coltheart, et al., 2001).

There are some existing lexical decision models developed on the basis of the localist view of lexical decision including the MROM model (Grainger \& Jacobs, 1996) and the DRC model (Coltheart, et al., 2001) and the CDP+ model (Perry, et al., 2007). These models can simulate several effects in lexical decision and the strategic influences on lexical decision by flexibly adjusting decision criteria. However, their results are almost all based on orthographic processing with little attention to other processing components in particular the semantic system. Thus the questions as to how these models implement the involvement of semantics in lexical decision, which presumably requires some feedback connections from semantics to their orthographic lexicon (Coltheart, et al., 2001) remain unclear. In particular, these localist models would find it difficult to account for the graded changes in the involvement of semantics depending on foil type. In the current model this graded effect emerges naturally as a consequence of increasing task difficulty.

In this paper we have followed Evans et al. (2012) by talking the size of the imageability effect as an index of semantic involvement, but future work could extend this in the model by developing additional metrics to quantify the involvement of semantics including a direct comparison of performance with and without the contribution from the semantic layer.

To summarise, this paper uses a model of human visual word recognition to explore the role of semantics in lexical decision. Crucially, the model was able to account for the graded semantic influences on lexical decision corresponding to the various types of foils, providing evidence for semantic influences on lexical decision.

#### Abstract

Category information is used to predict unknown properties of category members. Previous research has found that when categorization is uncertain, property predictions do not reflect integration of information across categories as normative principles and Bayesian models would suggest. Rather, people often base their predictions on only the most likely category and disregard information from less likely ones Research in category-based induction tends to elicit explicit, verbal responses which may not readily allow for integration of information across categories. This paper explores whether changing response mode can promote more normative use of category information in induction. Experiment 1 used an implicit measure of prediction: eye movements. The results suggest that when making predictions implicitly people integrate information across categories. The results of Experiment 2 suggest that the integration of information found in Experiment 1 were not a result of explicit strategies.

Keywords: category-based induction; reasoning; implicit processes.

## Introduction

The ability to use category-level information to infer information about novel objects aids our reasoning, social interactions, communication and predictions. By placing an object into a category, we can make predictions about it even though we have never encountered that particular object before. Because you know about the category of Chinese food in general, when you see some Chinese food cartons in your refrigerator you know that there is some chance that the food is spicy, but it's likely not. For our purposes, category-based induction refers to a process like the one described above (the extension of category information to a new item in that category). This process becomes more complicated when you are unsure what category an item belongs to. Imagine that your roommate has left unmarked cartons of leftover food in the refrigerator, and you can't tell whether they hold bland Chinese or spicy Indian food. Do you take an acid reducer before eating? You must make a prediction about the food's spiciness based on the characteristics you can observe.

To decide whether the food will be spicy, you should take into account both the possibility that it is Chinese food and the possibility that it is Indian food. This type of reasoning
is consistent with Bayesian approaches to classification and prediction in which people weight different possibilities by their prior likelihoods. Anderson (1991) proposed such a model of category-based induction ${ }^{1}$ in which the probability that an object with observed features, $F$, has an unobserved feature, $j$, is the weighted sum of the probabilities across all categories, $k$ (assuming they are mutually exclusive):

$$
\begin{equation*}
P(j \mid F)=\sum_{k} P(k \mid F) \times P(j \mid k) . \tag{1}
\end{equation*}
$$

Thus, if you were a Bayesian food thief you would take the probability that the unknown food is Chinese food and multiply that by the probability that Chinese food is spicy. Next you would take the probability that the food is Indian food and multiply that by the probability that Indian food is spicy. The sum of the two products is the probability that the food is spicy. This appears normatively correct, since it takes into account your uncertainty and weighs the strength of the prediction accordingly. If very certain that the food is Chinese food you should make a moderate prediction about the likelihood of it being spicy; if uncertain, you should make a stronger prediction. Surprisingly, however, previous research on induction with uncertain categories has provided evidence using both real-life and artificial categories that people usually base their induction on only a single category (Hayes \& Newell, 2009; Malt, Ross, \& Murphy, 1995; Murphy, Chen, \& Ross, 2012; Murphy \& Ross, 1994).

These findings are in contrast to those of perception and motor control research that often find that people integrate information across possibilities in a Bayesian manner (Kersten, Mamassian, \& Yuille, 2004; Tassinari, Hudson, \& Landy, 2006; Trommershäuser, Landy, \& Maloney, 2006; Trommershäuser, Maloney, \& Landy, 2008). In perception, Bayesian models are used to explain how the visual system takes ambiguous inputs and returns percepts that are most

[^38]likely. People use knowledge about prior probabilities of states of the world and the likelihood of each state given the visual stimulus to arrive at the most probable interpretation of the stimulus (Kersten et al., 2004). In motor control, one action may be best suited to achieve a goal, given the state of the world. But since perception is not perfect, the state of the world is uncertain. Models of action propose that people integrate information about the likelihood of the possible states of the world to make near optimal actions (Haruno, 2001). These actions are sensitive to the payoff structure of the task: Subjects make motor decisions that minimize costs, given the uncertainty of different motor outcomes and the costs and benefits associated with each action (Trommershäuser, Landy, \& Maloney, 2006; Trommershäuser, Maloney, \& Landy, 2008).

Why might people be unable, or unwilling, to combine information about two categories in category-based induction tasks, but are able to integrate across possibilities and weigh costs and benefits in seemingly more complex perception-action tasks? We suggest that this discrepancy can, in part, be explained by the distinction between implicit and explicit processes (Sloman, 1996). Explicit processes are conscious and rule-based, while implicit processes are unconscious and associative. Explicit reasoning is subject to a reasoning heuristic called the singularity principle, which states that people generally only consider one possibility at a time (Evans, 2007). More specifically, we suggest that response mode is critical to whether information is integrated across categories. In category-based induction tasks, subjects often explicitly report what category they think an item belongs to prior to making a prediction. In contrast, perception and motor control experiments tend to depend on implicit responses. Subjects in these experiments are not asked to explicitly consider the potential possibilities (states of the world) but are instead prompted to act on this information (often, but not always, with a motor response).

Chen, Ross, \& Murphy (in press) provided evidence that implicit and explicit responding lead to different use of category information during induction. In one experiment, subjects learned artificial categories of moving geometric figures defined by two features: shape and direction. At test, subjects were presented with a shape and asked to predict its direction either implicitly or explicitly. The implicit test was a novel, game-like motor task that elicited a speeded prediction, and the explicit test was a formally identical verbal task that elicited a conscious, unspeeded prediction.

The categories consisted of eight moving geometric figures (see Table 1). There were two critical shapes of interest: squares and hearts. Each of these shapes belonged to one of two categories, the target or secondary categories. The target category is the category that the shape is most likely to be in given its distribution in the categories. For example, there was a $66 \%$ chance that a square belonged to Category 1, the target category, and a $33 \%$ chance that it belonged to Category 2, the secondary category (that is, there were eight squares in Category 1 and four in Category 2). In the target category, half of the squares moved in the 1
o'clock direction and half moved in the 5 o'clock direction. In the secondary category, the critical shapes moved in only one direction. In Condition 1 , the squares moved to 1 o'clock; in Condition 2, which served to counterbalance the direction of the secondary category, they all moved to 5 o'clock. Therefore, if people only attend to the target category in predicting the direction of a new square, they should be indifferent between predicting movement toward 1 and 5 o'clock, and thus their average prediction should be around 3 o'clock. If they attended to both the target and alternative categories, they should have a preference, because the alternative category (Category 2) would break the tie (in different directions in the two conditions).

This design was replicated for another stimulus and other directions: For hearts, the target category was Category 4, and half of the hearts moved in the 11 o'clock direction and half moved in the 7 o'clock direction. The secondary category was Category 3, and its hearts moved either toward 11 or 7 o'clock, depending on condition (see Table 1). Thus, if people integrated information across categories they would shift their predictions depending on what condition they are in, that is, depending on the less likely, secondary category. All subjects went through an identical learning phase in which they learned all four categories, based on the objects' shapes and direction of movement.

For the implicit test, subjects saw each shape presented briefly in the center of the screen before it rapidly moved off the screen in one of the learned directions. The subjects' task was to catch the shape with their cursor before it disappeared from the screen. Subjects were unable to catch the shapes in the middle of the screen, so they had to place their cursor towards the edge of the screen. Subjects controlled cursor placement and movement with the mouse.

For the explicit test, subjects were presented with static shapes and asked three questions about them: what category the shape was most likely to belong to, the probability their categorization was correct, and what direction the shape was most likely to travel in.

Subjects performed both the implicit and explicit induction tasks (order of tasks was counterbalanced). The results revealed that the exact same category knowledge led to significantly different inductions. Implicit inductions were, on average, shifted towards the secondary category, showing evidence of integration of information across categories. Explicit inductions showed no evidence of normative integration across categories. This pattern of results suggests that response mode is critical in determining how category information is used in induction. This is not to say that all things that make categories implicit lead to integration across categories. In Experiment 4 of Chen et al. (in press), subjects learned categories implicitly and made predictions explicitly. These predictions showed no evidence of integration of information across categories.

While these results suggest that implicit response promotes integration of information across categories, they are in contrast to much research on category-based induction under uncertainty which has consistently found

Table 1: Category Structure used in Experiments 1 and 2 (and Chen et al., in press)

|  | Category 1 <br> (target for squares) |  | Category 2 <br> (secondary for squares) |  | Category 3 <br> (secondary for hearts) |  | Category 4 (target for hearts) |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Exemplar | Shape | Direction | Shape | Direction* | Shape | Direction* | Shape | Direction |
| 1 | Square | 1 | Square | 1/5 | Heart | 7/11 | Heart | 7 |
| 2 | Square | 1 | Square | 1/5 | Heart | 7/11 | Heart | 7 |
| 3 | Square | 1 | Square | 1/5 | Heart | 7/11 | Heart | 7 |
| 4 | Square | 1 | Square | 1/5 | Heart | 7/11 | Heart | 7 |
| 5 | Square | 5 | Rectangle | 1/5 | Diamond | 7/11 | Heart | 11 |
| 6 | Square | 5 | Rectangle | 1/5 | Diamond | 7/11 | Heart | 11 |
| 7 | Square | 5 | Rectangle | 1/5 | Diamond | 7/11 | Heart | 11 |
| 8 | Square | 5 | Rectangle | 1/5 | Diamond | 7/11 | Heart | 11 |

Note. The direction entries are clock directions ( $1=1$ o'clock, etc.).
*The first number refers to the direction in condition 1 , the second to condition 2.
that most people based their inferences on only a single category. In Experiment 1, we seek to replicate this result with a different implicit measure of induction: eye movements. In Experiment 2, we provide evidence that subjects are not consciously aware of the strategies used in this implicit induction task.

## Experiment 1

To examine whether subjects would integrate information across categories when making predictions implicitly, Experiment 1 used a cover task, in which predicting movement was incidental. Subjects learned the four categories of moving shapes used in Chen et al. (in press). During test they performed a cover task (same/different task) in which they saw the shapes appear in the center of the screen. The shapes were the same as the ones subjects had learned, except they now had diagonal stripes that were either tilted right or left. After their initial presentation in the center, the shapes moved towards the edge of the computer screen but momentarily disappeared behind an annulus that was on the test screen such that subjects were unable to tell which direction the shape was going to move. Shapes briefly reappeared from behind the annulus and then disappeared off the edge of the screen. When the shapes reappeared from behind the annulus, their stripes may have reversed their tilt (e.g., from left to right). Subjects' task was to report whether the tilt of the stripes was the same or different from when it appeared in the center of the screen.

Thus, subjects were never asked to predict direction or category as they were only questioned about the stripes. However, since the shapes only reappeared briefly, looking close to where they reappeared improved performance (e.g, for squares, it would be beneficial to look near 1 o'clock or 5 o'clock depending on where you thought it would go). Position of eye gaze just prior to the shape's reappearance is the dependent measure as it is a proxy for subjects' prediction of shape direction. If subjects integrate information across categories, fixations should, on average, be shifted towards the direction of the secondary category.

## Method

Design Subjects were randomly assigned to one of two between-subjects conditions. The conditions served to counterbalance the direction of the secondary categories.
Participants Subjects were 32 undergraduates at New York University who participated for course credit. Data from eight subjects were dropped for not fixating prior to the shape's reappearance on at least five trials. One subject was dropped for not reaching the performance criterion during learning.
Materials Stimuli for each category were 8 black shapes approximately 1.75 to 2.5 cm in length, as shown in Table 1. The same shapes were used during test except they had stripes (see Figure 1). The category structure was the same as that used in Chen et al. (in press). See Table 1 for details.

All stimuli were presented on the background of a light gray circle 30 cm in diameter centered on a black computer screen. Stimuli started in the center of the screen and then moved off the screen disappearing once they moved beyond the border of the circle. Eye movements were monitored with the SR Research (Ontario, Canada) EyeLink 1000.
Procedure The experiment consisted of three phases: 1) observation, 2) learning, and 3) test. A Macintosh computer presented the instructions and controlled all three phases. Eye movements were recorded during the test phase only.

Subjects were told that they would view four categories of moving shapes and were to learn what combination of shapes and directions belonged to each category for a memory test. During observation, all shapes from each category were presented singly. Each shape appeared in the center of the screen for 1 s , then moved horizontally (towards 3 o'clock for shapes in Categories 1 and 2, towards 9 o'clock for Categories 3 and 4) for .4 s , and then moved towards its assigned clock direction for .95 s until it disappeared off the edge of the gray circle (see Table 1 for directions). Each shape's category name appeared in the center of the screen for the entire time it was on the screen. All exemplars from Category 1 were presented, then all exemplars from Category 2, and so on.

Subjects were next told that they would see the same items as in the observation phase. They were to classify
each shape into one of the four categories by pressing a number key on the keyboard. At the beginning of each trial, a white fixation cross appeared in the center of the screen for 1 s . The shape then moved as they did in the observation phase. There was no time limit on responding. After answering, the correct answer appeared for 1.25 s . After an error, subjects viewed a repeat display (without responding) of the moving shape with the correct category displayed. There were four learning blocks in which each of the 32 items was tested in random order. Because of the category uncertainty of the critical items (e.g., a square could be in Categories 1 or 2 ), subjects could get no more than $75 \%$ correct, assuming they chose the most likely category for all presented stimuli. In all experiments subjects had to reach at least $50 \%$ correct during the final block of learning to be included in analysis.

The final phase of the experiment consisted of a 64-trial test in which subjects had to perform the same/different task while their eye movements were tracked by the EyeLink 1000. Subjects saw the same items they had seen in the previous phases except that the shapes would now move a little bit faster and have diagonal stripes on them. These shapes would appear in the center of the screen (for 1 s ) and continue to move along the same path as in previous phases. However, there was now a black annulus on the screen such that the shape would move horizontally (for .25 s ) and then disappear behind the annulus for .7 s . The shape would then reappear from behind the annulus just before it disappeared from the screen. (After the shape's reappearance from behind the annulus it was visible for .15 s before it disappeared.) Recall that all stimuli were presented on a gray circle 30 cm in diameter. The annulus $(24 \mathrm{~cm}$ in diameter) was centered on this image. Its center hole had a diameter of 8 cm (see Figure 2).

The stripes on a test object were either tilted left or right when the shape initially appeared (see Figure 1). The subjects' task was to report whether the direction of the stripes was the same or different when it reappeared. The direction of stripes remained the same for half of the trials and changed for the other half. Subjects saw a 1.25 s feedback message. There were five practice trials prior to the test phase. As shapes only briefly reappeared from behind the annulus, looking close to where shapes reappeared was beneficial. Thus, fixation location just prior to the shape's reappearance was used as a proxy for prediction of direction and as the dependent measure. (Recall that horizontal movement for the critical shapes did not indicate its category as the horizontal direction was the same for Categories 1 and 2, and Categories 3 and 4.)

Figure 1: Example of stimuli used in the test phase of Experiments 1 and 2.

Figure 2: Illustration of the implicit induction task. The shape appeared in the center of the screen for 1 s . It then moved horizontally for .25 s and disappeared behind the annulus while traveling on its path (learned in phase 1). Subjects reported whether the diagonal lines had changed when it reappeared. Arrows indicate the shape's path when
it was visible and did not appear in the experiment.
Data Analysis Responses for critical shape trials were coded such that a position exactly in between the two possible directions of the shape was 0 degrees, and a shift from that point towards the direction reinforced by the secondary category was coded as positive. For example, for the squares in Condition 1 (which might move to 1 o'clock or 5 o'clock), the 3 o'clock position was 0 degrees, the 1 o'clock position (the direction of the secondary category) was 60 degrees, and the 5 o'clock position was -60 degrees. In Condition 2, the latter values were reversed. We obtained the mean fixation position for each subject by averaging the mean fixation position for squares and hearts. Thus, use of a single category (i.e., use of only the target category) is evidenced by an average prediction of 0 deg. Normative use of categories is evidenced by a positive average prediction, as this represents a shift from 0 deg in the direction of the secondary category.

Trials in which the fixation position was greater than 100 degrees or less than -100 degrees were not included in the analysis because the subject was fixated on the opposite side of the screen from where the shape traveled, indicating that the subject either forgot where the shapes went, or did not see the shape correctly prior to its movement. Additionally, trials where fixation was within the hole of the annulus were excluded from analysis. When subjects looked at the center of the screen while doing the task, they were effectively not making a prediction about direction.

## Results \& Discussion

Subjects were on average $66.4 \%$ correct (chance $=25 \%$ ) during their last training block, suggesting that they learned the categories quite well. (Recall that maximum performance was $75 \%$, if subjects always classified
ambiguous items into the most likely category.) Performance on the same/difference task averaged $72 \%$.

As explained above, integration of information across categories is evidenced by a shift from 0 deg in the direction of the secondary category, which we coded as positive. This is indeed what we found. The mean fixation position for the critical shapes, $(M=7.5 \mathrm{deg}, S D=8.9)$, was significantly greater than $0 \mathrm{deg}, t(23)=4.1, p<.01, d=.84$, indicating that people's predictions of direction were integrated across the two categories. The mean fixation position was positive for 21 of the 24 subjects. These results are consistent with those of Chen et al. (in press) and suggest that implicit induction promotes integration of information across categories. A question for future research will be to examine how categories are used during implicit induction. The multiple category use found in Experiment 1 may be a result of a feature-level strategy (e.g., using information about only squares when making a prediction about where a square will go) rather than a category-level strategy like that described in Eq 1 (see Griffiths et al., 2011, for similar ideas).

Perhaps subjects did not truly induce the objects' direction but learned to change their eye movements via practice in doing the task. To examine this possibility we compared the mean fixation position for the first and second blocks of testing. The difference between the mean fixation positions for the first and second blocks was not significant $(M s=6.2$ and $8.8 \mathrm{deg}, S D s=9.1$ and 11.9), $t(23)=1.0, p$ $>.05, d=.25$ suggesting that subjects' normative use of categories was not a result of learning during test. The positive shift in eye movements was significant in block 1, $t(23)=3.3, p<.01, d=6.8$, and in block $2, t(23)=3.6, p<$ $.01, d=.76$.

## Experiment 2

Experiment 1 revealed that people use information from multiple categories when making inductions implicitly. However, it is possible that the placement of eye fixation was not the result of implicit processes but instead the result of a conscious strategy (i.e., after practice subjects could have realized that they would perform better when they looked closer to the direction reinforced by the secondary category). Experiment 2 tested this explanation. Subjects completed the full learning procedure of Experiment 1. They then saw a few example trials of the same/different task and then reported (using feedback from the eyetracker) where they would look to best perform the task. This question sampled subjects' explicit beliefs about where they would look. If the results match those of Experiment 1, this would suggest that the fixations were the result of an explicit strategy.

## Method

Participants Subjects were 21 New York University undergraduates who participated for course credit. Data from four subjects were dropped for not fixating on at least
three trials. One more subject was dropped for not reaching the performance criterion during learning.
Materials and Design Identical to Experiment 1.
Procedure The procedures of the observation and learning phases were identical to those used in Experiment 1. As with Experiment 1, eye movements were only recorded during the test phase. The test phase consisted of a 16-trial test in which subjects were asked to report where they would look in order to best do the same/different task that subjects in Experiment 1 performed. Subjects saw the same five practice trials used in Experiment 1 and then were told that they would not be doing the task but rather reporting where they would look just prior to the shape's reappearance from behind the annulus to best do the task. In order to keep the dependent measures of the two experiments similar, we used eye position to indicate this prediction. A white dot on the display indicated where the subjects were looking. The task was to look at the location on the screen that they thought would be best to do the same/different task they had just observed. They then saw a test screen (gray circle with the annulus) and were instructed to look around the screen to get a sense of how the white dot corresponded to their eye gaze.

The test phase consisted of four blocks in which each shape was tested once in random order (except that shapes were not queried twice in a row). Each test trial started with the presentation of the shape in the center of the screen for 1 s. It then moved horizontally for .25 s until it disappeared behind the annulus (the shape never reappeared). Subjects then saw the white dot that marked their eye gaze on the screen. To report their location, subjects moved their eyes until they were satisfied with the location of the white dot and then pressed the enter key. The white dot stayed on the screen for 1.25 s so that the subjects could see their answer.

## Results \& Discussion

Subjects were on average $68.2 \%$ correct (chance $=25 \%$ ) during their last training block, near the $75 \%$ maximum, suggesting that they learned the categories quite well.

As in the analysis of Experiment 1, subjects' responses for the critical shapes were coded such that the time corresponding to the point exactly in between the two possible directions of the shape was 0 degrees ( 3 o'clock for squares and 9 o'clock for hearts, and a shift towards the direction reinforced by the secondary category was positive). To find the mean prediction (the amount of shift from 0 deg towards the secondary category) for each subject, we calculated the mean prediction for each shape and took the average of the two. The mean prediction ( $M=$ $0.2 \mathrm{deg}, S D=2.9 \mathrm{deg}$ ) was not significantly different than the average observed direction for the shapes in their target category only ( 0 deg ), $t(15)=0.2, p>.05, d=.07$, suggesting that subjects were not basing their responses on multiple categories. Subjects chose locations around 0 deg the majority of the time. In fact, $84 \%$ of all responses were with within 10 deg of 0 deg. In contrast, in Experiment 1, only $25 \%$ were in this range.

These predictions from this experiment show no integration of information across categories. This suggests that the integration of information across categories found in Experiment 1 was not the result of a conscious decision or strategy and provides further evidence that response mode is critical to how category information is used in induction.

## General Discussion

The results of Experiment 1 suggest that people integrate information across categories when making inductions implicitly. The results of Experiment 2 revealed that explicit prediction of eye fixation position in the same/different task showed no evidence of integration of information, suggesting that subjects were unaware of the strategies used to perform the task. Taken together, these results suggest that response mode is critical in determining when people integrate information across categories when making inductions and that the single category focus found in previous research on category-based induction may result from conscious reasoning strategies. These results are consistent with the findings of Chen et al. (in press), that speeded catching of a stimulus also showed integration across categories, but verbal predictions did not. These results also help explain the discrepancy between studies of induction in reasoning vs. perception and action.

Our findings suggest that implicit responses can, at least sometimes, lead to greater use of available information than our conscious, explicit responses do. This is particularly important because many everyday predictions are about items whose categorizations we may be unsure of. Doctors may have to predict which treatment is most likely to work even though they are not certain what the correct diagnosis is. A person who is walking alone at night and sees an unknown person approaching may have to decide whether to avoid the person despite being unsure whether that person belongs to the category of mugger or pedestrian. The results of the present experiments help in understanding which situations and contexts people are most likely to consider alternative possibilities and make predictions based on relevant information from them.

Additionally, many of these inferences can be made either implicitly or explicitly (e.g., one might run upon seeing an unknown person approaching, but given more time, one may exclude less likely possibilities and act as if certain that the unknown person is a pedestrian). In fact, in social psychology, a similar distinction has been made between automatic and controlled processes in prejudice. Automatic processes are often associated with stereotype activation (a type category-based induction) which, in low-prejudice people, conflicts with explicit attitudes and is inhibited in favor of explicit beliefs (Devine, 1989). Thus, the explicit system's bias to disregard or avoid information from alternative categories (that made it less normative in our task) could, in other cases, lead to more normative responses. Our research shows that this distinction is crucial for understanding when category-based predictions are more likely to be accurate or inaccurate.

# General Instruction Following in a Large-Scale Biologically Plausible Brain Model 

Xuan Choo (fchoo@uwaterloo.ca)<br>Chris Eliasmith (celiasmith@uwaterloo.ca)<br>Center for Theoretical Neuroscience, University of Waterloo<br>Waterloo, ON, Canada N2L 3G1

#### Abstract

We present a spiking neuron brain model implemented in 318,870 LIF neurons organized with distinct cortical modules, a basal ganglia, and a thalamus, that is capable of flexibly following memorized commands. Neural activity represents a structured set of rules, such as "If you see a 1, then push button A, and if you see a 2 , then push button B". Synaptic connections between these neurons and the basal ganglia, thalamus, and other areas cause the system to detect when rules should be applied and to then do so. The model gives a reaction time difference of 77 ms between the simple and two-choice reaction time tasks, and requires 384 ms per item for sub-vocal counting, consistent with human experimental results. This is the first biologically realistic spiking neuron model capable of flexibly responding to complex structured instructions.

Keywords: neural engineering; spiking neuron model; instruction following; instruction processing; cognitive control; cognitive architectures

## Introduction

One of the hallmarks of complex cognition is the ability to perform a multitude of tasks using the same underlying architecture. When given an instruction, the human brain is capable of processing and executing the instruction without the need for extensive rewiring of the underlying neural connections. As far as we are aware, no neural model to date has been shown to exhibit this ability.

Eliasmith et al. (2012) describes what is currently the world's largest functional brain model. While the model, called Spaun (for Semantic Pointer Architecture Unified Network), is able to perform 8 different cognitive tasks without necessitating changes to its architecture, the knowledge needed to complete these 8 tasks is hard-coded into the action selection mechanism (the basal ganglia) of the model, making it unable to perform any task other than the predefined 8. In this paper, we propose an extension to the Spaun action selection component making it capable of processing generic instructions.

## Terminology

Four key concepts are discussed in this paper: states, actions, rules, and instructions.

States are internal variables that the action selection system monitors to figure out what is the best action to perform. States can be both internal (e.g. goal memories, working memories (WM)) and external (e.g. visual input) to the system.

Actions are atomic commands within the architecture, and are typically motor commands (e.g. "write the number $X$ ", "push the $X$ button") or cognitive commands (e.g. "remember the word $X$ ", "route information from WM area $X$ to WM area
$Y$ ", "add 1 to the value in WM area $X$ "). Apart from motor and cognitive commands, actions can also be utilized to change the values of the model's states.

Rules are conditional statements typically of the form "IF $X$, THEN $Y$ " (e.g. "If you see a 1, then push button A") where $X$ is a set of conditions which have to be met for the set of actions $Y$ to be executed. More generally, in Spaun, rules are statistical maps between cortical states and actions.

An instruction is a combination of rules or actions that can be executed sequentially (e.g. "Remember the number 1 ; add 1 to that number; write the result") or in any order (e.g. "If you see a 1 , then push button A; If you see a 2 , then push button B").

## Spaun

The architecture of Spaun (the Semantic Pointer Architecture, or SPA) is composed of 9 distinct but interconnected modules (see Figure 1A). Of interest to this paper is how the action selection module interacts with the rest of the model. Fundamentally, the action selection module of Spaun is identical to the basal ganglia (BG) based production system described in (Stewart, Bekolay, \& Eliasmith, 2012), and functions similarly to the action selection component of production system models (e.g. (Anderson, 1996)).

In these systems, action selection is hard-coded by a predefined set of rules. To select an action, the BG monitors internal cortical state variables and executes a rule whose antecedent best matches the values of the internal state variables (see Figure 1B). Critically, to encode instructions, the transitions between each rule in the instruction has to be hardcoded into the BG as well. For example, if the instruction was to perform ACTION-A followed by ACTION-B, and then $A C T I O N-C$, the following rules would have to be encoded into the BG :

$$
\begin{aligned}
& \text { IF } \text { INIT, THEN } \text { state }=A C T I O N-A \\
& \text { IF } \text { state }=A C T I O N-A, \text { THEN } \text { state }=A C T I O N-B \\
& \text { IF } \text { state }=A C T I O N-B, \text { THEN } \text { state }=A C T I O N-C
\end{aligned}
$$

Several ACT-R models (e.g. (Taatgen \& Lee, 2003), (Taatgen, 1999)) able to follow instructions, however no neural implementation has been previously discussed.

Aside from its architecture, Spaun is also unique in the way information is represented. Information is encoded and represented using semantic pointers (Eliasmith, In Press). These representations are used in the SPA to define a type of vector symbolic architecture (VSA). In typical VSAs, the vector

Figure 1: A) High-level architecture of Spaun. B) Method by which Spaun chooses an action. The action selection system monitors cortical state variables (solid arrows), selects an action that bests matches these states, and effects the action on efferent modules (dotted arrows).
that represents the number ONE and the vector that represents the number TWO would be chosen from a random distribution and thus have no direct relation to each other. In the SPA however, the semantic pointer for the number TWO is computed as the bound combination of the semantic pointer ONE with a vector that represents the concept ADD1, thus imparting semantic meaning to each vector:

$$
\mathbf{T W O}=\mathbf{O N E} \circledast \mathbf{A D D 1}
$$

Similarly, the semantic pointer for the number THREE can be computed as follows:

$$
\begin{aligned}
\mathbf{T H R E E} & =\mathbf{T W O} \circledast \mathbf{A D D 1} \\
& =\mathbf{O N E} \circledast \mathbf{A D D 1} \circledast \mathbf{A D D 1}
\end{aligned}
$$

## Vector Symbolic Architectures

Vector symbolic architectures have four core properties. First, information is represented by high-dimensional vectors usually chosen from a random distribution.

Second, vectors can be combined using a superposition operation (denoted with $\mathrm{a}+$ ). Of note, the vector result of the superposition operation is similar to the original vector operands, where similarity is measured by a dot product.

Third, vectors can be bound together using a binding operation (denoted with a $\circledast$ ). Unlike the superposition operator, the vector result of the binding operation is dissimilar to the original vector operands.

Last, an approximate inverse operator (denoted with *, such that $A^{*}$ is the approximate inverse of $A$ ) is defined such
that binding $A$ with $A^{*}$ results in approximately the identity vector $\mathbf{I}\left(A \circledast A^{*} \approx \mathbf{I}\right)$. This property of the approximate inverse can be used to unbind previously bound vectors.

Both the superposition and binding operations are analogous to addition and multiplication in scalar mathematics, and are often associative, commutative, and distributive.

In the SPA, vector addition is used for superposition, and circular convolution is used for binding, bearing close similarity to the Holographic Reduced Representation (Plate, 2003).

