## Introduction

In this paper, we explore different ways of distributing information between collaborative learners, with the goal of promoting the interactive construction of mathematical principles during learning from collaborative comparison of worked examples. In doing so, we address the more fundamental question of what characterizes optimal knowledge interdependence in collaborative learning, as assessed by measures of individual learning and transfer.

Collaborative learning has the potential of engaging students in forms of interactive knowledge construction that yield learning outcomes beyond those within the reach of an individual learner (Chi, 2009). However, this requires a certain amount of knowledge interdependence between students, that is, the individual students should hold a certain amount of unshared (unique) knowledge, ideas, and perspectives. The deliberate creation of knowledge interdependence is an important factor in many instructional methods for fostering collaborative learning, with the jigsaw collaboration script as their prototype. In a jigsaw
collaboration script, each learner becomes an expert for a specific domain before collaborating with other learners who have studied a different domain. To ensure fruitful collaboration, the distribution of expertise within groups typically ensures that "none of the group members has enough information or knowledge to solve the task alone" (Dillenbourg \& Jermann, 2007, p. 292), establishing true knowledge interdependence.

In fact, differences in prior knowledge and perspectives can lead to fruitful knowledge co-construction, in which ideas are critically evaluated, knowledge is elaborated and restructured, and more abstract representations are derived (Andriessen, Baker, \& Suthers, 2003; Schwartz, 1995). When learners integrate and transform their complementary knowledge resources, new knowledge can be created that no individual learner would have been capable of constructing (Deiglmayr \& Spada, 2011). On the other hand, research on group information processing shows that much of students` unshared knowledge remains unshared in real group discussions. For example, Buchs, Butera, and Mugny (2004) showed that students studying with a jigsaw collaboration script learned substantially less about their partner's domain of expertise than about their own, even though they were instructed to teach one another during a face-to-face learning phase. Deiglmayr and Spada (2011) showed that students had severe difficulties integrating interdependent information that was distributed between them.

Educators face the challenge of creating knowledge interdependence in a way that ensures that learners' discussions, and the cognitive activities involved, are focused on the most relevant learning content. Establishing true knowledge interdependence, as in classical jigsaw-type collaboration scripts, may not always be the optimal way to achieve this goal. Rather, we argue that superficial knowledge interdependence is often the better solution. Superficial knowledge interdependence denotes that core structures, such as domain principles and important concepts, remain shared between learners, while only contextual information, such as illustrative examples or application contexts, is distributed between learners. The fact that all relevant structural information is given to all students from the beginning maximizes the chance that each learner becomes familiar with the relevant principles via constructive learning processes, while the distributed
context information still creates sufficient interdependence for fostering truly interactive knowledge construction (Chi, 2009). In this paper, we test this "shared structure, distributed context"-hypothesis in a schema-abstraction learning setting (learning by collaborative comparison), with a learning domain that allows for a straightforward distinction between structure and context (word problems instantiating mathematical principles within different application contexts).

## Learning by collaborative comparison

Comparing and contrasting worked examples has proven an efficient way of fostering learning and transfer (for recent reviews see Alfieri, Nokes, \& Schunn, in press, and RittleJohnson \& Star, 2012). According to this approach at least two carefully constructed worked examples, which are instantiation of the to-be-learned principle or schema, are presented simultaneously in space and time. Learners are prompted to compare and contrast the examples in order to identify commonalities and differences (e.g., Gentner, Loewenstein \& Thompson, 2003; Schalk, Saalbach, \& Stern, 2011). These activities require learners to map and structurally align aspects of the worked examples, which "leads to learning via abstraction, rerepresentation, inference-projection, and difference-detection" (Gentner, 2010, p. 753). These are higher-order learning processes in which learners need to focus on deep, structural information rather than on contextual features, and to elaborate the to-be-learnt principles. In our collaborative comparison script, students begin with slightly different sets of examples from which they have to generate joint explanations of principles. This presumably fosters principle-based comparisons and elaboration via processes of grounding (Andriessen et al., 2003; Schwartz, 1995) and knowledge co-construction (Chi, 2009). Because the to-be-learnt principles (structural information) are embedded within different cover stories (contextual information), collaborative comparison as an instructional method allows to design well-controlled tests of the "shared structure, distributed context"-hypothesis.

## The domain: Learning to reason with probability

The relevant principles that students could learn in our experiment were urn models. These models serve to describe the probability of a series of random events (i.e., multilevel random experiments) in basic probability theory and allow for differentiating precisely between structure (urn models and the principles underlying them) and context (application contexts in the form of story problems).

A sound understanding of basic probability theory is a fundamental precondition for acquiring the ability to solve problems in statistics and, as such, is required in many professions and academic disciplines. High quality teaching seems to be particularly important as reasoning about probabilities does not come naturally to most people, and biases and misconceptions are abundant (Kahneman, Slovic, \& Tversky, 1982). Basic principles of probability theory and stochastics are introduced quite early in high school
mathematics. In Switzerland, for example, the principles governing multilevel random events (the learning domain from which our learning materials were taken) is introduced as early as in eighth grade. Typical problems are, for example, finding the probability of getting twelve points when throwing two dice, or finding the likelihood of guessing the right combination of numbers in a lotto game. The ultimate goal is that mathematical/statistical knowledge acquired in school will be applied outside the classroom and in students' later work; that is, that transfer occurs (Singley \& Anderson, 1989). However, transfer does not come about naturally even for these basic probability theory principles, and even university students have difficulties with basic stochastic concepts (Gal, 2002).

## The present research

In our experiment, university students had the chance to refresh and deepen their knowledge about basic probability theory, specifically, their knowledge about multilevel random events. The most important conceptual knowledge learners need to acquire when learning about multilevel random events is the ability to differentiate between four different urn models, in which random events are modeled as balls being drawn from an urn.

We combined learning through collaboration with learning triggered by comparing and contrasting worked examples in a collaborative comparison script. The script was modeled after a prototypal jigsaw script with an individual and a collaborative learning phase, implemented within a computer supported collaborative learning (CSCL) environment. Learning materials consisted of worked examples, which embedded the to-be-learned urn models in different cover stories. We varied whether, prior to collaboration, students became experts for one urn model (MODEL experts: true knowledge interdependence) or for one cover story (STORY experts: superficial knowledge interdependence). This setting allowed us to test our hypothesis that superficial knowledge interdependence would be more effective than true knowledge interdependence in fostering students` learning.

## Method

## Participants

Participants were 87 students of universities in Zurich (Switzerland), majoring in a wide range of subjects (students of mathematics or statistics were excluded). All participants spoke German or Swiss German as a native language. They were paid for participation. Participants were randomly assigned to triads and conditions. We excluded three triads from analysis because at least one of their members did not pass the threshold of four out of six correct answers in a basic prior knowledge test. This test assessed basic skills necessary for learning about multilevel random events (e.g. finding the likelihood of single random events in story problems; adding and multiplying fractions), or because they did not follow instructions. These exclusion
criteria left a total of 78 participants ( 42 female, 33 male) in 26 triads. Their age ranged from 18 to 36 years $(M=24.4$, $\mathrm{SD}=4.0$ ).

## Materials

Four urn models from probability theory (specifically, multilevel random events) were the core learning content of our learning environment. These four models result from combinations of two principles: relevance of order (the order in which balls are drawn from an urn is relevant vs. irrelevant) and replacement (the balls are drawn with replacement vs. without replacement). We will refer to these four models as Model 1 (order relevant, without replacement), Model 2 (order relevant, with replacement), Model 3 (order irrelevant, without replacement), and Model 4 (order irrelevant, with replacement). Story problems exemplified the four urn models by embedding them in simple cover stories (see Table 1 for examples). We used three different story problems, adapted with modifications from Berthold and Renkl (2009). In the remainder of this paper, these stories will be referred to as Story 1 (random events $=$ the distribution of bicycle helmets among participants in a biking course), Story 2 (random events = ranking results in a competition among equally capable skijumpers), and Story 3 (random events $=$ the drawing of unlabeled gas bottles from cupboards in a chemist`s lab). In the learning materials, we used nine story problems that result from crossing Models 1-3 with Stories 1-3. They were presented in the form of worked examples, that is, together with an arithmetic solution approach and a final numerical solution (as in Table 1). The three problems resulting from crossing Model 4 with Stories 1-3 were used as transfer tasks in the post test. All materials were presented within a computer-based learning environment.

## Measures and Scoring

Pretest In addition to the six basic knowledge questions used for screening participants (see Participants), the pretest contained four story problems assessing learners' prior knowledge about Models 1-4. The cover stories differed from those used in the learning phase. For each problem, one point could be obtained for generating an equation that corresponded to the model underlying the story problem.

Posttest The posttest had three sections. Within each section, the order of tasks was randomized. For each task, one point could be obtained for generating an equation that corresponded to the correct model. In the first section, three familiar tasks represented Models 1-3, each embedded in one of the Stories 1-3 that students already knew from the learning environment, but with new numerical values. In the second section, six direct application tasks embedded Models 1-3 in novel cover stories (two tasks for each model). The third section comprised the three tasks that result from crossing Model 4 with Stories 1-3. These Model 4 transfer tasks were included to measure transfer of the principles underlying Models 1-3: Since the four urn models result from crossing the principles relevance of order (relevant / irrelevant) and replacement (with / without), the fourth model can be derived from the other three. Students were told that the transfer tasks constituted a new type of model, but that they would be able to solve them by combining what they had learned during the learning phase.

## Procedure

Students came to our lab in groups of up to 18 participants. After a brief introduction, they were randomly assigned to computer work stations. Each student sat in his or her own cubicle, so that there was no face-to-face contact possible between learners. Students did not know with whom they

| You and your friend participate in a two day mountain bike course. Each day, the instructor brings five bicycle helmets in five different colors which are randomly distributed among the course participants in the morning, and collected again in the evening. On both days, you are the first to receive a helmet, and your friend is the second. What is the probability for you to get the red helmet on the first day and the yellow helmet on the second day? | The four ski jumpers Adam, Beat, Christoph, and Daniel test a newly build ski-jumping hill today. The four ski jumpers have all performed equally well on previous competitions, thus, it only depends on random factors (e.g., wind regime) which of them will jump the greatest distance. There are two rounds of jumps. What is the probability that Adam will be on the first rank and Daniel on the second rank after the first round of jumps? | A chemist stores noble gases in two safes. There are the same three noble gases (argon, krypton, and xenon), in three identical single bottles, in both safes. Unfortunately, her colleague forgot to label the bottles. For her experiments, the chemist needs two different gases. The chemist takes one bottle out of each safe. What is the probability for her to obtain one bottle of argon and one of xenon? |
| Approach Solution | Approach Solution | Approach Solution |
| $\frac{1}{5} * \frac{1}{5} \quad=\frac{1}{25}$ | $\frac{1}{4} * \frac{1}{3} \quad=\frac{1}{12}$ | $\frac{1}{3} * \frac{1}{3}+\frac{1}{3} * \frac{1}{3} \quad=\frac{2}{9}$ |

were collaborating, and were logged into the system with an anonymous, gender-neutral nickname. After arriving at their workstations, students filled in a questionnaire on demographic variables and worked on the pretest individually. Afterwards, and before starting the learning phase, students received an introducing to the chat tool, and the three students who had been assigned to the same triad engaged in a brief warming-up chat session. The learning phase was segmented into an individual learning phase followed by a collaborative learning phase. Table 2 gives an overview of the worked examples presented in both phases, along with the self-explanation prompts provided (abbreviated for the individual learning phase).

Table 2: Learning materials (worked examples) for both experimental conditions. Worked examples are denoted by their combination of Model (M1-3) and Story (S1-3).

| $\Omega_{A} \Omega_{B} \Omega_{C}$ | Why does the solution require both addition and multiplication? |

The experimental variation was established in the individual learning phase, in which each learner studied three worked examples that were presented side-by-side on one screen. Learners were prompted to compare the examples and to list the most important similarities and the most important differences. Each member of a triad was assigned a different set of examples, so that, among them, the three learners studied all nine examples that result from crossing Models 1-3 with Stories 1-3. In the MODEL-experts condition, each triad member became an expert for a different urn model (true knowledge interdependence), whereas in the STORYexperts condition, each triad member became an expert for a different cover story (superficial knowledge interdependence).

In the collaborative learning phase, materials and instructions were identical for all triads, regardless of experimental condition. Three sets of worked examples, corresponding to Models 1-3, were presented on three consecutive screens (see Table 2). Thus, each and every learner was exposed to all nine worked examples during the collaborative learning phase. The triads compared and contrasted the worked examples and generated collaborative self-explanations. For each set of worked examples they were prompted to focus on one specific feature of the urn model being exemplified (see Table 2 for details). Triads used the chat tool in order to discuss their answer. Once group members had agreed on a joint solution, they went on to the next screen. After the collaborative learning phase, students worked on the posttest individually. All in all, the experiment took about 100 minutes.

## Results

There were no relevant differences between experimental conditions in participants` age, final high school math grade, or performance on the basic knowledge test used for participant screening (all $t \mathrm{~s}<|1.5|$; all $p \mathrm{~s}>.15$ ). Further, conditions did not differ significantly in the proportion of females/males $\left(\chi_{(d f=l)}^{2}=.83 ; p=.36\right)$. Conditions also did not differ in the distribution of students who solved $0,1,2$, 3 or 4 of the pretest Models 1-4 tasks correctly $\left(\chi_{(d f=3)}^{2}=\right.$ $.42 ; p=.94$ ) indicating similar levels of prior knowledge (see Table 3 for mean proportions correct).

Table 3: Mean proportions correct (and standard deviations) of pre- and post-test scores (total $N=78$ )

|  | MODEL <br> Experts | STORY <br> Experts | whole <br> sample |
| :--- | :--- | :--- | :--- |
| pretest: |  |  |  |
| Models 1-4 total | $.55(.24)$ | $.54(.26)$ | $.55(.25)$ |
| Models 1-3 only | $.68(.25)$ | $.66(.25)$ | $.67(.25)$ |
| Model 4 only | $.18(.39)$ | $.21(.41)$ | $.19(.39)$ |
| posttest: |  |  |  |
| Models 1-3 familiar | $.76(.26)$ | $.79(.24)$ | $.78(.25)$ |
| Models 1-3application | $.75(.23)$ | $.76(.19)$ | $.75(.21)$ |
| Models 1-3 combined | $.75(.22)$ | $.77(.19)$ | $.76(.20)$ |
| Model 4 transfer | $.46(.44)$ | $.62(.35)$ | $.54(.40)$ |

Before analyzing the post-test scores, we calculated intraclass correlations for the members of each triad in order to test for a possible hierarchical data structure. In no case was the ICC above .05 (all $F \mathrm{~s}<1.1$; all $p \mathrm{~s}>.40$ ), indicating only unsystematic agreement in post-test scores between triad members and, thus, a non-hierarchical data structure. Therefore, we calculated all further analyses on the level of individual learners $(\mathrm{N}=78)$. Given that our data is made up by series of 0 vs. 1 (correct vs. incorrect) responses, we calculated generalized logit regression models (using SPSS`s GENLIN procedure, with a logit link function) rather than $t$-tests or ANOVAs (Jaeger, 2008). However, for ease of comparison, Table 3 gives the scores that students in
the two experimental conditions obtained as mean proportions correct. Students in both conditions achieved very similar scores on the Models 1-3 familiar and the Models 1-3 direct application tasks. The differences between these two post-test sections (as within-subjects factor), experimental condition (as between-subjects factor), and their interaction were all statistically non-significant in a generalized logistic regression (all Wald $-\chi^{2}{ }_{(d f=1)}<2.6$; all $p \mathrm{~s}>.11)$. We therefore formed a combined posttest score (Table 3: Models 1-3 combined).

We first looked at students` posttest performance on tasks representing Models $1-3$, that is, the learning content we directly taught. Table 3 shows that students in both conditions showed an overall gain in their performance from pre- to posttest. We calculated a generalized logistic regression with solution rate as the dependent variable, time (pretest: Models 1-3 vs. posttest: Models 1-3 combined) as within-subjects factor, and experimental condition as between-subjects factors. Only the effect of time was significant $\left(\right.$ Wald $\left.\left.-\chi^{2}{ }_{(d f}=1\right)=6.5 ; p=.01\right)$. These findings indicate that both conditions were effective in improving the recognition and application of the three urn models that were directly taught.

On the Model 4 transfer tasks, however, students` posttest performance was notably higher in the STORY-experts condition (Table 3). Figure 1 shows that the absolute solution rate shows a U-shaped distribution in the MODELexperts conditions, while the mode of the distribution in the STORY-experts condition is at the highest end of the distribution. This difference in distribution of scores between conditions is statistically significant $\left(\chi^{2}{ }_{(d f}=3\right)=$ 8.55; $p=.04$ ).

To further scrutinize the differential effects on transfer in both conditions, we took students' prior knowledge into account. We tested the effects of experimental condition, prior knowledge (specified as a covariate), and their interaction, on the number of correctly solved Model 4 transfer tasks in a generalized logistic regression model. We chose the combined pretest score for Models 1-4 as the most reliable and most informative predictor; however, analyses with performance on only the items for Models 1-3 yielded the same pattern of results; the same was true when the 15 students who had already mastered the Model 4 task in the pretest were excluded from analysis. All postulated
predictors in the model (experimental condition, prior knowledge, and their interaction) were shown to significantly predict performance on the Model 4 transfer tasks (for parameter estimates see Table 4; overall model likelihood ratio: $\left.\chi^{2}{ }_{(d f=3)}=39.83 ; p<.001\right)$. The significant interaction indicates that learners low in prior knowledge profited more in the STORY-experts condition than in the MODEL-experts condition: Prior knowledge showed a significant, positive correlation with transfer performance in the MODEL-experts condition (Spearman`s \(r=.56, p<\) .001) but a smaller, statistically non-significant correlation in the STORY-experts condition (Spearman`s $r=.25, p=$ .13).

Figure 1: Distribution of learners (by experimental condition) who solved 0, 1, 2, or all 3 Model 4 transfer tasks correctly

## Discussion

In the present study, we aimed at testing the hypothesis that in collaborative learning settings superficial knowledge interdependence is more effective in fostering individual learning than true knowledge interdependence. Specifically, we tested whether collaborative learning supported by a jigsaw-type collaboration script is more effective when the knowledge interdependence established between students ensures that the to-be-learnt, structural information (in our case, the three urn models) is shared from the beginning, while only contextual information (in our case, the cover

stories) is distributed between learners (shared structure distributed context hypothesis).

The results partially support our hypothesis: Students in the STORY-experts condition (superficial knowledge interdependence) did profit more from our CSCL learning environment than students in the MODEL-experts condition (true knowledge interdependence), but only on the transfer tasks. In both conditions, students gained to a similar degree from pre- to post-test for the three models that had been trained. Since students in both conditions learned with a highly structured learning environment and with carefully constructed worked examples, this finding is reassuring. Still, STORY-experts outperformed MODEL-experts on the transfer tasks, which required them to combine the principles behind the three trained models in order to derive a solution for a fourth model that had not been introduced within the learning environment. Learners with low prior knowledge profited particularly from the superficial knowledge interdependence realized in the STORY-experts condition, that is, they were more likely to obtain a high score on the transfer tasks in this condition.
We assume that these effects arise because the superficial knowledge interdependence realized in the STORY-experts condition (1) ensures that each learner becomes familiar with all relevant principles via constructive learning processes already during the preparatory individual learning phase, while (2) the distributed context information still creates sufficient interdependence for fostering truly interactive knowledge construction (Chi, 2009). However, further fine grained analyses of individual learning (e.g. self-explanations during individual learning phase) and of collaborative processes (e.g., discourse analyses of chats) are needed to be able to precisely identify the underlying cognitive and interactive processes. Analyses currently under way include coding the quality of students` selfexplanations, as a measure of the level of expertise they gained during the individual learning phase, as well as analyses of the patterns of contributions, both qualitatively and quantitatively, made within story expert and model expert triads. Further experiments will include additional test and transfer tasks in order to increase the reliability of the pre- and post-test measures, and will be designed to enable direct comparisons with purely individual (constructive) learning conditions.

#### Abstract

Non-integer rational numbers, such as fractions and decimals, pose challenges for learners, both in conceptual understanding and in performing mathematical operations. Previous studies have focused on tasks involving access and comparison of integrated magnitude representations, showing that adults have less precise magnitude representations for fractions than decimals. Here we show the relative effectiveness of fractions over decimals in reasoning about relations between quantities. We constructed analogical reasoning problems that required mapping rational numbers (fractions or decimals) onto pictures depicting either partwhole or ratio relations between two quantities. We also varied the ontological nature of the depicted quantities, which could be discrete, continuous, or continuous but parsed into discrete components. Fractions were more effective than decimals for reasoning about discrete and continuous-parsed (i.e., discretized) quantities, whereas neither number type was particularly effective in reasoning about continuous quantities. Our findings show that, when numbers serve as models of quantitative relations, the ease of relational mapping depends on the analogical correspondence between the format of rational numbers and the quantity it models.

## Introduction

## Mathematical Understanding as Relational Reasoning

Mathematics is in essence a system of relations among concepts based on quantities. A core problem with math education, particularly in the United States, is that greater focus is placed on execution of mathematical procedures than on understanding of quantitative relations (Richland, Stigler \& Holyoak, 2012; Stigler \& Hiebert, 1999; RittleJohnson \& Star, 2007). An early manifestation of this problem involves teaching of non-integer rational numbers in the standard curriculum-typically, first fractions and subsequently decimals. Students often leave middle-school (and often enter community college: see Stigler, Givvin \& Thompson, 2010; Givvin, Stigler \& Thompson, 2011)
without having grasped how fractions relate to decimals, or how either number type relates to integers. This conceptual disconnection in turn contributes to a compartmentalization of mathematical operations (e.g., multiplication of fractions is treated as unrelated to multiplication of integers; Siegler et al., 2011; Siegler \& Pyke, 2012).

Although mathematical relations are typically construed as internal to the formal system of mathematics, the application of mathematics to real-world problems also depends on grasping relations between mathematical concepts and the basic ontological distinctions among the concepts to which mathematics must be applied. Rather than treating mathematical concepts as purely formal, both children and adults are naturally guided by a process of semantic alignment, which favors mapping certain mathematical concepts (and their associated operations) onto certain conceptual types. Bassok, Chase and Martin (1998) demonstrated that the basic mathematical operations of addition, subtraction, multiplication, and division are typically conceptualized within a system of relations between mathematical values and objects in the real world. Specific mathematical operators are semantically aligned with particular relationships among real-world objects. For example, addition is aligned with categorical object relations (e.g., people find it natural to add two apples plus three oranges, because both are subtypes of a common category, fruit), whereas division is aligned with functional object relations (e.g., a natural problem would be to divide ten apples between two baskets). Semantic alignment has been demonstrated with both children and adults (e.g., Martin \& Bassok, 2005), and for many adults the process is highly automatic (Bassok, Pedigo, \& Oskarsson, 2008). Although natural semantic alignments are implicitly acknowledged in the construction of textbook word problems (Bassok et al., 1998), teachers seldom discuss these alignments with their students. This gap may contribute to the difficulty of conveying how and why mathematical formalisms "matter" in dealing with realworld problems.

## Discreteness Versus Continuity

A particularly important ontological distinction relevant to mathematical modeling involves the nature of quantities, which can be viewed as either discrete or continuous. Roughly, some entities are viewed as comprising a set of individual objects (e.g., a number of apples in a basket), whereas others are viewed as a continuous mass without individuation (e.g., a bucket of water). Although continuous, as well as, discrete quantities can be subdivided, in the case of continuous quantities the divisions are arbitrary in the sense that they do not isolate conceptual parts (e.g., one could distinguish between subsets of red and green apples in a basket by saying that $2 / 3$ of the apples are red and $1 / 3$ are green, but there is no psychological difference between the water contained in $2 / 3$ of a bucket and in the complementary $1 / 3$ of the bucket). Importantly, discreteness versus continuity is a distinction based fundamentally not on physics, but on psychology. For example, a pile of sand is viewed as a continuous quantity even though we know it is composed of individual grains, because those units are too small and interchangeable to be typically viewed as "important". The impact of this basic ontological distinction has been documented both in young babies (e.g., Spelke, Breilinger, Macomber, \& Jacobson, 1992) and in adults (Bassok \& Olseth, 1995). For example, Bassok and Olseth found that college students viewed an increase in attendance at an annual conference as discrete (since it is based on a change between magnitudes associated with two discrete events well-separated in time), but viewed an annual increase in a city's population growth as continuous (since it is based on changes stemming from the psychologicallyconstant process of gaining and losing undifferentiated individual residents).

The ontological distinction between discreteness and continuity underlies the linguistic distinction between count and mass nouns, which is syntactically important in English and many other natural languages (Bloom \& Wynn, 1997). Infants and young children are able to make distinctions among continuous quantities (Clearfield \& Mix, 2001; Fiegenson, Carey \& Spelke, 2002). However school-aged children have an advantage when performing operations with discrete quantities (e.g., counting; Gelman, 1993) over performing operations with their continuous counterparts (e.g., measurement in general; Nunes, Light \& Mason, 1993). Indeed, measurement of continuous quantities depends on the introduction of arbitrary equal-sized units, which serve to parse a continuous whole into countable subparts (e.g., a continuous length can be broken down into some number of inches or centimeters). The ability to discretize continuous concepts (as contrasted with the lack of a natural operation to make discrete concepts continuous) leads to asymmetries in transfer of mathematical operations. For example, college students can transfer the equation for calculating the sum of an arithmetic progression (discrete concept) to solve a physics problem requiring solving for final velocity after constant acceleration (continuous concept), but find transfer in the opposite direction
(continuous to discrete) nearly impossible (Bassok \& Holyoak, 1989; Bassok \& Olseth, 1995).

## Fractions as Relational Representations

As the first non-integer number type introduced to elementary-school students, fractions pose particular challenges. Research indicates that children have difficulty integrating fractions into their already well-established understanding of whole numbers (Staflyidou \& Vosniadou, 2004; Vamvakoussi \& Vosniadou, 2010; Ni \& Zhou, 2005), and even adults at community colleges seem to lack fundamental understanding of how to use fractions (Stigler et al., 2010). Research on understanding fractions has primarily focused on the ability to grasp and manipulate their integrated magnitude value associated with the $a / b$ form. Although adults can compare fractions based on integrated magnitudes (Schneider \& Siegler, 2010), this process is very slow and error-prone relative to performing the same task with decimal equivalents (DeWolf, Grounds, Bassok \& Holyoak, in press). The difficulty of making magnitude comparisons with fractions presumably reflects their bipartite structure (numerator divided by denominator), which makes them both formally and conceptually distinct from integers. In contrast, decimals have a unitary structure more similar to integers (though not identical; Cohen, 2010).

However, even though the internal structure of fractions apparently hinders access to precise integrated magnitudes, this same structure may facilitate understanding of key relations. In particular, the $a / b$ form can be aligned with the concepts underlying relations such as part/whole, subset/set, ratio, and rate. When children are first taught the concept of a fraction, some type of pictorial representation is often provided, such that each of the two values in the fraction are structurally aligned with two separate elements in the picture. For example, take the very common example of cutting up a pizza pie into pieces. A child might be taught that $4 / 5$ is equivalent to 4 slices of a pizza pie that is divided into 5 slices. This type of mapping is also encouraged with verbal examples (e.g., 4 out of every 5 dentists recommend a certain toothpaste). Such instructional practices highlight the relational nature of fractions and encourage children to reason about fractions relationally.

We propose that semantic alignment will also modulate people's understanding of fractions. Fractions seem particularly appropriate as models of relations between sets of discrete elements. The representations typically used to teach fractions focus on discrete countable units that can map to the numerator and denominator values. For example, the pizza is sliced into exactly the number of pieces in the denominator before the numerator pieces are counted up. Rapp and Bassok (in preparation) reviewed a math textbook series and found that very rarely are students encouraged to think about fractions with continuous representations, such as a number line. In fact, continuous measures (e.g., length, weight) are almost exclusively represented with decimals. Rapp and Bassok also found that, consistent with this

Figure 1: Examples of types of pictures used in analogy problems.
training, college students show a preference for using fractions rather than decimals to describe relations between discrete quantities, and use decimals to describe magnitudes of continuous quantities.

## Analogical Reasoning with Quantitative Relations

Our study was designed to test the hypothesis that, due to their relational structure $(a / b)$, fractions are better suited than decimals for representing relations between countable quantities. To this end, we compared analogical reasoning with either fractions or decimals, while varying the ontological distinction between discrete and continuous concepts. Figure 1 shows examples of variations in discreteness versus continuity. The pictorial stimuli were based on discrete elements (top), continuous rectangles (bottom), or continuous rectangles parsed into discrete units (middle). We hypothesized that semantic alignment would yield higher accuracy and faster response times for solving analogies using fractions rather than decimals for the discrete and continuous-parsed pictures. The fraction advantage was predicted to disappear or even reverse for the continuous pictures, where the semantic alignment is most difficult.

## Method

## Participants

Participants were 52 undergraduates at the University of California, Los Angeles (mean age $=21 ; 30$ females) who received course credit, randomly assigned in equal numbers to the two between-subjects conditions.

## Materials and Design

The study was a 2 (number type: fractions vs. decimals) X 2 (relation type: ratios vs. part/whole fractions) X 3 (picture

Figure 2: Example of an analogy problem (part/whole fraction trial with continuous-parsed pictures).
type: continuous, continuous-parsed, discrete) design, with number type as a between-subjects factor and relation type and picture type as within-subjects factors.