## Encoding Instructions

Instructions are encoded using a positional encoding schema similar to that used in Spaun and in the Ordinal Serial Encoding model of serial working memory (Choo, 2010). Each rule in the instruction is tagged (bound) to a position vector to indicate its relative order within the instruction. For example, the instruction "1. RULE1; 2. RULE2" is encoded as

$$
\mathbf{I N S T R}=\mathbf{P} 1 \circledast \text { RULE1 }+\mathbf{P} 2 \circledast \text { RULE2 }
$$

where P1 and P2 are the position vectors. Importantly, since the position vectors are also semantic pointers, the position vectors have some relation. That is to say $\mathbf{P 2}=\mathbf{P} 1 \circledast$ ADD1, and likewise for subsequent position vectors.

Individual rules in the instruction are encoded as a superposition of the conditions that make up the antecedent and the actions that make up the consequence of the rule. For example, the rule "IF STATEA THEN ACTIONB" is encoded as

$$
\mathbf{R U L E}=\operatorname{ant}(\mathbf{S T A T E A})+\mathbf{A C T I O N B}
$$

where $\operatorname{ant}()$ is a randomly generated linear operator applied to the STATEA vector that serves to disambiguate the antecedent and consequent components of the rule.

State conditions are encoded by binding vectors that describe the state being monitored with the state value required for the rule to be executed. Thus, the state condition "state $=$ $\mathbf{A}^{"}$ is constructed as

## $\boldsymbol{S T A T E A}=\boldsymbol{S T A T E} \circledast \mathbf{A}$.

Other conditions can also be combined in this state representation. For example, if the state conditions was "vision $=\mathbf{3}$ and state $=\mathbf{A}$ " (i.e. looking at a 3 while in state A), then the state representation would be

$$
\text { VIS3\&STATEA }=\text { VISION } \circledast 3+\text { STATE } \circledast \text { A. }
$$

Actions are encoded by combining the bound result of an "action" descriptor with the specific action to be performed with an optional bound result of a "data" descriptor with the specific data to be used with the action. A "write the number 2 " action is thus represented as

$$
\mathbf{W R I T E} 2=\text { ACTION } \circledast \mathbf{W R I T E}+\text { DATA } \circledast 2 .
$$

Combining all of the representations above, the full encoding of an instruction can be demonstrated. As an example the instruction:

> 1. IF vision $=0$, THEN push button A
> 2. IF vision $=1$, THEN push button B
is encoded as

$$
\begin{array}{r}
\mathbf{I N S T R}=\mathbf{P 1} \circledast[\operatorname{ant}(\mathbf{V I S I O N} \circledast \mathbf{0})+ \\
\text { ACTION } \circledast \mathbf{P U S H}+\text { DATA } \circledast \mathbf{B T N A}]+ \\
\mathbf{P 2} \circledast[\operatorname{ant}(\mathbf{V I S I O N} \circledast \mathbf{1})+ \\
\text { ACTION } \circledast \mathbf{P U S H}+\mathbf{D A T A} \circledast \mathbf{B T N B}] \tag{1}
\end{array}
$$

It is important to note that at the end of this computation, the instruction is encoded as a single vector with the same dimensionality as the original atomic components.

## Decoding Instructions

With the instruction encoding schema presented above, the instructions can be decoded in one of two ways: by using positional information, and by using the values of the states in the system.

Sequential Decoding of Instructions A rule associated with a specific position within the instruction can be retrieved by binding the instruction vector with the inverse of the position vector.

$$
\begin{align*}
\text { rule } & =\mathbf{I N S T R} \circledast \mathbf{P} \mathbf{1}^{*}  \tag{2}\\
& =\mathbf{P} \mathbf{1}^{*} \circledast \mathbf{P} 1 \circledast \mathbf{R U L E} 1+\mathbf{P} \mathbf{1}^{*} \circledast \mathbf{P} \mathbf{2} \circledast \mathbf{R U L E} 2 \\
& =\mathbf{I} \circledast \mathbf{R U L E} 1+\mathbf{P} \mathbf{1}^{*} \circledast \mathbf{P} \mathbf{2} \circledast \mathbf{R U L E} 2 \\
& \approx \mathbf{R U L E} 1
\end{align*}
$$

Given the rule vector, it is possible to retrieve information related to the consequent by binding it with the inverse of the "action" descriptor or the "state" descriptor.

$$
\begin{align*}
\text { action }= & \text { rule } \text { ACTION }  \tag{3}\\
= & {[\operatorname{ant}(\text { VISION } \circledast \mathbf{0})+\text { ACTION } \circledast \mathbf{P U S H}+} \\
& \quad \text { DATA } \circledast \mathbf{B T N A}] \circledast \boldsymbol{A C T I O N}^{*} \\
\approx & \mathbf{I} \circledast \mathbf{P U S H}=\mathbf{P U S H}
\end{align*}
$$

Likewise,

$$
\begin{aligned}
\text { data }= & \operatorname{rule} \text { DATA } \boldsymbol{D A T}^{*} \\
= & {[\operatorname{ant}(\text { VISION } \circledast \mathbf{0})+\boldsymbol{\text { ACTION }} \circledast \mathbf{\text { PUSH }}+} \\
& \quad \text { DATA } \circledast \text { BTNA }] \circledast \text { DATA }^{*} \\
\approx & \mathbf{I} \circledast \text { BTNA }=\mathbf{B T N A}
\end{aligned}
$$

After the rule has been executed, the next rule can be computed by incrementing the position vector ( $\mathbf{P 2}=\mathbf{P} 1 \circledast$ ADD1)) and repeating Equations 2, $3 \& 4$ with this new position vector.

Conditionally Responsive Decoding of Instructions An instruction can also be decoded using the values of the state conditions. In order to do so, the value of the state condition(s) is bound to its associated state descriptor(s), and the inverse of this result is bound to the instruction vector to yield the position of the rule that best matches the state condition(s). Using Equation 1 as an example, if the vision state condition had a value of 1 , the position of the rule that best matches this can be found like so:

$$
\begin{align*}
p o s= & \mathbf{I N S T R} \circledast\left(\text { ant }(\text { state }) \circledast \text { state_val }^{*}\right)^{*}  \tag{5}\\
= & \mathbf{I N S T R} \circledast(\operatorname{ant}(\mathbf{V I S I O N}) \circledast \mathbf{1})^{*} \\
= & \mathbf{P 1} \circledast[\operatorname{ant}(\boldsymbol{V I S I O N} \circledast \mathbf{0}) \ldots] \circledast(\operatorname{ant}(\text { VISION }) \circledast \mathbf{1})^{*}+ \\
& \mathbf{P} 2 \circledast[\operatorname{ant}(\boldsymbol{V I S I O N} \circledast \mathbf{1}) \ldots] \circledast(\operatorname{ant}(\boldsymbol{V I S I O N}) \circledast \mathbf{1})^{*} \\
\approx & \mathbf{P} \mathbf{2} \circledast[\mathbf{I}+\ldots] \approx \mathbf{P} \mathbf{2}
\end{align*}
$$

Once the position vector has been retrieved, the sequential instruction decoding equations can then be used to obtain the action and data associated with the rule.

## The Model

With the ability to encode and decode general instructions, modifying the existing Spaun action selection module to take advantage of this is straightforward. It only entails the addition of a instruction processing module that implements the instruction decoding equations (Eq $2-5$ ) above. The output of this module then become new state variables which the action selection system monitors when selecting an appropriate action (see Figure 2).

Figure 2: Proposed modification to Spaun's action selection system with the addition of an instruction processing module (italicized). As in Figure 1, state monitoring is indicated with a solid arrow, and action effects with a dotted arrow.

Validation of the model comes in the form of behavioural analysis as well as matching the model dynamics to human timing data. The model is implemented with spiking neurons and biologically realistic synaptic time constants in order to generate realistic temporal dynamics.

## Neural Representation

Fundamental to the SPA is the vector-based representation of information. We use methods of the Neural Engineer-
ing Framework (NEF) to accomplish this in spiking neurons (Eliasmith \& Anderson, 2003). Georgopoulos et al. (1986) demonstrated that motor neurons are well characterized as having responses driven by their preferred direction to movement in two dimensions. The NEF generalizes this notion to suggest that neurons can represent any number of dimensions, and the neuron's preferred direction determines its activity with regards to its input in a given vector space. Mathematically, the current $J$ flowing into a neuron can be calculated using as

$$
\begin{equation*}
J(\boldsymbol{x})=\alpha(\mathbf{e} \cdot \boldsymbol{x})+J^{\text {bias }} \tag{6}
\end{equation*}
$$

where $\alpha$ and $J^{\text {bias }}$ are neuronal scaling terms, e is the neuron's preferred direction (or encoding vector), and $\boldsymbol{x}$ is the vector to be represented. The inner product computes the similarity between the encoding and input vector and determines how much current is being fed to the neuron. The leaky integrate-and-fire (LIF) neuron model equation is then used to convert this current into a firing rate.

$$
\begin{equation*}
a(\boldsymbol{x})=G[J(\boldsymbol{x})]=\frac{1}{\tau^{r e f}-\tau^{R C} \ln \left(1-\frac{J^{t h}}{J(\boldsymbol{x})}\right)} \tag{7}
\end{equation*}
$$

In the equation above, $\tau^{r e f}$ is the neuron refractory time constant, $\tau^{R C}$ is the neuron RC time constant, and $J^{t h}$ is the neuron threshold firing current. With a population of neurons, it then possible to derive optimal decoding vectors that can be used to convert the neural activity back into the high dimensional vector space. Eliasmith and Anderson (2003) demonstrate how these decoders $\mathbf{d}$ can be computed.

$$
\begin{align*}
\mathbf{d} & =\Gamma^{-1} \Upsilon, \text { where } \\
\Gamma_{i j} & =\int a_{i}(x) a_{j}(x) \mathrm{d} x \quad \Upsilon_{i}=\int a_{i}(x) x \mathrm{~d} x \tag{8}
\end{align*}
$$

An estimate of the original vector $x$ can then be generated by multiplying each neuron's decoding vector with its activity.

$$
\begin{equation*}
\hat{x}=\sum_{i} a_{i}(x) \mathbf{d}_{i} \tag{9}
\end{equation*}
$$

The encoding and decoding vectors can also be used to determine the optimal connection weights between two neural populations.

$$
\begin{equation*}
w_{i j}=\alpha_{j} \mathbf{e}_{j} \mathbf{d}_{i} \tag{10}
\end{equation*}
$$

Taking into account a specific function while solving for the decoding vectors yields the set of connection weights that will cause the neurons in the post-synaptic population to compute said function. For example,

$$
\begin{equation*}
\widehat{f(x)}=\sum_{i} a_{i}(x) \mathbf{d}_{i}^{f} \tag{11}
\end{equation*}
$$

where $\mathbf{d}^{f}$ are the decoding vectors solved with the function $f$ incorporated into Equation 8. In other words, these equations allow us to build a spiking neuron model that performs arbitrary specified computations. See Eliasmith and Anderson (2003) for additional details.

## Neural Implementation

The model proposed here relies on two key functions: the binding operation and working memory.

The binding operation is performed by a two step process. First the Fourier transform (FT) of both input vectors is computed, and these are multiplied element-wise. Performing an inverse Fourier transform (IFT) on this result provides the desired answer. That is,

$$
\begin{equation*}
\mathbf{A} \circledast \mathbf{B}=\operatorname{IFT}(F T(\mathbf{A}) \odot F T(\mathbf{B})), \tag{12}
\end{equation*}
$$

where $\odot$ is the element-wise multiplication operation. The FT, IFT and element-wise multiplication are functions that can be computed by spiking neurons using the methods discussed in the previous section (see Equation 11).

The working memory component is identical to that used in Spaun. This component is implemented by a recurrent network that is able to stably store information over time. The storage and retrieval of information is determined by gates controlled by the basal ganglia.

## Response Timing

In this section we compare the behaviour of the model to two different tasks: the choice reaction time task, and a sub-vocal counting task. The choice reaction time task demonstrates the model's ability to perform unordered instructions, while the sub-vocal counting task demonstrates the model's ability to perform sequential instructions. Note that for both of these tasks, the architecture of the model remains the same, with the only difference being the instruction vector and visual stimuli that it is required to process.

## Conditionally Responsive Decoding - Two-Choice and Simple Reaction Time Task

To test the model's ability to account for human instruction processing time, it was tested with the two-choice (CRT) and simple reaction time (SRT) tasks described in Grice, Nullmeyer, \& Spiker (1982). Since the input stimuli and motor action performed are similar in both of these tasks, any difference in reaction time can be attributed to the speed at which the different instructions are processed.

In the two-choice reaction time task, the subject is instructed to push one of two buttons, the identity of which is indicated by some sort of visual stimuli. To simulate this with the general instruction following model, it is given the instruction:

$$
\begin{aligned}
& \text { 1. IF } \text { vision }=\text { ZERO, THEN } \text { state }=\text { Push, } \text { motor }=\mathbf{A} \\
& \text { 2. IF vision }=\mathbf{O N E}, \text { THEN } \text { state }=\text { Push, } \text { motor }=\mathbf{B}
\end{aligned}
$$

Figure 3 demonstrates the model performing this instruction. In the simple reaction time task, the subject is instructed to push a single button in response to a single stimulus. This task requires no instruction processing so the rule:

$$
\text { IF vision }=\mathbf{T W O}, \text { THEN } \text { state }=\text { Push, } \text { motor }=\mathbf{C}
$$

Figure 3: Neural response data for the two-choice reaction time task. Shown are the decoded representations for two neural populations (an internal state memory, and the motor output), and the visual stimulus provided. Also displayed is the spiking neural data associated with each of the neural populations. Note that only the cognitive components (i.e. no input stimuli processing lag nor motor lag) of the reaction time task are being simulated in this model.
is encoded directly in the basal ganglia. By doing so, the model is able to execute the desired action when presented with the appropriate stimuli without requiring any additional processing in the instruction processing module.

The model reports a reaction time difference of $77 \pm 34$ ms between the two tasks, while Grice, Nullmeyer, \& Spiker report a reaction time difference of $81 \pm 72 \mathrm{~ms}$ for human subjects.

## Sequential Decoding - Sub-vocal Counting

For this task, the model was given a sub-vocal counting instruction. This instruction is formatted as sequence of actions, and thus have no antecedent.

$$
\begin{aligned}
& \text { 1. } \text { memory }=\text { Store, data }=X \\
& \text { 2. state }=\text { Add } 1 \\
& \text { 3. state }=\text { Write, } \text { motor }=\text { memory }
\end{aligned}
$$

In the instruction above, the variable $\boldsymbol{X}$ is a vector representing a digit from 0 to 9 . Instructions requiring more than one count (e.g. add 1 twice), have the second action repeated the appropriate number of times (and appropriately renumbered). Figure 4 illustrates the model peforming the sub-vocal counting task for one count.

The mean reported count time per item is $384 \pm 29 \mathrm{~ms}$ which falls well between the reported human range of $344 \pm$ 135 ms (Landauer, 1962), and provides a much better match to the human data than Spaun's reported count time per item time of $419 \pm 10 \mathrm{~ms}$ (Eliasmith et al., 2012).

## Simulation Details

In total the model is made up of 318,870 spiking LIF neurons, and uses 256 -dimensional semantic pointers. It should be noted that Spaun utilizes semantic pointers with 512 dimensions, and this was reduced for this model to decrease the amount of time required to simulate the experiments. It takes $275 \pm 25$ seconds of CPU time to simulate 1 second of simulation time on a machine with a 3.40 GHz Core i7-3770 quad-core CPU and 16 GB of RAM.

## Discussion

The model presented in this paper demonstrates the ability to process and execute generic instructions without needing any changes to the underlying architecture. It is also able to reproduce response times in human reported ranges based purely on the temporal dynamics of the underlying neural implementation - without the need for data fitting of any kind.

Because the model utilizes semantic pointers to represent information, it is also highly scalable. The maximum number of concepts the model is able to represent is dependent on the dimensionality of the semantic pointer used, and not on the number of knowledge nodes present in the model. Crawford, Gingerich and Eliasmith (Crawford, Gingerich, \& Eliasmith, 2013) demonstrate that the entirety of WordNet (117,659 concepts) can be represented using 512 dimensional semantic pointers. Increasing the proposed model to utilize 512 dimensional semantic pointers would add an additional 287,488 neurons to the model.

One major limitation to this model, however, is its inability to learn frequently executed instructions. In essence, even

Figure 4: Neural response data for the sub-vocal counting task. Shown are the decoded representations for three neural populations (an internal state memory, working memory (WM), and the motor output), and the visual stimulus provided. Also displayed is the spiking neural data associated with each of the neural populations. Note that the ADD value for the state variable indicate both the start and end of the number addition action.
if it is presented with multiple instances of the same instruction, it is unable to form an expert action for that instruction. This issue is currently being investigated and integrating this ability in the proposed model remains as future work.

This paper also makes no mention of how the model could construct a new instruction vector given purely a visual stream of words or symbols. Concurrent work done by Stewart and Eliasmith (Stewart \& Eliasmith, 2013) provides insight on how this issue can be made tractable.

#### Abstract

In this paper we propose a hidden Markov model (HMM)based method to analyze eye movement data. We conducted a simple face recognition task and recorded eye movements and performance of the participants. We used a variational Bayesian framework for Gaussian mixture models to estimate the distribution of fixation locations and modeled the fixation and transition data using HMMs. We showed that using HMMs, we can describe individuals' eye movement strategies with both fixation locations and transition probabilities. By clustering these HMMs, we found that the strategies can be categorized into two subgroups; one was more holistic and the other was more analytical. Furthermore, we found that correct and wrong recognitions were associated with distinctive eye movement strategies. The difference between these strategies lied in their transition probabilities.

Keywords: Hidden Markov Model (HMM); eye movement; scan path; holistic processing; face recognition.

## Introduction

In the late $19^{\text {th }}$ century, soon after Edmund Huey's invention of the world's first eye tracker, researchers discovered that in many daily life activities, eye movements were rapid, discontinuous, and interrupted by temporary fixations (Wade \& Tatler, 2011). Nowadays, this finding has been widely accepted and described as the 'saccade and fixate' strategy (Land, 2011). Eye movements were found to facilitate face learning and recognition. For instance, Henderson et al. (2005) showed that when participants were restricted to view face images only at the center of the images, their recognition performances were significantly lowered than when they were allowed to view the images freely. Autistic patients, who could not judge facial expressions correctly, were found to have abnormal eye fixations patterns (Pelphrey et al, 2002).

Empirical studies on the relationship between eye movement and face recognition have primarily been focusing on identifying the regions of interest (ROIs). A ROI is a region on the face which people frequently fixate in, such as the two eyes. Early studies often divided a face into several regions and then identified the ROI through comparing the frequencies of each region being fixated in. However, this approach suffered from the lack of an objective manner to divide faces. For instance, Barton et al. (2006) defined the two eyes as two irregularly shaped

ROIs, while Henderson et al. (2005) defined the two eyes as one ROI. Another problem is that the predefined ROIs may not really represent the data because different individuals have different saccade patterns. More recent studies attempted to discover ROIs directly from data. A commonly adopted way was to generate statistical fixation maps. A fixation map can be created by identifying the location of fixations and convolving a Gaussian kernel on each fixation. Two fixation maps can be compared by Pixel test, which discovers statistically significant differences in pixels (Caldara \& Miellet, 2011). Using fixation maps, it was found that the upper center (i.e. the nose) and the upper left (i.e. the left half of the nose and the left eye) parts of a face were the two most frequently viewed areas (Hsiao \& Cottrell, 2008). This result was consistent with an earlier study which used the Bubbles technique in discovering regions with diagnostic features in face recognition (Gosselin \& Schyns, 2001). Fixation maps also showed that children from different cultural backgrounds demonstrated different eye fixation patterns (Kelly et al, 2011).

The use of fixation maps in face recognition studies had been fruitful. However, as discussed earlier, eye movements combine saccades and fixations. The fixations recorded in eye movement studies should be considered as time-series data that are collected over time. The eyes fixate at a location shortly, before a saccade brings them to the next location. Many studies showed that saccades can be influenced by top-down expectations as well as bottom-up inputs. Yarbus's (1965) well-known eye movement studies showed that depending on what people expect to see, they exhibited different saccade patterns when looking at the same target image. Mannan et al. (1997) discovered that saccades were more likely to be driven to the more 'informative' areas of an image, such as the edges and the high-spatial-frequency areas. These findings imply that the target location of a saccade could be a variable that has a set of possible values; different values could be associated with different probabilities. In this sense, eye movements may be considered as a stochastic process, which could be better understood using time-series probabilistic models. The fixation maps, however, do not contain temporal information.
Currently, there are two methods for describing the temporal information in eye movement data. One is the string-editing method. It requires an image to be divided
into several ROIs, each labeled with a letter, so that a sequence of eye fixations can be described by a string. Two strings are then compared by measuring their Levenshtein distance (Goldberg \& Helfman, 2010). This method does not capture the temporal information very precisely because the measure of Levenshtein distance does not precisely represent the sequential differences between two strings. For instance, the strings CAT and BAT differ in their first element, while the strings CAB and CAT differ in their last element. In both cases, however, the Levenshtein distance is one. The other method is to generate fixation maps by fixation and compare between conditions (Caldara \& Miellet, 2011). For instance, if an experiment has two conditions, all the first fixations in each condition can be used to generate a fixation map. A comparison between the two fixation maps will show whether the two groups differ significantly in their first fixations. However, the problem associated with this method is that the significant areas are likely to be scattered so that the pattern could be hard to interpret. In this paper, we propose to use a time-series statistical model, the hidden Markov model (HMM) with Gaussian emission densities, to analyze eye movement data. We show that HMMs can 1) summarize a person's general eye movement strategy, including person-specific ROIs and saccade patterns, 2) reveal between-subject similarities and differences of eye movement patterns, and 3) discover the association between recognition performance and eye movement strategies. In the next section, we will 1) briefly describe the experiment in which we collected the data, and 2) explain the HMMbased method in more length.

## Method

## Experiment

A total of 32 Chinese participants were recruited at the University of Hong Kong. The experiment was divided into a training phase and a testing phase. In the training phase, participants were shown a total of 20 frontal face images. In the testing phase, participants were shown 40 frontal face images; 20 were new images and 20 were the ones appearing in the training phase. They were asked to judge whether they had seen the faces before. Their responses in the testing phase were recorded together with the fixations they made before the response. Eye movements were tracked and recorded using the Eyelink II eye-tracking system. On average, participants made 2.5 fixations per trial, ranged from one to three (this average was 1.8 fixations in Hsiao \& Cottrell, 2008).

## Model

HMMs are widely used to model data generated from Markov processes (Barber, 2012). A Markov process is a process whose present state is determined only by its previous state. The states in an HMM are not directly observable, so that the current state of the process can only be inferred from 1) the association between the assumed hidden state and the observed data, and 2) the likelihood of transiting to
the assumed state from the previous state. The association among the observable data and the hidden states are summarized using probability distributions; each distribution represents the likelihood of a hidden state generating the data. The probabilities of transiting from one state to other states are summarized in a transition matrix; each element represents the probability of that transition. An HMM also has a vector of prior values; each value indicates the probability of the HMM starting from the corresponding state.

For instance, natural language processing is one area in which HMM has been widely applied. The observable data are the words in a corpus, and the hidden states are the word-class tags, such as nouns, verbs, and adjectives. An HMM cannot directly observe the word-class tags of the words, but can infer them from the observed words and the likelihood of transiting from one word-class to another.

In the context of face recognition, the HMM contains a number of hidden states, which each represents a different ROI of the face. The directly observable data is the fixation location, which belongs to a particular hidden state (ROI). The distribution of fixations in each ROI is modeled as a two-dimensional Gaussian distribution in a Cartesian space. Over time, the transition from the current hidden state to the next state represents the saccade pattern, i.e., movement between ROIs, which is modeled by the transition matrix of the HMM. In summary, the hidden states of the HMM correspond to the ROIs of the face, where each is observable through a two-dimensional Gaussian emission density of fixations, and the transitions between hidden states represent the saccade patterns.

Given a set of chains of fixations, we estimated the parameters of the HMM using a two-stage procedure. We first learned the ROIs on the face from the fixation data. Ignoring the temporal information, the ROIs can be seen as a mixture of two-dimensional Gaussian distributions, i.e., a Gaussian mixture model (GMM). In this study, we used the variational Bayesian framework for Gaussian mixture models (VBGMM) to estimate the Gaussian parameters, as well as the number of GMM components (Bishop, 2006). This Bayesian hierarchical method puts prior distributions on the GMM parameters, and uses approximation methods to find the maximum a posteriori (MAP) estimate. One important feature of VBGMM is that it can automatically estimate the optimal number of ROIs and 'deactivate' the redundant ones. After discovering the GMM components, or the ROIs, we next estimated the transition probabilities and prior probabilities of the hidden states, using the forwardbackward algorithm (Bishop, 2006).

In this study, we aim to use HMMs to address two questions. Firstly, we wanted to discover the eye movement strategy of each individual in order to reveal the common strategies shared by a subgroup of the participants. Secondly, we wanted to explore whether accuracy at face recognition was related to eye movements. To address the first question, we trained one HMM per subject, using fixations collected from all the trials of the subject, in order to represent the general eye movement pattern of that subject. To
cluster the subjects' HMMs, we used the variational hierarchical EM algorithm (VHEM) for HMMs (Coviello et al, 2012). The VHEM algorithm takes HMMs as inputs, separates the inputs into subgroups, and estimates a representation HMM for each subgroup.

To address the second question, we trained two HMMs per subject, using fixation sequences collected from all the correct trials (i.e., correct HMM) and all the wrong trials (i.e., wrong HMM), respectively, to represent two eye movement strategies that led to different performances. We compared the correct HMMs to the wrong HMMs using subject analysis, based on the differences in log-likelihoods of the observed data, in order to examine whether eye movement strategies that lead to correct or wrong responses have significantly different patterns. Specifically, for the fixation sequences of a participant leading to correct responses, we calculated the log-likelihoods of observing the sequences from the correct HMM, and then computed the mean. We also calculated the mean log-likelihood from the wrong HMM using the same sequences. Doing this on all the 32 participants yielded two vectors of mean loglikelihoods, one represented the mean log-likelihoods of the correct HMMs generating the correct eye movements, and one represented the mean log-likelihoods of the wrong HMMs generating the correct eye movements. The differences between the mean log-likelihoods for each subject is an approximation to the Kullback-Leibler (KL) divergence between the correct HMM and the wrong HMM, which is a measure of difference between two distributions (Bishop, 2006). Similarly, we also calculate the mean log-likelihoods of the fixation sequences leading to incorrect responses under the wrong and correct HMMs.

## Results

## Section 1.1- Summary of all eye movement patterns

In order to model a participant's eye movement patterns, we pooled all the fixations that a participant made, regardless of their sequential order, and applied the VBGMM to discover a mixture of Gaussian distributions. We then used the found Gaussian components and the fixations in the forward-backward algorithm to estimate the transition probabilities and the prior values of the Gaussian components. The fixations put into the forward-backward algorithm were in their sequential orders. Each participant's eye movements were modeled by an HMM. Using the VHEM to group all HMMs into one cluster, the VHEM generated a representation of the cluster which summarized the eye movement patterns of all the participants in one HMM. Figure 1 below shows the representation HMM and the fixation map of all the fixations combined. Figure 2 below shows the fixation maps per each fixation.

The left image in figure 1 shows the HMM model. For instance, the prior value of the red region suggests the probability of a first fixation belonging to that region. The probability of the next fixation transits from the red into the green region is 0.07 .

Figure 1: The image on the left shows the three GMM components of the HMM. Each colored region represents a ROI (red, green, or blue). The transition probabilities and the prior values are summarized in the table beneath. The image on the right shows the fixation map of all the fixa-
tions.

Figure 2: From the left to the right, the three images show the first, second, and third fixations that all subjects made.

From the comparison between the VHEM output and the fixation map of all the fixations combined, it can be seen that the VHEM output was spatially similar to the fixation map. The fixation map showed that most fixations landed in the middle of the face, with some slightly to the right. The three Gaussian components found using the VHEM demonstrated a similar tendency. One advantage that the VHEM output has over the fixation map is that on top of the spatial distributions, it provides the temporal information of the eye movement data in the forms of the prior values and the transition probabilities.

The transition probabilities and the prior values suggested that in general, fixations were more likely to start from the red and the blue regions and to remain in or shift between the two regions. The chance of beginning from the green region was lower. However, these fixations were more likely to stay in the same region than moving to the other regions. The fixation maps are shown in Figure 2. While there appears to be some movement between fixations, the fixation maps carry no information about the actual saccade pattern. However, using the results from the HMM analysis, we can better interpret the fixation maps. The higher probabilities of remaining in the same regions and the lower probability of starting from the green region may have re-
sulted in the fixations forming three separate clusters at the third fixation; the cluster corresponded to the green region was less compacted.

## Section 1.2-Two general strategies

Another advantage of using the HMM-based method is that the VHEM can group the input HMMs into several subgroups and generate a representation HMM for each subgroup. These would reveal the eye movement patterns shared by the participants in the same subgroup. The VHEM adopts a bottom-up, data-driven approach. It estimates the distance between an input HMM and a representation HMM. The distance between an input HMM and all the representation HMMs are then normalized, which gives a probability-based measure of how likely the input HMM belongs to a subgroup.

Using the VHEM, we discovered two subgroups, as shown in Figure 3 below.

|  | Holistic strategy | Analytic strategy |  |
| :---: | :---: | :---: | :---: |
|  |  |  |  |
|  |  |  |  |
|  |  |  |  |
|  |  |  |  |
|  |  |  |  |
|  |  |  |  |
|  |  |  |  |
|  |  |  |  |
|  |  |  |  |
|  |  |  |  |
| Holistic blue |  |  |  |
| prior values | 0.33 | 0.39 | 0.11 |
| from red | 0.65 | 0.24 | 0.17 |
| from green | 0.22 | 0.61 | 0.63 |
| from blue | 0.12 | 0.25 | to blue |
| Analytic | to red | to green | 0.47 |
| prior values | 0.06 | 0.47 | 0.39 |
| from red | 0.39 | 0.22 | 0.22 |
| from green | 0.03 | 0.75 | 0.70 |
| from blue | 0.05 | 0.25 |  |

Figure 3: The two representation HMMs of the two subgroups are shown in the left and the right images respectively.
It can be seen that the representation HMM on the left was more 'condensed'. The three Gaussian components were relatively small in size and were squeezed toward the center of the face. This pattern was similar to the "Eastern pattern" found in a previous study (Kelly et al., 2011) that was argued to represent a more holistic strategy. The HMM representation on the right, on the other hand, was more 'spread'. The three Gaussian components were large and more separated from one another. This pattern could be loosely associated with the "Western pattern" (Kelly et al., 2011) that represented a more analytic way of perceiving a face.

The table below shows the probabilities of the 32 HMMs belonging to the two subgroups. Each HMM was a model of a participant's eye movement patterns, so that the two numbers of each participant can be conceptualized as the degree to which the participant was biased to holistic or analytic eye movement strategies. Overall, 10 participants used holistic pattern, while 22 used the analytic strategy.