The analogy problems were constructed using each of the three ontological types illustrated in Figure 1: discrete, continuous-parsed, and continuous. An example problem appears in Figure 2. These analogy problems were in the format $\mathrm{A}: \mathrm{B}:: \mathrm{C}: \mathrm{D}$ vs. D', where the source analog ( $\mathrm{A}: \mathrm{B}$ ) consisted of a picture and a number (fraction or decimal). The task required making a choice of the correct number to complete the target analog. The number type was always the same across the source and target.

Solving an analogy problem required first identifying the relationship in the A picture characterized by the number given as B . This relationship could be part-whole or a ratio between two parts. In Figure 2, the A picture indicates 4 green units out of a total of 6 , making a part-whole relation of $4 / 6$ (. 67 in a matched problem using decimals). An alternative ratio relation in Figure 2 is based on the units of red relative to green (i.e., $2 / 4$, or .50 in decimal notation). Once the higher-order relation between A and B was extracted, the solution required identifying the same relation type in target picture C , and choosing the corresponding number as D term. D' mapped to the alternative relationship.

As Figure 2 illustrates, the same two colors were used in the A and C pictures, and the color relationship was maintained, such that the same color mapped to the same part of the relation in both A and C. This constraint served to identify which part (lesser or greater) mapped to the numerator in a ratio relation. Color assignments varied across trials, so the same color might indicate the lesser subset on one trial and the greater subset on another. The actual test trials contained only red and green colors (practice trials were given that had yellow and brown colors). The discrete items were circles, squares, crosses, trapezoids, and cloud-like shapes. Continuous and continuous-parsed items differed in width, height and

Figure 3: Percent accuracy for solving analogy problems using fractions or decimals for each quantity type.
orientation (vertical or horizontal). For each trial, the source and target were randomly assigned for each participant so that the only thing that was consistent between the two was the higher-order relationship (ratio or part/whole) and the color mapping. The fractions and decimals were always less than one and decimals were shown rounded to two decimal places.

## Procedure

Stimuli were displayed with Macintosh computers using Superlab 4.5, and response times and accuracy were recorded. Extensive instructions and practice was provided prior to beginning the test trials. Participants were told that there were two different types of relations between the pictures and values. For the ratio relationship, participants were shown a picture with 1 O and 2 X 's. For the fractions condition this was explained as " $1 / 2$ amount of O's per amount of X's;" for the decimals condition it was explained as ". 50 amount of O's per amount of X's." The part/whole relationship was represented with a picture of 2 O 's and 3 $X$ 's. For the fractions condition this was explained as " $2 / 5$ of the total is the amount of O's;" for the decimal condition it was explained as ". 40 of the total is the amount of O's." The first of these explanations of the ratio and part/whole relations was shown with discrete items. The following screen showed the same values paired with continuousparsed pictures. A third screen showed the same values paired with continuous pictures.

After this introduction, participants completed an example trial in which they were shown the source ( $\mathrm{A}: \mathrm{B}$ ), asked to figure out the type of relation (ratio or part/whole) in their head, and press the space bar. After the space bar was pressed, the target (C:D vs. D') was shown on the screen below the source so that the two components were on the screen simultaneously. Participants were asked to select which of two numbers ( D or $\mathrm{D}^{\prime}$ ) shared the same relationship with the picture as the relationship provided in the source. Half of the time, D appeared on the right side of the screen. They made their selection by pressing the $z$ key

Figure 4: Response times for correctly solving analogy problems using fractions or decimals for each quantity type.
for the number shown on the left and the $m$ key for the number shown on the right. The $z$ and $m$ keys were labeled with "L" and "R", respectively, so that participants could remember which key went with each number. After completing the initial example trial, participants were shown the correct answer, with an explanation of which relationship was shared between the source and target.

Participants then completed 12 practice trials. Feedback was given for incorrect trials, in the form of a red " X " on the screen. After the practice trials had been completed, a screen was displayed informing participants that the actual test trials were beginning. For each trial, the source was shown, then the participant pressed the spacebar when they determined the relationship. The target was then shown in addition to the source. Feedback was continued for incorrect trials. There were 72 test trials ( 12 for each of the 6 within-subjects conditions). The specific pictures, numbers, and pairings used in the test trials were different from those used in practice trials. Relation types and picture types were shown in a different random order for every participant.

## Results

Accuracy and mean response time (RT) on correct trials were computed for each condition for each participant. A mixed factors ANOVA was used to compare differences in RT and accuracy. No reliable overall differences were obtained between the two relation types (part-whole and ratio) on either measure; hence all results are reported after collapsing across this variable. Figure 3 presents the pattern of performance based on accuracy, and Figure 4 presents the pattern based on mean correct RT. Both dependent measures revealed an overall advantage for solving analogies based on fractions rather than decimals, with the advantage most pronounced for pictures of discrete quantities. For accuracy, both number type, $F(1,50)=8.65, p=.005)$, and picture type, $F(2,49)=33.52, \mathrm{p}<.001$, were highly reliable, as was the interaction of the two factors, $F(2,49)=25.20, p<.001$. Planned comparisons indicated that accuracy was higher for fractions than decimals for the discrete condition ( $87 \%$ vs.
$66 \% ; t(50)=5.38, p<.001)$ and the continuous-parsed condition ( $80 \%$ vs. $67 \% ; t(50)=3.17, p=.003$ ), but did not differ for the continuous condition $(61 \%$ vs. $65 \% ; t(50)=$ $.93, p=.36$ ).

RTs were measured from the onset of the source display on the screen to the selection of the target answer. Response times for incorrect answers were excluded from analyses. In addition, outliers were trimmed to exclude any times that were greater than three standard deviations from the mean (roughly 2\% of response times). As shown in Figure 4, the RT pattern closely resembled that for accuracy. In particular, there was a reliable interaction between number type and picture type, $F(2,49)=16.19, p<.001$. Planned comparisons indicated that RTs were faster with fractions than decimals for the discrete condition ( 8.5 s vs. 12.8 s ; $t(50)=2.70, p=.01)$, with a strong trend for the continuousparsed condition ( 8.3 s vs. $11.2 \mathrm{~s} ; t(50)=1.87, p=.067$ ). RTs for fractions versus decimals did not differ reliably for the continuous condition ( 9.3 s vs. $7.7 \mathrm{~s} ; t(50)=1.45, p>$ .15).

## Discussion

The results of the current study demonstrated an overall advantage for fractions over decimals in a relational task. Moreover, this advantage was moderated by the ontological nature of the depicted quantities. Participants were better able to extract relationships for discrete and continuousparsed pictures when fractions were mapped to the quantities, rather than decimals. There was no difference in performance on the continuous pictures between fractions and decimals. This pattern suggests that fractions are semantically-aligned with relations between countable, discrete quantities. Performance with decimals was relatively flat (and generally poorer) for all picture types.

These results support two basic claims about semantic alignment for specific types of quantities. First, people can and do align quantities with numbers. Second, ease of alignment depends on two factors: the type of number format (fractions vs. decimals), and the type of quantities (countable, i.e., discrete and continuous-parsed, vs. continuous).

The central difference between fractions and decimals is that their formats provide an explicit representation of relations (fractions) or of relation magnitudes (decimals). That is, fractions have a bipartite structure $(a / b)$ that expresses a specific relationship between two natural numbers, $a$ and $b$. Decimals represent the magnitudes of such fractional relations. This difference has important implications for how people align these numbers with specific quantities. For fractions, alignment should be simple when the numerator and denominator can be readily mapped onto distinct subsets, A and B. Our results show that this is indeed the case when $A$ and $B$ are comprised of countable entities, depicted by the discrete and continuousparsed picture types. However, alignment should be difficult when $A$ and $B$ are continuous quantities, as the task
becomes more like a magnitude assessment. Despite the explicit relation $(a / b)$, it is difficult to assess the magnitude of A and the magnitude of B , which makes the overall mapping more complicated. Decimals represent magnitudes of relations without specifying the relational parts. Hence, mapping to the A and B sets is difficult irrespective of whether the sets are shown as discrete or continuous quantities.

The current pattern of results is consistent with the schooling experience of our participants (Rapp \& Bassok, in preparation). Typically, students learn about fractions from part/whole and set/subset examples (Sophian, 2007; Mack, 1993). However, the goal of such examples is not to help children understand that fractions represent relations. Rather, they are provided to help children understand the existence of values smaller than 1 . That is, as discussed earlier, the main focus of initial instruction about fractions is to convey their magnitude. This focus is problematic because, while fractions are well-suited for representation of relations, they are poorly suited for representation of magnitudes (DeWolf et al., in press; Stigler et al., 2010). Our findings also suggest that if decimals were taught prior to fractions, children might have a better opportunity to learn about magnitudes smaller than 1. Because decimals have a unitized format, like whole numbers, they might provide an easier opportunity for children to master the idea of magnitudes smaller than 1. Fractions, then, might be taught later than decimals with an emphasis on their status as a relationship between two natural numbers. The magnitude of such relational representations would not be limited to values smaller than 1 (ratios).

Interestingly, Moss and Case (1999) implemented a curriculum with $4^{\text {th }}$ graders in Canada that reorganized the order of rational number instruction. Children were first taught percentages (in the context of volumes and on number lines), then decimals, and lastly fractions. Fractions were explained simply as another way to represent a decimal. By contrast, typical curricula describe teaching decimals as another way to represent a fraction. Moss and Case found that children taught number types in this novel sequence suffered less interference from whole-number strategies when using other rational numbers, and achieved a deeper understanding of them. Though Moss and Case did not emphasize fractions in the relational context we have discussed here, it seems that introducing the idea of magnitudes less than 1 with decimals rather than fractions may be preferable.

In summary, understanding how non-integer rational numbers align to specific types of quantities, and how format can affect ease of semantic alignment, has important implications for how we conceptualize and teach fractions and decimals. It is important to foster understanding of fractions beyond simple algorithmic procedures, and to bolster conceptual understanding in order to address the difficulties children and adults face in understanding fractions.

# Learning to Perceive Coherent Objects 

Nimrod Dorfman ${ }^{1}$ (nimrodd@weizmann.ac.il) Daniel Harari ${ }^{1}$ (danny.harari@weizmann.ac.il)<br>Shimon Ullman ${ }^{1}$ (shimon.ullman@weizmann.ac.il)<br>${ }^{1}$ Department of Computer Science, Weizmann Institute of Science, Rehovot, Israel

#### Abstract

Object segregation in a visual scene is a complex perceptual process that relies on the integration of multiple cues. The task is computationally challenging, and even the best performing models fall significantly short of human performance. Infants initially have a surprisingly impoverished set of segregation cues and their ability to perform object segregation in static images is severely limited. Major questions that arise are therefore how the rich set of useful cues is learned, and what initial capacities make this learning possible. Here we present a computational model that initially incorporates only two basic capacities known to exist at an early age: the grouping of image regions by common motion and the detection of motion discontinuities. The model then learns significant aspects of object segregation in static images in an entirely unsupervised manner by observing videos of objects in motion. Implications of the model to infant learning and to the future development of object segregation models are discussed.

Keywords: Visual perception; computational modeling; development; object segregation; figure-ground.

## Background and Goals

We naturally perceive the scene around us as containing coherent objects, separated from each other and from their background. Even in a complex image such as Figure 1A, we can count for example the number of distinct cars, delineate their boundaries, etc. The ability to segregate the scene into objects, delineate their boundaries, and determine occlusion relations (termed here 'object segregation'), relies on a complex set of processes, which integrate multiple cues that are only partially understood.

Infants' initial ability to segregate scenes into coherent objects is rudimentary and it does not make use of even basic salient 'Gestalt' properties such as uniformity of texture, brightness or color, the smooth continuity of boundary contours, occlusion cues and the like (Spelke et al. 1993). For instance, infants at 3 months of age do not appear to distinguish that the shape in Figure 1B is likely to be composed of two distinct components. The contrast between Figures 1A and 1B illustrates the span of learning accomplished in performing object segregation. The ability to segregate objects based on multiple cues develops quickly already in the first year of life, but the learning process continues over an extended period of time (Kovaks et al. 1999). The process of learning object segregation raises fundamental questions for cognitive development and computational modeling of vision. For cognitive development, it is of basic interest to understand the innate capacities and learning mechanisms that allow the system to

Figure 1: Object segregation, infant to adult capacity. (A): A complex scene, easily segregated by an adult. (B): At 3 months, infants do not appear to divide the figure into two components (after Spelke et al. 1993).
start from a surprisingly limited capacity for segregating the world into coherent objects, and reach the capability of the adult system. For computational modeling of vision, an intriguing possibility is to try to surpass the capabilities of current models by following a strategy similar to human development, namely, start with the appropriate set of basic capacities and learning mechanisms and allow the model to develop on its own the final segregation capabilities.

In the current study we focus on specific sub-problems within this broad domain. We develop a model that incorporates simple basic capacities, which are known empirically to already exist in young infants. It uses them to segregate familiar objects and to extract and use so-called 'boundary ownership' cues (indicating boundaries as well as figure/background direction) for static object segregation. The model initially has no ability to segregate objects in static images, but it can compute visual motion and motion discontinuities. It is exposed in an unsupervised manner to video sequences containing moving objects. It uses them to segregate familiar objects in static images and to learn local boundary ownership cues. These are used as cues for static object segregation, applied to novel objects.

In the next sections we briefly summarize relevant background from developmental studies of object segregation, followed by a presentation of the current model.

## Early Development of Object Segregation

Initial object segregation by infants is based almost exclusively on dynamic cues, which are then used to learn static object segregation. We focus below on two main
aspects of using visual motion for object segregation: grouping by common motion, and the use of motion discontinuities. We also comment briefly on the use of static cues.

Common Motion Infants use visual motion to group together adjacent regions that move together. These grouped image entities, discovered through motion, are also stored in memory and can subsequently be identified in static images (Needham 2001, Needham \& Baillargeon 1998, Needham \& Modi 1999, Spelke 1990, Spelke et al. 1989). For example, if 4.5 months old see in a static image a region A next to a second region B , their expectations are shaped by their recent experience of seeing these regions in motion. If $A$ and $B$ moved together, infants will treat them as a unit and will be surprised if they move separately, but not if they saw A or B moving alone. The grouping of regions into a single unit depends on their common motion: if two regions differ in their image motion, even if they remain in contact, they are treated as separate objects (Spelke 1990, Spelke et al. 1989). Retention in memory of the formed unit is limited in time (about 24 hours at 4.5 months of age), but grows gradually with age (Needham \& Baillargeon 1998, Needham \& Modi 1999). This use of stored object representations for segregation is termed 'object-based segregation', and it can generalize with more experience to other similar objects ('class based' segmentation), provided that the differences are initially small (Needham \& Modi, 1999). Two regions moving together can also be grouped together to form a single unit when they are non-contiguous but separated behind an occluder (Kellman \& Spelke 1983) provided that the parts are roughly aligned (Johnson \& Aslin 1996).

Motion Discontinuities In addition to region grouping based on common motion, infants are also sensitive from an early age ( 5 months or earlier) to dynamic cues created by the boundaries of moving objects (e.g., Granrud et al. 1984).

Static Cues In terms of static cues, at 3-5 months contiguous regions that are not separated by a visible gap tend to be grouped together, and are expected for example to move together rather than separately (Needham \& Baillargeon 1998, Spelke 1990, Spelke et al. 1989). At this age they show little or no evidence for using grouping principles based on uniformity of color, texture, and continuity of bounding contour in object perception. At 9 months the effect of such grouping cues is still weak (Spelke et al. 1993). The learning of static cues is gradual, and appears to depend on familiarity with many objects (Needham \& Modi 1989, Spelke 1990).

Following extended learning, perceptual organization into distinct objects and their boundaries develops into a complex process that relies on a rich set of cues. In addition to image-based, or bottom-up properties, organization into objects depends on top-down cues, based on familiarity with
specific objects and object classes. The different cues and their integration into a full segregation scheme are still a subject of active research in both human studies and computational modeling. Yearly competitions and evaluations of natural image segmentation ${ }^{1}$ show consistent improvements, but current performance is still significantly below human performance. Due to space limitations, we will not review here different modeling efforts. The closest to the current study is the SANE (segmentation according to natural examples) model by Ross et al. (2009), where, like in the current study, motion segmentation was used to guide static segmentation. However, the SANE model does not use the two main components of the current model: learning boundary-ownership cues near a boundary, and learning object-based segregation. It uses instead local binary $5 \times 5$ boundary elements, with no ownership information, and their pair-wise relationships.

## Goals of the Current Study

As reviewed above, infants are sensitive to motion cues for segregation, but lack sensitivity to most static cues for objects identity. It is therefore natural to ask how static segregation cues may be learned during development, guided by dynamic cues. We focus on two dynamic cues that are prominent in early infant perception. The first is common motion, guiding object-based segmentation. That is, infants naturally segregate adjacent image regions that share common motion, and can identify similar configurations in static images. One goal is therefore to model this learning of object-based segregation. Second, infants are sensitive to dynamic cues created by the boundaries of moving objects, and these are used by the model to learn useful static boundary cues. Although boundary ownership cues appear to play a major role in human object segregation (e.g. McDermott 2004, Ghose \& Palmer, 2010), they are not usually used in computational models, in part because it is still unclear which features are useful for assigning boundary ownership. A possible outcome of a model for the unsupervised learning of boundary ownership features could be, therefore, the extraction and use of such features in future segmentation models and algorithms.

## The Model

The current learning model has initially two 'innate' capacities for using visual motion to learn object segregation. The first is the capability to group together adjacent regions based on their common motion. A representation of the grouped shape is stored and can then be used for segregating similar shapes in novel static images. The second capacity is to extract motion discontinuities. These are used as teaching signals to extract image features located along object boundaries, together with a labeling of the figure/background sides, and

[^57]subsequently use them to locate novel object boundaries and identify the figure direction in new static images. These two components and how they are used by the learning model are described in subsequent sections, following a brief description of the training data used for learning.

## Training and Testing Data

Data consisted of 48 movies, each depicting an object (doll, banana, remote control etc.) moved by hand in front of a textured background ( 12 objects, 12 backgrounds). For each movie, there are 3 other movies showing the same object on a different background, 3 movies showing different objects on the same background; the remaining 41 have different object and a background. Each movie is one minute long ( 1500 frames), frame size varies between $520 \times 720$ pixels to $576 \times 752$ pixels.

## Object-based Segregation

The goal of object-based segregation is to learn the appearance of a specific object, such as the doll, fruit, etc., in our movies, and then find the full extent of the object and separate it from its background under new settings. The part of the model that deals with object-based segregation is based on an object detection model used, with some variations, in computer vision schemes, termed 'star model'. For the purpose of object segregation, the model is augmented with a 'back projection' stage. Since this part relies on existing object detection models it will be described here briefly.

The input to the object-based segregation is an image in a movie, together with the visual motion associated with the image. The scheme used for motion computation was an available optical flow algorithm (Sun et al. 2010) combined with background subtraction, assuming that the camera itself is stationary (as in Ross \& Kaelbling, 2009).

The motion computation divides the image into two components: a stationary one, and a set of one or more moving regions. One of the moving regions is selected for further processing. The selected region is covered by local image descriptors, each one representing the appearance of a local region. The implementation used the standard SIFT image descriptor (Lowe 2004) because computationally, it is robust and efficient, and biologically, it is similar to intermediate level units used in modeling (e.g. S2 units in the cortical H-Max model, Riesenhuber \& Poggio 1999). A single reference point C is selected at the center of the selected region, and for each image descriptor $F_{i}$, the displacement $\mathrm{V}_{\mathrm{i}}$ from its location to the center C is stored. The object defined by the moving region is therefore represented by its center C , and the set of image descriptors $\left(\mathrm{F}_{\mathrm{i}}\right)$, each one with its displacement $\mathrm{V}_{\mathrm{i}}$ from the object's center.

Figure 2: Examples of object-based segregations produced by the algorithm. Bottom right: an erroneous example.

Segregation of Static Images If the same or similar object appears in a new image, it can be detected and segregated based on the above representation, using the following algorithm. The new image is represented by its local SIFT descriptors. For each descriptor $F$ in the image, we find its $\mathrm{K}=25$ nearest neighbors among the descriptors of the stored object. Each neighbor $F_{k}$, votes for the location of the center C according to the displacement $\mathrm{V}_{\mathrm{k}}$. Votes are weighted by the similarity between F and $\mathrm{F}_{\mathrm{k}}$, and aggregated over the image. If an image location C obtains a sufficient number of total votes, an object is detected, centered at location C . The full object is then segregated by a 'back projection' step: all image descriptors that contributed their votes to the selected location are identified as components of the detected object. A final object/background decision is made by an automatically set threshold.

Results - Speed and Generalization In infants, even a few seconds of observing an object in motion already affects subsequent segregation of the same object in static images (e.g. Needham, \& Baillargeon 1998). The segmentation is effective for images of the same or similar object and generalizes gradually to less similar objects (Needham, \& Baillargeon 1998, Needham \& Modi 1999). Object-based segregation in the model showed similar characteristics. Brief ( 5 seconds) training was sufficient for learning object segregation of a specific object in subsequent parts of the movie, with some generalization to a different pose and different background. The object is often grouped by motion with the holding hand; the two can be separated when the hand is learned as an object on its own (Ullman et al. 2012). Figure 2 shows example segregations.

Figure 3: Detecting object boundaries. Left: Original image, with object-based segregation. Object is located, but boundaries are inaccurate. Center: Detection of boundary features. Warm colors indicate figure side of boundary, cold colors - ground side. Both object and background were not seen during training of boundary detector. Right: Combining object-based segregation with boundary detections. Object is detected with correct boundaries.

Results were tested by learning an object model in each movie using 5 sec and 40 sec segments, and testing on both later parts of the same movie, as well as the same object in other movies, with different backgrounds and larger variations in pose and lighting. Agreement between the true object (extracted by motion) and the model segregation were measured by the standard score $\mathrm{s}=|T \cap S| /|T \cup S|$, where T is the true object and S the segmented. Mean scores for 5 -sec training were $\mathrm{s}=0.3 \mathrm{vs} .0 .23$ on same vs. different movies, and for $40-\mathrm{sec}$ training $\mathrm{s}=0.49,0.36$ respectively. Effects of training time and generalization are highly significant (1-tailed t-test, $n=1200, p<10^{-6}$ in all comparisons).

The object-based segregation in the model segregates the general object region but it does not accurately delineate the boundaries. Since the object is represented by local appearance patches, it is sensitive to texture properties inside the object, in agreement with infant's object-based segregation (Needham \& Modi, 1999). In contrast, the model shows limited accuracy around object boundaries; it will be interesting to test this prediction in infants' vision (see discussion).

## Learning Boundary Features

The accurate delineation of boundaries is important for interacting with objects, e.g. for grabbing, finding free space to place them, etc. This is obtained in the model by a second mechanism, which uses motion discontinuities to learn static cues for occluding boundaries, as described next.

Learning Process To learn useful boundary features, motion discontinuities are used to guide the extraction of static boundary features and their figure-ground labeling. The learning procedure is simple, proceeding along the following stages. In each frame of the training movies, motion discontinuities are detected, and at each pixel along the boundary, image patches are extracted at 5 different sizes (ranging from $12 \times 12$ pixels to $60 \times 60$ pixels). Each patch is represented by a rotation invariant SIFT descriptor, producing a fixed-size descriptor regardless of original patch size. The motion signal is also used to label the figure part (which is moving in the training images) and background part (which is stationary) in each stored patch. From these, a subset of boundary patches is later selected, as described in the Results section below.

Use In Static Images The learned boundary features are then used to identify likely object boundaries in novel static images. Given a static input image, local SIFT features are extracted at the same 5 sizes, densely over the entire image. For each feature, its 25 nearest neighbors in the stored set of trained boundary features are extracted (using a fast approximation algorithm, Arya \& Mount 1993). These neighbors are used to estimate the likelihood of an object boundary at this location, and to identify the figure side of the potential boundary. Specifically, each neighbor i has a SIFT descriptor $D_{i}$ and an object direction $\theta_{i}$. For an image patch with descriptor $D$, we define the predicted object direction $\theta$ and a score $S$ as follows:

Figure 4: 25 examples of top-scoring boundary detection features, chosen by cross validation testing over 48 folds. Individual features are not reliable on their own - it takes at least 1,000 features to get good predictions (see text).

$$
\begin{gathered}
v=\sum_{i=1}^{25} e^{-\frac{\left\|D-D_{i}\right\|_{2}^{2}}{2 \sigma^{2}} v_{i},} \quad v_{i}=\left[\begin{array}{c}
\cos \theta_{i} \\
\sin \theta_{i}
\end{array}\right] \\
\theta=\operatorname{atan} 2(v), \quad S=\|v\|_{2}
\end{gathered}
$$

Where atan2 is a 4-quadrant arctangent function. $\sigma$ is set to 0.25 . $\theta, \mathrm{S}$ are then used to estimate the figure/background direction at the patch in question. Estimations of all patches are added together weighted by $S$ and smoothed by a spatial Gaussian function (positive in the figure, negative in background side). This yields a single total figure-score at each image location, where a positive score is likely to be the figure side of an object boundary.

Results Examples of boundary detection are shown in Figure 3. We used statistical testing to compare the density of boundary features in a region ( 10 pixels) around object boundaries compared with inside the object and on the background. Density was significantly higher around the boundaries compared with internal or external regions. In contrast, object-based segregation produced higher density in internal regions compared with boundary or external regions (1-tailed t-test, $n=1200 \mathrm{p}<10^{-6}$ in all comparisons).

Types And Number Of Boundary Features Psychophysical and computational studies of boundary features have suggested several types of informative boundary features, including: interposition (T-junctions), surface junctions, such as Y-junctions and arrow-junctions, and extremal edges, or folds, (Geisler et al. 2009, Ghose \& Palmer 2010) coming from the projection of an occluding edge curving smoothly in 3D, typically creating a highlight or shadow along the curving edge.

The current study used automatically labeled object boundaries, identified by motion discontinuities.

Figure 5: Object segmentation with the GrabCut algorithm. Left: Segmentation produced by the algorithm using default initialization. Right: Segmentation results with initialization by our segregation score maps.

Consequently, it became possible to extract and study a much richer set of boundary features compared with previous studies that used human annotated boundaries (Geisler et al. 2009, Fowlkes et al. 2007). The learning process produced a rich and varied set of boundary cues. Their analysis revealed the following properties. (i) Individual boundary features are probabilistic in the sense that they contribute information to the correct figure direction, but individual features are usually not definitive on their own. When training on 100,000 boundary features, the correct figure side is predicted in novel boundary features $78 \%$ of the times. (ii) Boundary features are consistent across image sets and are therefore useful for generalization to novel images. Our testing was done in 48 cross-validation folds, each time testing one movie, and excluding all movies with the same object or background from training data. (iii) There is a large set of useful boundary features, and using a restricted subset is less accurate than using the larger set. We selected the best performing features by cross-validation folds, and tested sets of different sizes, yielding $75 \%$ accuracy for 10,000 patches, $71 \%$ for $1,000,65 \%$ for $100,54 \%$ for 50 . Nonetheless, the improvement diminishes for very large sets, suggesting that saturation may be reached at some point, and there is no need to memorize every observed feature. Exploring mechanisms of feature retention is left for future work. (iv) Among the top-scoring boundary features (examples in Fig. 4) there is a significant fraction that can be labeled 'extremal edges'. These have only recently been found to play a crucial role in human vision (Ghose \& Palmer 2010), and have not been tested in infants' object segregation. Our model focuses on learning boundary features, and does not model their integration within a fully functional segregation system. To illustrate their contribution we therefore used them as input to an existing algorithm (GrabCut, Rother et al. 2004); results are
illustrated in Figure 5. The figure shows performance of the algorithm in its standard form (left), and the same algorithm when supplied with our object and boundary scores.

## Discussion

The model demonstrates how static object segregation can be learned effectively guided by two motion based mechanisms known to be innate or early learned in infants' vision: grouping by common motion and sensitivity to motion discontinuities.

These mechanisms are used by the model for two complementary goals: common motion is used for objectbased segregation, and motion discontinuities are used for learning static occlusion cues. In agreement with infants learning, the learning of object-based segregation by the model is fast, with initial sensitivity to details of the object's internal texture. It identifies well the region of the object with reduced accuracy near the boundaries. Boundary cues require more prolonged learning, but they appear to generalize broadly to novel object images. The set of useful boundary features found by the model is large and varied, including a major contribution from extremal edges, which have played a limited role in modeling so far.

The results of the study suggest a number of interesting directions for further research. In terms of infant studies, it will be of interest to test their capacity for object segregation based on extremal cues, which, to the best of our knowledge have not been tested so far. Another prediction that can be tested is whether object-based segregation by infants, which is sensitive to internal texture, will exhibit insensitivity to the object's boundary. Computationally, it will be interesting to compile a large set of useful boundary features that could be used by future segmentation algorithms. Finally, since scene segmentation in natural images is still a challenging open problem, it will be of interest to extend the current approach and examine whether following human development, by letting object segregation (including cues not considered in the current model) be guided and learned using dynamic cues, could lead to the emergence of models approaching human segregation capacities.