Table 1: Summary of the normalized log-likelihoods of the subjects belonging to the two subgroups.

| ID | Holistic | Analytic | ID | Holistic | Analytic |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 01 | 0 | 1 | 17 | 0 | 1 |
| 02 | 0 | 1 | 18 | .04 | .96 |
| 03 | 1 | 0 | 19 | 0 | 1 |
| 04 | 1 | 0 | 20 | 1 | 0 |
| 05 | 0 | 1 | 21 | 1 | 0 |
| 06 | 0 | 1 | 22 | 0 | 1 |
| 07 | 1 | 0 | 23 | 0 | 1 |
| 08 | 0 | 1 | 24 | 0 | 1 |
| 09 | 0 | 1 | 25 | 0 | 1 |
| 10 | 1 | 0 | 26 | 1 | 0 |
| 11 | 0 | 1 | 27 | 0 | 1 |
| 12 | 0 | 1 | 28 | 1 | 0 |
| 13 | 1 | 0 | 29 | 1 | 0 |
| 14 | 0 | 1 | 30 | .02 | .98 |
| 15 | 0 | 1 | 31 | 0 | 1 |
| 16 | 0 | 1 | 32 | 0 | 1 |

The log-likelihoods suggested that the two subgroups were very distinctive from each other. To confirm whether they really represented two distinctive eye movement patterns, we randomly created 50 pseudo-data chains; each was a sequence of three pseudo fixations. We measured the loglikelihoods of the two HMMs generating the pseudo-data. Paired t-test showed that the log-likelihoods generated by the two HMMs were significantly different, $\mathrm{t}(49)=-12.81$, $\mathrm{p}<.001$; mean log-likelihood difference was 13.84. The finding further confirmed that the two eye movement patterns were distinctive from each other.

## Section 2 - Association between performance and eye movement patterns

To investigate whether the differences in recognition performance are associated with different eye movement patterns, we trained per participant an HMM on all the fixations collected from the correctly responded trials (correct HMM), and an HMM on all the fixations collected from the incorrectly responded trials (wrong HMM). We compared the mean log-likelihoods of the data being generated by the two HMMs.

Paired t-test showed that the mean log-likelihoods of correct data being generated by the correct HMMs ( $\mathrm{M}=$ 18.13) were significantly higher than the mean loglikelihoods of correct data being generated by the wrong HMMs ( $\mathrm{M}=-18.42$ ), $\mathrm{t}(31)=-2.58, \mathrm{p}=.01$. The mean loglikelihoods of the wrong data being generated by the wrong

HMMs ( $\mathrm{M}=-17.9$ ) was also significantly higher than the mean log-likelihoods of correct data being generated by the wrong HMMs $(\mathrm{M}=-18.53), \mathrm{t}(31)=-4.58, \mathrm{p}<.001$. The results suggested that the two sets of HMMs were significantly different from each other. Figure $4-7$ below illustrate the HMMs and the fixation maps of a few subjects.

Figure 4: The correct and wrong HMMs of subject 1.

Figure 5: The correct and wrong HMMs for subject 2.

Figure 6: The correct and wrong HMMs of subject 3.

Figure 7: From the left to the right, the three images show the difference between the fixation maps of correct and the wrong responses of the three subjects shown in Figure 4-6.

From the figures above, we see that in some cases, the key difference between the wrong and correct HMMs can be discovered from the temporal rather than the spatial domain of the data. For instance, for subject 1 , the correct and the wrong HMMs were spatially similar, but the wrong HMM had a different set of prior values and transition probabilities. If the subject started looking at the image from the right eye, the response is more likely to be incorrect. ${ }^{1}$

One disadvantage of comparing fixation maps between correct and wrong responses can be seen from figure 7 above. The pixel test in each case discovered many significantly different regions. These regions are all over the face, which make them very hard to be qualitatively explained.

## Discussion

[^39]In this paper, we have proposed an HMM-based method to analyze eye movement data and demonstrated several advantages.

Firstly, our method can learn the ROIs for each person from the data together with their temporal information. This provides the information for describing and inferring the scan paths. Although fixation maps can be generated by fixations, such that the maps could be used to show the distributional difference of fixations over time, they do not contain transition information so that describing and inferring scan paths are impossible.

Secondly, using VHEM, the HMMs can be grouped into clusters based on their similarities. Our finding of this clustering showed that participants demonstrated either a holistic strategy or an analytic strategy. The two strategies were significantly different from each other.

Lastly, by comparing the correct and the wrong HMMs, we showed that the 'correct' eye movements were significantly different from the 'wrong' eye movements, and that the difference to a considerable extent can be attributed to the transition differences instead of spatial distribution differences. Comparison of the fixation maps of correct and wrong responses also showed the differences between the 'correct' and 'wrong' eye movements, but the differences were too spread so that the results lacked identifiable patterns. Also, the fixation map method was not able to show the difference in transition probability between eye movements in correct and wrong trials.
The lack of empirical findings to support the scan path theory caused eye movement researchers' lack of interest in sequential information (Henderson, 2003). Our findings, however, suggest that sequential information could be associated with performance. Theoretically, given a chain of fixations, using the two HMMs, the accuracy of the response can be predicted. This further justifies using HMMs to describe and analyze eye movement patterns. Future work will test this hypothesis.

In the current study, we pooled all the fixations together to find the ROIs because we assumed that the ROIs are the same across fixations. An alternative approach that does not rely on this assumption is to train the GMMs by fixation, so that at each fixation, there are a unique set of ROIs. An HMM in this case will have time-dependent states. For future research, we attempt to investigate this further.

In summary, here we show that eye movements can be better studied and understood using HMMs. With HMMs, we can describe both the spatial and the sequential aspects of eye movements. We also show that clustering the HMMs can yield interesting between-group differences. The two subgroups roughly correspond to more holistic and more analytic strategies. We further show that correct and wrong recognitions have different eye movement patterns and that the differences can be found in the transition probabilities.

# Uniquely human developmental timing may drive cerebral lateralization and interhemispheric collaboration 

Ben Cipollini (bcipolli@cogsci.ucsd.edu)<br>Department of Cognitive Science, 9500 Gilman Dr<br>La Jolla, CA 92093 USA<br>Garrison Cottrell (cottrell@eng.ucsd.edu)<br>Department of Computer Science and Engineering, 9500 Gilman Dr<br>La Jolla, CA 92093 USA

#### Abstract

Cerebral lateralization is intertwined with virtually every cognitive function that we think makes us human. Yet a clear dichotomy has never been explained: lateralized processing suggests independent, local development of neural circuits, but the complementary nature of lateralized functions and extremely strong functional coupling between homologous areas suggest robust interhemispheric interactions. Here, we review literature and present modeling evidence that this dichotomy can be explained by the uniquely steep trajectory of human post-natal brain growth. This drastic volumetric change cause most long distance, interhemispheric connections to be more unreliable than shorter, intrahemispheric connections, leading to lateralization. Strong interhemispheric collaboration is enabled by the later maturation and myelination of long-distance callosal connections. We also review and reanalyze a well-cited modeling paper (Ringo, Doty, Demeter, and Simard (1994)) thought to show a relationship between the degree of hemispheric coordination and length of conduction delays, showing that previous claims have a clear alternative explanation.

Keywords: corpus callosum; lateralization; asymmetry; conduction delays;

## Introduction

A single concept, supported by a single paper, has dominated thought as to the origins of cerebral lateralization. The modeling work of Ringo et al. (1994) has been exclusively and extensively cited to support the notion that large magnitude conduction delays, due to the large human brain size, enable cerebral lateralization. This delay magnitude hypothesis has intuitive appeal, as it supports another long-held notion: that some combination of large brains and functional lateralization have made us human.

There is no denying the importance of functional lateralization in human cognitive abilities; we are functionally lateralized in virtually all cognitive functions that we think are special to our species, including language, high-precision manual use of tools, spatial processing abilities, and even our emotional processing (Gazzaniga, 2000; Craig, 2005). There is also no denying, however, that the lateralized hemispheres are also tightly coupled in terms of both their complementary abilities (Gazzaniga, 2000; Hellige, 2006) and their functional coupling (Stark et al., 2008). This dichotomy is simply not captured by the delay magnitude hypothesis. Nor does the hypothesis account for the anatomical and functional asymmetries that appear throughout the animal kingdom (Rogers \& Andrew, 2002; Rogers, 2009) in organisms with small
brains. Whether or not the delay magnitude hypothesis is correct, it certainly is not complete.

We hypothesize that functional lateralization is not caused by the magnitude of conduction delays. First, we'll review literature that supports our hypothesis. We'll present a reanalysis of Ringo et al. (1994) that severely restricts the scope of their results. We'll propose a new hypothesis that the developmental trajectory of human brains enables functional lateralization-specifically, that the vast and accelerated postnatal expansion of brain size and delayed maturation of the corpus callosum causes unreliable timing of interhemispheric information in pre-adult humans. We'll review literature supporting this hypothesis, then we'll present our own model supporting the plausibility of our developmentalhypothesis. Finally, we'll summarize our results and discuss implications of our findings to the general phenomena of lateralization, asymmetry, and cognition.

## The failure of conduction delay magnitude

Callosal axons are especially long in humans, due to their need to traverse through our large, highly gyrified brains to connect to the opposite hemisphere. Because the average conduction velocity of axons does not sufficiently compensate for the additional axon lengths when compared to smallerbrained animals, the resulting interhemispheric transmission delay over the majority of callosal axons is longer in human brains. The delay magnitude hypothesis suggests that this increased delay would cause less interhemispheric collaboration and therefore enable cerebral asymmetry.

While the anatomy and physiology of callosal axons is well-established, their seemingly intuitive effects on interhemispheric collaboration is supported by a single model in a single paper (Ringo et al., 1994). Here, we argue against the delay magnitude hypothesis in two parts. First, we present 4 results from the literature that are inconsistent with the delay magnitude hypothesis. Second, we show that the model itself does not support the hypothesis.

## 1. Increased interhemispheric collaboration is associated with an increase in slow fibers

Larger corpus callosum size is associated with less lateralization. This is true for regions of the corpus callosum, as well as the corpus callosum as a whole. The midbody of the callosum, which carries fibers to and from motor
cortex, is larger for individuals with less lateralization in handedness (Witelson, 1989; Luders et al., 2010). Callosal cross-sectional area is proportionally larger for left-handers (Witelson, 1985), who show less functional lateralization than right-handers.

Within humans, larger corpus callosum size is associated with a larger number of thin fibers, not with the thickness of fibers (Aboitiz, Scheibel, Fisher, \& Zaidel, 1992). This suggests that those with more interhemispheric collaboration have significantly more slow fibers-just the opposite of what the delay magnitude hypothesis would predict.

## 2. Homotopic areas show functional coupling

The corpus callosum largely connects corresponding (homotopic) areas between left and right cerebral hemispheres. Thus, according to the delay magnitude hypothesis, homotopic areas connected with slow, thin fibers (Aboitiz \& Montiel, 2003) should show weak functional connectivity. In fact, this is not the case at all. For example, when examining interhemispheric correlations through resting-state fMRI, Stark et al. (2008) found very strong interhemispheric correlations between association areas. Reduced interhemispheric coherence (measured with EEG) at locations away from primary sensory/motor cortices has been measured in mental disabilities or diseases, such as dyslexia (Dhar, Been, Minderaa, \& Althaus, 2010) and schizophrenia (Hoptman et al., 2012).

Hellige (2006) points out that functional specializations tend to be complementary. For example, visual processing of the left hemisphere seems biased towards high frequency processing, while the right hemisphere seems biased towards low-frequency processing (Sergent, 1982; Ivry \& Robertson, 1998). If there is less interhemispheric integration due to more independent processing, then why would the two hemispheres show any type of relationship at all? The delay magnitude hypothesis offers no answer.

## 3. Longer delays may support coordination

The corpus callosum in larger brains doesn't simply have longer conduction delays; it also has a broader range of conduction delays. Innocenti (2011) reviewed data suggesting that a broader range of conduction delays supports a broader range of oscillations across the corpus callosum (Caminiti, Ghaziri, Galuske, Hof, \& Innocenti, 2009), which may increase the stability of those oscillations (Roberts \& Robinson, 2008). The current belief is that these oscillations are necessary for binding of information between two distant cortical areas (Fries, 2005); stabilization of inter hemispheric oscillations would presumably enhance interhemispheric communication. Thus, longer delays may be associated with improved ability to coordinate interhemispheric integration.

## 4. Shorter delays are detrimental in development

Many ideas of how the human brain may be unique have been debunked, including suggestions that the human brain is specially gyrified or has a unique fundamental asymmetry. Human brains are clearly unique developmentally-as precocial
mammals (born with our eyes open), we are the only species known to extend the accelerated rate of prenatal brain growth well beyond birth (Martin, 1983). This means that the rate of brain growth is especially high in humans.

Lewis and Elman (2008) used a version of Ringo et al.'s model to show that, the steeper the developmental brain growth curve, the more detrimental interhemispheric connections are to learning. This is due to the fact that, as brain size changes more quickly, the conduction delays change more as well, and those larger changes are more detrimental to learning. As their model "matured", even though the magnitude of delays were longer, because they were more stable, they promoted interhemispheric collaboration.

The delay magnitude hypothesis only addresses mature, adult brains. We suggest that taking a developmental angle to this problem may give more general results.

## 5. Delays only affect the onset of communication

Figure 1: (a) The model architecture of Ringo et al. (1994). Information flows from bottom to top; left model hemisphere is to the left, and right model hemisphere is to the right. Arrows represent full connections between pre- and post-synaptic units. All delays are 1 time-step, except the interhemispheric ("callosal") connections, whose delay were varied across conditions. Note the shared output nodes, which allow an (unintended) path for fast interhemispheric coordination independent of the "callosal" connections.
(b) The model architecture of Lewis and Elman (2008) simplifies the structure and splits the inputs and outputs.

## The model failed to control all interhemispheric transfer

 Although Ringo et al. aimed to separate interhemispheric communication through long conduction delays, their model setup failed to do so (Fig. 1a). In addition to their "callosal" connections that were varied with short and long delays, their model also had converging connections from the hemispheres to a shared bank of output nodes, whose delays were always short. Thus, even if they re-trained their models without any "callosal" connections, the hemispheres would still show interhemispheric dependence; one hemisphere would not be able to complete the task without the other. ${ }^{1}$ This issue is[^40]an important confound in interpreting their results.
This issue was addressed in the only paper to follow-up the Ringo et al. study, by simply splitting the output nodes into two separate banks (Lewis \& Elman, 2008), as depicted in Fig. 1b. All modeling work in this paper uses this same split-output architecture.

## The results are often misunderstood and misinterpreted

Fig. 3 describes the Ringo et al. methods; Fig. 3a shows the original results. Citations to this paper are often made to support the notion that functional lateralization is inevitable, given the human brain size. This is a misrepresentation of the Ringo et al. results. In the paper, the authors only claim that lateralization at short settling times is caused by long delays. Tasks that allow "multiple passes" across the callosum were interpreted to show indistinguishable results across delays.

In fact, the original Ringo et al. results do not show anything except a static delay in interhemispheric coordination, of exactly the value of a single pass across the model corpus callosum. When we transpose the results from the two models by this value ( 9 time steps), the two models are indistinguishable (see Fig. 2 for details). This suggests that the only change in interhemispheric interactions found by their model is a simple, static delay in onset of interhemispheric communication, of a value equal to the time it takes for information to move from one hemisphere to the other. Note that this onset of activity may be mediated by "gigantic" callosal fibers-the largest $0.1 \%$ of fibers that do vary with brain size (Olivares, Montiel, \& Aboitiz, 2001; Wang, 2008), an effect not captured in this model.

The model does not provide any evidence of qualitatively reduced interhemispheric interaction, only weak evidence for a (slightly) delayed one.

## Our hypothesis: changes in timing reliability

The delay magnitude hypothesis fails to explain the basic dichotomy of how functional areas become both lateralized and functionally coupled. The developmental time-course of the thin callosal fibers suggest a two stage process to us: an initial stage where all associative / pre-frontal white-matter connections are immature, favoring local processing, and then a later stage were white-matter connections mature and come on-line. This pattern is well-supported in white matter in general, with some support in the corpus callosum as well (e.g. the anterior, frontal portion) (Jernigan, Baar, Stiles, \& Madsen, 2011). Current imaging technologies can only detect particular types of maturational changes, with those that we outline below (relatively small changes in fiber diameter) currently excluded.

As mentioned above, previous work by Lewis and Elman suggested that unreliability in conduction delays could affect interhemispheric processing. However, though human postnatal brain growth is fast compared to other species, it is still quite slow compared to the time-scale of plasticity in the brain. Based on their work, we suggest that any factor that

Figure 2: (a) Original data from Ringo et al. (1994), showing performance of networks after lesioning interhemispheric fibers, for two networks with different interhemispheric delays ( 1 time-step vs. 10 time-steps). Different networks were required to process across a range of times (x-axis; 15-75 time-steps), while they were trained to output binary strings that were associated with particular input binary strings. After training, "callosal" connections were lesioned, and network performance was measured. The network with the shorter interhemispheric delays ( $\mathrm{D}=1$; empty triangles) shows poorer performance on networks running for fewer time-steps ( x -axis $=15-30$ time-steps); this was interpreted as indicating less interhemispheric interaction.
(b) We expect a network with delay=1 and delay=10 to have a difference of 9 time-steps to the onset of hemispheric interaction. We shifted the $\mathrm{D}=1$ curve by 9 time-steps later (right on the x -axis) to allow us to visualize any qualitative difference in the interhemispheric interaction outside of this difference in onset. The overlap of the curves suggest that there is no other variation in interhemispheric communication besides this simple static delay.
disrupts the reliability of timing between cortical areas will have a detrimental effect on their coordination.

In reviewing the developmental literature, we did find one source of variability in the coordination of timing that is relevant to the corpus callosum: unreliable conduction delays in unmyelinated fibers with a thickness less than $0.5 \mu \mathrm{~m}$ (Wang, 2008). Interestingly, in all adult animal species, callosal fibers are rarely found with a thickness below $0.5 \mu \mathrm{~m}$ (Aboitiz \& Montiel, 2003). However, neonates have a preponderance of such fibers ${ }^{2}$ (Berbel \& Innocenti, 1988; LaMantia \& Rakic, 1990). While some of these small-diameter, unmyelinated fibers persist into adulthood, many become myelinated and all become more reliable by increases in their diameter (Aboitiz \& Montiel, 2003).

Thus, we have a mechanism that fits all of our criteria: initially thin axon diameters decrease the reliability of the timing of information on a timescale relevant to neural processing (individual spikes), and follow a developmental trajectory that would initially support more independence (through less

[^41]reliable timing), with developmental maturation tending towards interhemispheric collaboration (more reliable timing).

We hypothesize that association areas develop with decreased interhemispheric contributions, due to the unreliability of interhemispheric signals through small, unreliable fibers. This allows for the hemispheres to develop independently, which enables asymmetries to develop. Developmental changes in these fibers (diameter increases and myelination) make them reliable, and interhemispheric coordination comes online. In the discussion section, we'll expand this hypothesis to show exactly how it can address each of the questions laid out above.

## Methods

We implemented a version of Lewis and Elman's model (Fig. 1b), which uses rate-coded leaky-integrator units. We suggest this is plausible: asymmetries are linked to higher-order cortical areas (Sergent, 1982; Schenker, Sherwood, Hof, \& Semendeferi, 2007) which tend to interconnect over the corpus callosum using slow fibers (Aboitiz \& Montiel, 2003) that are suggested to use rate-coding, rather than spike-time coding employed by thicker, faster fibers (Wang, 2008).

All connections in the model carry a delay; in all simulations cited and implemented, intrahemispheric delays are set to 1 time-step. Each hemisphere consists of 5 input units, fully connected to 15 hidden units. The hidden units have full recurrent self-connections, as well as full feed-forward connections to 5 output units. 3 hidden units from each hemisphere connected fully and reciprocally to each other as a model "corpus callosum"; these were the only shared connections between the hemispheres ${ }^{3}$. For all simulations, only these interhemispheric connections were manipulated.

As in the previous studies, the task for the network was to learn associations between input binary strings and output binary strings. We used a version of backpropagation through time appropriate for learning with conduction delays (Pearlmutter, 1989), for calculating our error gradients, and used resilient backpropagation for computing our gradient updates (Riedmiller \& Braun, 1993). We used the sumsquared error function function ${ }^{4}$.

We found that learning in the networks with published learning rates was slow; we also found that the degree of interhemispheric communication was dependent on parameters that were not varied in each study. We chose parameters to optimize learning speed, while balancing between interhemispheric and intrahemispheric dependencies ${ }^{5}$. Since the purpose of this study was to examine changes in intrahemispheric and interhemispheric processing, and not their actual magnitude, this seemed a reasonable approach.

[^42]For this study, we set a fixed total time (30 time-steps) and interhemispheric delay ( 10 time-steps).

## Experimental Setup

We measured two values for performance: the classification error was the percentage of output nodes that were not within 0.5 of their expected output value ( +1 or -1 ), and the training error was the average (sum-squared) error at each output node. For each of these values, the lesion-induced error was computed as difference between performance of the intact and lesioned network, as was done in Lewis and Elman. Again following that paper, our dataset contained both intrahemispheric patterns ( $50 \%$ of the input patterns), one hemisphere could determine its output without receiving any information from the other, as well as interhemispheric patterns ( $50 \%$ of the input patterns), one hemisphere had to receive information from the other hemisphere to choose between 4 possible output strings. This allowed a more nuanced analysis of network performance differences.

Importantly, we operationalized unreliable conduction delays as Gaussian noise of the activity (instantaneous firing rate) transmitted over fixed (reliable) delays. In a rate-coding system, variation in the arrival of individual spikes, or a missing spike, leads to jitter in the instantaneous firing rate. We implemented this jitter directly in our rate-coded network as Gaussian noise on the activity, on a per-synapse basis. The jitter was a function of the delay at each synapse ${ }^{6}$.

We ran 25 no-noise networks first (without any noise introduced on interhemispheric connections), to establish baseline measures. The networks were trained until they had zero classification error or until 1000 training epochs elapsed. Every 100 epochs, we measured error in the in-tact networks, as well as lesion-induced error. We then duplicated this procedure for 25 noise networks, which were identical except for having random Gaussian noise ( $2 \%$ of average unit activity) injected on the interhemispheric connections.

We thought that introducing Gaussian noise would cause interhemispheric information to be less reliable than intrahemispheric information, causing intra-hemispheric patterns to be learned more independently of the other hemisphere, and delaying learning of interhemispheric patterns. Therefore, we predicted that (1) the learning trajectory of the network with interhemispheric noise would be more gradual (i.e. have a smaller slope), and asymptote earlier. We also predicted that lesion-induced error would be lower in the noise vs. no-noise networks.

## Results

Fig. 3a shows learning trajectories of classification error, for no-noise and noise networks on both in-tact and lesioned conditions. As predicted, learning in the noise networks was slower and reached asymptote at a higher error than the nonoise networks. We show these results for comparison to pre-

[^43]vious papers. Fig. 3b shows the learning trajectories for learning error, on the same set of networks. Notice that, consistent with our predictions, lesion-induced error (the difference between corresponding intact and lesioned curves) is smaller for the noise networks vs. the no-noise networks on both measures. Interestingly, for learning error (a more nuanced measure of network performance), noise networks had less error in the lesioned networks than the no-noise networks.

Figure 3: Changes in (a) classification error and (b) training error over training epochs, for noise and no-noise networks in-tact and lesioned conditions.

In order to examine these results more closely, we computed lesion-induced error on for the noise and no-noise networks for training error, then separated them into intrahemispheric and interhemispheric patterns (Fig. 4a). The noise networks showed less lesion-induced error for both interhemispheric and intrahemispheric patterns. Looking more closely at the differences between noise and no-noise networks (Fig. 4b), we find the surprising result that noise networks had much less lesion-induced error for intrahemispheric patterns than the non-noise networks, while the two had relatively equal levels of lesion-induced error for interhemispheric patterns.

These results indicate that the network with noisy interhemispheric fibers tried to accomplish the task (as much as possible) intrahemispherically, particularly in cases where both hemispheres are necessary to complete a task.

## Discussion

We argued that current thought on interhemispheric integration fails to explain a basic dichotomy: how interhemispheric segregation may be necessary for developing asymmetries, but must be overcome to produce interhemispheric coupling found in adults. We showed that ideas based on the magnitude of conduction delays cannot explain interhemispheric segregation, nor can they explain strong interhemispheric coupling. We suggested that the especially steep developmental gradient of humans may hold the key. Our literature review revealed that two properties of these fibers might cause such a pattern: their changing length and their changing reliability in timing. The latter is relevant on the necessary timescale, so we focused our work here on examining the effects of changes in the reliability of the timing of information.

Figure 4: (a) Lesion-induced error for both noise and nonoise networks, split into interhemispheric and intrahemispheric patterns. (b) Difference between noise and no-noise networks for lesion-induced error; positive values mean more lesion-induced error in no-noise networks.

The results of our computational experiments showed that timing unreliability, in the form of Gaussian noise of our instantaneous firing rate, could induce more independent development of the cerebral hemispheres. This effect need not be related to the magnitude of conduction delay-but in mammalian brains it is: longer fibers have both longer delays and more jitter in their timing. These effects are also temperaturedependent (Wang, 2008); perhaps a mechanism leading to the large number of asymmetries found in cold-blooded species (Rogers \& Andrew, 2002).

Our simulations also hinted at how asymmetry may emerge. We found that noisy callosal fibers led networks to try and use local, intrahemispheric processing, even for patterns requiring interhemispheric information. This type of early local processing is an indication that these networks may encourage developmental asymmetries.

Finally, we note a few recent papers on the benefits of noise in learning (Ermentrout, Galn, \& Urban, 2008; Faisal, Selen, \& Wolpert, 2008; Vincent, Larochelle, Lajoie, Bengio, \& Manzagol, 2010). We intend to investigate whether initially noisy interhemispheric interactions facilitate both generalization and specialization of the hemispheres. Shared processing of highly salient features may allow each hemisphere to select secondary features that it is more specialized to process.

# Systems from Sequences: an Iterated Learning Account of the Emergence of Systematic Structure in a Non-Linguistic Task 

Hannah Cornish (hannah@ling.ed.ac.uk)<br>Kenny Smith (kenny@ling.ed.ac.uk)<br>Simon Kirby (simon@ling.ed.ac.uk<br>University of Edinburgh, School of Philosophy, Psychology and Language Sciences, Language Evolution and Computation Research Unit, 3 Charles Street Edinburgh, EH8 9AD, UK

#### Abstract

Systematicity is a basic property of language and other culturally transmitted behaviours. Utilising a novel experimental task consisting of initially independent sequence learning trials, we demonstrate that systematicity can unfold gradually via the process of cultural transmission.

Keywords: Iterated Learning; Cultural Evolution; Sequence Learning

## Introduction

Language, like many other culturally-transmitted aspects of human behaviour, works as a system: individual words or phrases do not behave independently of one another but instead form part of a mutually reinforcing system of conventions. This is at the heart of what we mean when we talk about the grammar of language - grammar exists only to the extent that individual utterances are non-independent, and related to one another in systematic ways. This is so obviously true of language, and other cultural systems such as music, that it hardly seems to stand in need of explanation. But where does this basic fundamental property come from? Why are individual utterances not independent? After all, they arguably are for all other systems of communication in nature. Even when we discount the fact that non-human animals can only convey a finite set of meanings, many animal communication signals are gradable and related to one another only as much as they are produced by the same vocal apparatus (Fitch, 2010). This stands in stark contrast to human language, resting as it does on a system of infinitely reusable discrete signals ${ }^{1}$.

We propose that the answer lies in the nature of cultural transmission. In systems like language which are transmitted by iterated learning ${ }^{2}$, the most transmissible behaviours are those that are most learnable (Smith, Kirby, \& Brighton, 2003). Cultural evolution tends therefore to maximise learnability (Christiansen \& Chater, 2008; Kirby, Cornish, \& Smith, 2008). One way to increase learnability of a set of behaviours is for those behaviours to behave systematically, so

[^44]that learning one will increase the ease with which others will be learned. In other words, we should expect cultural evolution to create systems of dependence between previously independent learned behaviours.

In this paper we present an experimental paradigm in which we can observe the cultural evolution of such systematicity in a task which involves many initially independent learning trials. Our task is purposefully non-linguistic, but designed to have relevant similarities with language. Specifically, it is a simple immediate sequence-recall task based around the Simon Game. This was a children's electronic game developed by Milton-Bradely in 1978 with four coloured illuminated buttons arranged on its surface in a circle. These buttons lit up to display a random sequence and the player's goal was to repeat this sequence back immediately. This task has a number of useful properties for our purposes. Firstly, although it is clearly non-linguistic, thereby making it unlikely that participants will bring any language-specific biases to it, the task nevertheless involves sequence learning, which is highly relevant to the linguistic domain (Misyak, Christiansen, \& Tomblin, 2010; Christiansen, Conway, \& Onnis, 2012). Secondly, the task is overtly one in which each sequence acts as an independent task. The player can be scored on their learning of each sequence immediately after recall. This is in contrast to a typical artificial language learning task (e.g., Gomez \& Gerken, 2000) which might involve learning a set of sequences for recall at a later stage.

Our question is the following: given this kind of simple independent sequence recall task, will cultural transmission nevertheless lead to the evolution of systematicity in the set of sequences? In effect, can an implicit system-wide learning effect exert influence on the evolution of the set of sequences? To test this, we create an iterated version of the Simon Game in which the sequences produced by one participant in the task become the sequences that the next participant in the experiment is exposed to. We start with a set of 60 random sequences, and observe whether these sets evolve in such a way to make learning easier, and whether they do so by becoming more systematically structured.

## Methods

The experiment utilises a diffusion chain paradigm, a technique used widely amongst researchers investigating cultural
transmission (e.g., Mesoudi \& Whiten, 2008), whereby all learners (apart from those in the initial generation) are trained on the output of previous learners.

## Participants

In total, 40 participants (mean age $21 \mathrm{y}, 11 \mathrm{~m}$; females $=25$ ) were recruited from the University of Edinburgh's graduate employment service, to take part in a visual memory experiment involving sequences of flashing coloured lights. Each participant was allocated at random into one of four different chains (A, B, C, D), consisting of ten generations each. All learners received $£ 7$ remuneration for taking part.

## Procedure

The task itself was simple: participants were shown a light sequence on a touch-screen tablet device, and then asked to immediately reproduce it by tapping the sequence back. The layout of the Simon Game is shown in Figure 1. Once a complete sequence has been input (Figure 1.a), immediate accuracy feedback is given (Figure 1.b). Participants could then request another sequence.

Figure 1: A diagram showing the layout of the Simon Game: (a) participants see a sequence on the screen, and are asked to immediately reproduce it; (b) feedback is then given on the task.

In all, participants were trained and tested on 60 different sequences, seeing each sequence once in each of two rounds in random order, making 120 exposures in total. In order to catch obvious mistakes in sequence entry, if any participant submitted a sequence of length 6 or shorter, this was rejected by our software, and the target sequence would reappear at a random point later in the player's round for them to reattempt. The 60 sequences produced in the second round were collected to be used as training stimuli for the next learner in the chain.

## Initial Sequences

Although subsequent learners were trained on the output of the previous learner, the four initial participants were trained on a set of sequences that adhered to the following properties: (i) the length of each sequence was 12 ; (ii) each sequence consisted of 3 flashes of each colour (red, blue, green, yellow); (iii) these colours appeared in random order. This resulted in a set of 60 sequences which had no structure.

## Results

The sequences were analysed in order to determine (1) whether the individual sequences would adapt to become easier to learn over time, and (2) whether individual sequences would co-evolve together to form a collective system. In order to assess these effects, we look at quantitative measures of learnability and structure, along with an additional measure examining the degree of divergence between the four chains into specific lineages. We also qualitiatively examine some of the evolved sequences at the ends of the chains, and note some striking structural regularities.

## Learnability

To determine the learnability of a sequence set at a given moment in time, we first need a measure of how accurately each sequence is reproduced. For this we calculated the intergenerational error using the Levenshtein (1966) edit-distance between each target sequence and response from the participant, normalised for length of sequence (Kirby et al., 2008) ${ }^{3}$ : we count the minimum number of insertions, deletions and substitutions required to turn one sequence (input) into another (output), dividing this by the length of the longer sequence. From the normalised edit distance of each individual sequence, we then calculate the average error of the sequence set. For consistency with our later analysis we converted this into mean similarity (1-error), shown in Figure 2 below.

Figure 2: Graph showing the average mean similarity score of sequences in each set over generations. Error-bars represent the $95 \%$ confidence intervals across the four chains, here and throughout.

[^45]As Figure 2 indicates, the sequence sets become easier to learn over time: reproduced sequences become more similar to their targets. In order to determine whether this cumulative increase in similarity was significant, we ran Page's (1963) $L$ trend test. This reveals a significant increase in similarity over generations, both when including ( $L=1469, m=4, n=10$, $p<.0001$ ) and excluding ( $L=1074, m=4, n=9, p<.0001$ ) the initial set of sequences, which had not been produced by participants.

## Structure

One possible explanation for the increase we see in learnability could simply be that early participants are forgetting parts of each sequence, leading to the sequences eventually becoming short enough to be more easily reproduced by later learners. In order to assess this claim, we examined the average length of sequences across each chain for any signs of change. Figure 3 confirms that that there was no significant reduction in sequence length over the course of the experiment. Given that length is in fact highly stable across each generation, some other feature of the sequences must be responsible for their increase in learnability.

Figure 3: Graph showing the average length of each sequence by generation. Sequence length remains stable throughout the experiment, ruling out a simplistic explanation for the improvements to performance in Fig. 2.

The other possibility is that the sequences have become structured in some way. In order to determine whether this is the case or not, we examined the composition of the sequences in each set, using two different metrics. The first is a measure of dispersion, which looks at how similar each sequence is to other sequences within that set. This is calculated using the same distance metric as before, this time comparing the distance of each sequence from all other sequences within
that generation, rather than across generations between target and reproduction. This figure, when averaged over all pairs of sequences, returns the amount of dispersion within the set at a given generation. Figure 4 shows that over time, individual sequence sets lose variation as the sequences within them begin to resemble one another ( $L=1980, m=4, n=11$, $p<.0001$ ). This could happen if, for instance, smaller subsequences come to be shared across whole sequences within the set.

Figure 4: Graph showing the mean of the normalised dispersion score of the four sequence sets over generations. Dispersion decreases cumulatively over generations, indicating that sequence sets are becoming more self-similar over time.

In order to explore this idea further, the second measure looks at compression. This is related to the notion of Kolmogorov complexity (Kolmogorov, 1963), and is essentially a measure of how easy it is to compress data into a smaller representation. If a dataset contains repetitions (redundancy), then the algorithm can exploit that by creating a shorter representation to substitute for the larger one, and thus the size of the file can be reduced. We tested this directly by computing the compression ratio (size of the file after compression/size of the file before compression) ${ }^{4}$ in order to assess how much structure was present in each sequence set (Fig. 5).

Figure 5 demonstrates that there is a decrease in the compression ratio over time ( $L=1964.5, m=4, n=11, p<.0001$ ). This shows that the sequences are becoming structured, and further supports the idea that those sequences produced later on in the chains have become fractionated into smaller higherfrequency units which repeat within sequence sets.

[^46]

Figure 5: A graph showing the mean compression ratio over generations. Sequence sets become more compressible over time, indicating that there is more structure in later sequences than in earlier sequences.

## Identifiability

The decrease in dispersion scores and compression ratios across our four chains could be due to a universal bias pulling all of the sequences towards a similar (structured) attractor. If this were the case, we would expect to find that a given sample of sequences drawn from within a chain, at a certain generation, would look fairly similar to any other sample of sequences drawn from any other chain at that same generation. In order to to determine whether there are in fact different types of structural patternings in our data, organised across the different lineages, or just one kind of structural patterning shared amongst all chains, we used a measure of lineage divergence (referred to as identifiability) taken from Matthews, Roberts, and Caldwell (2012). This determines (for each sequence) the within-group similarity and the across-group similarity, and then calculates a proportion: [within-group similarity/(within-group similarity + across-group similarity)]. This returns a value between 0 and 1 , where values above 0.5 indicate higher overall withingroup similarity, and values below 0.5 indicate higher acrossgroup similarity.

Figure 6 shows, the initial sequences (generation 0 ) are not identifiable as coming from their particular chain. This is to be expected due to the fact that they were all randomly constructed according to the same procedure. However, sequences do begin to diverge into separate lineages. A onesample Wilcoxen test confirms that the within-group identifiability of sequences from all chains produced by participants (generations 1-10) were significantly higher than our

Figure 6: Graph showing how the average identifiability of each sequence increases over time. The dashed line represents chance levels.
expected chance level of $0.5(Z=-5.86, N=40, p<.0001)$. Furthermore, our trend analysis reveals that this effect is cumulatively increasing over time ( $L=1901, m=4, n=11, p<.0001$ ), such that sequences drawn from later generations are significantly more likely to resemble sequences from within their own lineage, than from those of any other lineage.

## Qualitiative analysis

The quantitative results all point towards the fact that our independent sequences are gradually becoming structured as a collective, and that they do so in ways which are specific to different lineages. What then might some examples of these systematic structures look like? Figure 7 shows a sample of sequences that came from chain A.

As Figure 7.a shows, the initial set of sequences contain very little obvious structure. By generation 10 however (Figure 7.b), a common pattern has emerged. In fact, of the 60 sequences in this set, just over half of them begin with an initial alternation pattern of red-yellow-red-yellow, or red-red-yellow-yellow. This is frequently followed by a cyclical pattern - moving around the Simon board in either a clock-wise or anti-clockwise direction from a given starting point (usually red in this case) - which can itself be repeated to extend the sequence. This kind of structure lends itself easily to being analysed into hierarchically arranged sub-parts, containing non-adjacent dependencies. Figure 7.c shows one such possible analysis of this kind ${ }^{5}$.

[^47]

Figure 7: Some examples of sequences from chain A: (a) a sample of six random sequences at generation 0 ; (b) those same sequences at generation 10; (c) sequences at generation 10 again, bracketed to highlight their nested hierarchical structure. This bracketing can be used to generate tree-structures (as shown in example v) which more clearly demonstrate the nature of the system.

As to be expected from the identifiability results however, the way in which the other chains are organised is noticeably different, both to the statistical measures employed earlier, and to the human eye. These different styles can be easily contrasted visually in Figure 8, again by drawing a sample of six strings from the set to illustrate general structural regularities in the final generations.

Figure 8: Some examples of sequences from the final generations of chains $\mathrm{B}, \mathrm{C}$ and D . There are clear qualitative differences between the sequences across these different chains, and from chain A in Figure 7 above.

In contrast to the distinctive alternation found in chain A , chain B favours the more cyclical patterns, and shows a very dominant tendency to begin all sequences with a red ( $92 \%$ ). Chain C also places restrictions on the identity of the first colour: green is most common ( $48 \%$ ), followed by yellow ( $30 \%$ ) and red ( $22 \%$ ), but never blue. It also contained the highest proportion of sequences with two or more of the same colour adjacent to one another (58\%: as compared to A $28 \%$, B 35\% and D 23\%). Finally, Chain D seems to prefer triplets and alternations as reusable sub-sequences.

In summary, the qualitative analysis of the chains reveals that sequence-sets can become systematic in multiple ways. Some commonalities do exist across lineages - for instance, a
strategy of repeated alternation of two colours was present in all chains. However, (i) the frequency with which a given strategy was employed, (ii) where it was employed (sequence-initially, sequence-medially, or sequence-finally), and (iii) with what particular colour combinations it was employed, all varied, contributing to the development of a unique 'profile' for each lineage.

## Discussion

We have presented an experiment in which participants attempt to immediately recall visually presented sequences. The sequences that participants produce become the sequences which subsequent participants try to recall. In this way, we create lineages of sequences in an experimental simulation of cultural evolution. These lineages are potentially independent of each other, since the initial set of sequences are generated at random and participant responses are gathered immediately after each sequence.

The effect of cultural evolution in the experiment is that the sequences become easier to recall correctly. In other words, errors introduced by participants are in the direction of easier sequences. How is this achieved? We see that the set of sequences at each generation becomes self-similar, suggesting that the sequences are not operating independently any more. This conclusion is confirmed if we look across separate chains in the experiment: the sequences are more similar within a chain, and less similar across chains. Additionally, the set of sequences at each generation in the experiment becomes more compressible, as system-wide structure starts to emerge.
The systematic structure in sequences shows tantalising evidence of hierarchy, although a deeper analysis will have to await further analytic tools being applied. For example, in some chains we see the emergence of pairs of pairs of colours. We also see a pattern in which some sequences are "doubled" versions of others in the set. So, for example, the sequence prefix "rryyrryy" in chain A matches the prefix "ryry". It is tempting to suggest that this provides evidence of a grammar with centre embedding of the form $\left(A^{n} B^{n}\right)^{m}$, although such an analysis is premature without further probing of the way in which these sequences are processed. Building on work such as Christiansen and Ellefson (2002), recent attempts have been made to tease apart the different cognitive mechanisms at work when processing non-adjacent dependencies resembling these sequences in language (Vries et al., 2012; Christiansen et al., 2012). This may provide further clues as to why these particular structures emerge in this study. Likewise, studying the process of emergence itself, using iterated sequence learning tasks in the laboratory as we have done, may help us better understand the way these learning and processing biases shape behaviour at the population level.

## Conclusion

A hallmark of complex culturally transmitted behaviours in humans, such as language and music, is their systematic
structure. Instances of behaviour do not behave independently, but form part of a system of mutually reinforcing conventions. Here we show that such systematic structure can emerge in an experimental task through the process of cultural transmission even when the task is designed to minimise the influence of domain specific biases and with no explicit reward for treating behaviours as co-dependent. We propose that this result is suggestive of a similar process operating in the origins of behaviours like language in humans. Cultural evolution favours transmissible behaviours. A solution to the challenge of becoming more transmissible is for behaviours to form part of a system, thus increasing their learnability. Language, our most systematic suite of behaviours, bears the hallmark of just such a process of cultural optimisation.

# On the Dynamics of Information Accumulation in Recognition 

Gregory E. Cox, Nicholas J. Lewis, Richard M. Shiffrin<br>(grcox, njlewis, shiffrin)@indiana.edu<br>Department of Psychological and Brain Sciences, Cognitive Science Program, Indiana University<br>1101 E. Tenth St., Bloomington, IN 47405 USA

#### Abstract

Inspired by a dynamic approach to recognition memory (Cox \& Shiffrin, 2012), we present results from a recognition memory experiment in which the time at which diagnostic information arrives is unconsciously varied. Contrary to the predictions of most models, performance improves when diagnostic information is available later, rather than earlier. These results are accounted for by a dynamic model of recognition, where the time at which information starts to be accumulated for a recognition decision can vary independently of when features are available to be sampled from the test display. The same model is shown to be able to reproduce the priming results of Jacoby and Whitehouse (1989), originally attributed to a fluency heuristic. The ability to account for such seemingly disparate results with a single model illustrates the utility of a dynamic approach to recognition.

Keywords: Episodic memory; recognition memory; memory models.

## Introduction

Recognition continues to be a rich source of evidence regarding the processes and mechanisms that underly episodic memory performance. Throughout its long history in psychology and cognitive science, recognition memory experiments have collected measures of reaction time. Despite this, most theories in recognition memory have been concerned only with accuracy. Most of the few models of recognition that also make predictions about response time (Hockley \& Murdock, 1987; Mewhort \& Johns, 2005; Malmberg, 2008; Nosofsky \& Stanton, 2006) assume nonetheless that the evidence is stationary over time (an exception is Brockdorff \& Lamberts, 2000). Thus, it would appear that much work remains to be done to better understand the fine-grained temporal aspects of the recognition process.

As a step in that direction, Cox and Shiffrin (2012) introduced a model of recognition that was based on the gradual accumulation of features over time. As features are sampled, they are added to a memory probe which is then compared to all the traces in memory (or at least those above a certain threshold level of activation), resulting in a "familiarity" value. Familiarity will move up and down over time in a noisy fashion as features get sampled; positive changes in familiarity are evidence in favor of an "old" decision, while negative changes favor a "new" decision. However, because only a finite number of features can be sampled, familiarity will eventually reach a (noisy) asymptote. Thus, the evidence for the recognition process in this model is inherently nonstationary. Furthermore, its predictions will vary greatly with experimental manipulations that affect the timing with which different information becomes available.

There is evidence that, even outside of experimental manipulations to that effect, the nature of the evidence for recognition may vary over time. Information about the "oldness" of individual items is available quite early in processing, while associative information (e.g., whether a word pair was studied in intact or rearranged order) requires approximately an additional 200 ms to become available (Gronlund \& Ratcliff, 1989). And Hintzman and Curran (1994, Experiment 3) found that, when tested with a foil that was a plural or singular form of a word that had been studied in the opposite plurality (e.g., "apple" was studied and "apples" was tested), subjects' tendency to endorse the foil initially increased but then reversed at longer response lags. These results are consistent with a recognition process that accumulates information over time, but at different rates for different kinds of information (e.g., Brockdorff \& Lamberts, 2000).

In an attempt to better understand the dynamics of the recognition process, we first present results from an experiment in which stimuli were constructed from a set of components which varied in diagnosticity as to whether the stimulus is old or new. In some conditions, components became visible at different times, allowing us to assess the effect of presenting diagnostic information later or earlier. These results are explained in the context of a dynamic model of recognition (Cox \& Shiffrin, 2012). The mechanisms employed can also be used to explain the "fluency" results of Jacoby and Whitehouse (1989).

## Experiment 1: Dynamic Presentation

In this experiment, the diagnosticity of information arriving at different times was varied unconsciously.

## Participants

55 undergraduate students from Indiana University participated in the experiment for course credit.

## Stimuli

All stimuli for a given list were generated from two prototypes consisting of random consonant triads, displayed in a triangular manner to minimize the effect of a left-to-right reading preference, e.g., $\mathrm{X}^{\mathrm{L}} \mathrm{K}_{\mathrm{K}}$ and $\mathrm{Z}_{\mathrm{J}} \mathrm{D}_{\mathrm{J}}$. An old item was made from a prototype by replacing one of its letters with another consonant. This resulted in 6 old items for each prototype ( 2 replacements each for the three letters) and a total of 12 old items for study. The prototypes were not studied. New items were generated in a similar manner by replacing a single prototype consonant with a new randomly selected consonant that did not appear at study. This structure allows the sin-

Figure 1: Observed and predicted mean accuracy (A) and mean correct RT (B) for Experiment 1. Error bars denote $95 \%$ confidence intervals.
gle unique consonant to be diagnostic as to whether an item is old and new.

## Procedure

The stimuli were presented centrally on a computer screen. During the study phase, participants were instructed to study the triads as they appeared on the screen and to remember them for a later test of memory. Individual triads were presented in random order for 1 s each with a 1 s blank screen between triads. During the test phase, the participants were instructed to respond whether the presented triad came from the previously studied list. Old and new responses were randomly mapped to the "A" or "L" key for each participant. In the static condition, all letters became visible at the same time. In the dynamic conditions, letters appeared sequentially at a rate of 30 ms (below the threshold for conscious detection) and stayed on until the end of the trial. For new triads, the unique consonant could appear as the first (diagnosticearly) or last (diagnostic-late) letter in the sequence. For old triads, the non-prototype consonant could appear second (diagnostic-early) or last (diagnostic-late). After a recognition judgment was made, the screen was cleared and the next test trial began after 1 s .

## Results

Observed hit rate (HR) and false alarm rate (FAR) are shown in Figure 1A. FAR for dynamic-late is significantly lower than for dynamic-early $(t(54)=2.73, p=0.008)$ or static presentation $(t(54)=3.42, p=0.001)$, which are not significantly different from one another. HR does not differ significantly between conditions. RT for both hits and correct rejections (CR; Figure 1B) is marginally slower in the dynamic conditions than static (for hits, $t(51)=2.04, p=0.05$; for CR, $t(53)=2.06, p=0.04$ ), but otherwise does not differ between conditions.

## A Dynamic Model for Recognition

We now provide a technical description of a model that can account for these effects of dynamic presentation. The model given here is a further development of the one described by Cox and Shiffrin (2012), although the present version is conceptually quite similar and is able to account for the same effects as the original version.

## Structure of Probe and Memory Traces

Events-for example, the study of a memory list item—result in the formation of a memory trace in long-term memory (LTM). Both a memory trace and a memory probe consists of a finite number of features, the number being determined by short-term memory capacity limitations. $N_{x}$ features arise from the context in which the event occurs, for example, the time, location, and internal state of the participant. These features are stable across all study and test trials. There are also $N_{c}$ content features which contain information about the event itself. For example, the memory trace formed from studying a word would include content features related to the word's spelling, phonology, and semantics. For the moment, we do not specify the exact nature of each feature, nor do we assume that the memory system "knows" whether a given feature is a content or context feature. For simplicity, we assume that all features are binary, e.g., " 0 " or " 1 ", with an equal prior probability for each value.

In the full model, different kinds of events can be encoded with different kinds of features. For example, the trace formed from studying a word will contain orthographic, phonological, and semantic features while the trace formed from studying a picture of a face will contain features relating to the shape of the eyes, nose, mouth, etc., and their relative positions. The low degree of featural overlap between traces of different types means that probing with, for example, a word will not tend to activate traces of faces. In this paper, all items in a given experiment are of the same type, so this aspect of the model does not come into play.

## Feature Sampling

Prior to the presentation of a test item, the only features present in the probe are context features since those are persistent in the environment. Once a test item (or prime) is presented, content features may also enter the probe. We assume that content features are sampled as a Poisson process, with sampling events occurring at exponentially distributed intervals according to $f(\tau)=\frac{1}{\rho_{T}} \exp \left(-\frac{\tau}{\rho_{T}}\right)$ at test with rate $\rho_{T}$ and rate $\rho_{S}$ at study. On each sampling event, all the available content features have an equal probability of being selected for sampling. Whichever is selected, the correct value of the feature is stored in the probe with probability $c$, otherwise a random value is stored (in this case, either 0 or 1 with equal probability). ${ }^{1}$ Note that, because all content features have an equal probability of being sampled on each sampling event, it is possible to sample a value for a feature that already has a value in the probe. In that case, the most recently sampled value replaces any previously stored value.

We assume that the same feature sampling process occurs at study. The probability that an available content feature will have a value stored, given limited study time $T_{s}$ and sampling rate $\rho_{S}$ features per second, is $1-\left(1-1 / N_{c}\right)^{\rho_{S} T_{S}}$, which in-

[^48]creases with both $\rho_{S}$ and $T_{s}$. While not all $N_{c}$ content features may end up being stored in a trace, we assume that all context features have a stored value.

## Comparison of Probe to Memory

At a given time $t$, the probe consists of a set of context features as well as whatever features of the test item have been sampled by that time. The probe is compared to each trace in LTM. These comparisons result in a set of likelihood ratios, $\lambda_{i}(t)$ for each trace $i$ in LTM, reflecting the likelihood that the probe and trace encode the same item versus the likelihood that they encode different items (c.f., Shiffrin \& Steyvers, 1997; McClelland \& Chappell, 1998).

Likelihood The features of the probe and a memory trace are aligned and compared individually. In the current restricted version of the model, the only features that affect the likelihood are those in which a value is stored in both the probe and trace, and the values either match or mismatch. For simplicity, we assume the same value of $c$ at study and test, so there are four ways a feature value might match if the probe and trace encode the same item: the value was correctly copied at both study and test (with probability $c^{2}$ ); a value was copied correctly at either study or test but not the other and matches by chance (with total probability $c(1-c)$ ); or the value was copied incorrectly at both study and test but still matches by chance $\left(2\left[\frac{1}{2}(1-c)\right]^{2}\right)$. Summing these probabilities yields the probability of a feature value match given that the probe and trace encode the same item: $\operatorname{Pr}(M \mid$ Same $)=c^{2}+c(1-c)+\frac{1}{2}(1-c)^{2}$. Similarly, if the probe and trace encode the same item, the stored values could mismatch if the value in either the probe or the trace or both were sampled incorrectly and failed to match by chance: $\operatorname{Pr}(N \mid$ Same $)=c(1-c)+\frac{1}{2}(1-c)^{2}$. If the probe and trace encode different events, then regardless of whether either value were sampled correctly, they could only match or mismatch by chance: $\operatorname{Pr}(M \mid$ Diff. $)=\operatorname{Pr}(N \mid$ Diff. $)=\frac{1}{2}$.

Since features are encoded independently of one another, the likelihood ratio across all features is the product of the likelihood ratios for the individual features. Letting $N_{M}(t)$ and $N_{N}(t)$ be the number of feature value matches and mismatches, respectively, the relative likelihood that a probe and trace encode the same versus different events is

$$
\begin{aligned}
\lambda_{i}(t) & =\left[\frac{\operatorname{Pr}(M \mid \text { Same })}{\operatorname{Pr}(M \mid \text { Diff. })}\right]^{N_{M}(t)}\left[\frac{\operatorname{Pr}(N \mid \text { Same })}{\operatorname{Pr}(N \mid \text { Diff. })}\right]^{N_{N}(t)} \\
& =\left(1+c^{2}\right)^{N_{M}(t)}\left(1-c^{2}\right)^{N_{N}(t)}
\end{aligned}
$$

Familiarity Because the number of event traces in memory is likely to be quite large, we assume that there is a threshold for activation and only those traces whose likelihood ratios are greater than this threshold contribute to familiarity. For simplicity, we set this threshold equal to 1 . The familiarity at time $t, \phi(t)$, is the average likelihood ratio among the active traces: $\phi(t)=\left\langle\lambda_{i}(t): \lambda_{i}(t)>1\right\rangle$.

## Making a Recognition Decision

The raw familiarity $\phi(t)$ is not used directly to make a recognition decision, as its absolute value can fluctuate with a variety of factors that would preclude the setting of consistent decision criteria (Cox \& Shiffrin, 2012). Rather, changes in $\log \phi(t)$ are used to make a recognition decision ${ }^{2}$. Positive changes in $\log \phi(t)$ are evidence that the test item is old while negative changes are evidence that the item is new. The evidence state at time $t$, denoted $B(t)$, is the accumulated change in $\log \phi(t)$ since a given start time. If accumulation starts at $t=0$, then $B(t)=\sum_{\tau=1}^{t} \log \phi(\tau)-\log \phi(\tau-1)=$ $\log \phi(t)-\log \phi(0)$.

When $B(t)$ reaches criterion $\beta_{O}$, an "old" response is made and if it reaches $\beta_{N}$, a "new" response is made. However, because at most $N_{c}$ content features are available for sampling, $\log \phi(t)$ will reach a noisy asymptote. As a result, criteria cannot be constant over time because, for some trajectories of $B(t)$, there is a non-zero probability that they will never reach either criterion. Thus, we allow the decision bounds to start at initial values $\beta_{O}^{0}$ and $\beta_{N}^{0}$ and gradually collapse according to a power function of time $r(t)=\left(\frac{t}{t+1}\right)^{N_{c}}$, scaled by the number of available features $N_{c}$. The resulting decision bounds are given by

$$
\beta_{O}(t)=\beta_{O}^{0}-r(t)\left(\frac{\beta_{O}^{0}-\beta_{N}^{0}}{2}\right), \beta_{N}(t)=\beta_{N}^{0}+r(t)\left(\frac{\beta_{0}^{0}-\beta_{N}^{0}}{2}\right) .
$$

## Response Time Predictions

As is standard in RT modeling, we assume that the observed response time arises from a decision component and a residual component, i.e., $T_{o b s}=T_{D}+T_{R}$. The number of samples needed to reach criterion determines the decision component of the RT. If $N_{s}$ samples are taken to reach criterion, then because sampling is a homogeneous Poisson process, the decision time is a sample from a Gamma distribution with rate $\rho_{T}$ and shape $N_{s}$ and expected value $\bar{T}_{D}=\rho_{T} N_{s}$.

The residual component of the RT is due to a number of factors, including the time needed to execute the motor actions needed to make a response. $T_{R}$ may also vary with factors that affect the ability to successfully recognize a stimulus. We do not yet model this process in detail; instead, because we only predict mean RT in the studies reported here, we only assume that the residual process has some stationary mean value such that the mean predicted RT is $\bar{T}_{o b s}=\bar{T}_{R}+\bar{T}_{D}$.

## Model fitting

To fit the model to each experiment reported here, we first selected by hand a set of reasonable values for the key memory parameters $\left(N_{c}, N_{x}, c\right.$, and $\left.\rho_{S}\right)$ and any experiment-specific parameters. The remaining parameters-principally the initial decision bounds $\beta_{o}^{0}$ and $\beta_{N}^{0}$, sampling rate at test $\rho_{T}$, and mean residual time $\bar{T}_{R}$-were fit by minimizing the sum of squared error to each available group data point (hit and FA

[^49]

Figure 2: Mean values of $\log \phi(t)$ for the conditions of Experiment 1. Profiles for targets are in blue and foils in red; black lines show time-varying decision bounds.
rates and mean RTs for each response type in each condition) using the SIMPLEX algorithm from several different random start points. As a result, we cannot claim that the fits reported here are the best possible, but our aim is to demonstrate the qualitative behavior of the model, rather than a strict quantitative fit.

## Accounting For Experiment 1

We assume that the stimuli in Experiment 1 are represented by a set of $N_{c}$ content features, where $N_{p}$ features represent each of the three consonants and $N_{w}$ features represent their configuration/conjunction ( $N_{c}=3 N_{p}+N_{w}$ ). Within the 2 categories defined by a prototype, items share $2 N_{p}$ features (i.e., 2 letters) but differ in their "diagnostic" (unique) letter and configural features. Foils also share $2 N_{p}$ features with one of the categories of studied items, but contain a third letter and configural features that differ from all studied items. In the static conditions, all $N_{c}$ features are available to be sampled from the beginning of the trial $(t=0)$. In the dynamic conditions, when the first letter appears $(t=0)$, only the $N_{p}$ features representing it are available for sampling into the probe. When the second letter appears $(t=\delta)$, its features become available for sampling as well. When the final letter appears ( $t=2 \delta$ ), all content features- including the $N_{w}$ configural features-become available for sampling.

Because our interest is in explaining the qualitative patterns in Experiment 1, and because a wide variety of parameter values are capable of producing such patterns, we arbitrarily let $N_{p}=5, N_{w}=15$, and $\delta=10$. Study time was fixed at $T_{S}=1$ second. With these parameter values, along with others given in Table 1, the resulting mean value of $\log \phi(t)$ for each condition is shown in Figure 2. All conditions reach the same asymptotes, but take very different routes to get there. In the early diagnostic condition, foil and target profiles separate widely early on, as would be expected, while in the late diagnostic condition, both foils and targets produce increasing mean familiarity before dividing.

A static model that only used the asymptotic value of familiarity would, incorrectly, make the same predictions for all three conditions. However, most dynamic models-including

Table 1: Parameter values used in the simulations.

| Overall |  | Exp. 1 | Exp. 2 |  |  |
| ---: | ---: | ---: | ---: | ---: | ---: |
| Param. | Value | Param. | Value | Param. | Value |
| $N_{c}$ | 30 | $\rho_{s}$ | 40 | $\rho_{s}$ | 57 |
| $N_{x}$ | 30 | $\beta_{0}^{0}$ | 5.279 | $\beta_{0}^{0}$ | 6.160 |
| $c$ | 0.86 | $\beta_{N}^{0}$ | -5.291 | $\beta_{N}^{0}$ | -5.975 |
|  |  | $\rho_{T}$ | 100 | $\rho_{T}$ | 95 |
|  |  | $\bar{T}_{R}$ | 0.438 | $\bar{T}_{R}$ | 0.360 |
|  |  | $N_{p}$ | 5 | $\pi$ | 0.25 |
|  |  | $N_{w}$ | 15 | $\eta$ | 0.76 |
|  |  | $\delta$ | 10 | $K$ | 200 |
|  |  |  |  | $\bar{T}_{C}$ | 0.016 |

the one outlined above-would incorrectly predict an increase in FAs for the dynamic-late condition due to the increased probability of reaching $\beta_{O}(t)$ early on. A critical feature of our model, however, is that it accumulates changes in familiarity, not absolute familiarity. If instead of accumulating $\log \phi(t)-\log \phi(t-1)$ from $t=0$, accumulation began when all features were available (at $t=2 \delta$ ), the resulting evidence state would be $B(t)=\log \phi(t)-\log \phi(2 \delta)$, as shown in Figure 2B. This delay leads to predictions that match the data: overall greater RT in the dynamic conditions, relatively little difference in HR, and a marked decrease in FAR for the dynamic-late condition (see Figure 1). The FAR prediction arises because the first $2 \delta$ samples for a foil in the dynamiclate condition all tend to match the studied items, so ignoring those early matching samples means that the later nonmatching samples are emphasized.

Why wait to begin accumulating changes? Although the dynamic presentation was fast enough that participants could not know which letters came on in what order, they could perceive that the display was noisy or "flickery". Rationally, one would not want to risk accumulating noise and so it makes sense that participants would wait until the display was sufficiently clear to begin accumulating evidence for recognition (e.g., Smith, Ratcliff, \& Wolfgang, 2004). This kind of waiting is also analogous to discounting in short-term recognition (Huber, Shiffrin, Lyle, \& Ruys, 2001), in that evidence is down-weighted when it is attributed-perhaps erroneouslyto noise.