#### Abstract

Standard working memory (WM) updating tasks confound updating requirements with generic WM functions. We introduce a method for isolating a process unique to WM updating, namely the removal of no-longer relevant information. In a modified version of an established updating paradigm, to-be-updated items were cued before the new memoranda were presented. Longer cue-stimulus intervals-that is, longer removal time-led to faster updating, showing that people can actively remove information from WM. Well-established effects of item repetition and similarity on updating RTs were diminished with longer removal time, arguably because representational overlap between out-dated and new information becomes less influential when out-dated information can be removed prior to new encoding. The benefit of removal time was found only for partial updating, not for complete updating of entire memory sets. We conclude that removal of out-dated information can be experimentally isolated, and that removal is a unique, active WM updating process.

Keywords: Working memory updating; Executive functions
Imagine you ask a colleague for his phone extension and he replies: "It's 3266 . No, hang on, in my new office it's 3257 ." Ideally, one should easily discard the last two digits of the outdated information (i.e., " 66 ") and replace them in working memory (WM) with the correct digits (i.e., " 57 "). However, this updating of WM content is no trivial task, and outdated information often continues to affect WM (Oberauer, 2001).

WM updating has been identified as one of three primary executive processes (Miyake, Friedman, Emerson, Witzki, \& Howerter, 2000). Updating has been claimed to be the only executive process to predict fluid intelligence (Friedman et al., 2006). However, most updating tasks used in previous research (e.g., Miyake et al., 2000) not only require WM updating but arguably also measure general WM abilities. This has led some to conclude that updating tasks constitute reliable assays of general WM capacity (Schmiedek, Hildebrandt, Lövdén, Wilhelm, \& Lindenberger, 2009).

This creates an unsatisfactory situation. If WM updating tasks measure just the same as other WM tasks such as complex span tasks, then why call them updating tasks? Both conceptually and theoretically, updating can be distinguished from maintenance and processing in WM. If updating is to be established as a non-redundant construct, it must be isolated and measured separately from other WM processes.

In a recent individual-differences study, we identified a processing component that was independent of general WM
capacity and unique to situations that demanded WM updating (Ecker, Lewandowsky, Oberauer, \& Chee, 2010). In that study we analyzed the processing components involved in widely used WM updating tasks, and we identified three separable components: retrieval, transformation, and substitution. Ecker et al. found that retrieval and transformation operations co-varied with general WM capacity, but that the substitution component did not. We thus argued that substitution is the only process that uniquely represents WM updating, without being "contaminated" by any association with WM. One implication of this analysis is that previous studies measuring WM updating did not separate variance unique to updating from the variance of generic WM processes.

In this article, we further decompose the components of WM updating. In Ecker et al. (2010), we suggested that information substitution can be further subdivided into the removal of outdated information and the encoding of new information. As encoding is a simple and generic operation involved in many cognitive tasks, we argue that it is the removal process that lies at the heart of memory updating. Accordingly, we focus on the removal of information from WM. Here we show that removal of outdated information can be separated experimentally from encoding of new information.

Our removal measure is based on the work of Kessler and Meiran (2008). In the updating paradigm they used, items (e.g., letters or digits) are presented in a set of individual frames. Items are then repeatedly updated by presenting new items in some frames. On each updating step, between one and $n$ items are updated, where $n$ is the memory set size (equal to the number of frames). Participants had to press a key at the end of each step to indicate that they finished updating.

Kessler and Meiran (2008) proposed a distinction between local and global updating. Local updating refers to changes made to individual items, whereas global updating refers to the integration of all items in the current memory set after individual items were changed. A key piece of evidence for this distinction comes from the observation (Experiment 3 in Kessler \& Meiran, 2008) that updating RTs increased with the number of to-be-updated items up to $n-1$ items, but updating was much faster again when all $n$ items were to be replaced on a given step. Thus, updating latencies depended in a nonmonotonic fashion on the number of to-be-updated items. Kessler and Meiran (2008) explained this non-monotonicity
by assuming that partial updates require a complex sequence of (1) unbinding of the integrated representation of the previous memory set, (2) substitution of some but not all items (i.e., the actual local updating), followed by (3) re-binding the new set as part of the global updating process. In contrast, when the entire set is updated, steps (1) and (2) can be omitted, the old set is simply discarded and a new memory set is encoded and globally updated.

Our interpretation of the non-monotonicity of updating latencies is a specific instantiation of the ideas of Kessler and Meiran (2008), motivated by a computational model of WM, SOB (Lewandowsky \& Farrell, 2008). SOB is a two-layer neural network in which items (represented in one layer) are associated to position markers (represented in the other layer) through Hebbian learning, which rapidly modifies the matrix of connection weights between the two layers. In the present updating paradigm, the position marker would represent the location of the item's frame on the screen. Forgetting in SOB is entirely based on interference; there is no time-based decay. To avoid overloading of the system in the absence of decay, an interference model requires a mechanism to remove outdated information; such a mechanism is implemented in the most recent version of SOB (see Oberauer, Lewandowsky, Farrell, Jarrold, \& Greaves, 2012). Removal of a specific item involves retrieving that item by cueing with its position marker, and "unlearning" the association between that item and its position. Unlearning is computationally implemented as Hebbian anti-learning. Thus, in SOB the idea of "unbinding" (cf. Kessler \& Meiran, 2008) refers specifically to the unbinding of selected items from their position markers. Both encoding and removal of individual items take time (cf. Oberauer, 2001). By contrast, wholesale removal of an entire memory set can be achieved by simply resetting the entire weight matrix, which we assume to be a very rapid process. This explains why updating the entire memory set is faster than partial updating.

In SOB, removal of old information and encoding of new information are described as two separate processing steps. It follows that updating should be facilitated if a cue about what information needs to be removed is given ahead of the to-be-encoded new information. In standard WM updating tasks-including the one used by Kessler and Meiran (2008)—removal can only begin when the new item(s) are presented. For example, when updating the telephone extension from from 3266 to 3257 , one can only begin removing the " 66 " when given the " 57 ". Hence updating times in such a task will include both time for removal and time for encoding. In our new updating task we present cues indicating which items are to be updated before presenting the new to-be-encoded stimuli. People can use the cue only to selectively remove old items from the memory set, not to encode new information. By varying the cue-stimulus interval, we vary the available time for removal. If longer available removal time leads to faster updating RTs, people must have used the cuestimulus interval for removal or unbinding. We tested this
idea in a series of four experiments.

## Experiment 1

In Ecker et al. (2010), we found that repeating (i.e., maintaining) an item during an updating task carries a benefit of nearly 400 ms . Experiment 1 tested the idea that this benefit should diminish when people are given the opportunity to remove outdated information before encoding the (identical) updated item.

## Method

Experiment 1 used a letter updating task in which each trial consisted of an encoding stage, an updating stage with multiple updating steps, and a final recall stage. Participants encoded 3 letters, presented simultaneously in individual frames. This was succeeded by an unpredictable number of updating steps; each updating step involved only a single, randomly selected letter. In most cases, the outdated letter was replaced with a new letter, but sometimes the letter repeated. Each update was cued before the new letter was presented (the respective frame turned red and bold). Presentation time of this cue-henceforth referred to as removal time-was either 200 ms or 1500 ms . The longer cue should be sufficient time for removal, whereas the shorter cue should be just enough time to focus attention on the to-be-updated frames without permitting removal. After each updating step, the frames were blanked for 500 ms or 1800 ms in the long and short removal-cue condition, respectively, ensuring equal retention intervals in both conditions. The experiment had a 2 (repetition no/yes) $\times 2$ (removal time: short/long) withinsubjects design.

Participants We tested 15 participants, mainly students from the University of Western Australia (UWA).

Apparatus \& Procedure The experiment was controlled by a MatLab program. There were 32 trials, each featuring on average 9 updating steps (the number of updating steps ranged from 1 to 21 ). The probability of item repetition during updating was set at $p=0.15$. We chose this low rate of repetition to ensure that removal of outdated information was still an attractive strategy. At each updating step, participants were required to press a key when they had finished updating (max. response time was 5 s ). This updating RT was the dependent variable of main interest. At the end of each trial, participants were prompted to recall all three letters in random order.

## Results

Updating response time data are shown in Figure 1.
A $2 \times 2$ repeated measures ANOVA on updating RTs with the factors repetition (no/yes) and removal time (short/long) yielded a main effect of repetition, $F(1,14)=15.23, M S E=$ $0.03, p<.01, \eta_{p}^{2}=0.52$, a main effect of removal time, $F(1,14)=9.78, M S E=0.01, p<.01, \eta_{p}^{2}=0.41$, and crucially, a significant interaction, $F(1,14)=8.22, M S E=0.01$, $p=.01, \eta_{p}^{2}=0.37$. The interaction indicates that the effect of
repetition on updating RTs is larger with short removal (265 ms ) than long removal time ( 86 ms ).

Figure 1: Updating response times from Experiment 1. Vertical bars denote within-subject standard errors of the mean.

## Discussion

Experiment 1 demonstrated that the benefit of item repetition during memory updating (Ecker et al., 2010) is strongly reduced if participants are given sufficient time to remove outdated information prior to the encoding of the updated information. In a sense, if there is no time for removal, a condition with repeating items does not require true memory updating-the established item representation in WM can be maintained, no information needs to be removed and substituted-hence the time advantage of repetition. In contrast, to the degree that an item is removed from WM, the time taken to encode a new item into that position will no longer depend on the identity of the removed item. This result pattern supports our notion that active removal of information is integral to WM updating under normal conditions (i.e., when there is no opportunity to "outsource" the removal process.

## Experiment 2

Experiment 2 had a similar rationale. Previous research (Lendinez, Pelegrina, \& Lechuga, 2011) had shown that updating numbers is quicker when the new to-be-remembered number is similar to the outdated number. Experiment 2 tested whether this benefit would diminish if participants were given sufficient time to remove the outdated number before encoding the new number.

## Method

The task in Experiment 2 was very similar to Experiment 1, but it used two-digit numbers. During updating, about half the updates used similar and dissimilar numbers, respectively. This was achieved by manipulating both the proximity of numbers (proximal/distant) and the repetition
of one of the digits (yes/no). This resulted in four updating conditions, which had different probabilities of occurrence: proximal/repeating (e.g., updating from 18 to 19 ; $p=.15$ ), proximal/non-repeating (e.g., updating from 20 to $18 ; p=.15$ ), distant/repeating (e.g., updating from 59 to 19 ; $p=.15$ ), and distant/non-repeating (e.g., updating from 18 to 59; $p=.50$ ). Proximal updates ranged from -3 to +3 (excluding zero); distant/repeating updates were constrained to multiples of 10 , and distant/non-repeating updates used prime numbers from 13 to 83 . Filler updates with intermediate proximity ( $\pm 4-8$ ) were used with $p=.05$. Positive and negative updates were randomly intermixed (this was not considered an experimental factor). Removal time was again an additional factor (short/long).

Participants We tested 27 UWA students.
Apparatus \& Procedure The apparatus and procedure was identical to Experiment 1, with the exception that the experiments had 36 trials.

## Results

Updating response time data are shown in Figure 2.

Figure 2: Updating response times from Experiment 2. Vertical bars denote within-subject standard errors of the mean.

For the sake of simplicity, we collapsed the three 'similar' conditions into one, and ran a $2 \times 2$ repeated measures ANOVA with the factors similarity (low/high) and removal time (short/long). We found reliable main effects of similarity, $F(1,26)=11.38, M S E=.01, p<.01, \eta_{p}^{2}=0.30$, and removal time, $F(1,26)=101.43, M S E=.02, p<.001, \eta_{p}^{2}=$ 0.80 . Most importantly, these main effects were qualified by a significant interaction: the similarity effect was larger with short removal time ( 116 ms ) than long removal time ( 38 ms ), $F(1,26)=6.04, M S E=.01, p=.02, \eta_{p}^{2}=0.19$.

## Discussion

Experiment 2 demonstrated that a well-documented similarity effect in memory updating is diminished when participants
are given time to remove a to-be-updated item from memory before encoding the new item. This supports our notion of removal: We assume that the similarity effect in memory updating arises because of representational overlap between the replaced and the new item. That is, two similar numbers share a digit and/or a region in number space, and to the degree that only new features are substituted, not entire item representations, this similarity will facilitate updating. Yet, the more an item representation is removed before the updated number can be encoded, the less facilitation there will be.

Having established some support for our notion of removal, we now turn to a test of our prediction that an active removal process is only utilized during partial updates, not global updates (which unlike partial updates can be achieved more efficiently by 'wiping' memory, or in SOB terms, by resetting the weight matrix).

## Experiment 3

Based on the distinction between slow selective removal and fast resetting of the weight matrix, we predicted that longer removal times should lead to a substantial time gain in partial updating, but little gain on updating steps replacing the entire memory set.

In Experiment 3, the letter updating task was modified such that each updating step could update the memory set either partially or entirely (i.e., 1-, 2-, or 3-frame update).

## Methods

Participants Sixty-nine UWA undergraduates participated.
Apparatus and Procedure Apparatus and procedure were identical to previous experiments except that on each step, new letter(s) were presented in 1,2 , or 3 frames, and that there were 28 trials in total.

## Results

Updating response time data are shown in Figure 3.
A two-way repeated measures ANOVA on updating response times yielded a significant main effect of the number of updated frames, $F(2,136)=64.30, M S E=0.03, p<$ .001, $\eta_{p}^{2}=0.49$, a significant main effect of removal time, $F(1,68)=281.68, M S E=0.02, p<.001, \eta_{p}^{2}=0.81$, as well as a significant interaction, $F(2,136)=109.55, M S E=0.01$, $p<.001, \eta_{p}^{2}=0.62$. Planned contrasts showed that on average it took significantly longer to update two frames compared to one ( 1.44 seconds vs. 1.26 seconds; $F(1,68)=$ $146.29, M S E=0.02, p<.001$ ) and that with 1 or 2 frames, updating took significantly longer with short as compared to long removal time ( 1.53 vs. 1.17 seconds; $F(1,68)=320.14$, $M S E=0.03, p<.001$. However, updating three frames was relatively quick ( 1.23 seconds), and removal time had a negligible impact on updating time when all three frames were updated. While the removal time effect was statistically significant (arguably due to the large sample size and power; 1.26 vs. 1.20 seconds; $F(1,68)=13.59, M S E=0.01, p<.001)$,
it was much smaller with three frames than with one or two frames ( 53 vs .362 ms ).

## Discussion

The results of Experiment 3 support our hypothesis that partial updating of a memory set involves a process of active removal. "Bringing forward" this removal process by cueing the to-be-updated frames prior to presentation of the new items sped up partial updating substantially. This time saving of roughly $300-400 \mathrm{~ms}$ can be interpreted as the time that is required to remove information from WM.

In contrast, the opportunity to remove items from memory before presentation of new memoranda brought no substantial advantage when the entire memory set was updated. This finding supports our notion that memory can be cleared almost instantly, and that updating of an entire memory set does not require the time-consuming selective removal process.