## Experiment 2: Fluency

It turns out that essentially the same mechanism—missing the first few samples before beginning accumulation-can explain an apparently unrelated result in the recognition literature: the so-called "fluency effect". It is based on the idea that the subjective feeling of familiarity, rather than the presence or absence of a memory trace, leads one to decide that an item is old, and that this feeling can arise from multiple sources (Jacoby \& Dallas, 1981). One such source is a "fluency heuristic" in which people detect the relative ease of perceptual processing of a test item and use this as a sign of past experience. Jacoby and Whitehouse (1989) demonstrated that old and new words preceded by a subliminal matching prime increased the probability of judging a word as old. In terms of fluency, the subliminal flash provides a head start in processing thereby increasing fluency and giving the illusion of familiarity regardless of whether the word was old or new. We
present a replication of these results and show how a dynamic model of recognition can account for them without appealing to a fluency heuristic.

## Participants

81 undergraduate students from Indiana University participated in the experiment for course credit.

## Stimuli

Stimuli consisted of concrete nouns of moderate length and frequency drawn from the Toronto word pool. 90 words were selected for study, and another 90 served as foils at test. In addition, 60 words served as different primes at test.

## Procedure

The stimuli were presented in lowercase letters in the center of a computer monitor. In the study phase, participants were instructed to read words aloud as they appeared on the screen and to remember them for a later test of memory. The study phase was divided into two blocks, one with words presented for 1 s , another with words presented for 3 s (the order of the blocks was randomized).

During the test phase, participants were instructed to respond whether the presented test word came from the study list ("old") or from the set of new words. Old and new responses were randomly mapped to the "A" or "L" key for each participant. Each recognition test word was preceded by a nondiagnostic subliminal prime: on $1 / 3$ of trials, the prime was identical to the test word, on another $1 / 3$ of trials, the prime was a different word that had not been previously seen, and on another $1 / 3$, the prime was a neutral string of characters (XOXOXO). On each trial, a pre-mask ( \&\&\&\&\&\&\&) was presented for 500 ms followed by a prime (same, different, or neutral) for 50 ms and a post-mask for an additional 500 ms . The screen went blank for 300 ms before the test word was presented. After the participant made a response, the screen was cleared for 1865 ms until the next test trial. Participants were not informed that the primes would be present.

## Results

Prior to analysis, trials with RT that were too fast (less than 200 ms ) or too slow (longer than 3 s ) were excluded ( 273 out of 14580 total trials). The observed mean probability of responding "old" in each condition is shown in Figure 3A. Replicating the original result of Jacoby and Whitehouse (1989), participants are significantly more likely to endorse an item that was preceded by an identity prime than a neutral prime $(t(80)=12.0, p<0.001)$. Surprisingly, they are also more likely to endorse an item that was preceded by a different prime than a neutral one $(t(80)=2.91, p=0.005)$, an effect also remarked on, but unexplained, in the original work of Jacoby and Whitehouse (1989). Observed mean correct RT are shown in Figure 3B. Identity primes speed hits $(t(80)=-10.7, p<0.001)$, but slow CR $(t(80)=2.68$, $p=0.009)$ relative to neutral primes. Different primes also

slow CR relative to neutral primes $(t(80)=3.21, p=0.002)$, but have no significant effect on RT for hits $(t(80)=0.93$, $p=0.35$ ).

## The Dynamic Account of Fluency

The core of our account of the fluency effect lies in the assumption that the prime, if it is a word, contributes some features to the probe before features begin to be sampled from the test item and accumulation begins. In the case of an identical prime, this is exactly like changing the start time of accumulation in Experiment 1, since it eliminates the effects of the first few samples, as shown in Figure 4. Notice that, for both targets and foils, the first few samples in the neutral prime condition will, on average, produce negative changes in familiarity. If the prime word is identical to the subsequent test item, "pre-loading" the first few features eliminates some of these negative changes, making it harder to reach $\beta_{N}(t)$ and increasing the probability of responding "old" for both targets and foils.

The initial negativity for targets is a consequence of how the set of activated traces changes over time as features accumulate in the probe, as outlined in Figure 5. Before any content features are sampled, the probe contains only context features and the active traces tend to be those from recent

| Features | Start <br> Context <br> only | Early <br> Context and some <br> content | Late <br> Context and all content |
| :--- | :--- | :--- | :--- |
| Traces <br> active for <br> target | List traces <br> (good <br> match) | List traces (moderate <br> match), target trace <br> (moderate match) | Some list traces (poor <br> match), target trace (good <br> match), some history traces <br> (poor match) |
| Traces | List traces | List traces (moderate | Some list traces (poor <br> match), some history traces |
| active for | (good <br> foil | match) |  |
| (poor match) |  |  |  |

Figure 5: Outline of the evolution of familiarity as a function of feature and trace activation over time.
experience, i.e., the study list. If just a few content features are sampled, most or all list traces will remain active, even though most will not match on content features. As an example, say you had studied the list "table", "moon", "parent" and were shown "table" at test. If you had only sampled features of the first letter (" t "), they would only match 1 out of 3 study items. It is only after many content features have been sampled (e.g., another several letters) that list traces that do not match the target drop below the threshold for activation and the match to the target trace takes precedence, raising the average likelihood.

This kind of priming effect also operates for different primes. Because the first few sampled features will not match most of the list traces in any case, the features that leak from a different prime will also tend to eliminate some initial negative changes, leading to an increased probability to say old to both targets and foils. However, if the test word differs from a prime word, this also impairs word recognition by introducing competition between the prime word and the test word (McClelland \& Rumelhart, 1981; Segui \& Grainger, 1990). If we assume that, as in Experiment 1, participants wait until they have a clear percept before beginning accumulation, it is reasonable to suggest that participants wait until this competition is resolved (i.e., they have a clear percept of the word) before beginning accumulation. This takes some time, during which some of the prime features-which are no longer being actively sampled or maintained-have a chance of deactivating and losing their sampled values, thereby separating the different and same prime predictions.

In sum, we assume that each of the prime's features has a probability $\pi$ of being sampled into the probe by the time accumulation begins. There is a constant mean duration $\bar{T}_{C}$ required to resolve the competition during word recognition in the different-prime condition, during which there is a probability $\eta$ that any sampled prime feature will deactivate. The features of the study and test words are assigned randomly. We also assume that, because participants have prior experience with words, there are $K$ traces of each word from life history that can be activated at test (their context features are assigned randomly; values used for these parameters are given in Table 1). As shown in Figure 3C-D, the model predicts the canonical "fluency" finding of increased $p$ ("Old") with an identical prime, as well as decreased RT for hits and increased RT for CR. It also exhibits the observed small positive priming effect for different primes.

## Discussion

We have shown how a dynamic model of recognition that allows the start time of accumulation to vary independently of feature sampling can account not just for the novel results of our dynamic presentation study, but for older findings previously attributed to a fluency heuristic. Further, this model is able to predict the observed positive priming from novel, different primes, a prediction made by no other extant recognition model. These seeming disparate predictions fall directly out of the core feature of the model, namely, that it is changes in familiarity from a given start time, not absolute familiarity, that drive recognition decisions.

The model and these results thus illustrate the importance of knowing when information for recognition becomes available. Here, we have assumed that unconscious priming and dynamic presentation result in features being sampled before changes get accumulated for recognition, but other manipulations (e.g., manipulations of salience or contrast) might also influence the start time of accumulation, which would be fruitful questions for further study. We suggested that, to account for results in the different-prime condition in Experiment 2, responses are slowed by an increased difficulty in recognizing the test word. Although this suggestion remains to be formalized in a model, it emphasizes the need to consider all the possible processes that contribute to recognition. Creating this kind of unified model requires a dynamic approach, which not only suggests new answers to issues like fluency, but new questions.

#### Abstract

Previous research suggests that people often recall individual items when sets are smaller than four and aggregate set features for sets larger than four. One intriguing possibility is that the process of aggregating sets creates summary representations that maintain the statistical properties of the set itself. For sets of numbers, this process might implicitly create approximate means. We report the results of two experiments investigating memory for number sets and its relation to working memory and metacognitive monitoring. In both experiments, participants were shown a series of data sets that varied in size ( 4,6 , or 8 numbers) and variance ( $10 \%$ or $20 \%$ of the mean) and were then presented with an actual value from the set and the set mean. In Experiment 1, participants were asked to select the actual value, and in Experiment 2, participants were asked to select the set mean. Results indicated that the proportion of correct selections and metacognitive confidence decreased with set size. Working memory was related to performance only when the set size was 6 . The findings suggest that participants often erroneously reported the set mean as being a member of the set and that this effect increased for sets larger than four. The findings suggest that the process of aggregating number sets results in approximate means.

Keywords: Number sets; Representation; Metacognition.

## Introduction

Data interpretation (i.e., interpreting numbers in context) is critical to everyday reasoning. Numbers are represented in two ways, as an approximate magnitude and as a symbolic value (Dehaene, 2009). Previous research suggests that people compare single numbers as analog magnitudes, meaning that numbers are represented as approximate rather than exact values. Key evidence for this argument is that comparisons are faster and more accurate as the ratio of difference between values increases (Feigenson, Dehaene, \& Spelke, 2004; Hyde, 2011). Yet little is known about how people represent numerical data sets. Previous research involving the cognitive processing of number sets suggests that people's comparisons are highly related to the statistical properties of the sets. Specifically, as the ratio of mean differences between number sets increase and variance within each set decreases, comparisons to assess which set has the higher mean become faster and more accurate (Masnick \& Morris, 2008). These findings suggest that
when asked to make number comparisons, people implicitly (i.e., without deliberate effort) represent the properties of number sets, such as means and variance, rather than information about individual numbers.

## Sets vs. Individuals

A well-replicated finding is that people individuate items (i.e., represent individual values within a set) for sets smaller than four (Scholl, 2001). For example, given a set of three dots, participants are likely to remember the individual dots rather than the properties shared by the dots (Airely, 2001). Given sets larger than four, people aggregate items, or average over sets retaining information about set features (Scholl, 2001; Masnick \& Morris, 2008). For example, given a set of a dozen dots of various sizes, participants were likely to erroneously recall a dot that represents the average size, rather than correctly recall an actual dot from the set they viewed (Airely, 2001). Earlier research suggested two separate memory stores for individual versus aggregated sets. For example, Feigenson, Dehaene, and Spelke (2004) suggested one system for individuating small values $(<4)$ and another system for aggregating larger sets. However, recent research (Hyde, 2011) suggests that the difference in representation may be functional (i.e., due to differences in strategy) rather than structural (i.e., separate stores).

The process of aggregating appears to maintain information about the statistical properties of sets. Previous research on category learning provides evidence that aggregating over individual objects results in a prototype, or a most representative set member. Researchers have suggested that the process of aggregating yields "a measure of central tendency" (e.g., an average or prototypical category member; Medin, Altom, \& Murphy, 1984, p. 334). Early research into prototypes suggested that when people aggregate across multiple exemplars, they extract a prototypical category member that represents an average of category features (Medin et al., 1984; Nosofsky, Denton, Zaki, Murphy-Knudsen, \& Unverzagt, 2012). For example, a robin is often seen as a prototypical bird because it shares most of the features common among birds.

Numbers provide an intriguing extension of this work because aggregation of sets may produce approximate
measures of central tendency. Specifically, encoding a set of numbers may implicitly provide information about the set mean. The reviewed research suggests two related effects. One, for small set sizes ( $<4$ ), participants will encode individual set members. For larger set sizes (> 4), participants will aggregate across values, losing information about individual values. Two, the process of aggregating values creates summary representations of the number sets, including approximate mean and variance values.

## Set Encoding and Working Memory

Working memory (WM) is often described as the processes and mechanisms involved with the maintenance of task relevant information necessary for performance of cognitive tasks (Miyake \& Shah, 1999). In the current study, we predict that set representation is more likely to occur as the number sets increase in size because maintenance of all items from larger sets requires greater WM resources than maintenance of items from smaller sets. Therefore, we also predict that participants with larger WM capacity should be able to maintain a greater number of items in WM and correctly identify presented items.

## Set Encoding and Metacognitive Monitoring

A secondary focus of this experiment was to investigate the influence of metacognitive monitoring on the representation of number sets. Monitoring refers to one's judgment of their current cognitive processing, specifically, the degree to which a process is deliberate and a rough estimate of one's performance (Dunlosky \& Metcalfe, 2009). We assessed monitoring through participant confidence judgments.

## Aims and Predictions

This experiment extends the work of Masnick and Morris (2008) by examining how people represent and remember number sets, and how accurately they judge their memory for number sets. Independent variables were number set size ( 4,6 , and 8 ) and coefficient of variation ( $20 \%$ and $10 \%$ of mean). Dependent variables were number selection accuracy, reaction time, confidence judgments, strategy use, and working memory capacity. We predicted that people would erroneously recall seeing set means or medians rather than actual numbers from the sets as set sizes increased. As suggested by Hyde (2011), different strategies are predicted to be associated with encoding goals. Specifically, encoding individual numbers is expected to be associated with longer reaction times than encoding set aggregates, because the latter is a relatively implicit process. Finally, we predicted that number recall and mean identification would be related to confidence judgments in terms of accuracy, or that they would increase or decrease together.

## Experiment 1

## Method

Participants. Participants ( $\mathrm{N}=51$ ) were undergraduate students at a Midwestern state university. The average age was $22.04(S D=6.84), 84 \%$ of the participants were female and most were of Caucasian descent.

Procedure. Experiment 1 consisted of two counterbalanced tasks: the number set task and a working memory task. All participant tasks were presented using E-Prime software. The number set task consisted of 126 trials. Each trial had four parts, described here in order of presentation (see Figure 1a).

Figure 1. Number set and working memory task procedures.
First, a fixation cross was presented to focus the participant's attention. Then, a number set was shown (details of the sets and presentation durations below). Next, two numbers were presented, an actual value from the set and the mean or median value from the set. The participant was asked to indicate which of the two numbers was in the set presented in the previous slide by pressing a computer key. The two numbers and indication prompt remained on the screen until the participant chose an answer. After responding, participants were asked how sure they were of their answer. Confidence judgment response options were presented as follows: 1) $0-25 \%$, 2) $26-50 \%$, 3) $51-75 \%$, \& 4) $76-100 \%$. The response options and prompt remained on the screen until the participant chose an answer.

There were four sets of stimuli, each preceded by a set of instructions explaining the process outlined above to the participant. The first six number sets were practice trials and were not analyzed. Experimental trials included 40 sets of
four numbers (each set presented for 2 s ), 40 sets of six numbers (each set presented for 2.5 s ), and 40 sets of eight numbers (each set presented for 3 s ). Each set consisted of three digit numbers. Within each set size, 10 sets were drawn from one of four variance types. Set variance was either $10 \%$ (low variance) or $20 \%$ (high variance) of the set mean. For half of the choice trials, participants were shown the set mean. For the remaining half, participants were shown the set median; although for sets of 4 the mean and median were identical.

The three blocks of experimental trials were presented sequentially, randomized within-participants. The presentation location of the actual value and mean or median value was also randomized so that the actual value and mean were presented on the left or right side of the screen in $50 \%$ of trials. After completing all number set trials, participants were surveyed about their strategy use during the task. Participants were presented nine strategy descriptions (see Table 1) and were asked to estimate how often they used each strategy during the experiment using the following scale: 1) never, 2) some trials, 3) most trials, or 4) always. The response options and prompt remained on the screen until the participant chose an answer.

Table 1: Strategy Descriptions and Examples.

| Strategy | Example |
| :--- | :--- |
| Look at the first digit. | The "1" in 125. |
| Look at the second digit. | The " "in 125. |
| Look at the third digit. | The "5" in 125. |
| Try to figure out the <br> average. | Calculate mean value. |
| Find the biggest number. | Scan set for highest value. |
| Find the smallest number. | Scan set for lowest value. |
| Just get a sense of the <br> numbers. | Scan set values. |
| Look for a number that is <br> not like other numbers. | Find any value unlike other <br> values. |
| Try to memorize specific <br> numbers. | Memorize a few numbers. |

Participants were also given the alphabet mathematics working memory task (cf. Was, Rawson, Bailey, \& Dunlosky, 2011). The general format of this task was as follows (see Figure 1b): the words "Get Ready" preceded a letter or set of nonadjacent letters (presented for 2.5 s ), followed by a prompt containing a transformation direction and number (ex. "Forward 2"). The participant then counted forward or backward from the given letter or set of letters by the number given. The transformation prompt remained on the screen until the participant was ready to choose an answer from a list of eight alternatives. Participants were instructed to solve the problem before advancing to the response alternative screen. Once a participant had advanced to the response alternative screen, a time limit of 6 s was imposed to prevent one from solving the problem while examining the alternatives in the response window.

This pattern spanned four practice trials and a set of 24 stimuli, which was preceded by a set of instructions explaining the process outlined above to the participant. Feedback of "Correct!" or "Incorrect" was given for each response. More detailed feedback was given during the practice trials. Specially, if a correct answer was given it was accompanied by a brief explanation of why that answer was correct, but if an incorrect answer was given it was accompanied by a more detailed explanation of how the correct answer would have been attained. The block of 24 stimuli was randomized within-participants.

## Results and Discussion

Participants were most accurate ( $M=.79, S D=.12$ ) in their responses for sets of four numbers. Accuracy (see Figure 2) then declined as set size increased to six ( $M=.68$, $S D=.10)$ and again when it increased to eight ( $M=.61, S D$ $=.08)$. Participants were also most confident $(M=3.05, S D$ $=.52$ ) in their responses for sets of four numbers. Confidence also declined as set size increased to six ( $M=$ 2.63, $S D=.54$ ) and again when it increased to eight ( $M=$ 2.43, $S D=.63$ ).

## Exp. 1 Accuracy

Figure 2. Mean accuracy scores for Experiment 1.
Reaction times (see Figure 3) for sets of four ( $M=$ 2269.37, $S D=585.34$ ) were faster than for sets of six $(M=$ 2338.76, $S D=620.24$ ), but not faster than for sets of eight ( $M=2197.69, S D=618.27$ ).

## Exp. 1 Reaction Time

Sets of $4 \quad$ Sets of $6 \quad$ Sets of 8

Figure 3. Mean reaction times for Experiment 1.

Repeated measures ANOVA were used to analyze all main variables. There was a significant decline in accuracy as set size increased, $F(2,104)=59.94, p=.000, \eta^{2}=.535$. More specifically, accuracy decreased significantly as set size increased from 4 to $6, F(1,52)=39.62, p=.000, \eta^{2}=$ .432, and as set size increased from 6 to $8, F(1,52)=20.98$, $p=.000, \eta^{2}=.288$.

There was a significant decrease in reaction times as set size increased, $F(2,104)=5.15, p=.007, \eta^{2}=.090$. While there was no significant difference in reaction time between sets of 4 and sets of $6, F(1,52)=2.48, p=.121, \eta^{2}=.046$, there was a significant difference in reaction time between sets of 6 and sets of $8, F(1,52)=11.38, p=.001, \eta^{2}=.180$.

There was a significant decrease in confidence in one's answer as set size increased, $F(2,104)=52.07, p=.000, \eta^{2}$ $=.500$. Contrasts showed significant decreases in confidence as set size increased from 4 to $6, F(1,52)=$ $55.80, p=.000, \eta^{2}=.518$, and as set size increased from 6 to $8, F(1,52)=12.19, p=.001, \eta^{2}=.190$. Zero-order correlations indicated a positive relation between selection accuracy and confidence judgment for set size of $4, r(52)=$ $.58, p=.000$, and set size of $6, r(52)=.45, p=.001$, but not set size of $8, r(52)=.19, p=.173$.

We compared the effect of high and low variance number sets, aggregated across set size. A paired samples t-test indicated that there was greater accuracy when variance in the number set was higher $(M=.72)$ than when it was lower $(M=.67), t(52)=4.30, p=.000, d=1.181$. However, there was no significant difference in reaction times between high ( $M=2301.25$ ) and low ( $M=2260.82$ ) variance, $t(50)=$ $1.39, p=.171, d=.393$.

No correlations were found between working memory or any of the variables of interest, so we performed a mean split of the participants based on working memory task performance and conducted independent samples $t$-tests to compare the groups in terms of accuracy. There was no significant differences between groups based on sets of 4, $t(51)=.46, d=.02, p=.65$, or sets of $8, t(51)=.95, d=.02$, $p=35$. However, the group scoring above the mean on the WM task performed better than the group scoring below the mean when set size was $6, t(51)=2.08, d=.06, p=.04$, 95\% CI [.002, .114].

The most frequently used strategies were to "just get a sense of the numbers" ( $M=3.19, S D=.90$ ) and to "try to memorize specific numbers" ( $M=2.87, S D=1.01$ ). These data reflect the general pattern in recall accuracy, as participants likely tried to memorize numbers from the sets of 4 , and then were forced to abandon that strategy in favor of "just getting a sense of the numbers" as set sizes exceeded four. This pattern supports the finding of Scholl (2001) that people individuate items for sets smaller than four. One of the least frequently used strategies was to "try and figure out the average" ( $M=1.26, S D=.62$ ). This low rating provides some evidence that the participants were not consciously calculating the mean for the number sets. This pattern is interesting because their response patterns indicate that they chose the mean or median value of the set more
often than the actual value from the set as set size increased. This pattern supports findings that people aggregate items for sets larger than four (Scholl, 2001; Masnick \& Morris, 2008).

The results demonstrate a clear effect of set size in that participants were more likely to recall the actual value given smaller set sizes (e.g., 4) than larger set sizes (e.g., 8). This finding is consistent with findings using different types of stimuli (e.g., dots) suggesting that encoding individual items is the default operation until the number of items exceeds working memory limits, demonstrated as four elements in previous research (Ariely, 2001; Feigenson et al., 2004). Once working memory limits are reached, the default operation appears to be encoding the set as an aggregate. The data also suggest that the process of aggregating numbers yields as approximate mean. As set size increased, participants were more likely to select the set mean rather than the actual value as the number they had seen in the experiment. Further, when the numbers varied less and were within a smaller range, accuracy also decreased. It became more difficult to distinguish set members from their mean when the set members were more similar.

Working memory capacity also played a role in the ability to identify presented values. When the sets presented contained six items, individuals scoring above the mean on the WM task out performed those scoring below the mean. When the set size was four, WM capacity was not taxed for either group, and when set size was eight, WM capacity was likely exceeded for both groups.

In general, the confidence level of the participants fell along with their performance, although the influence of metacognitive monitoring on number recall was greater for sets of 4 and sets of 6 than for sets of 8 . The participants showed accurate recognition that their performance was declining as set size, and task difficulty, was increasing. The lack of correlation between recall and confidence accuracy for sets of 8 may be related to the pattern of strategy use, as this set size would have been too large for one to memorize the numbers presented, as well as large enough to pose difficulty in trying to get a sense of the whole set.

## Experiment 2

One possible limitation of Experiment 1 is that the task explicitly asked participants to attend to and encode individual values. Experiment 2 provided the same experimental conditions but changed instructions to ask participants to identify the set mean. This task parallels the Deese-Roediger-McDermott (DRM) paradigm (Deese, 1959; Roediger \& McDermott, 1995), as participants will study lists that are comprised of numbers (rather than words) related to a non-presented response target (Sugrue \& Hayne, 2006). The change in instructions changes the task demands and likely changes the strategy used for the task. Specifically, if participants are asked to recall set means, they will be less likely to encode individual values. Previous research demonstrates that although people are relatively
accurate when estimating set means, estimation accuracy decreases with set size (Peterson \& Beach, 1967).

## Method

Participants. Participants ( $\mathrm{N}=27$ ) were undergraduate students at a Midwestern state university. The average age was $20.67(S D=5.88), 70 \%$ of the participants were female and most were of Caucasian descent.

Procedure. The number sets and working memory tasks for experiment two followed the same procedure as for experiment one, except that for number sets participants were asked to indicate which of the two numbers represented the average of the set of numbers (rather than which of the values was actually in the set).

## Results and Discussion

Participants were most accurate $(M=.71, S D=.19)$ in their responses for sets of four numbers. Accuracy (see Figure 4) then declined as set size increased to $\operatorname{six}(M=.62$, $S D=.14$ ) and again when it increased to eight ( $M=.58, S D$ $=.13$ ). Participants were also most confident ( $M=2.76, S D$ $=.64$ ) in their responses for sets of four numbers. Confidence also declined as set size increased to six ( $M=$ 2.37, $S D=.66$ ) and again when it increased to eight ( $M=$ $2.15, S D=.56$ ).

Figure 4. Mean accuracy scores for Experiment 2.
Reaction times (see Figure 5) for sets of four ( $M=$ 2743.02, $S D=673.50$ ) were slower than for sets of $\operatorname{six}(M=$ 2512.29, $S D=951.66$ ). Reaction times for sets of eight ( $M$ $=2238.00, S D=922.49$ ) were faster than for sets of six.

As in Experiment 1, repeated measures ANOVA were used for all main analyses. There was a significant decline in accuracy as set size increased, $F(2,52)=9.00, p=.000$, $\eta^{2}=.257$. Contrasts showed that accuracy decreased significantly as set size increased from 4 to $6, F(1,26)=$ 7.26, $p=.012, \eta^{2}=.218$, but not as set size increased from 6 to $8, F(1,26)=2.32, p=.140, \eta^{2}=.082$.

Figure 5. Mean reaction times for Experiment 2.
There was a significant decrease in reaction times as set size increased, $F(2,52)=11.01, p=.000, \eta^{2}=.298$. There was no significant difference in reaction time between sets of 4 and sets of $6, F(1,26)=3.76, p=.063, \eta^{2}=.127$, but there was a significant decrease in reaction time between sets of 6 and sets of $8, F(1,26)=13.98, p=.001, \eta^{2}=.350$.

There was a significant decrease in confidence ratings across set size, $F(2,52)=22.44, p=.000, \eta^{2}=.463$. Contrasts showed significant decreases in confidence as set size increased from 4 to $6, F(1,26)=18.52, p=.000, \eta^{2}=$ .416 , and as set size increased from 6 to $8, F(1,26)=8.55, p$ $=.007, \eta^{2}=.248$. Zero-order correlations indicated no relation between identification accuracy and confidence judgment for set size of $4, r(27)=.07, p=.709$, set size of $6, r(27)=-.07, p=.708$, or set size of $8, r(27)=.33, p=$ . 087.

We compared high and low variance, aggregated across set size. A paired samples t-test indicated that there was no difference in accuracy when variance in the number set was higher $(M=.64)$ than when the variance was lower ( $M=$ .64), $t(26)=.184, p=.855, d=.072$. However, there was a significant difference in reaction times between high ( $M=$ 2543.05) and low ( $M=2439.62$ ) variance, $t(26)=2.24, p=$ $.034, d=.879$.

No correlations were found between working memory or any of the variables of interest, so we performed a mean split of the participants based on working memory task performance and conducted independent samples t-tests to compare the groups in terms of accuracy. There was no significant differences between groups based on sets of 4 , $t(25)=-1.07, d=-.09, p=.29$, on sets of $6, t(25)=-1.50, d$ $=.15, p=.146$, or sets of $8, t(25)=-1.03, d=.31, p=.311$.

The most frequently used strategies were to "just get a sense of the numbers" $(M=2.85, S D=1.02)$ and to "look at the first digit" $(M=2.59, S D=.93)$. As with experiment one, most participants tried to get a sense of each number set. Predictably, fewer participants cited memorization ( $M=$ $2.33, S D=1.07$ ) as a frequently used strategy than those from experiment one, as this would not have been necessary due to the change in answer format. These data reflect the general pattern in identification accuracy, as participant performance stabilized once the sets grew larger than 4
numbers, the point at which one would expect participants to have a better chance at inferring set characteristics rather than trying to focus on memorizing individual numbers. This pattern supports the finding that people individuate items for sets smaller than four, but aggregate items for sets larger than four (Scholl, 2001; Masnick \& Morris, 2008).

These results reveal a similar pattern of behavior as in Experiment 1, with a few exceptions. One exception was that variance in set size did not affect accuracy in identifying the mean in the same way it did identifying members of the original set. Another exception is that working memory did not appear to play a role in accuracy, even in the largest sets, when identifying the mean. It is possible that differences between a recognition task and a slightly more inferential task are playing a role, but more data with direct comparisons will be necessary to explore this issue in more detail.

## General Discussion

Our results provide new insights into how people represent number sets. One, it appears that number sets and nonnumerical sets are aggregated similarly. Number sets of four appear to be accurately encoded as individual values, likely represented as symbolic values. Larger sets appear to be encoded as aggregates and represented as analog magnitudes. It appears that the process of aggregating over sets results in an approximate mean. In Experiment 1, as set size increased, participants were increasingly likely to erroneously select the set mean, rather than the actual value from the set. It appears that even with larger sets, participants quickly approximated means, though less accurately, than for smaller sets.

The results suggested that strategies are important in creating different representations. One intriguing piece of evidence from Experiment 1 is that reaction times for sets of four and eight were shorter than for sets of six. This suggests that participants might have been attempting to use the same individuation strategy with sets of four and six. In correspondence, we found a relation between working memory capacity and performance only for those with high capacities and only for sets of six items. This outcome was not surprising, because the individuation strategy would be more difficult for sets of six than for sets of four. This suggestion is supported by a decline in accuracy and confidence from sets of four to sets of six.

In conclusion, our results suggest that memory for number sets is similar to memory for sets of objects in that sets smaller that four are likely to be individuated while sets larger than four are likely to be aggregated. The process of aggregation appears to maintain approximate representations of the statistical properties of the sets. One possible explanation for the lack of relation between working memory and recall accuracy found in this study is that the tasks themselves load on spatial working memory, rather than verbal memory (Morris \& Masnick, 2008).

# Unified Modeling of Proactive Interference and Memorization Effort: A new mathematical perspective within ACT-R theory 

Arindam Das, Wolfgang Stuerzlinger<br>Computer Science and Engineering, York University, Toronto, Canada<br>\{arindam, wolfgang\} @cse.yorku.ca

#### Abstract

We parsimoniously model the effect of proactive interference and memorization effort in learning stable graphical layouts. We model the visual search cost, i.e. the number of distractors visually encoded while looking for a target item, as a reasonable surrogate of onscreen proactive interference. Further, we show that a novel quantity that we term "effort factor" is an acceptable estimate for comparing the memorization effort across different access cost of onscreen information during the early stages of practice.

Keywords: ACT-R declarative memory, Proactive Interference, Memorization Effort, User Interface

## Introduction

Onscreen information is an important part of daily life today - On one hand, they are prevalent in handheld devices like smart-phones and tablets; On the other hand, they can also be found in critical displays in aircraft and other machinery. The screens usually display a structured set of items for the user to interact with. When interacting, it is rare that users remember the position of every item in the set perfectly. One explanation for this forgetting effect is proactive interference caused by distractor items seen during the visual search for the desired item. Proactive interference causes loss of memory activation. In contrast, explicit memorization of item locations helps to mitigate the effect of such interference. People exert mental effort in order to accomplish such memorization.

A study in flight simulation training (Waldron et al., 2008) found that temporarily decreasing the availability of onscreen information for pilots orients pilots more towards memory-based interaction strategies. This in turn helps them better remember critical information such as the aircrafts' location. The study established that an increase in information access cost increases the perceptual-motor effort. This normally encourages users to choose the highest performance option of using fewer perceptual-motor operations but more memory operations, even if memory retrieval is imperfect.

Rowe et al. (2008) empirically suggested that "practice" and "memorization" positively influence visuo-spatial learning while "proactive interference" impacts it negatively. On the other hand, Altmann et al. (2002) proposed a theory that not only holds proactive interference but also "decay" (i.e. loss of memory activation with passage of time) responsible for forgetting. Taking into account the mutually constraining effects of "practice", "memorization" effort, "decay" and "proactive interference", an integrated, yet simple and easily applicable performance model is possible that would reflect the effect of these phenomena on visuo-spatial learning.

Following this idea, we propose a simple mathematical model of visuo-spatial learning that combines the effect of "practice" in terms of practice time, the effect of "decay" in terms of a small numeric constant, the effect of "proactive interference" in terms of visual search cost, and the effect of "memorization" effort in terms of a newly introduced model parameter, an effort factor, explained later. All these effects are expressed in a single equation of memory activation. To achieve this goal, we adapt an existing memory activation equation of ACT-R theory developed by Anderson et al. (1998). We focus on the cognitive aspects of interaction more than the perceptual-motor control complexities in our model. Therefore, we leverage the empirically proven axioms of ACT-R theory that the time cost of a visual encoding is a constant and that a motor response can be modeled as an average value, according to the task specific behavior, such as a mouse movement.

Guided by Altmann et al. (2002), we implement our mathematical model in a spreadsheet and validate it against previous empirical data collected by others.

## ACT-R Theory of Declarative Memory

The ACT-R theory by Anderson et al. (1998) describes a modular system that aims to replicate the human mind. The theory is a framework of mathematical equations that models the neural computations in order to realize human dynamic behavior.

The core of ACT-R declarative memory builds upon the notion of memory activation. It posits that memory encodings of items have different levels of activation to reflect their past use: items that have been used recently or items that are used very often receive a high activation. This activation decays over time if the item is not used. When the cognitive system needs to retrieve an item, memory returns the one with the highest activation at that instant. The job of memory retrieval is complicated by the noise in activation levels, which can temporarily make an item more active than the current one, or which can temporarily push all items below a threshold, thereby making the cognitive system transiently unable to recall information (Altmann et al., 2008; p. 604). Furthermore, the activation of an item controls its speed of retrieval. We focus on the following three equations behind the ACT-R declarative memory system that we leverage in our current work.

## ACT-R Activation Equation

The equation describing the activation, $A$, of an item in the memory is given by
$A=B+\varepsilon \quad$ Activation Equation
where $B$ is the base-level activation of the item discussed later in detail and $\varepsilon$ is the noise component. Noise is assumed to cause transient fluctuations in activation levels. Guided by Altmann et al. (2002), we implement the noise $\varepsilon$ as a constant for our modeling purposes. In the complete ACT-R memory model, environmental context and relevance to the current goal also influences the activation of an item (Gray et al., 2006, p. 481). However this component introduces additional complexity not relevant to our modeling effort in this work. Being guided by Gray et al. (2006) we have therefore omitted the component here.

## ACT-R Base-Level Activation Equation

The equation describing the base-level activation of an item in memory is given by

$$
\begin{equation*}
B=\ln \left(\sum_{j=1}^{n} t_{j}^{-d}\right) \quad \text { Base-Level Activation Equation } \tag{2}
\end{equation*}
$$

where $n$ is the number of "practices" of the item completed so far, $t_{j}$ is the age of the $j$-th practice of the item, and the negative exponent $d$ is the decay constant that controls how quickly the activation decreases. As postulated by ACT-R theory, the $d$ term thus models the loss of memory strength with the passage of time. The equation therefore represents the strength of a memory item as the sum of a number of individual memory strengthening, each corresponding to a past practice event. It implies that each time an item is practiced, the activation of the item receives an increment in strength that decays away as a power function of time.

## ACT-R Reaction Time Equation

The activation of an item discussed earlier controls its speed of retrieval. The time required for the declarative memory to respond to a request (recognition or recall) for an item is given by the following equation:
$R T=I+F * e^{(-f * A)}$ Reaction Time Equation
where $I$ is an intercept time reflecting the time cost of perceptual (visual) encoding and motor response. $F$ is the latency factor, and maps activation to time. $f$ is the latency exponent. The purpose of parameters $F$ and $f$ is only to scale the time to retrieve an item from memory. They remain fixed across all experimental conditions.

The time cost of a visual encoding is set at 185 ms which is taken from the estimate used by ACT-R (Anderson \& Lebiere, 1998, pp. 150-151) for human attention to move to an object at a location.

The time cost of a motor response is set according to the task specific behavior. The task we model involves finding a pre-cued item on a structured layout of graphical buttons presented on a computer screen and then selecting it by clicking on the appropriate button using a mouse (Ehret, 2000, 2002). Guided by Ehret (2000), Gray et al. (2006) and Card et al. (1978), we estimate the average time cost of a motor response to be 300 ms for our modeling purposes.

## The Model

We next propose our extension to the base-level activation equation in order to account for the effect of proactive interference and memorization effort. We do so largely by adapting existing cognitive constructs rather than developing entirely new ones.

## Proactive Interference Modeling

Our approach adapts ACT-R's classic model of memory strength to account for proactive interference. In other words, we account for the effects of distractors that get visually encoded or cumulated before the encoding or accumulation of the target item, during a visual search. We accomplish this by replacing the decay constant, $d$, of the base-level activation equation, with a function consisting of a constant term and a varying term. The constant term models the loss of memory strength with passage of time as before. The new varying term models the loss of memory strength due to proactive interference. Our proposal for modeling the combined effect of decay and interference on memory activation is in line with the observations of Altmann et al. $(2002,2008)$ which indict both decay and proactive interference for forgetting.

The varying term we propose is governed by the visual search cost - the number of distractors that get visually encoded prior to encoding the target item when one tries to find an item on a user interface. The encoded number of distractors during a search contributes to a measure for the proactive interference effect: The lower the number of distractors visually encoded during a search for a target item, the lower should be the "loss" of activation of the target item. Hence, the next recall of that item will be affected by its higher activation, leading to the lowering of its retrieval time. This will show an improvement in "search and selection" performance time during exploration of the interface. Our hypothesis is grounded in the primary research result of Underwood (1957) on proactive interference, namely, the effect that the number of previously learned items has on the recall of the target item: The lower the number of previously learned items is, the lower is the forgetting effect and therefore the lower is the recall latency for the target item.

We propose a decay rate, $d_{j}$, calculated for an item, after $j$ practices of the item are completed, as follows:

$$
\begin{equation*}
d_{j}=h+0.5 * X_{j-1} / N \quad \text { Decay Rate Equation } \tag{4}
\end{equation*}
$$

where $h$ represents the time-based decay constant, the fraction 0.5 is a scaling factor (our choice of 0.5 is explained in the next paragraph), $N$ is the total number of items on the layout and $X_{j-1}$ is the number of distractors visually encoded at the time of $j^{\text {th }}$ practice. Naturally, $j$ has to be larger or equal to 1. $X_{0}$ denotes the number of distractors encoded at the first practice. When $X_{j-1}$ is 0 , i.e. when the user is able to complete the task by direct recall, without going through any explicit visual search, the decay rate equation degenerates to $d_{j}=h$. This implies that, in the absence of the impact of distractors, decay in activation occurs only
with the passage of time as modeled by the classic baselevel activation equation.

We introduce the varying term $0.5 * X_{j-1} / N$ to represent the loss of memory activation due to proactive interference. It transforms the number of distractors, $X_{j-1}$, to a "decay" value suitable for ACT-R theory. We assume such values to be ranging from 0 to 0.5 : Since 0 implies no decay, it can be considered as a lower bound. The value of 0.5 is used as the default decay constant in the classic ACT-R theory (see Anderson et al., 1998). Therefore 0.5 can be considered as a valid upper bound for our work. The ratio $X_{j-1} / N$ ranges from 0 to 1 . Consequently, the varying term $0.5 * X_{j-1} / N$ results in a value in the desired interval, 0 to 0.5 . The $0.5 * X_{j-1} / N=0.5$ refers to a situation where the maximum possible number of distractors is encountered, i.e. when $X_{j-1}=N$, leading to the highest level of proactive interference effect. This, in turn, reduces the term to the maximum of 0.5 . On the other hand, $0.5 * X_{j-1} / N=0$ implies an absence of impact from distractors, and therefore no proactive interference effect as a consequence. This occurs when the user is able to complete the task by direct recall.

Our model of proactive interference is adapted from the model of Das et al. (2010). Our work is a significant improvement over their model of proactive interference because firstly, our decay rate equation contains less number of free parameters (decay constant $h$ is the only free parameter in our equation) and secondly, our equation is constrained by the total number of items, $N$, of a layout under scrutiny. Consequently, the chances for data overfitting decrease significantly in our model.

## Memorization Effort Modeling

Our modeling of memorization effort is guided by the soft constraints hypothesis of Gray et al. (2006). The soft constraints hypothesis is a rational analysis approach which proposes that the mixture of perceptual-motor and cognitive resources allocated for interactive behavior is adjusted based on temporal cost-benefit tradeoffs, such that the least-effort path of executing the visuo-spatial task at hand, gets implicitly chosen. As perceptual-motor effort increases, users will normally choose the least-effort option of fewer perceptual-motor operations and more memory operations, even if the memory retrieval is imperfect. We term the effort exhausted in carrying out the memory operations as "memorization effort".

The soft constraints hypothesis concludes that the tradeoff between selecting the perceptual-motor versus cognitive behavior minimizes the total effort (and hence performance cost) measured in the currency of time (Gray et al., 2006, p. 463). Motivated by the hypothesis, we introduce a parameter in the base-level activation equation of ACT-R (Equation 2) as a coefficient of practice time and include it inside the logarithmic term (shown later in Modified BaseLevel Activation Equation). We call this novel parameter effort factor. We hypothesize the effort factor to be the "temporal" representation of the memorization effort expended to accomplish a visuo-spatial learning task. The works of Anderson (1983, p. 277) as well as Stewart et al. (2007, p. 235), also motivate our choice for the adoption of
an effort factor, as they suggested the usage of a cost factor similar to ours, albeit in different domains.

## Modified Base-Level Activation Equation

With the decay rate equation and the effort factor parameter conceptualized, we modify the base-level activation equation (Equation 2) to

$$
\begin{equation*}
B=\ln \left(k \sum_{j=1}^{n} t_{j}^{-d_{j}}\right) \tag{5}
\end{equation*}
$$

## Modified Base-Level Activation Equation

Equation 5 is obtained by adding two new elements $d_{j}$ and $k$ to Equation 2. We explain the new elements below.
$d_{j}$ describes the new decay rate equation (Equation 4) that sums up two terms: one representing the traditional timebased "decay" constant and the other representing the "loss of activation due to proactive interference".

The element $k$ is the aforementioned effort factor parameter. We explain $k$ in the context of learning layouts that vary in the information access costs (henceforth referred to as "access cost") associated with their items. The access cost differs in terms of representativeness of item labels. Our context of learning accounts for the fact that the total practice time for learning is held constant across all layouts (i.e. for every level of access cost).
If all model parameters, except $k$, in Equations 1, 3, 4 and 5 are left at fixed values across layouts that differ in access costs, then we hypothesize two properties about $k$ while comparing layouts in terms of reaction time estimates $(R T)$ of Equation 3 as follows:
(i) First, we hypothesize that one value of $k$ corresponds to one particular layout, i.e. one particular access cost condition.
(ii) Second, a lower value of $k$ would correspond to higher memorization effort whereas a higher value of $k$ would correspond to lower memorization effort. The Appendix provides an argument for this.

Our modified base-level activation equation is therefore a hypothesis that accounts for the combined effect of "practice time", "memorization" effort, "proactive interference" and "decay" on visuo-spatial learning performance. We validate our hypotheses later in this work.

Our model of memorization effort is adapted from the work of Das et al. (2012). Their model did not account for proactive interference which is the central constraint compared to decay in learning in situations where learning is affected by distractors (Altmann et al., 2002, 2008). Moreover, they had varied the values of multiple model parameters across different conditions of access cost leaving their model vulnerable to overfitting.

## Validation

In order to validate our model, we use existing experimentally derived data sets for human performance over several practice sessions for location learning of items in a stable layout. Our goal is to focus on the novice to expert transition because of two reasons. On one hand, the effect of proactive interference is most pronounced during
this transition phase. On the other hand, the effect of memorization effort to overcome such interference is also evident in this stage. We therefore concentrate on modeling early sessions of skill development. Each data set we validate against corresponds to a certain access cost in terms of label representativeness of graphical buttons that were laid out on a computer screen. The task we model involves finding a pre-cued button and selecting it using a mouse.

We next explain the rationale behind all model parameter values that were fixed across all experimental conditions.

The time-based "decay" constant $h$ in the decay rate equation was fixed at $h=0.058$. We are motivated here by Pavlik et al. (2005, p. 572), who used it as a decay intercept albeit in a different modeling context. In the absence of any inter-trial data in the empirical study that we validate against, we assume that there have been insignificant pauses between any two consecutive trials. Hence, a relatively small value for the time-based "decay" constant is appropriate, implying that the decay due to passage of time had been minimal. Since the focus of our decay rate equation is to model the effect of proactive interference, we place greater emphasis on the role of distracting information. In this regard, we are motivated by the discourse of Altmann et al. (2002) who argues for the influential role of proactive interference in forgetting compared to the role of decay in the domain of distractoraffected learning. Our choice of a very small value of the time-based "decay" constant is therefore appropriate.

The activation noise $\varepsilon$ in the activation equation was fixed at $\varepsilon=0.28$, a value in line with other applications of this equation in the domain of graphical user interface (e.g., Gray et al., 2006).

The latency factor $F$ in the reaction time equation is left at its default value of $F=1 \mathrm{sec}$, as per classic ACT-R theory.

The latency exponent $f$ in the reaction time equation is fixed at $f=0.65$. On carrying out sensitivity analysis, we found that setting $f$ at 0.65 instead of 1 substantially reduces the root-mean-square error (RMSE) value between the human data and its corresponding model data. It has very negligible influence on the correlation between them.

As we discuss below, the effort factor $k$ of the Modified Base-Level Activation Equation is the only parameter that we varied across conditions in order to account for the relative differences in memorization effort spent in learning layouts with different access costs (conditions).

## Circle of Buttons Experiment

Knowing an object's location can reduce a user's task time, errors, and frustration. As the number of screen objects increases, so does the utility of location knowledge. Ehret (2002) carried out an experiment that tests how well users learn the location of buttons arranged in a circle on a computer screen and how the mechanisms underlying location learning interact with the level of meaningfulness of button labels. He used a "search and select" task in which, for a given trial, participants were presented a particular color and were required to find and click the button associated with that color. The correct button was one among the twelve buttons that remained in constant positions throughout the experiment. The contour and shape
of every button was always visible across all conditions (Ehret, 2000; Figure 2, p. 27). To discourage errors, when participants clicked the wrong button the computer would beep five times, a dialog box would appear, and the trial would have to be repeated (Ehret, 2002; p. 212).

Ehret's observations were point-of-gaze data collected via an eye-tracker. In order to validate our model we extracted three data sets from his observations. The data sets were mean "visual search and select" time (reaction time) from an experiment, limited to the first 10 sessions of practice, since learning plateaued off after the tenth session. In his study, Ehret (2002; 2000, p. 19) had reported two costs, the visual search cost which is the number of buttons visually encoded before the target button is found and the verification time, which is the time required to decide whether the button visually encoded is really the target or not. For a given session, we arrived at the mean human reaction time per button by multiplying the mean visual search cost with the mean verification time corresponding to that session.

The three data sets differed in the level of meaningfulness of labels associated with the buttons. The first set of data was obtained while searching for a pre-cued color in buttons labeled with the name of color written in English. The aim was to have a meaningful association between a color and the button representing the color. The second set of data was obtained while searching for buttons labeled with arbitrary icons. The aim was to reduce the meaningfulness of the association between a color and the button representing it. The third set consisted of the reaction times for searching and selecting a pre-cued color among buttons with no labels on them. The aim was to eliminate any meaningfulness of the association between a color and the button representing it. The data sets thus contain three sets of reaction times corresponding to the three different levels of difficulty in accessing information: textual label, arbitrary label and invisible label. Each condition therefore represented a certain level of access cost, the textual label condition being the lowest cost condition among them. The total practice time was held constant across all conditions. It is to be noted that for the arbitrary and invisible label conditions, a tooltip was provided for each button to aid the subject, if memory failed. Accessing the tooltip for a button revealed a small rectangle containing the color associated with it. The cost of accessing this tip was a one-second delay between moving the mouse cursor to the button and the appearance of the tooltip.

Our choice of data aligns with our modeling objective. We aim to model the combined effect of visual search cost (the surrogate of proactive interference) as well as memorization effort on reaction time, over a reasonable number of practice sessions. Ehret's data shows that for any given access cost condition, the visual search cost decreases over practice sessions implying that proactive interference decreases with practice. However, Ehret's data further shows that during the search for a pre-cued color, as the access cost increased from textual to arbitrary to invisible label conditions of buttons, so did the time to visually verify and decide (verification time) whether a button currently under scrutiny is indeed the target or not, at any given session. The verification time was observed to be the lowest
for the textual label condition and highest for the invisible label condition. In other words, the layouts with higher access cost featured higher verification time to identify the correct item, implying higher effort to learn those layouts compared to the ones with lower access cost. As posited by the soft constraint hypothesis and given the same amount of practice time across all conditions, the higher perceptual cost of arbitrary and invisible label conditions results in a higher memorization effort for those label conditions compared to the memorization effort required for the textual label condition.

For our validation, we had to make a few assumptions, as certain information was not mentioned explicitly in the work of Ehret (2002). The assumptions are the same across all conditions as follows: Each practice session took 37.5 seconds to complete - since 16 sessions took 10 minutes or 600 seconds as expressed in a related work by Ehret (2000, p. 136). We also assume the inter-session periods to be constant. Also, except for the target pre-cue, we assume that environmental context cuing is minimal and irrelevant for our purposes.

## Validating the Proactive Interference Effect

We provide an example scenario on how the effect of proactive interference on spatial learning can be modeled using our new model. Ehret (2002) had an onscreen layout of graphical buttons labeled with icons where each icon is arbitrarily associated with a color. A subject's task was to visually search for a pre-cued color among the buttons and click the appropriate button when found using a mouse. The pre-cued color always appeared at the center of the circle. In case the subject's memory failed to recall the color associated with a button, she could access the button's tooltip to know its color by moving the mouse cursor over it. The tooltip appeared after a one-second delay once the mouse cursor was moved to the button.

The mean numbers of distractors measured in Ehret's experiment in the arbitrary label condition are 5.27, 2.93, $2.58,2.34,2.31,1.61,1.49,1.31,1.36$ and 1.14 corresponding to sessions 1 to 10 . We input these numbers in the decay rate equation of our model to obtain the mean activation value per item for each session. We adjust the value of $k$ in our model to 0.068 for the experimental condition (i.e. arbitrary labeling condition). The other model parameters stay fixed at the values discussed earlier. We fit our model to the empirical reaction time for a button. We found the $\mathrm{R}^{2}$ of the fit to be .993 implying a qualitative correspondence between human and model results.

The effect of proactive interference was also evident in the textual label condition. After substituting the values of mean numbers of distractors for this condition (measured in Ehret's experiment) in the decay rate equation, we again found a close match between the human and model results with $\mathrm{R}^{2}=0.978$. Our adjusted value of $k$ was 0.500 in this condition.

As apparent from the decay rate equation, a change in the number of distractors changes the decay rate. While modeling the proactive interference, we noticed that the mean number of distractors per item, $X_{j-1}$ in the decay rate equation influences the shape of the curve at each sessionpoint. A small change in the decay rate, $d_{j}$, (at the level of
$10^{-2}$ ) is found to have noticeable impact on the reaction time estimates. This is particularly true for the first few sessions of practice.

Figure 1. Reaction times per item (button) for textual, arbitrary and invisible label conditions.

## Validating the Comparison of Memorization Effort

Figure 1 shows the fit of our model to the human data in terms of reaction times. We compared the effort factor $k$ for the invisible label condition against the textual label condition. We found $k=0.056$ for the difficult to access invisible labels, compared to $k=0.500$ for the easily accessible textual labels. Furthermore, $k$ was 0.068 for the difficult to access arbitrary labels, compared to $k$ being 0.500 for the easy to access textual labels. The comparison of $k$ in both instances thus points to lower values of $k$ for layouts with high access cost (high perceptual cost) compared to the conditions where relevant information is easily available in the environment. We therefore conclude that the comparison of memorization effort via our new effort factor $k$ follows the soft constraint hypothesis to a significant extent.

With $\mathrm{R}^{2}=0.978, \mathrm{RMSE}=0.215$ for the textual, $\mathrm{R}^{2}=$ 0.993 , $\mathrm{RMSE}=1.153$ for the arbitrary and $\mathrm{R}^{2}=0.941$, RMSE $=0.785$ for the invisible conditions, the correlation between the human and model data were good. The RMSE as a percentage was $13 \%$ for textual and $15 \%$ for invisible condition. However, the percentage RMSE for arbitrary condition being $38 \%$ was higher than the $20 \%$ mark suggested by John and Newell (1989). The RMSE for the arbitrary condition therefore implied a high error.

## Discussions

Our work in this paper introduces two mathematical terms, one to account for the effect of "proactive interference" (PI) and the other to account for the effect of "memorization effort". We add them to an existing memory activation equation of ACT-R theory that hitherto accounted for the effects of only "practice" and "decay".

In this work, we have left all but one model parameter fixed across all conditions, thereby omitting the scope of overfitting significantly. The effort factor $k$ is the only model parameter that we varied in order to reflect the
differences in the memorization effort across different accessibility conditions.

Earlier, Altmann et al. (2002) had used ACT-R theory to mathematically model the effect of PI on recall probability. On the other hand, we have mathematically modeled the effect of PI on response latency.

Our modulation of decay rate to reflect PI is motivated by the approach of previous researchers such as Pavlik et al. (2005), Cochran et al. (2006) who had modulated the decay rate to model phenomena, albeit different from PI.

Previously, Ehret $(2000,2002)$ had used ACT-R theory to model memorization effort. Unlike ours, his approach involved computer-based simulation. In this work, we provide an alternative look at Ehret's modeling endeavor. We do so through a mathematical model.

Initially, to keep our modeling endeavor simple, we started out by creating separate models of proactive interference as well as memorization effort. While developing the standalone model of proactive interference, we tried to leave the effort factor constant across all conditions. On the other hand, while developing the standalone model of memorization effort, we tried to leave the decay rate constant across all conditions. In both cases, however, we were unable to identify fixed values for model parameters. Rather, every "access cost" condition demanded a separate set of values for multiple model parameters to fit the data in a satisfactory manner. This motivated us to model proactive interference and memorization effort in a unified way.

Our mathematical model has its limitations. (i) At any given trial for searching a target location on a layout, when the number of distractors $X_{j-l}$ encountered is much less than the total number of items $N$ on the layout, we assume that proactive interference owing to that trial has been negligible. This situation may arise when $N$ is very large. Further investigation is warranted to identify a practical upper limit on $N$. (ii) Our model is restricted to comparing layouts that have the same number of items in them. (iii) We do not consider the level of similarity between distractors and target. (iv) Increased recall latency observed in high PI conditions can be caused by interference of the target with distractor activations at the time of retrieval. We have not considered that. (v) ACT-R theory has a threshold parameter that specifies a minimum activation below which an item is invisible to the cognitive system. Similar to Altmann et al. (2002), we assume no such threshold. As the threshold parameter is not a variable in the equations we use, this assumption does not impact our work directly.

Our model concentrated purely on the cognitive aspects of interaction; thus it did not model the motor control complexities involved in the spatial search and selection processes on graphical user interfaces. In reality though, these are all important factors that influence the overall user experience.

The advantages of our proposal are its simplicity and transparency. However, it is an ad hoc alternative focused at solving a specific problem in a specific way. We do not claim that we have arrived at a "generic" solution.

## Appendix

If the effort factor $k$ is varied while leaving other model parameters at fixed values across different accessibility conditions, then a lower value of $k$ would correspond to higher memorization effort whereas a higher value of $k$ would correspond to lower memorization effort. The reason is as follows. A lower $k$ (in Equation 5) results in a higher $R T$ (in Equation 3). Higher values of $R T$ s are typically evident in the early stages of practice for layouts with higher access costs (see the empirical data in Ehret, 2002). However according to the soft constraint hypothesis, learning a layout with higher access cost would require a higher number of memory operations compared to perceptual-motor operations. Consequently, we conclude that a lower value of $k$ refers to a higher number of memory operations and therefore reflects higher memorization effort. In contrast, a higher value of $k$ refers to a lower number of memory operations and therefore reflects lower memorization effort.

# Integrating Cognitive Principles to Redesign a Middle School Math Curriculum

#### Abstract

Does a middle school mathematics curriculum that is redesigned using principles based in cognitive research improve student outcomes? To test whether research can be effectively translated into practice, the Connected Mathematics Project 2 (CMP2) curriculum was revised according to four principles 1) integrating visual with verbal information, 2) prompting for self-explanation of correct and incorrect worked examples, 3) spacing learning over time, and 4) using formative assessment. This study of $6^{\text {th }}$ grade and $8^{\text {th }}$ grade mathematics education addresses the research question: "Do students who are exposed to specific redesigned CMP2 curriculum modules (treatment) exhibit greater improvements in mathematics performance in the module-specific content area than their counterparts exposed to the regular CMP2 curriculum (control)?" Preliminary analyses show statistically significant effects of the redesigned CMP2 units in three of the four curricular units in this study.

## Introduction

Lab-based research in cognitive and learning sciences has led to a number of recommendations for improving learning and instruction (e.g., Pashler et al., 2007). Tightly controlled experiments have shown that learning can be enhanced with strategies such as mapping between visual representations, prompting for explanation of worked examples, using quizzing to promote learning and spacing practice opportunities over time. The vast majority of studies focus on specific strategies in isolation rather than how principles may be combined. If these research findings are to be meaningfully applied to classrooms, the synergistic effects of the strategies must be tested in real-world settings. In the current paper, we describe a large-scale effort of the National Center on Cognition and Mathematics Instruction (Math Center) in the United States to bridge research and practice by applying cognitive principles to redesign an existing mathematics curriculum and testing the efficacy of these materials.

To test the synergistic effects of research-based instructional strategies, the Math Center applied four
principles to redesign Connected Mathematics Project 2 (CMP2), a widely-used middle school (grades 6-8) mathematics curriculum. The Math Center team selected cognitive-based principles shown to improve student learning: 1) integrating visual with verbal information to promote the integration of concepts, 2 ) prompting for selfexplanation of correct and incorrect worked examples, 3) carefully spacing the learning of critical content and skills over time, and 4) using quizzes to provide focused feedback and adjust instruction to the needs of students.

The CMP2 curriculum is an NSF-funded, research-based curriculum for grades 6-8 that covers topics emphasized in both national and state standards and aligns well with key ideas from the NCTM (2006) Focal Points. Key features of the curriculum are that it (1) is organized around important mathematics ideas and processes, e.g., number sense, symbolic reasoning, and probability, (2) is problemcentered, and (3) builds and connects concepts across problems, units, and grades. Each year of the curriculum is divided into eight units; each unit includes a student booklet and accompanying teacher materials to support instructional practice.

Applying the principles to revise instructional materials (e.g., the print curriculum) and instructional practice (e.g., what happens in the classroom) required expertise across many fields. Teams devoted to cognition research, mathematics, professional development, and production collaborated to ensure that the revised materials were grounded in the research findings, were mathematically accurate and appropriate (in terms of student development and curriculum standards), were clearly specified for teachers, and were produced with a high level of technical quality. The iterative, multi-layered design process that we have developed for integrating the cognitive principles with the CMP2 curriculum applies not only in the context of mathematics instruction, but also to bridging research with instructional design across content areas.

## The Principles

The following four principles were selected as they have demonstrated effectiveness in student learning, have broad
applicability to instruction, and can be readily implemented in a range of curricular materials.

Integrating Visual and Verbal Information Combining visual information with verbal descriptions serves two important functions in mathematics instruction: 1) ensuring that text for instruction and problem-solving are perceived and understood and 2) promoting fluency in mapping between representations (e.g., equations, diagrams, graphs, or tables). To maximize learning benefits, research suggests that visual and verbal information should be integrated (e.g., Clark \& Mayer, 2003; Larkin \& Simon, 1987; Moreno \& Mayer, 1999) and task-irrelevant information should be removed (e.g., Harp \& Mayer, 1998). Visual cues such as color, proximity and grouping can support integration. Removing "seductive details;" that is, representations that are engaging but only tangentially related to the topic of instruction or the problem at hand (e.g., Harp \& Mayer, 1998), helps learners focus on relevant information. To apply the visual mapping principle, researchers removed irrelevant images, added visual cues (e.g., color), and modified existing images to facilitate mapping.

Worked Examples In mathematics, students must learn to fluently carry out procedures across a variety of problem types. Interleaving problems to solve with worked examples of how to solve a problem improves student learning (Zhu \& Simon, 1987; Clark \& Mayer, 2003). Prompting students to explain worked examples further increases learning by facilitating the integration of new information. (Chi, 2000; Roy \& Chi, 2005). In worked example exercises, students see complete or partially worked out solutions (which can be correct or incorrect) and explain the rationale behind problem solving steps or the error that was made in an incorrect example. Positive effects of interleaving worked examples have been reported in a variety of courses (Clark \& Mayer, 2003; Paas \& Van Merrienboer, 1994; Sweller \& Cooper, 1985). Worked examples are more effective and more efficient for learning and transfer because they allow students to spend limited cognitive resources on understanding the ideas underlying the solutions rather than on generating solutions (Sweller, 1999). Further, explaining both correct and incorrect worked examples promotes greater learning than correct examples alone (Siegler, 2002; Siegler \& Chen, 2008; Rittle-Johnson 2006). To apply the worked examples principle, researchers modified existing homework activities to include worked examples that prompt for self-explanation of problem solving steps.

Spaced Learning and Formative Assessment Extensive research in cognitive psychology has demonstrated large retention advantages when learners have multiple opportunities over time to practice key facts, concepts, and knowledge rather than few instances of "massed" practice, a phenomenon called the spacing effect (Cepeda et al., 2006; Rohrer \& Taylor, 2007). When learners practice recalling and applying relevant information through quizzing, they
are more likely to retain that knowledge for a greater period of time. Spacing instruction and practice reinforces connections between key ideas and promotes transfer.

Periodic testing provides students with opportunities to practice retrieving knowledge, reflect on the state of their knowledge, and transfer knowledge to new problems (Butler \& Roediger, 2007; Roediger \& Karpicke, 2006; Rohrer, 2009). Cycles of feedback and reflection that allow for revision and knowledge updating can help learners master targeted concepts and skills (e.g., Pavlik et al., 2007). Evidence from classroom learning contexts shows that the formative use of assessment can enhance instructional effectiveness (e.g., Black \& Wiliam, 1998); here, formative assessment is defined as a process used by teachers and students that provides feedback to adjust ongoing teaching and learning to improve students' achievement of intended instructional outcomes. In the revised materials, teachers were provided with quizzes and instruction on how to use feedback formatively in the classroom.