The speed-up induced by the long removal cue did not increase with the number of to-be-updated items. This unexpected observation seems to imply that removing one item from WM takes as long as removing two items. There are two possible explanations. One is that removal of multiple items can occur in parallel. While this is a theoretical possibility, it is at odds with SOB's notion that items must be retrieved individually to be removed by anti-learning. ${ }^{1}$

The second explanation is that people use the removal time only to remove one item, even when two items are about to be updated. This might be an efficient strategy because itemspecific removal is likely to require the focus of attention, and switching the focus of attention to a new item takes time (cf. Garavan, 1998). Thus, the most efficient use of removal time

[^58]might be to focus on the first to-be-removed item and remove it, then wait. As soon as the new item(s) are presented, one of them can immediately be encoded in the currently focused frame. Only then would the focus move on to the second to-be-updated item (if there is one).

This interpretation is in line with a recent proposal by Kessler and Oberauer (2013), namely that partial updating also involves task-switching, which participants may likewise try to avoid. This notion assumes that, without substantial pre-cued removal time, participants scan the items from the beginning of the list to the end, starting in a maintenance mode (M). Hence, if the first item on the list is not updated, people might refresh that representation, then move to the next item. As soon as they encounter an item that requires updating, they switch to updating mode and actively remove that item from WM (U). Updating frames 1 and 3 would hence require 3 switches, (M)UMU; updating frames 1 and 2 two switches, (M)UUM; updating frames 2 and 3 one switch, (M)MUU. In the case of 1 -frame updates, updating frame 1, (M)UMM, and updating frame 2, (M)MUM, both require two switches, but updating frame 3 only requires one switch, (M)MMU. A strategy of scanning the list up to the first to-be-updated item, switching to updating mode, removing the item, and waiting would hence minimize both focusswitch and task-switch costs.

We applied multi-level regression analysis to the data of Experiment 3 to confirm the importance of task switching as specified above. We coded processes required at each updating step with the following parameters: The number of items to encode ( $\mathrm{E} ; 1-3$ ), the number of items to remove ( $\mathrm{R} ; 0-2$ ), and the number of task switches (SW; 0-3). Additional parameters were introduced in the modeling, including a wipe (W) parameter (coding the discarding of an entire memory set), and a refresh (RF) parameter (coding the number of non-updated, to-be-refreshed items). Importantly, coding differed for short and long removal time conditions. For example, with long removal time a two-frame update of frames 2 and 3 would involve no refreshing or switching: Participants could use the removal time to refresh the first item, switch to updating mode for frames 2 and 3 , remove the letter in frame 2, then wait to encode the new letter in frame 2 , and remove the old and encode the new letter in frame 3 ( $R F=S W=W=0 ; R=1 ; E=2$ ). In contrast, if removal time is short, participants would have to refresh the first item, switch once, remove two items and encode the two replacement items ( $W=0 ; R F=S W=1 ; R=E=2$ ).

A model including both removal and task switch parameters achieved the best fit; UpdatingRT $=704+156 * E+$ $87 * R+393 * S W-95 E * S W$, with a coefficient of determination $C O D=0.437$ and a Bayes Information Criterion $B I C=23403$. (BIC of the best-fitting model without removal parameter was 23475; according to Raftery (1996) this provides very strong evidence in favor of the removal model).

## Experiment 4

Experiment 3 suggested that people only remove one item even with long removal time. We argued this is in fact efficient behavior as it minimizes focus and task switch costs. Yet, an alternative hypothesis is that people would have removed more information had they had more time. Experiment 4 tested the idea that with sufficient removal time, people might remove more than one item, and thus show shorter updating RTs in conditions that would benefit from the removal of more than one item.

## Methods

Participants We tested 34 UWA undergraduates.
Apparatus and Procedure Apparatus and procedure were identical to Experiment 3 except for the addition of a third, very-long removal time condition (i.e., removal time conditions of 200,1500 , and 3000 ms ), and the omission of the full update condition (i.e., either 1 or 2 frames were updated with each updating step). There were 15 trials in total.

## Results

Updating response time data are shown in Figure 4.

Figure 4: Updating response times from Experiment 4. Vertical bars denote within-subject standard errors of the mean.

A $2 \times 3$ repeated measures ANOVA on updating RTs with the factors number of updated frames (1 vs. 2) and removal time (short/long/very long) yielded a main effect of frame number, $F(1,33)=71.66, M S E=0.03, p<.001$, $\eta_{p}^{2}=0.68$, a main effect of removal time, $F(2,66)=167.88$, $M S E=0.02, p<.001, \eta_{p}^{2}=0.84$, but no significant interaction, $F(2,66)=2.06, M S E=0.02, p>.10, \eta_{p}^{2}=0.06$. Results showed that it took longer to update two frames than one, and that more removal time led to faster updating RTs. However, the effect of removal time was strong when comparing the short ( 200 ms ) and long ( 1500 ms ) conditions, but negligible when comparing long and very-long ( 3000 ms ) conditions. The lack of interaction means that doubling re-
moval time did not lead to quicker updating, not even in the 2frame updates where performance could have benefitted from the removal of both to-be-updated items.

Applying the regression models (as specified in Exp. 3), we found that a simple model provided the best fit: UpdatingRT $=901+131 * R+255 * S W$, with $C O D=$ $0.38, B I C=6865$. (Note that the more complex model specified in Exp. 3 did explain more variance than this simple model when fit to the data of Exp. 4, but had a higher overall BIC. The BIC for the best removal-free model was 6880; this is strong evidence in favor of the simple removal model.)

## Discussion

Experiment 4 showed that in the present task people only removed one item in anticipation of an update, even when this update concerned more than one item. This supports our notion that people avoid focus and task switching when removing information from WM during updating.

## General Discussion

In this article we have introduced a novel measure of WM updating. Traditional WM updating tasks arguably measure general WM processes in addition to updating, whereas it is the removal of information from WM that is specific and unique to WM updating. We demonstrated that giving people preparation time to remove information from WM speeds up updating when new information is subsequently presented, but only when a subset of the memory set is updated. Updating an entire memory set does not benefit (much) from preparation time, arguably because-in line with the predictions derived from SOB (Lewandowsky \& Farrell, 2008; Oberauer et al., 2012)-the time-consuming removal process only applies to individual items, whereas an entire memory set can be removed by instant resetting of the weight matrix. Our notion of removal by unlearning item-position associations is a specific incarnation of the more general idea advanced by Kessler and Meiran (2008), who suggested that partial updating of memory sets involves "dismantling" or "unbinding" the old representations.

Whereas our research is guided by and supports the SOB model, it is important to note that other researchers have provided independent evidence for the existence of an active and attention-demanding removal process. For example, Fawcett and Taylor (2012) have shown that directed forgetting of an item (1) slows down responses on an unrelated secondary task for up to 2.6 seconds, and (2) impairs incidental memory for a subsequent distractor, in particular when the directed forgetting of the studied item is successful.

We assume removal to be crucial to maintaining a functional WM system that can efficiently focus on relevant information. Further research is needed to ascertain whether removal abilities co-vary with WM capacity, whether they predict intelligence-related variance, or whether they relate to other executive functions.

#### Abstract

Generating explanations and making comparisons have both been shown to improve learning. While each process has been studied individually, the relationship between explanation and comparison is not well understood. Three experiments evaluated the effectiveness of explanation and comparison prompts in learning novel categories. In Experiment 1, participants explained items' category membership, performed pairwise comparisons between items (listed similarities and differences), did both, or did a control task. The explanation task increased the discovery of rules underlying category membership; however, the comparison task decreased rule discovery. Experiments 2 and 3 showed that (1) comparing all four category exemplars was more effective than either within-category or between-category pairwise comparisons, and that (2) "explain" participants reported higher levels of both spontaneous explanation and comparison than "compare" participants. This work provides insights into when explanation and comparison are most effective, and how these processes can work together to maximize learning.

Keywords: Explanation; comparison; categorization; learning.

## Introduction

Explanation (i.e., answering "why" questions) and comparison (i.e., describing the similarities and differences between entities) are both powerful learning processes. Although they have typically been studied independently, they are often interconnected. Asking people to generate explanations can invite implicit comparison, and the patterns that people discover by comparing can motivate a search for explanations. For example, explaining why someone prefers coffee versus tea might lead one to identify similarities and differences between the two beverages, and comparing coffee and tea might provide insights into why a person would prefer one over the other. Explanation and comparison can also support similar ends: both promote abstraction and generalization, and both facilitate the discovery of patterns that are deep in a system's underlying structure (for reviews, see Gentner, 2010, on analogy and comparison; Lombrozo, 2012, on explanation).

Although explanation and comparison can generate similar effects, these two processes might rely on different cognitive mechanisms and exert different constraints on learning. Explanation has been hypothesized to improve learning through a variety of mechanisms, including an
increase in metacognitive awareness (Chi, 2010) and an increase in attention and engagement (e.g., Siegler, 2002), among others. In the context of category learning, generating explanations also enables learners to generalize beyond a specific set of observed data. In particular, Williams and Lombrozo (2010, 2013) proposed a subsumptive constraints account of how explanation impacts learning, whereby explaining leads people to interpret individual cases as part of a general pattern. As a result, explanation can help people unify multiple observations and focus on patterns with broader scope, increasing the discovery of rules that account for $100 \%$ of the data versus only $75 \%$ (Williams \& Lombrozo, 2010).

One mechanism by which comparison has been hypothesized to support learning is by promoting explicit structural alignment, leading people to focus on alignable differences between two entities (i.e., differences that are embedded in a common relational structure) (Gentner, 1983; Gentner \& Markman, 1997). Since comparison causes people to analyze these differences in the context of the common structure, comparison can illuminate deeper similarities and support the formation of an abstract relational schema, even (and especially) when the items being compared have surface differences (Gentner et al., 2009). For example, the analogy "an atom is like a solar system" highlights the fact that an atom consists of electrons orbiting around a nucleus, whereas a solar system consists of planets orbiting around the sun. Across a number of domains, comparing two examples that are superficially dissimilar but share a common relational structure supports transfer more effectively than studying the same examples separately (e.g., Kurtz, Miao, \& Gentner, 2001; Loewenstein, Thompson, \& Gentner, 2003).

Despite the abundance of research showing that explanation and comparison can (individually) enhance learning, few studies have investigated the effects of both explanation and comparison on the same experimental task. Kurtz, Miao, and Gentner (2001) found that comparing two analogous examples of heat flow helped participants discover similarities between the two examples more effectively than describing and explaining the same examples sequentially. Additionally, comparison was most effective when participants performed a task that involved listing which elements of the second scenario corresponded to specific elements of the first scenario. In another study, Nokes-Malach et al. (2012) found that introductory physics
students who explained the solutions to worked examples of physics problems achieved greater "near" transfer than participants who compared pairs of problems, but both groups performed similarly on "far" transfer and outperformed participants in a control condition. While these studies provide valuable insights into the conditions under which explanation and comparison are most effective, many questions remain open.

The present studies examine whether and how explanation and comparison interact to support learning novel categories. Previous work using similar materials (alien robots) has found that relative to control conditions, participants prompted to explain why individual robots belong to particular categories are more likely to discover a categorization rule that accounts for all cases (Williams \& Lombrozo, 2010, 2013). The present studies extend this work by investigating whether having participants compare robots also facilitates category learning, and whether participants who perform both explanation and comparison tasks are more likely to discover categorization rules than participants who perform only one of these tasks.

We hypothesize that comparison and explanation play complementary roles in category learning. Comparison may be crucial for identifying similarities among members of the same category and differences between members of different categories. In contrast, explanation should encourage learners to seek broad patterns within and across categories, potentially drawing upon the similarities and differences identified through comparison. Very broadly, these hypotheses predict that participants should be more effective in discovering categorization rules to the extent that they both compare and explain, with explanation being especially important in discovering broad patterns.

Three experiments evaluated these predictions. In Experiment 1, participants were randomly assigned to study the robots in one of four ways: (1) explain why individual robots are members of a particular category, (2) compare pairs of robots that belong to the same category, (3) perform both the explanation and comparison tasks, or (4) engage in a "free study" control task. Experiments 2 and 3 evaluated the effectiveness of different types of comparison prompts: between-category pairwise comparison and "group" comparison, respectively. We included a "group" comparison prompt to see whether it would be more effective at improving participants' ability to integrate pairwise comparisons and detect broad patterns.

## Experiment 1

## Method

Participants One-hundred-sixty-one adults participated through the Amazon Mechanical Turk marketplace. An additional 56 participants were tested, but excluded because they failed a catch trial or had previously completed a similar experiment. Participants were paid for participation.

Materials The stimuli (see Fig. 1) were eight robots adapted from Williams and Lombrozo (2010, 2013). Four robots (AD) were classified as Glorp robots and the other four robots (E-H) were classified as Drent robots.

Figure 1: Robots used in Exp. 1-3
Four rules could be used to categorize robots as either Glorp robots or Drent robots. Two rules were " $100 \%$ rules" that could be used to categorize all eight robots and two rules were " $75 \%$ rules" that could be used to categorize six of the eight robots (i.e., two robots were anomalous with respect to each $75 \%$ rule). The four rules were as follows:
(1) Foot rule (100\%): All Glorp robots have feet with pointy bottoms; all Drent robots have feet with flat bottoms.
(2) Antenna rule ( $100 \%$ ): All Glorp robots have a right antenna (from the robot's perspective) that is longer than the left antenna; all Drent robots have a left antenna that is longer than the right antenna.
(3) Elbows/knees rule (75\%): Three out of four Glorp robots (A, B, D) have elbows but no knees; three out of four Drent robots (F, G, H) have knees but no elbows. One Glorp robot (C) has knees but no elbows and one Drent robot (E) has elbows but no knees.
(4) Body shape rule (75\%): Three out of four Glorp robots (A, B, C) have a rectangular body; three out of four Drent robots (E, F, H) have a round body. One Glorp robot (D) has a round body and one Drent robot (G) has a rectangular body.

The robots also differed in body color; however, there were no systematic category differences in body color.

Procedure The procedure consisted of a study phase followed by a rule-reporting phase.

In the study phase, each participant was assigned to one of four study conditions: (1) comparison only, (2) explanation only, (3) both explanation and comparison, or (4) free study. In every condition, all eight robots appeared on screen for the duration of the study phase, as shown in Figure 1. The total study time ( 640 seconds) was equal across conditions. The study prompts and procedures for each condition were as follows.

Comparison only condition: "What are the similarities and differences between Glorp [Drent] robot X and Glorp [Drent] robot Y?" Participants were given 160 seconds to perform each comparison. The comparisons were presented
in the following order: A and $\mathrm{B}, \mathrm{F}$ and $\mathrm{H}, \mathrm{C}$ and $\mathrm{D}, \mathrm{E}$ and G . This order was chosen so that the four robots that were consistent with respect to both $75 \%$ rules were studied before the four robots that were anomalous with respect to one of those rules, making it more likely that participants would learn the $75 \%$ rules in addition to the $100 \%$ rules.

Explanation only condition: "Try to explain why robot X is a Glorp [Drent] robot." Participants were given 80 seconds to provide an explanation. The explanations were requested in the following order: $\mathrm{A}, \mathrm{B}, \mathrm{F}, \mathrm{H}, \mathrm{C}, \mathrm{D}, \mathrm{E}, \mathrm{G}$. This matched the order in the comparison condition.

Both explanation and comparison condition: Participants responded to both the explanation and comparison prompts above. To ensure that all the conditions were matched for study time, participants were given 40 seconds to respond to each explanation prompt and 80 seconds to respond to each comparison prompt. The order of the explanation and comparison prompts was counterbalanced across participants. Participants performed both tasks sequentially for each pair (e.g., explain A, explain B, compare A and B) before moving on to study the next pair of robots. The study order was otherwise the same as in the other conditions.

Free study condition: "Write out your thoughts below as you learn to categorize Glorp [Drent] robot X." Participants were given 80 seconds to study each robot. The study order was the same as in the other conditions.

At the end of each study period, the screen automatically advanced to the next robot or pair of robots. Participants could not advance before the study period had elapsed.

After each 160 seconds, participants solved a simple math exercise (e.g., " $9+7$ "). These exercises were included as a "catch trial" to verify that participants' attention was not diverted to other tasks. Response time was recorded and participants who took more than one minute to answer a question were excluded from analysis.

In the rule-reporting phase, participants listed the patterns they noticed "that might help differentiate Glorps and Drents." These responses were classified by a coder who was blind to experimental condition. Twenty-five percent of the data was independently coded for reliability by a second blind coder; agreement for each experiment exceeded $95 \%$. For each pattern that participants discovered, they also indicated (1) how many of the eight study robots could be categorized using that pattern and (2) how many new Glorp and Drent robots (out of 100) could be categorized using that pattern. Because answers to these two questions were contingent on the participant having discovered a particular rule, the sample sizes were relatively small and these data are not discussed further.

After completing the rule-reporting phase, participants answered debriefing questions regarding the extent to which they (1) generated explanations and (2) made comparisons, regardless of the task instructions, using a numerical response on a 1-7 scale, where 1 indicated "not at all" and 7 indicated "all of the time." Participants were then asked whether they had previously completed a similar study and answered a "catch trial" adapted from Oppenheimer,

Meyvisb, and Davidenkoc (2009) to find out whether they were reading the instructions. Participants who reported previously doing a similar study and participants who failed the catch trial were excluded from analysis.

## Results and Discussion

We first considered whether study task influenced the total number of rules discovered. A $2 \times 2$ ANOVA with explain prompt (yes/no) and compare prompt (yes/no) as betweensubjects factors and total number of rules discovered (0-4) as a dependent measure revealed no effects of condition ( $p$ s $>.15)$. We thus considered whether discovery of the $100 \%$ and $75 \%$ rules varied across study conditions (see Fig. 2).

A log-linear analysis of explain prompt (yes $/ n o$ ) $\times$ compare prompt (yes/no) $\times$ discovered a $100 \%$ rule (yes/no) revealed that performing the explanation task made participants significantly more likely to discover at least one of the two $100 \%$ rules, $\chi^{2}(1)=21.4, p<.001$. Performing the comparison task had the opposite effect: participants were less likely to discover a $100 \%$ rule, $\chi^{2}(1)=5.90, p=$ .015. There was no significant interaction ( $p=.67$ ). A comparable analysis on discovery of a $75 \%$ rule (yes/no) found that performing the explanation task made participants less likely to report a $75 \%$ rule, $\chi^{2}(1)=11.3, p$ $<.001$, with no effect of the comparison task, $p=.75$.

Figure 2: Rule discovery by study condition in Exp. 1, showing the percent of participants discovering at least one rule of each type.

These findings challenge our predictions in that a comparison prompt actually impaired $100 \%$ rule discovery, and that explanation and comparison did not have additive benefits. The findings do support the idea that explanation and comparison exert distinct constraints on learning, but raise an important puzzle: why didn't comparison - which has been shown to have robust and beneficial effects in other domains - improve performance on this task? We analyzed participants' self-reported explanation and comparison to better understand why the comparison task impaired performance, and in particular, whether the study prompts were effective at promoting explanation and comparison processes as intended.

A $2 \times 2$ ANOVA with explanation task (yes/no) and comparison task (yes/no) as between-subjects factors and
amount of self-reported explanation as the dependent variable showed that participants who performed the explanation task reported more explanation $(M=5.83, S D=$ 1.46) than participants who did not $(M=4.36, S D=2.09)$, $F(1,154)=27.7, p<.001$. Additionally, participants who performed the comparison task reported doing less explanation $(M=4.75, S D=2.06)$ than participants who did not $(M=5.49, S D=1.73), F(1,154)=7.26, p=.008$. Selfreported explanation was positively correlated with the number of $100 \%$ rules discovered, $r=.34, p<.001$.

A $2 \times 2$ ANOVA with explanation task (yes/no) and comparison task (yes/no) as between-subjects factors and amount of self-reported comparison as the dependent variable showed that participants who performed the explanation task reported doing more comparison ( $M=$ 5.62, $S D=1.64$ ) than participants who did not $(M=4.69$, $S D=2.05), F(1,155)=10.2, p=.002$. However, performing the comparison task did not affect the amount of reported comparison (Comparison: $M=5.13, S D=1.92$; No comparison: $M=5.21, S D=1.89$ ). Self-reported comparison was positively correlated with the number of $100 \%$ rules discovered, $r=.22, p=.006$, but the effect was not significant after controlling for reported explanation.

Two factors might help explain why the comparison task did not support discovery of the $100 \%$ rules. First, the comparison prompt failed to boost overall comparison (as reflected in self-reports), and additionally decreased selfreported explanation, which was beneficial to learning. Second, the comparison prompt may have constrained the particular types of comparisons that participants performed in unhelpful ways, restricting them to within-category, pairwise comparisons at the expense of between-category comparisons or category-wide comparisons. In particular, previous work has shown that between-category pairwise comparison can be more effective than within-category pairwise comparison for learning feature-based categories (Higgins \& Ross, 2011). The subsequent experiments evaluated these hypotheses by investigating whether between-category comparison (Experiment 2) or "group" comparison (Experiment 3) would support greater rule discovery than within-category pairwise comparison.

## Experiment 2

## Method

Participants One-hundred-sixty-one adults participated in the study through the Amazon Mechanical Turk marketplace. An additional 54 participants were tested, but were excluded because they failed a catch trial or because they had previously completed a similar experiment. Participants were paid for their participation.

Materials The stimuli were those in Experiment 1.
Procedure As in Experiment 1, the procedure consisted of a study phase followed by a rule-reporting phase.

The study phase was identical to Experiment 1 with the following changes. First, the total study time was reduced from 640 seconds to 360 seconds, with the time allotted for each study prompt reduced proportionally. Second, each participant was assigned to one of four study conditions: (1) the Experiment 1 explanation task, (2) the Experiment 1 within-category pairwise comparison task, (3) a betweencategory pairwise comparison task, or (4) an explanation task in which participants alternated explaining Glorp and Drent robots. Conditions (3) and (4) are described below.

Between-category pairwise comparison task: "What are the similarities and differences between Glorp robot X and Drent robot Y?" The comparisons were performed in the following order: A and $\mathrm{H}, \mathrm{B}$ and $\mathrm{F}, \mathrm{C}$ and $\mathrm{G}, \mathrm{D}$ and E .

Between-category explanation task: This task was identical to the Experiment 1 explanation task except that the robot study order matched the between-category pairwise comparison task.

The rule-reporting phase was identical to Experiment 1. After the rule-reporting phase, but before the debriefing questions, participants completed a recognition memory task. However, performance was very poor and did not differ across conditions; this task is not discussed further.

After completing the memory task, participants answered debriefing questions regarding the extent to which they (1) generated explanations, (2) made within-category comparisons, (3) made between-category comparisons, and (4) described the features of individual robots, all regardless of the task instructions. As in Experiment 1, participants were asked if they had previously completed a similar experiment and answered a "catch trial" question.

## Results and Discussion

We first analyzed the total number of rules discovered (0-4) in a $2 \times 2$ ANOVA with study task (explain/compare) and study order (between/within) as between-subjects factors. The explanation task resulted in a marginal increase in the total number of rules discovered, $F(1,157)=3.62, p=.059$.

Figure 3: Rule Discovery by Condition in Exp. 2

A log-linear analysis of study task (explain/compare) $\times$ study order (between/within) $\times$ discovered a $100 \%$ rule (yes/no) found that participants who performed the explanation task were more likely to discover a $100 \%$ rule
than participants who performed the comparison task, $\chi^{2}(1)$ $=10.0, p=.002$ (see Fig. 3), with no effect of study order. An equivalent analysis on discovery of a $75 \%$ rule (yes/no) found no effect of condition, $\chi^{2}(1)=.57, p=.45$.

As in Experiment 1, we found that the explain prompt was successful in boosting self-reported explanation (relative to compare), $F(1,149)=26.9, p<.001$, but that the compare prompt was not effective in boosting self-reported comparison (between-category comparison + withincategory comparison). In fact, participants prompted to explain reported significantly higher levels of total comparison that participants prompted to compare, $p=.005$.

These results suggest that the poor performance of participants prompted to compare in Experiment 1 was not due to the restriction to within-category comparisons. Experiment 3 thus considers whether a broader withincategory comparison, one that focuses on all four items at once, might lead to better learning.

## Experiment 3

## Method

Participants One-hundred-ninety-three adults participated in the study through the Amazon Mechanical Turk marketplace. An additional 60 participants were tested, but were excluded because they failed a catch trial or because they had previously completed a similar experiment. Participants were paid for their participation.

Materials The stimuli were those in Experiments 1-2.
Procedure As in Experiments 1-2, the procedure consisted of a study phase followed by a rule-reporting phase.

The study phase was identical to Experiment 2 except that the four study conditions were as follows: (1) the explanation task from Experiments 1-2, (2) the withincategory pairwise comparison task from Experiments 1-2, (3) a group comparison task in which participants simultaneously compared all four robots in each category, or (4) a group explanation task. Conditions (3) and (4) are described below. As in Experiment 2, the total study time in each condition was 360 seconds.

Group comparison task: "What are the similarities and differences between the Glorp robots (Robots A-D)?" After participants responded to this prompt, they received a similar prompt for the Drent robots.

Group explanation task: "Try to explain why robots A-D are Glorp robots." After participants responded to this prompt, they received a similar prompt for the Drent robots.

The rule-reporting phase was identical to Experiments 1 and 2. After completing the rule-reporting phase, participants received the same debriefing questions as in Experiment 2. No memory task was included in this study.

## Results and Discussion

We first analyzed the total number of rules discovered (0-4) across each of the four study conditions. A one-way

ANOVA revealed a significant difference in number of rules discovered, $F(3,189)=4.74, p=.003$. A Tukey posthoc analysis showed that participants who performed pairwise comparisons discovered significantly fewer rules than participants who performed individual explanations ( $p$ $=.013$ ) or group explanations $(p=.005)$, and marginally fewer rules than participants who performed group comparisons ( $p=.068$ ).

Figure 4: Rule Discovery by Study Condition in Exp. 3
We next analyzed whether the proportion of participants who discovered at least one $100 \%$ rule varied across conditions (see Fig. 4). A log-linear analysis of study task $\times$ discovery of at least one $100 \%$ rule (yes/no) found a significant effect of study task on whether participants discovered a $100 \%$ rule, $\chi^{2}(3)=26.4, p<.001$. Additional log-linear analyses found no difference in performance between the group comparison, group explanation, and individual explanation conditions, $\chi^{2}(1)=4.12, p=.13$; however, the pairwise-comparison prompt was significantly less effective than the other three, $\chi^{2}(1)=22.3, p<.001$, including the group-comparison condition, $\chi^{2}(1)=6.86, p=$ .009. A log-linear analysis of study task $\times$ discovered a $75 \%$ categorization rule (yes/no) found that the study task did not affect whether participants discovered a $75 \%$ rule, $\chi^{2}(3)=$ $.54, p=.91$.

These results suggest that the pairwise comparison condition was relatively ineffective not because comparison is an ineffective category learning strategy more generally, but instead because participants in the pairwise comparison condition focused on a prescribed set of comparisons involving two items at a time. When it comes to category learning, it may be important to consider the global structure of categories to effectively assess the cue and category validities of different features.

## General Discussion

The present study investigated whether generating explanations and making comparisons would improve people's ability to discover rules that could be used to categorize a set of novel objects. All three experiments found that performing an explanation task enhanced discovery of categorization rules that could account for all cases; however, the effects of the comparison tasks were
more varied. Performing either within-category or betweencategory pairwise comparisons did not support rule discovery. However, comparing all the category exemplars in each group did increase $100 \%$ rule discovery.

Our results are consistent with previous work demonstrating that engaging in explanation supports learning. In particular, we replicate the results of studies that have used similar materials (Williams \& Lombrozo, 2010, 2013). In the present study, the explanation task succeeded in helping participants discover abstract patterns that unified each of the categories. Furthermore, the explanation task stimulated spontaneous comparison, allowing participants to reap the benefits of comparison even if they were not explicitly asked to compare.

Surprisingly, we find that under some conditions engaging in a pairwise comparison task can impair learning. However, other types of comparison, such as comparing all the exemplars in each category, did promote learning, suggesting that comparison can be an effective strategy for learning novel categories. But importantly, some comparison prompts are more effective than others (see also Rittle-Johnson \& Star, 2009), and comparison prompts may be most effective when they stimulate a broad range of comparison processes. One question for future research is whether the combination of within-category and betweencategory pairwise comparisons can in fact be beneficial, or whether "group" comparison provides unique advantages.

It is also worth pointing out some of the limitations of this study. Overall, the eight robots were highly similar and easily alignable. This might explain why spontaneous comparison was so common among participants who completed the explanation task. The high rates of spontaneous comparison make it difficult to differentiate effects of explanation from effects of comparison; the question of whether explanation and comparison exert unique constraints on learning may be easier to address with a task that more effectively isolates each process.

In future work, we hope to explore whether explanation and comparison have additive effects in more difficult learning tasks, where we also anticipate benefits to comparing (to align features) before explaining (to identify patterns). More research is needed, but the present studies provide important steps towards understanding the relationship between explanation and comparison and how these processes can most effectively support learning.