## Method

The design of this study is a within-teacher clusterrandomized trial. The primary research question of this study is: "Do $6^{\text {th }}$ and $8^{\text {th }}$ grade students who are exposed to a redesigned curricular unit (treatment) show greater pre-topost test improvements in mathematics scores than students exposed to the unmodified curricular unit (control)?"

Participants Researchers collected data from $646^{\text {th }}$ grade teachers ( 1270 students at 45 schools) and $568^{\text {th }}$ grade teachers (1180 students at 42 schools). Teachers had prior experience with the CMP2 curriculum and came from a diversity of schools across seventeen states in the United States. Background characteristics of participating teachers and demographic characteristics of their students are presented respectively in Table 1 and Table 2.

Table 1: Professional background of participating teachers.

| Characteristic | $\mathbf{6}^{\text {th }}$ Grade | $\mathbf{8}^{\text {th }}$ Grade |
| :--- | :---: | :---: |
| Majored in math or math <br> $\quad$ education | $27 \%$ | $43 \%$ |
| Advanced degree | $64 \%$ | $66 \%$ |
| Mean years of teaching | 12.3 | 13.7 |
| $\quad$ experience | $(\mathrm{SD}=8.2)$ | $(\mathrm{SD}=7.6)$ |

Table 2: Demographic characteristics of participating students.

| Characteristic | $\mathbf{6}^{\text {th }} \mathbf{G r a d e}$ | $\mathbf{8}^{\text {th }}$ Grade |
| :--- | :---: | :---: |
| Socioeconomically <br> disadvantaged | $41 \%$ | $43 \%$ |
|  | Ethnicity |  |
| White | $67 \%$ | $60 \%$ |
| Black | $10 \%$ | $13 \%$ |
| Hispanic | $14 \%$ | $13 \%$ |
| Other | $9 \%$ | $14 \%$ |

Materials Two $6^{\text {th }}$ grade units and two $8^{\text {th }}$ grade units from the CMP2 curriculum were revised according to the cognitive principles described above. The $6^{\text {th }}$ grade units used in this study were Bits and Pieces III (decimals and percents) and Covering and Surrounding (area and perimeter). The $8^{\text {th }}$ grade units were Shapes of Algebra (linear equations and coordinate geometry) and Say it with Symbols (expressions and equations). Teams of researchers were formed for each of the principles. The cognitive research teams developed rubrics to identify whether the existing materials aligned with the cognitive design principles, and if not, to specify how the materials would be altered to be in compliance. Next each team made sequential revisions to the CMP2 materials. Changes that overlapped with other principles were discussed and resolved in biweekly meetings.

1. Concy Island Park wants a bumper-car ride with 24 square meters of floor space and 22 meters of rail section.
a. Sketch some floor plans for this request.
b. Describe the bumper-car ride in terms of its area and perimeter. Report what cach measure tells you about the ride.

Figure 1: A problem from the original Covering and Surrounding unit.

1. Concy lsland Park wants a bumper-car ride with 24 square meters of floor space and 22 meters of rail section.
a. Sketch some floor plans for this request.

Dominick completed the first two floor plans in a correct way, but his third plan does not meet the requirements. Look at his work, and then answer the questions below.

Dominick's third floor plan meets one requirement, but not the other. Which one does it fail to meet? How can you tell?
b. Describe the bumper-car ride in terms of its area and perimeter. Report what each measure tells you about the ride.
Figure 2: The revised version of the problem in Figure 1. A worked example has been incorporated into part a and the park photograph has been removed.

The mathematics team reviewed the revised curricular materials to ensure mathematical accuracy and
appropriateness. Finally, the production team worked with the cognitive and math content teams to clarify design decisions as necessary. Examples of the original and revised curriculum materials are shown in Figures 1 and 2. Concurrent with the production of the materials, the professional development team met to develop measures of fidelity of implementation and to identify effective ways to communicate the underlying rationale and practical implementation of the cognitive design principles to the participating teachers.

Design This study used a within-teacher design: each teacher provided data from two units of CMP2, one revised and one control. Whether a given unit was used in its original or redesigned format was counterbalanced across participants. Teachers were randomly assigned to one of two groups, A and B, as depicted in Table 1 below. Group A served as the experimental group for one of the curriculum units and Group B served as the experimental group for the other. When multiple teachers taught at the same grade level in the same school, half the teachers at the school were assigned to group A and half to group B.

Table 1: Assignment of teachers to group.

| Group | Treatment Unit | Control Unit |
| :--- | :---: | :---: |
|  | $6^{\text {th }}$ Grade |  |
| A | Bits and Pieces III | Covering and Surrounding |
| B | Covering and Surrounding | Bits and Pieces III |
|  | $8^{\text {th }}$ Grade |  |
| A | Say it with Symbols | Shapes of Algebra |
| B | Shapes of Algebra | Say it with Symbols |

Procedure All teachers attended a two-day, online, professional development workshop to introduce them to the research-based principles and implications for instructional materials and practice. During these sessions, teachers worked as groups and in pairs to plan instruction for the treatment units. Teachers administered pre-tests for both study units immediately following the professional development. Teachers then taught CMP2 in their normal curriculum order, administering post-tests immediately upon completion of each study unit, treatment and control. Teachers completed weekly instructional logs for both the treatment and control units, in which they described their implementation of the unit, including any application of the research-based principles. This enabled researchers to measure fidelity of implementation and estimate the achieved relative strength (Hulleman \& Cordray, 2009) of the treatment intervention by comparing the degree to which teachers implemented the research-based principles in their treatment vs. their control units.

## Measures

Researcher-developed assessments were used to evaluate student learning. The content of each curriculum unit was
carefully mapped in order to assess the content areas, skills, and contexts presented to students. The same mapping was performed on the assessments to ensure they were wellaligned to the curriculum unit. All items were field-tested to establish reliability. Assessments included approximately 16 multiple-choice items and two open-ended items. Approximately half of the items were derived from existing CMP2 materials, and the remaining items were taken from state, national and international standardized tests.

For each unit, two test forms were created with approximately half of the multiple-choice and both openended items as linking items. Test forms were randomly assigned by class such that half of the classes took form A for pretest and form B for posttest, and the other half of the classes took form B for pretest and form A for posttest. Open-ended items were scored by trained raters using a standardized holistic rubric. Researchers computed weighted kappas to measure both intra-rater and inter-rater reliability. Intra-rater reliability ranged from 0.90 to 0.99 . Inter-rater reliability ranged from 0.83 to 0.94 .

## Data Analysis

Item response theory (IRT) was used to equate the test scores across forms (Cook \& Eignor, 1991). A partial credit model was used to generate item parameters, scale scores ${ }^{1}$ for students, and assessment reliabilities, which ranged from $0.55-0.74$ on pre-test and $0.77-0.82$ on post-test.

ANCOVA models were used to estimate the treatment effects, controlling for pre-test scale scores and socioeconomic status. ANCOVAs for each unit were performed on students with complete demographic information and who completed both the pre-test and the post-test for that unit. The ANCOVA sample for each unit is shown in Table 2-the ANCOVA samples do not differ statistically from the full sample in their demographic makeup.

Table 2: ANCOVA sample for each unit.

| Unit | Control | Treatment |
| :--- | :---: | :---: |
|  | $6^{\text {th }}$ Grade |  |
| Covering and Surrounding | 481 | 384 |
| Bits and Pieces III | 431 | 496 |
|  | $8^{\text {th }}$ Grade |  |
| Shapes of Algebra | 349 | 371 |
| Say it with Symbols | 386 | 435 |

## Results

## $6^{\text {th }}$ Grade

To provide context for the IRT scale scores, traditional descriptive statistics for the overall change in students' performance from pre-test to post-test are shown in Table 3.

[^50]Students made meaningful gains from pre-test to post-test on both units.

Table 3: Mean $6^{\text {th }}$ grade assessment performance, all students

| Test section | Pre-test | Post-test |
| :---: | :---: | :---: |
|  | Covering and Surrounding |  |
| Multiple-choice | $41.2 \%$ | $61.0 \%$ |
| $\%$ correct | $(\mathrm{SD}=16.1 \%)$ | $(\mathrm{SD}=21.1 \%)$ |
| Open-ended | 1.3 | 2.2 |
| out of 7 points | $(\mathrm{SD}=0.9)$ | $(\mathrm{SD}=1.3)$ |
|  | Bits and Pieces III |  |
| Multiple-choice | $47.2 \%$ | $65.1 \%$ |
| $\%$ correct | $(\mathrm{SD}=20.9 \%)$ | $(\mathrm{SD}=23.1 \%)$ |
| Open-ended | 1.6 | 2.7 |
| out of 8 points | $(\mathrm{SD}=1.7)$ | $(\mathrm{SD}=2.1)$ |

Post-test scale scores for both $6^{\text {th }}$ grade units, holding pretest scores constant, are shown in Figure 3.

Figure 3: Post-test IRT scale scores for the $6^{\text {th }}$ grade units. Error bars represent $\pm 2$ standard error.

ANCOVA results are presented in Table 4 (mean-square error is shown in parentheses). Pre-test was significantly associated with post-test scores in both units.

$$
\text { Table 4: } 6^{\text {th }} \text { grade ANCOVA results }
$$

| Source | $\boldsymbol{d} \boldsymbol{f}$ | $\boldsymbol{F}$ | $\boldsymbol{p}$ | Partial $\boldsymbol{\eta}^{\mathbf{2}}$ |
| :--- | :---: | :---: | :---: | :---: |
| Covering and Surrounding |  |  |  |  |
| Pre-test | 1 | 288.93 | $<.001$ | 0.251 |
| Socioec. disadv. | 1 | 54.50 | $<.001$ | 0.060 |
| Treatment | 1 | 12.78 | $<.001$ | 0.015 |
| Error | 861 | $(0.46)$ |  |  |
| Bits and Pieces III |  |  |  |  |
| Pre-test | 1 | 352.13 | $<.001$ | 0.276 |
| Socioec. disadv. | 1 | 80.31 | $<.001$ | 0.080 |
| Treatment | 1 | 0.40 | .528 | $<0.001$ |
| Error | 923 | $(0.62)$ |  |  |

There was a statistically significant main effect of socioeconomic status in both units, with students who are not socioeconomically disadvantaged performing better than students who are. There was also a statistically significant
effect of treatment in Covering and Surrounding, with treatment out-performing control, but no statisticallydifferent differences between groups for Bits and Pieces III.

## $8^{\text {th }}$ Grade

Traditional descriptive statistics illustrating the overall change in students' performance from pre-test to post-test is shown in Table 5.

Table 5: Mean $8^{\text {th }}$ grade assessment performance, all students

| Test section | Pre-test | Post-test |
| :---: | :---: | :---: |
|  | Shapes of Algebra |  |
| Multiple-choice | $37.2 \%$ | $51.4 \%$ |
| $\%$ correct | $(\mathrm{SD}=15.1 \%)$ | $(\mathrm{SD}=20.6 \%)$ |
| Open-ended | 1.00 | 2.8 |
| out of 8 points | $(\mathrm{SD}=1.6)$ | $(\mathrm{SD}=2.5)$ |
|  | Say it with Symbols |  |
| Multiple-choice | $43.2 \%$ | $55.0 \%$ |
| $\%$ correct | $(\mathrm{SD}=17.3 \%)$ | $(\mathrm{SD}=21.4 \%)$ |
| Open-ended | 1.5 | 2.7 |
| out of 8 points | $(\mathrm{SD}=1.8)$ | $(\mathrm{SD}=2.4)$ |

Again, students made significant gains from pre-test to post-test on both units, although the $8^{\text {th }}$ grade assessments were relatively more difficult than the $6^{\text {th }}$ grade assessments. Post-test scale scores for both $8^{\text {th }}$ grade units, holding pretest scores constant, are shown in Figure 4.

Figure 4: Post-test IRT scale scores for the $8^{\text {th }}$ grade units. Error bars represent $\pm 2$ standard error.

ANCOVA results are presented in Table 6 (mean-square error is shown in parentheses). As in the $6^{\text {th }}$ grade units, pretest was significantly associated with post-test scores in both units and there was also a statistically significant main effect of socioeconomic status in both units, with students who are not socioeconomically disadvantaged performing better than students who are. Statistically significant effects of treatment were found for both units, with treatment outperforming control. Effect sizes for Shapes of Algebra and Say it with Symbols are similar.

Table 6: $8^{\text {th }}$ grade ANCOVA results

| Source | $\boldsymbol{d f}$ | $\boldsymbol{F}$ | $\boldsymbol{p}$ | Partial $\boldsymbol{\eta}^{\mathbf{2}}$ |
| :--- | :---: | :---: | :---: | :---: |
| Shapes of Algebra |  |  |  |  |
| Pre-test | 1 | 157.57 | $<.001$ | 0.180 |
| Socioec. disadv. | 1 | 34.09 | $<.001$ | 0.045 |
| Treatment | 1 | 6.58 | .011 | 0.009 |
| Error | 716 | $(0.55)$ |  |  |
| Say it with Symbols |  |  |  |  |
| Pre-test | 1 | 434.39 | $<.001$ | 0.347 |
| Socioec. disadv. | 1 | 26.99 | $<.001$ | 0.032 |
| Treatment | 1 | 9.72 | .002 | 0.012 |
| Error | 817 | $(0.46)$ |  |  |

## Discussion

Students demonstrated large learning gains for each unit, suggesting both versions of the CMP2 curriculum were effective. Further, three of the four units in this study produced statistically significant effects of the treatment manipulation. That is, the treatment materials produced an additional boost to student learning over and above the existing materials. Why were some treatment units more effective than others? One possible explanation for this differential effect is that Covering and Surrounding and Shapes of Algebra, two of the three units showing a statistically-significant treatment effect, are both more spatially-oriented units. Covering and Surrounding addresses area and perimeter and Shapes of Algebra emphasizes coordinate geometry. While Say it with Symbols focuses on expressions and equations, students must link symbolic representations to graphs and other figures. In contrast, Bits and Pieces III more strongly emphasizes symbolic and tabular representations. The more figureoriented units may allow for a more potent treatment, as the first cognitive principle directly relates to increasing the coherence in visual representations.

The current findings suggest that research-based instructional strategies can be applied synergistically to improve student outcomes in authentic classroom settings. These findings are of particular importance as the vast majority of existing research investigates design principles in highly controlled (and artificial) lab-based studies. Ongoing analyses will provide further insight into the nature of the treatment effects. We are currently analyzing teachers' instructional logs in order to better understand when and how they implemented the cognitive principles in their teaching practice, aside from using the revised student books. We would expect larger learning gains for students when teachers integrated the principles into classroom practice in addition to giving students the revised books. Additional studies are also being carried out at the sites of the partner institutions to investigate the effects of the additive effects of the principles. The Math Center team is also conducting a cluster-randomized trial of revisions to the entire $7^{\text {th }}$ grade CMP curriculum, taking place during the 2012-2013 and 2013-2014 academic years. If the effects of
the principles are cumulative throughout the school year, we would expect greater differences in performance

#### Abstract

Exploratory learning before instruction can benefit understanding, but can also be challenging. Individual differences in response to challenge, such as achievement motivation, may therefore moderate the benefits of exploratory learning. Higher mastery orientation generally leads to increased effort in response to challenge, whereas higher performance orientation leads to withdrawal. Children ( $2^{\text {nd }}-4^{\text {th }}$ grade; $N=159$ ) were given mathematical equivalence problems to solve as either an exploratory learning activity (before instruction) or as practice (after instruction). Higher mastery orientation was associated with improved learning from exploration. In contrast, performance orientation did not lead to learning improvements-and sometimes even hurt learning. Higher mastery orientation was also associated with more sophisticated problem-solving strategies during exploration. Although exploratory activities have the potential to advance strategy selection and subsequent learning, achievement motivation may boost or hinder these benefits.

Keywords: exploratory learning, achievement motivation, mathematics, strategy selection

## Introduction

Exploratory instructional activities can increase individuals’ understanding of new concepts. By wrestling with different solution approaches or conceptual perspectives in a trial-and-error fashion, learners encounter a broader range of both correct and incorrect strategies than might normally be encountered during more traditional "tell-then-practice" methods of instruction (Bonawitz et al., 2011). As a result, learners who explore a new concept before receiving direct instruction on the topic may develop a more sophisticated appreciation for why or how a particular solution approach is better, or worse, than another. This training potentially translates into deeper understanding and better retention of the material (Schwartz, Lindgren, \& Lewis, 2009).

For example, Schwartz et al. (2011) examined the learning of eighth-grade students who explored density problems before receiving instruction. These students exhibited better understanding of the problem structure and better transfer to novel problems at a later test compared to those who received instruction before solving the density
problems. Similar findings have been observed for ninthgrade students learning descriptive statistics (Kapur, 2012; Schwartz \& Martin, 2004) and college students learning cognitive psychology (Schwartz \& Bransford, 1998).

Although exploratory learning can enhance conceptual understanding, such exploration can be challenging for the learner. Compared to more traditional tell-then-practice instruction, learners typically make more mistakes during exploratory learning activities, and they must focus on those mistakes in order to develop more sophisticated conceptualizations of the problem (Kapur, 2010). This learning process often entails considerable effort, as individuals engage in trial-and-error learning or hypothesistesting (Kirschner, Sweller, \& Clark, 2006; Rittle-Johnson, 2006). Learners also may encounter considerably more confusion about how to proceed (Dewey, 1910). In some cases, these learning challenges may pose a "desirable difficulty" (Bjork, 1994) or "productive failure" (Kapur, 2010) that encourages learners to rethink their previous conceptions and develop better understanding, thereby preparing them to learn from further instruction (Schwartz \& Bransford, 1998). In other cases, the difficulty posed by exploratory learning may be too high (Kirschner et al., 2006).

## Achievement Motivation and Challenge

In this study, we ask whether some learners may be better motivated than others to cope with the challenges posed by exploratory learning and thereby capitalize on the instructional experience. Research on achievement motivation demonstrates that individuals approach learning events with different goals and conceptions of what constitutes "ideal" learning performance. These differences influence how individuals interpret and respond to challenge during learning (Dweck \& Leggett, 1988; Elliot \& McGregor, 2001). Individuals can have both mastery and performance goals to different degrees (Barron and Harackiewicz, 2006). Individuals higher in masteryorientation desire personal growth (i.e., learning goals) and tend to view challenge as an opportunity to learn something new. Therefore, they generally seek challenge and respond

[^51]to it with increased effort and interest. Individuals higher in performance-orientation desire to prove their ability (i.e., performance goals). As such, they tend to interpret effort as a sign of incompetence, leading them to interpret difficult learning activities as a potential threat and to withdraw from challenges (Dweck, 1986).

For example, Diener and Dweck (1978) compared how mastery- versus performance-oriented $4^{\text {th }}-6^{\text {th }}$ graders reacted to failure in a difficult category-learning task. Participants first completed several solvable categorization problems matched to their age group (with accuracy feedback). Afterward, they encountered four unsolvable problems, known to be too advanced for their age group. While completing the solvable problems, children with higher performance- versus mastery-orientation exhibited equal degrees of problem-solving accuracy and positive affect. They also had equally sophisticated problem-solving approaches. However, their behavior quickly diverged during the unsolvable trials. Children with higher masteryorientation responded with increased interest and effortattributing the setback to a need for more effort. In addition, they maintained a high degree of strategy sophistication or invented more sophisticated problem-solving strategies to successfully deal with the new challenge. In contrast, children with higher performance-orientation responded with increased negative affect and disinterest-attributing failure to lack of ability. These children defensively withdrew their effort or regressed to developmentally simpler strategies that could not lead to success. Thus, children with higher mastery-orientation learned more from this difficult task and solved more developmentally challenging problems. Similar observations have been made in confusing learning conditions (Licht \& Dweck, 1984).

## Current Study

Individuals may respond to exploratory learning activities like they respond to challenge more generally. That is, based on their typically positive reaction to challenge, learners with higher mastery orientation may be better equipped to deal with the potential confusion and intellectual obstacles posed by exploration. We examined this possibility by comparing the problem-solving strategies, and subsequent learning, of individuals higher or lower in mastery versus performance orientation. Children were instructed on a novel mathematical concept. Half were given instruction, and then solved practice problems with accuracy feedback (instruct-first condition). The other half received the same materials, but in reverse order: They first completed exploratory problem-solving with accuracy feedback, and then received instruction (solve-first condition).

Second- through fourth-grade children were taught the concept of mathematical equivalence-that values on both sides of the equal sign represent the same quantity. This concept is fundamental for future conceptual development in mathematics, such as early algebra understanding (McNeil \& Alibali, 2005). Children in these grades often lack a relational understanding of mathematical
equivalence (e.g., understanding that $2+3$ is "the same as" 5). Children often demonstrate their misconceptions of the equal sign with the strategies they use for mathematical equivalence problems such as $4+5+3=++3$ (e.g., McNeil \& Alibali, 2005). In these problems, children often view the equal sign as a procedural cue. For example, they may ignore the values to the right of the equal sign and sum the numbers on the left side (resulting in the incorrect answer 12; add-to-equals strategy). Or, they may sum every number in the equation, ignoring the sides delineated by the equal sign (resulting in the incorrect answer 15; add-all strategy).

These types of incorrect strategies reflect an operational understanding of the equal sign, and indicate a developmentally immature understanding of mathematical equivalence (Rittle-Johnson et al., 2011). Such responses also resemble learning errors identified in the achievement motivation literature, in which performance-orientation leads learners (e.g., $4^{\text {th }}-6^{\text {th }}$ graders) to perseverate on disconfirmed strategies or revert to less mature (e.g., preschool level) representations of a problem following failure trials (e.g., Diener \& Dweck, 1978).

## Hypotheses

Considering the literatures on exploratory learning and achievement motivation, we predicted different learning outcomes depending on the type of knowledge assessed. We assessed learner's knowledge of mathematical equivalence both immediately after they completed an individual tutoring session, and approximately two weeks later. We also examined problem-solving strategies during the tutoring session itself. These questions were examined by reanalyzing previously-reported-data (DeCaro and RittleJohnson, 2012) to examine the role of achievement motivation.

Conceptual Knowledge Our main interest in the present research was how achievement motivation affects learners’ conceptual knowledge, their ability to grasp the underlying principles of mathematical equivalence, following exploration. Prior work suggests that exploration primarily benefits conceptual knowledge (Schwartz et al., 2009), but is mistake-prone and initially more confusing than a tell-then-practice instructional approach (e.g., Alfieri et al., 2011). Previous research also indicates that individual differences in achievement motivation influence learning and performance primarily when learners encounter challenging tasks (Dweck, 1986). Mastery orientation typically leads learners to respond to initial setbacks with increased resolve, and by maintaining or inventing more sophisticated learning strategies (e.g., Diener \& Dweck, 1978). Thus, we expected higher mastery orientation to be associated with improved conceptual knowledge, specifically in the more demanding solve-first condition.

The prediction for performance orientation in the solvefirst condition is less straightforward. Higher performance orientation often leads learners to respond to setbacks with defensive withdrawal of effort and regressive thinking (e.g.,

Diener \& Dweck, 1978). Therefore, performance orientation may be detrimental to conceptual knowledge in the solvefirst condition. Alternatively, performance orientation may not actually hurt conceptual knowledge, compared to that obtained in the instruct-first condition; instead, it may simply hinder one’s ability to profit from the exploratory learning opportunity. This prediction is supported by Barron and Harackiewicz's (2005) multiple-motive hypothesis, which suggests that mastery and performance motives represent separate signals with different degrees of relevance for conceptual versus procedural knowledge. According to this hypothesis, the mastery motive is more relevant to conceptual knowledge than the performance motive, because understanding and deeper processing of information are more clearly central to personal development and less diagnostic of ability.

Procedural Knowledge We also evaluated procedural knowledge, or the ability to execute the correct action sequences to solve problems. Procedural knowledge is strongly correlated with conceptual knowledge (RittleJohnson \& Alibali, 1999). However, problem-solving assessments provide especially diagnostic information about ability. Therefore, according to Barron and Harackiewicz's (2005) multiple-motive hypothesis, performance orientation may be more relevant to procedural knowledge than mastery orientation (cf. Grant \& Dweck, 2003). We therefore predicted a positive, but weaker, relationship between mastery orientation and procedural knowledge in the solvefirst condition. Moreover, we predicted a negative relationship between performance orientation and procedural knowledge acquisition (cf. Dweck \& Leggett, 1988; Grant \& Dweck, 2003).

Problem-Solving Strategies In addition to assessing knowledge outcomes (after tutoring), we examined children's problem-solving strategies during tutoring. Such information may reveal how achievement motivation impacts learning from exploration. Because children in the solve-first condition completed the problems as an exploratory activity, we expected them to use poorer problem-solving strategies. Specifically, they might use fewer relational strategies that evidence understanding of the equal sign as a relational symbol. Instead, they might rely more on operational strategies, in keeping with developmentally simpler views of the equal sign as an operational symbol (i.e., "add-all" or "add-to-equals").
Although we thought the solve-first condition would be more challenging, we expected mastery orientation to promote a more adaptive response to these setbacks (cf. Diener \& Dweck, 1978). Specifically, mastery orientation should be associated with increased use of relational strategies and decreased use of operational strategies. In contrast, performance orientation should be associated with increased reliance on these developmentally simpler, operational strategies (and decreased use of relational strategies).

## Method

## Participants

Participants were $2^{\text {nd }}-4^{\text {th }}$ grade children at a suburban public school. Children who scored below $80 \%$ on a pretest assessing procedural and conceptual knowledge of mathematical equivalence were selected ( $N=159,56 \%$ female, age $M=8.5$ years, range 7.3-10.8 years). Approximately $18 \%$ were ethnic minorities (10\% AfricanAmerican, 6\% Asian, and 2\% Hispanic).

## Research Design and Procedure

Consenting children first completed a pretest in their classrooms, followed by a self-report measure of their achievement motivation. Within one week following the pretest, children selected for the study participated in individual tutoring sessions on mathematical equivalence. Children were randomly assigned to the instruct-first condition ( $n=79$ ) or the solve-first condition ( $n=80$ ). Children were additionally assigned to either self-explain (i.e., explain why particular answers were correct/incorrect) or solve extra problems instead; however, this manipulation had no discernible effects and will not be discussed further. The session ended with a posttest assessing children's procedural and conceptual knowledge. Approximately two weeks later, children completed an equivalent retention test.

## Tutoring Session

Conditions The instruct-first and solve-first conditions were identical, except that the presentation order for the instruction ("instruct") and problem-solving ("solve") portions of the lesson were reversed. Thus, in the instructfirst condition, the problems served as practice after a lesson on mathematical equivalence. In the solve-first condition, these problems served as an exploratory learning activity followed by formal instruction.

Instruction During instruction (adapted from Matthews \& Rittle-Johnson, 2009), children were taught about the relational meaning of the equal sign. Five number sentences (e.g., $3+4=3+4$ ) were individually shown on the computer. The experimenter explained the structure of each number sentence (i.e., that there are two sides) and the explicit meaning of the equal sign (i.e., that the equal sign means that both sides are "equal or the same").

Problem-Solving During the problem-solving phase, children completed six mathematical equivalence problems presented individually on the computer. Problems increased in difficulty from three operands (i.e., $10=3+$ ) to five operands (e.g., $5+3+9=5+$ ). Children could use pencil and paper to solve each problem. After entering their answer on the computer, children were asked to report their problemsolving strategy. Then they were shown the correct answer.

## Learning Assessments

Problem-Solving Strategies, Children's problem-solving strategies in the tutoring session were categorized as relational, operational, or other incorrect (kappa=.80). Relational strategies evidenced a deliberate attempt to equalize the values on each side of the equation or conceptualize the values as equivalent (Rittle-Johnson et al., 2011). Operational and other incorrect strategies both evidenced an erroneous conceptualization of the equal sign. However, operational strategies represented misconceptions previously identified as developmentally less sophisticated and fundamentally inadequate (i.e., add-all and add-toequals strategies; McNeil \& Alibali, 2005).

Posttest and Retention Test We measured children's conceptual and procedural knowledge of mathematical equivalence by adapting assessments from past research (Rittle-Johnson et al., 2011). Conceptual knowledge items assessed two key concepts: the symbolic meaning of the equal sign and the structure of equations (8 items; kappas=.89-.96). Procedural knowledge items consisted of ten mathematical equivalence problems. Answers to procedural knowledge items were scored as correct if they came within one point of the correct answer, to reduce false negatives. The retention test was identical to the posttest, but also included eight far-transfer items that will not be discussed further, due to space limitations. Because we were most interested in long-term learning, and because the results of the posttest mirrored those of the retention test, we report only the results of the retention test.

## Achievement Motivation

Achievement motivation items were adapted from Elliot and Church (1997). Two items assessed mastery orientation (e.g., "I want to learn as much as possible about math, even if I have to work hard"). Two items assessed performance orientation (e.g., "In math class, it is important for me to do well compared to others in my class"). Children responded on a 6-point, Likert-type scale ranging from 1 (Strongly Disagree) to 6 (Strongly Agree). Mastery-orientation and performance-orientation scores were created by averaging the two responses on each subscale (Elliot \& Church, 1997).

## Results

We examined the relationship between mastery and performance orientation and learning in the two tutoring conditions. We also examined children's problem-solving strategies during tutoring. We used hierarchical linear regression for all analyses. The predictors in the model were mastery orientation score, performance orientation score, condition (dummy-coded), and two interaction terms (Condition $\times$ Mastery Orientation, Condition $\times$ Performance Orientation). Preliminary analyses showed no significant two-way interactions between mastery and performance orientation, or three-way interaction with condition, so they were not included in the final model. Thus, the final model
represents the independent and joint effects of achievement motivation and tutoring condition on the dependent variables (Barron \& Harackiewicz, 2001). We also included children's age and conceptual and procedural knowledge pretest scores to control for prior knowledge. Each predictor was centered. Significant interactions were explored through simple slopes analyses. Estimated means were plotted at one SD above and below the mean, to represent the effect of low versus high achievement motivation on the dependent variable as a function of condition.

No significant main effects of performance or mastery orientation emerged ( $F s<1$ ). Therefore, only the results for Condition and Condition $\times$ Achievement Motivation interactions will be reported. Children in the instruct-first and solve-first conditions did not differ at pretest by their procedural knowledge, conceptual knowledge, or achievement motivation ( $F \mathbf{s}<1$ ). Mastery and performance orientation were not correlated: $r(156)=.08, p=.151$.

## Conceptual Knowledge

At retention test, a marginally significant main effect of condition emerged ( $B=.05$, $\mathrm{SE}=.03, p=.078$ ). Learners in the solve-first condition demonstrated higher conceptual knowledge than learners in the instruct-first condition. This effect of condition was qualified by a Mastery Orientation $\times$ Condition interaction ( $B=.08, \mathrm{SE}=.04, p=.059$ ). As depicted in Figure 1, higher mastery orientation was associated with higher conceptual knowledge acquisition in the solve-first condition ( $B=.08, \mathrm{SE}=.03, p=.009$ ), indicating that higher mastery orientation helped children learn from exploration. Mastery orientation was unrelated to conceptual knowledge in the instruct-first condition $(B=0)$. There was no Performance Orientation $\times$ Condition interaction ( $B=0$ ), indicating that performance orientation did not hurt conceptual knowledge.

Figure 1. Conceptual and Procedural Knowledge

## Procedural Knowledge

At retention test, the condition term was not significant ( $B$ $=.02$; Figure 1). A Mastery Orientation $\times$ Condition interaction emerged ( $B=.12, S E=.06, p=.036$ ). Higher mastery orientation was associated with a trend towards higher procedural knowledge in the solve-first condition ( $B$ $=.07, S E=.04, p=.118$ ), whereas it was associated with a trend towards poorer procedural knowledge in the instructfirst condition ( $B=-.05, S E=.04, p=.159$ ).

A significant Performance Orientation $\times$ Condition interaction also emerged ( $B=-.11, S E=.05, p=.041$; Figure 1). Higher performance orientation was associated with lower procedural knowledge in the solve-first condition ( $B=-.09, S E=.04, p=.035$ ) but was unrelated to procedural knowledge in the instruct-first condition ( $B=.02$ ). Higher performance orientation reduced gains in procedural knowledge from exploration.

## Performance during Tutoring Intervention

To provide further insight into how the knowledge acquisition observed at retention test may have emerged, we examined the problem-solving strategies children used during the tutoring session. Doing so indicates how children responded to difficulties encountered during exploration.

There was a main effect of condition on use of both relational strategies ( $B=-.12, \quad p=.01$ ) and operational strategies ( $B=.09, p=.01$ ). On average, children in the solvefirst condition used relational strategies less than children in the instruct-first condition-reflecting the overall difficulty of exploratory learning in the solve-first condition. This effect was qualified by interactions with both mastery orientation ( $B=.15, \mathrm{p}<.01$ ) and performance orientation ( $B=-$ .16, $p<.01$ ). As shown in Figure 2, higher mastery orientation was associated with increased use of relational strategies in the solve-first condition ( $B=.11, p<.05$ ). In contrast, higher performance orientation was associated with decreased use of relational strategies in this condition ( $B=-$ .11, $p<.05$ ). Neither mastery nor performance orientation were associated with relational strategy use in the instructfirst condition ( $B=-.03$ and $B=.04$ ). In fact, children in the solve-first condition with higher mastery orientation appear to have matched their instruct-first counterparts in use of relational strategies.

Operational strategy use was consistent with these findings. As shown in Figure 2, children in the solve-first condition used operational strategies more than children in the instruct-first condition. No interaction with mastery orientation was found ( $B=-.04$ ). However, performance orientation interacted with condition ( $B=.10, p<.05$ ). In the solve-first condition, higher performance orientation was associated with increased use of operational strategies ( $B=.09, p<.01$ ). This finding suggests that the difficulty of exploratory learning leads children higher in performanceorientation to adopt developmentally immature strategies. No relationship with performance orientation was found in the instruct-first condition ( $B=-.02$ ).

## Relational Strategies

Operational Strategies

Figure 2. Strategy Use during Tutoring Session

## Discussion

As predicted, children higher in mastery orientation learned a new mathematics concept better when a problemsolving session was used as an exploratory activity, rather than practice. That is, higher mastery orientation was associated with improved conceptual knowledge acquisition (and somewhat improved procedural knowledge) in a solvefirst condition where problem-solving preceded formal instruction. Higher performance orientation, in contrast, did not facilitate learning from exploration: These children performed at normal levels on conceptual knowledge acquisition and did worse than normal on procedural knowledge acquisition (i.e., problem-solving success).

These differences in learning from exploration could be attributed to the challenge inherent in such activities. Children in the solve-first condition were less likely to use relational problem-solving strategies, which indicate a sophisticated understanding of mathematical equivalence. They relied more on operational strategies, erroneously treating the equal sign as a procedural cue (e.g., to add only the numbers to the left of the equal sign).

However, this overall effect of condition was moderated by achievement motivation. Children higher in mastery orientation tended to use relational strategies during exploration, not operational strategies. Moreover, children higher in performance orientation-who desire to prove their ability and, therefore, avoid challenge-tended to revert to developmentally simpler operational strategies. This finding is consistent with findings in the achievement motivation literature (cf. Diener \& Dweck, 1978), and may help explain why exploration was only useful to some children. The challenge and confusion associated with exploratory learning may lead some children to explore
better strategies during learning, but lead others to perseverate on poorer strategies, which impede learning.

Recent discussions on exploratory learning versus direct instruction have concluded that there may be benefits of combining aspects of both approaches (cf. Alfieri et al., 2011). The current findings demonstrate that using exploratory problem-solving activities prior to instruction can be beneficial-but namely for children who have a mastery-oriented approach to learning mathematics.

Hence, the current findings highlight the importance of considering motivational influences on learning and strategy selection. Teachers may want to emphasize mastery and promote a forgiving learning environment to help nonmastery oriented students cope better with the inherent challenge posed by exploration. Future research is needed to see if the deleterious effects of performance orientation on strategy selection can be mitigated with mastery framing.

# Cost-Based Pragmatic Inference about Referential Expressions 

Judith Degen (jdegen@bcs.rochester.edu)<br>Dept. of Brain and Cognitive Sciences<br>University of Rochester

#### Abstract

We present data from three experiments addressing how much theory of mind reasoning is involved in production and interpretation of ambiguous referential expressions in an artificial language task, and how this interacts with the cost and availability of alternative utterances. When an unambiguous alternative is not available, listeners tend to draw simple Quantity inferences reminiscent of scalar implicatures (Grice, 1975). When an unambiguous alternative is available, fewer inferences are observed, but gradiently more as the cost of unambiguous alternatives increase. We outline a novel game theoretic model of pragmatic reasoning based on probabilistic back-and-forth reasoning about interlocutors' rational choices and beliefs. The model provides a good fit to the data and raises interesting issues for future research.

Keywords: Pragmatics; Game theory; Referential Expressions; Language production; Language comprehension.

## Introduction

People are lazy: when they speak, they like to save effort. But if speakers are too lazy and say too little, their listeners will not understand them. A good example is the choice and interpretation of referential expressions. A rational speaker who wants to establish reference should choose the most economic (shortest, easiest, least effortful) description that, according to his beliefs about the listener's dispositions to interpret utterances, will allow for the listener to safely infer the correct referent. A rational listener should take the speaker's production costs ${ }^{1}$ into account and so a rational speaker should in turn take that into account, etc. But this is an idealized picture. From an empirical point of view two related questions arise: 1) How much do speakers and listeners take into account each other's perspective? 2) How much influence do economy considerations have; do listeners weigh the speaker's production costs?

When it comes to referential language use, the latter question has not been investigated thoroughly, but the former question has been addressed in a variety of ways, both theoretically (Clark \& Marshall, 1981) as well as experimentally (Hanna, Tanenhaus, \& Trueswell, 2003; Keysar, Barr, \& Brauner, 2000). This paper aims to adress both questions and to bring theoretical and empirical approaches closer together. The paper's empirical contribution is to report on

[^52]experimental data from referential language games. Its theoretical contribution is a novel probabilistic model of back-and-forth reasoning that synthesizes recent Bayesian models (Frank \& Goodman, 2012) and game theoretic approaches (Camerer, Ho, \& Chong, 2004; Rogers, Palfrey, \& Camerer, 2009; Franke, 2011; Jäger, 2013).

Our experiments probed interlocutors' perspective-taking ability in a task where an artificial language left some relevant meaning features inexpressible or made some expressions costly. When critical meaning features are inexpressible, the situation is reminiscent of scalar implicature calculation (Grice, 1975). We manipulated how many steps of such reasoning were needed for communicative success and tested both comprehension (Exp. 1) and production (Exp. 2) to investigate question 1. Our design was chosen so as to improve on previous related studies where non-linguistic pictorial messages were used (Degen \& Franke, 2012) and where the availability of alternative expressions was not explicitly controlled (Stiller, Goodman, \& Frank, 2011; Frank \& Goodman, 2012). In addition, rather than making some messages entirely unavailable, we investigated the effect of variable production costs on interpretation behavior to address question 2 (Exp. 3). Rohde, Seyfarth, Clark, Jäger, and Kaufmann (2012) showed that listeners take into account message costs when messages are assigned an explicit dollar value. Here we investigate whether these results replicate when costs, as in real language use, are implicit.

The data from our experiments is explained well by a probabilistic model of back-and-forth reasoning. The model parameterizes how deeply interlocutors reason about each other's perspective and how close they are to being rational. Parameter values that best explain our data suggest that participants were reasonably rational and applied a small but non-negligible amount of theory of mind reasoning and that they took production costs into account in comprehension.

## Referential Language Games

Referential communication can be conceived of as a signaling game (Lewis, 1969): a sender (speaker) $S$ knows which referent he wants to talk about, but a receiver (listener) $R$ does not; $S$ chooses a referential description; if $R$ can identify the intended referent, communication is successful, otherwise a failure. Different games ensue for different sets of potential referents and referential expressions. In the critical trials of our experiments the referential games were isomorphic to the

Figure 1: Target implicature conditions. Hearers choose one of the Possible Referents $T=\left\{t_{\mathrm{t}}, t_{\mathrm{c}}, t_{\mathrm{d}}\right\}$. Speakers have Message Options $M=\left\{m_{\mathrm{t}}, m_{\mathrm{c}}, m_{\mathrm{d} 1}, m_{\mathrm{d} 2}\right\}$, shown here for ease of interpretation visually (the experiment used artificial words). Trigger items are indicated with asterisks: e.g., $t_{\mathrm{t}}^{*}$ is the referent to be communicated on complex production trials.
situations in Fig. 1. There were three possible referents in the form of monsters and robots wearing hats or scarves (not depicted in the example) as accessories. Additionally, there is a fixed set of possible descriptions that are available to the sender. Messages for monsters and hats were always available and were equally costly. Messages for robots and scarves were either not available at all (Exp. 1 and 2) or more costly (Exp. 3).

Experiments 1 and 3 tested participants' choice of referent for a given trigger message (comprehension). Experiment 2 tested their choice of message for a trigger referent (production). Trigger items for the critical conditions are marked with an asterisk in Fig. 1. Indices $t, c, d$ stand for target, competitor and distractor respectively. We refer to a game as in Fig. 1a as the simple condition, because it involves one step of Quantity reasoning similar to scalar implicature calculation (Grice, 1975). Hearing trigger message $m_{\mathrm{c}}^{*}, R$ should reason that $S$ must have meant target state $t_{\mathrm{t}}$, and not competitor state $t_{\mathrm{c}}$, because if $S$ had wanted to refer to the latter he could have used an unambiguous message. Conversely, when $S$ wants to refer to trigger state $t_{\mathrm{c}}^{*}$, he should not use the true but semantically ambiguous message $m_{\mathrm{c}}$, because he has an unambiguous message $m_{\mathrm{t}}$. Similarly, we refer to a game in Fig. 1b as the complex condition, because it requires performing similar reasoning twice in sequence (see also Degen and Franke (2012) for details).

## Experiment 1 - comprehension

Exp. 1 tested participants' behavior in a comprehension task using instantiations of the signaling games just described. ${ }^{2}$

## Methods

Participants Using Amazon's Mechanical Turk, 48 selfreported native English speakers were paid $\$ 1.00$ to participate. All were naïve as to the purpose of the experiment.

Procedure and Materials Participants engaged in an artificial language referential comprehension task. The experi-

[^53]ment proceeded in two stages: a language learning stage and an inference stage. Only the inference stage was of theoretical interest. In the language learning stage, participants learned four 3-character words ( $R A V, Z U B, X E K, K O R$ ) of the alien language Zorx. The words referred to visual features: ontological kinds (one of two monster species) and accessories (red or blue hat). Each unique word-to-feature mapping (24 total) occurred twice between participants to ensure effects were not artifacts of the particular mapping.

Language learning occurred in three steps. First, participants saw each word twice with a visual representation of its meaning. They were then presented with each word alongside two choices for the meaning of the word and had to click on the correct meaning. Finally, they were presented with each meaning in succession and had to produce the correct word by clicking on characters in a two-row character array. They repeated this process until achieving $100 \%$ accuracy on the production task. They then proceeded to the inference stage.

On each trial in the inference stage, participants saw three possible referents on a display (as in Fig. 1). Each referent differed systematically along two dimensions: its ontological kind (robot or one of two monster species) and accessory (scarf or either blue or red hat). In addition to these three referents, participants saw a Zorx word that they were told was sent to them by a previous participant whose task it was to get them to pick out one of these three referents. They were told that the previous participant was allowed to send a message expressing only one feature of a given referent, and that the other participant had learned the same words of Zorx they did (i.e., they could send monster/hat messages, but not robot/scarf messages).

Participants initially completed four production trials. They saw three referents, one of which was highlighted with a yellow rectangle, and were asked to send one of the Zorx words to another Mechanical Turk worker to get them to pick out the highlighted object. They were told that the other worker did not know which object was highlighted but knew the same language they did. The four production trials contained three unambiguous and one ambiguous trial which functioned as fillers in the main experiment.

Figure 2: Proportions of target, competitor, and distractor choices in critical and filler conditions for Exp. 1 (comprehension, left) and Exp. 2 (production, right).

Participants saw 36 experimental trials, with a 2:1 ratio of fillers to critical trials. Of the 12 critical trials, 6 occurred in the simple (one iterated reasoning step) and 6 in the complex (two steps) condition as described above (see Fig. 1).

Target position was counterbalanced (each critical trial occurred equally often in each of the 6 possible orders of target, competitor, and distractor), as were the target's features and the number of times each message was sent. Of the 24 filler trials, half used the displays from the critical conditions but the target was either $t_{\mathrm{c}}$ or $t_{\mathrm{d}}$ (as identified unambiguously by the trigger message). This was intended to prevent learning associations of display type with the target. On the other 12 filler trials, the target was either entirely unambiguous or entirely ambiguous given the message. That is, there was either only one object with the feature denoted by the trigger message, or there were two identical objects that were equally viable target candidates. Trial order was pseudo-randomized such that there were two lists (reverse order) of three blocks, where critical trials and fillers were distributed evenly over blocks. Each list began with three filler trials.

## Results and Discussion

Proportions of choices are displayed in Fig. 2 (left panel). As expected, participants were close to ceiling in choosing the target on unambiguous filler trials but at chance on ambiguous ones. This confirms that participants understood the task. On critical trials, participants' performance was intermediate between ambiguous and unambiguous filler trials. On simple trials, participants chose the target $66 \%$ of the time. On complex trials, the target was chosen less often (50\%).

To test whether the observed differences in target choices above were significantly different, we fitted a logistic mixedeffects regression to the data. Trials on which the distractor was selected were excluded to allow for a binary outcome variable (target vs. competitor choice). The model predicted the log odds of choosing a target over a competitor from a Helmert-coded Condition predictor. Three Helmert con-
trasts over the four relevant critical and filler conditions were included in the model, comparing each condition with a relatively less skewed distribution against the more skewed distributions (in order: ambiguous fillers, complex, simple, unambiguous fillers). This allowed us to capture whether the differences in choice distributions for neighboring conditions suggested by Fig. 2 were significant. We included the maximal random effects structure, i.e., by-participant random intercepts, by-participant random slopes for Condition, and by-item random intercepts.

Of the three contrasts, two reached significance; there were more target choices in the unambiguous filler condition than in the simple condition ( $\beta=4.08, S E=0.41, p<.0001$ ) and there were more target choices in the simple than in the complex condition ( $\beta=1.27, S E=0.47, p<.01$ ). However, there was no significant difference in target choices between the ambiguous filler and the complex condition $(\beta=0.38, S E=$ $0.45, p<.4$ ). This suggests that participants made simple, but not complex inferences.

## Experiment 2 - production

Exp. 2 tested participants' behavior in a production task using instantiations of the signaling games described above.

## Methods

Participants Using Mechanical Turk, 48 self-reported native speakers of English were paid $\$ 1.20$ to participate.

Procedure and Materials The experiment again proceeded in two stages: the language learning stage and the production stage. The procedure for language learning was the same as in Exp. 1. The procedure for the production stage was the same as on the production trials in Exp. 1. Participants saw 36 trials with a $2: 1$ ratio of fillers to critical trials. There were 12 critical trials ( 6 simple and 6 complex situations as in Fig. 1). Half of the fillers used the same displays as the critical trials, but one of the other two objects was highlighted. This meant that the target message was either unambiguous (e.g. when the highlighted object was $t_{\mathrm{t}}$ in Fig. 1(a) the target message was $m_{\mathrm{c}}$ ) or entirely ambiguous. The remaining 12 filler trials employed other displays with either entirely unambiguous or ambiguous target messages. Two experimental lists were created and counterbalancing ensured as in Exp. 1.

## Results and Discussion

Proportions of choices are displayed in Fig. 2 (right panel). To test whether the observed differences in target choices were different, the same logistic mixed-effects regression was fit to the data as in the Exp. 1 analysis. Trials on which a distractor message was sent were excluded to allow for a binary outcome variable (target vs. competitor choice).

Of the three Helmert contrasts, again only two reached significance; there were more target choices in the unambiguous filler condition than in the simple condition ( $\beta=$ $3.84, S E=0.47, p<.0001$ ) and there were more target choices in the simple than in the complex condition ( $\beta=$
$2.81, S E=0.50, p<.0001$ ). However, there was no difference between the ambiguous filler and the complex condition ( $\beta=-0.43, S E=0.37, p<.3$ ). This suggests that, as in comprehension, participants made simple, but not complex inferences.

## Experiment 3 -comprehension with costs

Exp. 3 tested whether listeners take into account speakers' preferences for producing minimally effortful messages. To this end, we introduced messages for the robot and scarf feature but varied the implicit cost of these messages via word length measured in characters. If listeners take into account their interlocutor's perspective, their behavior should approximate the results from the simple conditions of Exp. 1 (i.e., draw more Quantity inferences) as the message becomes more costly (and thus, more dispreferred/unavailable).

## Methods

Participants A total of 240 participants were recruited over Mechanical Turk who were all self-reported native speakers of English. They were paid $\$ 0.80$ plus a $\$ 0.10$ bonus if they completed the cost estimation stage in under one minute.

Procedure and Materials The experiment proceeded in three stages: the language learning stage, the cost estimation stage, and the inference stage. The procedure in the language learning and inference stage was the same as in Experiment 1 with the following three exceptions: a) the learned language contained two extra costly words (to refer to the robot and the scarf feature) in addition to four free words (to refer to monsters and hats), b) there were no complex, only simple conditions (Fig. 1) in the inference stage, c) there were only 12 rather than 24 filler trials, of which 6 were completely ambiguous and 6 were completely unambiguous.

The cost estimation stage was introduced to estimate participants' subjective cost function. Each of the nine permutations of feature combinations \{robot, green monster, purple monster $\} \times\{$ scarf, red hat, blue hat $\}$ was presented to participants one at a time and they were asked to send one of the Zorx words they had learned to another participant to get them to pick out the presented referent. As in the previous experiments, sending a message required spelling out the word on a virtual keyboard on the screen by clicking on each character individually. In addition, participants were told that they would receive a bonus if they completed this part of the study in under one minute. We hoped these two features of the task would increase participants' subjective costs associated with the objective increase in number of characters and thus encourage a message cost effect.

There were three cost conditions. In the NO-COST condition, the costly messages were of the same length as the free messages ( 3 characters). In the LOW-COST and HIGH-COST conditions, the costly messages were one and three characters longer than the free messages, respectively. LOW-COST and HIGH-COST were manipulated within participants (we refer to this group as the COST condition, 192 participants) and the

NO-COST condition consisted of a separate group of 48 participants. Thus the languages in the different conditions:

## Results and Discussion

Proportion of choices in the cost estimation stage (messages) and in the inference stage (referents) are shown in Fig. 3a and $3 b$. We analyzed participants' performance in both stages.

In the cost estimation stage, we analyzed participants' message choices for the four referents with one costly and one free message (i.e., referents with either a robot or a scarf feature). The NO-COST condition served as the baseline in the mixed effects logistic regression predicting the log odds of a costly over a free message choice. Cost condition was dummy-coded and entered as a three-level categorical predictor (NO-COST, LOW-COST, HIGH-COST). The model additionally included random by-participant and by-item intercepts as well as by-participant slopes for feature type (scarf or robot) to account for individual variability in participants' preferences for referring to these features. There was a significant decrease in the log odds of choosing the costly message compared to the NO-COST reference level when the message was HIGH-COST $(\beta=-0.83, S E=0.30, p<.01)$. For the LOW-COST message, the difference trended in the predicted direction ( $\beta=-0.44, S E=0.30, p<.14$ ). Thus, increasing message cost led to a small, but gradient decrease in preference to send the costly message.

Next, we analyzed participants' performance in the inference stage by fitting a mixed effects logistic regression model predicting target over competitor choices. Two Helmert contrasts over the three relevant cost conditions were included in the model, comparing each condition with a relatively lower cost against the higher cost level(s) (in order: no cost, small cost, high cost). The model additionally included byparticipant and by-item random intercepts. The difference between the NO-COST and other conditions did not reach significance, though it trended in the predicted direction ( $\beta=$ $-0.08, S E=0.05, p<.14$ ). However, there were significantly more target choices in the HIGH-COST than in the LOW-COST condition ( $\beta=0.25, S E=0.12, p<.05$ ). Thus, the gradient effect of message cost on message choice is in turn reflected in listener inferences: as the cost of the unambiguous message increases, listeners make more scalar inferences and begin to approximate the behavior displayed in Exp. 1, where robot/scarf messages were entirely unavailable.

## The Iterated Quantal Response Model

The observed production and comprehension behavior can be predicted by a parameterized model that returns a quantitative description of speaker and listener behavior. The iterated quantal response (IQR) model combines key features of socalled cognitive hierarchy models from behavioral economics

Figure 3: Experiment 3 results.
(Camerer et al., 2004; Rogers et al., 2009) with game theoretic models of pragmatic reasoning (Franke, 2011; Jäger, 2013). The resulting model is also very similar to, but slightly more general than recently popular Bayesian models (Frank \& Goodman, 2012; Bergen, Levy, \& Goodman, 2012).

We consider two parameters. Parameter $\tau$ models the depth of strategic reasoning that language users engage in. Parameter $\lambda$ models how successful language users are at making rational choices. The output of the model is a prediction of probabilistic speaker and listener behavior.
Signaling Games We model our referential tasks as signaling games. For our purposes, a signaling game is just a structure $\langle T, M, B, c\rangle$ with $T=\left\{t_{1}, \ldots, t_{\mathrm{a}}\right\}$ a set of $a$ different states (referents), $M=\left\{m_{1}, \ldots, m_{\mathrm{b}}\right\}$ a set of $b$ relevant descriptions, $B$ is a Boolean $(a, b)$-matrix with $B_{i j}=1$ if description $m_{\mathrm{j}}$ is true of referent $t_{\mathrm{i}}$, and $c=\left(c_{1}, \ldots, c_{b}\right)$ a vector of costs. ${ }^{3}$

Strategies A sender strategy $\sigma$ is a row-stochastic $(a, b)$ matrix, mapping each state onto a probability distribution over messages. A sender strategy describes how likely an average speaker would choose a message given that they want to talk about a given state. Likewise, since the receiver chooses states in $T$ as interpretations of an observed message, a receiver strategy $\rho$ is a row-stochastic $(b, a)$-matrix.

Expected Utilities A sender who believes that his listener plays $\rho$ has an $(a, b)$-matrix of expected utilities $\mathrm{EU}(\rho)=$ $\mathbf{T}(\rho)-c .^{4}$ A receiver who believes that his opponent plays $\sigma$ has a unique posterior belief $\mu_{\sigma}$ derived from Bayes' formula iff $\sigma$ has at least one non-zero entry in each column, i.e., each

[^54]message is expected to be sent with some positive probability (guaranteed by the quantal response function introduced below). This unique $\mu(\boldsymbol{\sigma})$ is just $\mathbf{N}(\mathbf{T}(\boldsymbol{\sigma}))$. The receiver's expected utilities are then $\mathrm{EU}(\sigma)=\mu(\sigma)$.

Best \& Quantal Responses Generally speaking, a response function maps expected utilities to choice probabilities. Rational choices maximize expected utility. In case of ties, rational agents are indifferent. If $U$ is an expected utility matrix, the rational best response function is $\operatorname{BR}(\mathrm{U})=\mathbf{N}(\max \operatorname{row}(\mathrm{U}))$. In contrast, the quantal response function assumes that agents make small mistakes in implementing the $\operatorname{BR}(\cdot)$ function. For given $U$, quantal response $\mathrm{QR}_{\lambda}(\mathrm{U})$ is the unique row-stochastic matrix with $\mathrm{QR}_{\lambda}(\mathrm{U})_{i j} \propto$ $\exp \left(\lambda \mathrm{U}_{i j}\right)$. Here $\lambda$ is a rationality parameter, with entirely random choices for $\lambda=0$ and $\lim _{\lambda \rightarrow \infty} \mathrm{QR}_{\lambda}(\mathrm{U})=\mathrm{BR}(\mathrm{U}) .{ }^{5}$

IQR The IQR model defines a hierarchy of player types. Unsophisticated level-0 behavior is anchored in the given semantics. Level- $(k+1)$ players play quantal responses to a belief that the interlocutor is of a lower type. Concretely, level-0 senders and receivers simply try to implement the semantic meaning: $\sigma_{0}=\mathrm{QR}_{\lambda}(B-c)$ and $\rho_{0}=\mathrm{QR}_{\lambda}\left(\mathbf{T}(B) I_{a}\right)$. Level$(k+1)$ player behavior is defined as a quantal response to a belief that the other player is at most of level $k$. Following the relevant literature in behavioral game theory (Camerer et al., 2004; Rogers et al., 2009), we subscribe to the simplifying assumption that the actual distribution of strategic types is a Poisson distribution $\operatorname{Pois}(\tau, k)=\tau^{k} / k!\exp (-\tau)$ with parameter $\tau$, and that agents know this. So, level- $(k+1)$ players' beliefs are derived by conditioning the underlying population distribution by the event that the opponent is less sophisticated: $f_{\tau}^{\leq k}(l)=\operatorname{Pois}(\tau, l) / \sum_{i=1}^{k} \operatorname{Pois}(\tau, i)$ if $l \geq k$ and 0 otherwise. This yields the following definition of level- $(k+1)$ players:

$$
\begin{array}{ll}
\sigma_{k+1}=\mathrm{QR}_{\lambda}\left(\mathrm{EU}\left(\rho_{\leq k}\right)\right) & \text { with } \rho_{\leq k}=\sum_{l \leq k} f_{\tau}^{\leq k}(l) \times \rho_{l} \\
\rho_{k+1}=\mathrm{QR}_{\lambda}\left(\mathrm{EU}\left(\sigma_{\leq k}\right)\right) \text { with } \sigma_{\leq k}=\sum_{l \leq k} f_{\tau}^{\leq k}(l) \times \sigma_{l}
\end{array}
$$

[^55]Given $\lambda$ and $\tau$, the model's behavioral prediction is the pair of strategies $\sigma^{*}=\sum_{k=1}^{\infty} f_{\tau}(k) \times \sigma_{k}$ and $\rho^{*}=\sum_{k=1}^{\infty} f_{\tau}(k) \times \rho_{k}$.
Model fitting As stated above, we fitted a mixed effects logistic regression to participants' behavior in the cost estimation task to estimate the difference $x$ between the log odds of costly vs. cheap message. Assuming that $x$ is the result of a quantal choice rule, we can compute the average subjective costs for a given fixed $\lambda$ as $c=x / 2 \lambda .{ }^{6}$ Using this, we determined a pair of parameters $\lambda$ and $\tau$ separately for the data on comprehension (Exps 1 and 3) and production (Exp. 2) using a least squares regression $(\lambda=4.825, \tau=0.625, r=0.99$ for comprehension; $\lambda=8.853, \tau=0.818, r=0.99$ for production). The prediction-to-data plot is given in Figure 3c.

These results are interesting in many respects. First, they serve as a proof-of-concept that a rather general game theoretic framework can predict behavioral data on language use and interpretation rather well. Second, the small but non-negligible $\tau$ indicates that participants in our experiment were able to perform one but not necessarily more steps of best response reasoning including considerations of production costs. Third, production behavior is better explained by higher values of $\lambda$ and $\tau$. This suggests that the model of Frank and Goodman (2012), which assumes that listeners perform two steps of optimization, while speakers perform exactly one, might be too inflexible. More relevant data is pending, but at present the more general model of Bergen et al. (2012) or the IQR model seem more realistic.

## Conclusion

The empirical contributions of this paper are two-fold. First, we provided evidence that language users can draw simple $a d$ $h o c$ scalar inferences in an artificial language paradigm. Second, we showed that even when the cost of an unambiguous message is only implicit (i.e., without telling participants explicitly that a message has a certain dollar value (Bergen et al., 2012; Rohde et al., 2012)), scalar inferences were drawn with increased frequency as costs of competing unambiguous messages increased. The theoretical value of this paper lies in the proposal for a probabilistic model of pragmatic reasoning that synthesizes previous Bayesian and game theoretic approaches. The model provides a good fit to the choice distributions of both speakers and listeners; and within listeners, for message cost effects, thus constituting a powerful model of pragmatic inference.

We conclude that not only do listeners take into account available utterances a speaker could have made, they also maintain a gradient estimate of production cost and take this into account in interpretation.

# Superficial, rather than true, knowledge interdependence in collaborative learning fosters individual knowledge transfer 

Anne Deiglmayr (anne.deiglmayr@ifv.gess.ethz.ch)<br>ETH Zurich, Research on Learning and Instruction, Universitaetsstrasse 41 8092 Zurich, Switzerland<br>Lennart Schalk (lennart.schalk@ifv.gess.ethz.ch)<br>ETH Zurich, Research on Learning and Instruction, Universitaetstrasse 41<br>8092 Zurich, Switzerland

#### Abstract

We test the hypothesis that superficial knowledge interdependence is more effective in fostering individual learning from collaboration than the true knowledge interdependence often realized by jigsaw-type collaboration arrangements. Based on research on group informationprocessing, we argue for the benefits of distributing only contextual information, but not core principles between learners, establishing superficial knowledge interdependence. In a computer-supported collaborative learning environment, 78 university students learned about stochastic urn models. Knowledge interdependence was established by systematically distributing learning materials within student triads, so that students either became experts for an urn model, establishing true knowledge interdependence, or for one of the embedding cover stories, establishing superficial knowledge interdependence. Afterwards, all triads worked on the same collaborative tasks, and were exposed to all models. Results show successful learning across conditions, but superior knowledge transfer in triads collaborating under superficial knowledge interdependence. Benefits were highest for low prior knowledge learners.