## Acknowledgments

We thank Dedre Gentner and members of the Northwestern University Language and Cognition Laboratory for valuable feedback on this work and Lena Lam for assistance with coding. #### Abstract

Several approaches to implementing symbol-like representations in neurally plausible models have been proposed. These approaches include binding through synchrony (Shastri \& Ajjanagadde, 1993), mesh binding (van Der Velde \& de Kamps, 2006), and conjunctive binding (Smolensky, 1990; Plate, 2003). Recent theoretical work has suggested that most of these methods will not scale well - that is, they cannot encode structured representations that use any of the tens of thousands of terms in the adult lexicon without making implausible resource assumptions (Stewart \& Eliasmith, 2011; Eliasmith, in press). Here we present an approach that will scale appropriately, and which is based on neurally implementing a type of Vector Symbolic Architecture (VSA). Specifically, we construct a spiking neural network composed of about 2.5 million neurons that employs a VSA to encode and decode the main lexical relations in WordNet, a semantic network containing over 100,000 concepts (Fellbaum, 1998). We experimentally demonstrate the capabilities of our model by measuring its performance on three tasks which test its ability to accurately traverse the WordNet hierarchy, as well as to decode sentences employing any WordNet term while preserving the original lexical structure. We argue that these results show that our approach is uniquely well-suited to providing a biologically plausible, human-scale account of the structured representations that underwrite cognition.

Keywords: knowledge representation; biologically plausible; scaling; neural; vector symbolic

## Introduction

One of the central challenges for contemporary cognitive modelling is scaling. As Jeff Hinton remarked in his address to the Cognitive Science Society, "In the Hitchhiker's Guide to the Galaxy, a fearsome intergalactic battle fleet is accidentally eaten by a small dog due to a terrible miscalculation of scale. I think that a similar fate awaits most of the models proposed by Cognitive Scientists" (Hinton, 2010). This observation can be taken as a challenge for cognitive modellers: Will the principles demonstrated in a small-scale cognitive model scale up to the complexity of a human-sized cognitive system? This scaling problem has often been thought to be a special challenge for biologically inspired approaches to cognitive modelling (Jackendoff, 2002). This is because the basic principles employed in such models often do not allow for a straightforward characterization of structured representations, despite the ubiquity of such representations in cognitive behaviour. This same concern is not as immediate for symbolicist approaches which typically take structured representations to be primitive (Anderson, 2007).

In this paper, we briefly review past connectionist approaches to addressing the problem of representing structure, and discuss recent criticisms of those approaches which suggest that they will not scale. We then present a new approach that we have developed that allows for the representation and manipulation of large-scale structured representations in anatomically and physiologically plausible models of brain function. In past work we have provided theoretical arguments suggesting that this approach will scale better than others (Stewart \& Eliasmith, 2011). Here, our focus is on empirically demonstrating that claim. We do so by encoding the central structural relations in WordNet into neural representations in a spiking network. We present the results of three experiments showing that 1 ) this information can be decoded for arbitrary lexical items, 2) lexical hierarchies of any depth within WordNet are successfully represented, and 3) these lexical representations can be combined to represent structured sentences with the same methods.

## Past Approaches

There have been many approaches to representing structure in connectionist networks. We consider three of the most successful: 1) binding through synchrony; 2) mesh binding; and $3)$ conjunctive binding.

The suggestion that structured cognitive representations could be constructed using binding through synchrony (Shastri \& Ajjanagadde, 1993) was imported into cognitive modelling from the earlier hypothesis that feature binding in vision can be accounted for by the synchronization of neurons in visual cortex (von der Malsburg, 1981). Recently, this approach has seen a revival in the DORA architecture (Doumas et al., 2008) and its variants, which focus on representing structures for analogical reasoning. In these models, the temporal relationships between connectionist nodes are employed to represent structured relations. Structured representations (e.g. bigger(Fido, Sarah)) are constructed out of four levels of representation, where nodes in higher levels represent more complex structures via their connections to nodes in lower layers. As has been argued in more detail elsewhere, this kind of representational scheme will not scale well (Stewart \& Eliasmith, 2011; Eliasmith, in press) because the number of nodes needed to support arbitrary structured representations over even small vocabularies (e.g. 6000 lexical items) is larger than the number of neurons in the brain.

Notably, this is not an issue with the use of synchrony per se, but rather with the the way binding has been mapped to network nodes. However, it has also been suggested that synchrony itself will not scale well to binding complex structures (Stewart \& Eliasmith, 2011; O'Reilly \& Munakata, 2000).

A different approach to structured representation has been taken by van Der Velde \& de Kamps (2006) in their work on the Neural Blackboard Architecture (NBA). To avoid the exponential growth in resources, the NBA employs "neural assemblies." These assemblies are temporarily bound to particular symbols using a mesh grid of neural circuits (e.g. bind(noun1, Fido)). Larger structures are then built by binding these assemblies to roles using a gating circuit (e.g. gate(agent1, bind(noun1, Fido))). Neural assemblies that bind roles and their gated word assemblies are used to define higher level structure assemblies which can be used to represent sentential structures. The use of temporary binding in this manner significantly reduces the resource demands of this approach compared to DORA. However, as argued in Stewart \& Eliasmith (2011) and demonstrated in more detail in Eliasmith (in press), just to represent simple sentences of the form relation(agent, theme) from a vocabulary of 60,000 terms, this approach requires about $480 \mathrm{~cm}^{2}$ of cortex, approximately one fifth of total cortical area. This is much larger than known language areas which account for both representation and processing of linguistic terms. Consequently, while the NBA has improved scalability compared to DORA, it remains implausible.

The final approach we consider is the class of proposals broadly called conjunctive coding approaches, or, more recently, Vector Symbolic Architectures (VSAs; (Gayler, 2003)). In general, these approaches propose some kind of nonlinear vector operation to bind two vectors together. The earliest and perhaps best known such approach is that proposed by Smolensky (1990), which employs the tensor product as the binding operation. The model presented in this paper employs a VSA which uses circular convolution as the binding operation (after Plate (2003)). The crucial difference between using the tensor product vs. using circular convolution is that for an n-dimensional vector, a tensor binding results in an $n^{2}$-dimensional vector, whereas the circular convolution binding results in an $n$-dimensional vector. This computational difference results in severe scaling differences when considering possible biological implementations. In particular, tensor products scale exponentially poorly as the depth of the structure increases. For example, Eliasmith (in press) shows that encoding a sentence where lexical items have hierarchical relations of depth two or greater (e.g. Sarah isA(person isA(mammal))) will require approximately 625 $\mathrm{cm}^{2}$ of cortex. Again, this is significantly larger than relevant language areas.

The above considerations suggest two main challenges for connectionist implementations of structured representations: lexical scaling and hierarchical scaling. Lexical scaling means having a lexicon that is as large as an adult hu-
man's vocabulary. Hierarchical scaling refers to being able to encode the depth of grammatical and lexical relations found in adult humans. Any method that claims to provide appropriate scaling will have to demonstrate success along both of these dimensions. The approach that we adopt in this work employs a neural implementation of a VSA which uses circular convolution for binding. The purpose of this paper is to demonstrate empirically that our approach successfully meets both of these challenges.

## Theoretical Approach and Methods WordNet

The target of our efforts - the human-scale knowledge base that we will be encoding - is WordNet, a manually constructed lexical database of the English language (Fellbaum, 1998). WordNet's design is intended to reflect the organization of concepts in a psychologically plausible way using a handful of common relationships. In WordNet words are divided into "synsets" or synonym sets of words that have the same meaning. Words that have multiple meanings are listed in multiple synsets, so the fundamental unit in WordNet is not a word but a word sense. Each synset is linked to other synsets by relations, of which there are several types. The two relation types that are of the most interest are hypernymy and holonymy. A hypernym of a concept is the general type of the concept (i.e. dog has the hypernym canine); a holonym of a concept is something that that concept is a part of (i.e. lock has the holonym door). These relations are explicitly encoded in the lexicon we employ. The inverse of the hypernym and holonym relations are also implicitly included in our encoding, although we do not test their extraction as this requires more complex control of signal flow that is beyond our present scope. The depiction of lexical relations found in WordNet is slightly simplified, though it is sufficient for our purposes; a complete description of the simplifications made can be found in Fellbaum (1998).

Each synset can be defined in terms of its relationships with other synsets. This means that a term such as dog can be defined as:

$$
\begin{equation*}
\operatorname{dog}=\text { isA }(\text { canine }) \text { and partOf }(\text { pack }) \tag{1}
\end{equation*}
$$

We will make extensive use of this type of representation in our model. We think of the relations in (1) as belonging to the dog synset, and pack and canine as the targets of the relations.

## Vector Symbolic Architectures

VSAs in general provide a means for representing structured knowledge using high-dimensional vectors. This makes VSAs amenable to neural implementation using the Neural Engineering Framework, which shows how to systematically use populations of spiking neurons to represent vectors and functions thereof (Eliasmith \& Anderson, 2003). In a VSA, each symbol to be represented is randomly assigned a high-dimensional vector. Two core operations are provided, each of which takes two vectors as input and returns a third.

Binding $(\circledast)$ two vectors returns a third vector that is disimilar to both of the original vectors. The superposition $(+)$ of two vectors returns a third vector that is similar to both of the original vectors. Here we employ a close relative of Holographic Reduced Representations (Plate, 2003), a type of VSA in which binding is implemented via circular convolution, superposition is implemented via vector addition and vectors representing symbols are randomly chosen from the D-dimensional unit sphere. The circular convolution returns a vector which has the same dimension as the two input vectors, which is a significant improvement over the tensor product VSA discussed in the Past Approaches section.

We can use these operations to encode graph-like structures such as WordNet. First we fix a dimension D for our vectors ( $\mathrm{D}=512$ in our model). Then each WordNet synset and each relation type is assigned a random vector on the D dimensional unit sphere called an ID-vector. Each synset is also assigned a second D-dimensional vector, built-up using the VSA operations, which stores the structural information about the synset. To construct this vector, for each relation belonging to a particular synset, we bind the ID-vector for the relation type to the ID-vector for the target of the relation. We then superpose the results from all the relations. The following equation demonstrates this process for the dog synset:

$$
\begin{equation*}
\operatorname{dog}=\text { isA } \circledast \text { canine }_{\text {ID }}+\text { partOf } \circledast \text { pack }_{\text {ID }} \tag{2}
\end{equation*}
$$

where all variables on the right-hand side are ID-vectors. We have disambiguated the two vectors assigned to a synset by denoting the ID-vector with the ID subscript. What makes (2) useful is that dog preserves information about its constituents; we can use a third operation, dereferencing, to determine what a given vector is bound to in dog. The dereferencing operation is performed by binding dog with the inverse of the given vector. As an example, imagine we want to extract the synset that the dog synset is related to via the isA relation type. We bind $\operatorname{dog}$ with $\overline{\mathrm{isA}}$, the inverse of the isA vector:

$$
\begin{align*}
& \operatorname{dog} \circledast \overline{\mathrm{isA}} \\
& =\left(\mathbf{i s A} \circledast \text { canine }_{\mathbf{I D}}+\text { partOf } \text {. } \text { pack }_{\text {ID }}\right) \circledast \overline{\mathbf{i s A}} \\
& =\text { isA } \circledast \text { canine }_{\text {ID }} \circledast \overline{\text { isA }}+\text { partOf } \not \text { pack }_{\text {ID }} \circledast \overline{\text { isA }} \\
& \approx \text { canine }_{\text {ID }}+\text { partOf } \circledast \text { pack }_{\text {ID }} \circledast \overline{\mathbf{i s A}} \tag{3}
\end{align*}
$$

Equation (3) shows that $\boldsymbol{\operatorname { d o g }} \circledast \overline{\mathrm{isA}}$ is canine ${ }_{\text {ID }}$ superposed with another vector which can effectively be regarded as noise. All that remains is to remove that noise, and we will discuss methods for doing so below.

We call vectors constructed in the manner of dog in (2) semantic pointers because they are a compressed representation of their constituents, and preserve similarity (i.e. semantic) relations in their compressed form. In addition, the dereferencing operation is similar to the dereferencing of pointers in programming languages. Semantic pointers have a wide range of uses; indeed, they are central to the Semantic Pointer

Architecture (Eliasmith, in press) which was used to create Spaun, currently the world's largest functional brain model, which is able to account for several perceptual, motor and cognitive behaviours (Eliasmith et al., 2012).

Now, given a semantic pointer representing a synset, we can traverse the connections between that synset and related synsets by dereferencing its semantic pointer with the IDvector of a relation type, obtaining a noisy version of the IDvector of the target of the relation, as demonstrated in (3).

After this initial dereferencing, we must still determine how to remove the noise from the vector returned by the dereferencing operation. Looking again at equation (3), we see that $\operatorname{dog} \circledast \overline{\mathbf{i s A}}$ is similar to canine ${ }_{\text {ID }}$ since it consists of canine $_{\text {ID }}$ superposed with a noise vector, and is dissimilar to the rest of the ID-vectors ( pack $_{\text {ID }}$, isA, partOf) since they are related to $\boldsymbol{\operatorname { d o g }} \circledast \overline{\mathbf{i s A}}$ via the binding operation. A cleanup memory, which returns the vector in a vocabulary which is most similar to a given input vector, is a potential solution to this denoising problem. However, we want our model to be able to traverse the full WordNet hierarchy, not just a single relation, and ID-vectors alone contain no structural information. We need to have some way to move from the ID-vector for a synset to its semantic pointer. We can perform both the denoising and mapping to semantic pointer in one step by using an associative cleanup memory rather than a pure cleanup memory. In short, we take the noisy ID-vector returned by the dereferencing operation and feed it into an associative cleanup memory mapping each synset's ID-vector to its semantic pointer, thus obtaining a clean semantic pointer which can then be used in further traversals.

## Neural Representation and Computation

Thus far we have described VSAs and how they can be used to encode structural knowledge such as WordNet, but have not yet said anything of how to implement them in neurons. For this purpose we turn to the Neural Engineering Framework (NEF), a set of methods for building biologically plausible models using principles for neural representation, computation and dynamics (Eliasmith \& Anderson, 2003). The central idea behind the NEF is that a group of spiking neurons can represent vectors over time, and that connections between groups of neurons can compute functions on those vectors. More precisely, a group of neurons represents any of a set of vectors, that is, a vector space. The NEF provides a set of methods for determining what the connections need to be to compute a given function on the vector space represented by a group of neurons. Suppose we wish to compute the function $y=f(x)$, where vector space $x$ is represented in population A , and vector space y is represented in population B. To do so, the NEF assumes that each neuron in A and B has a "preferred direction vector." The preferred direction vector is the vector (i.e. direction in the vector space) for which that neuron will fire most strongly. Consequently, the spiking activity of every neuron in a population A can be written

$$
\begin{equation*}
a_{i}(x)=G\left[\alpha_{i} e_{i} x+J_{\text {bias }}\right] \tag{4}
\end{equation*}
$$

where $a_{i}$ is the ith neuron in the population, $G$ is the spiking neural nonlinearity, $\alpha_{i}$ is the gain of the neuron, $e_{i}$ is the preferred direction (or encoding) vector, and $J_{\text {bias }}$ is a bias current to account for background activity of the neuron. The elements in the square brackets determine the current flowing into the cell, which then drives the spiking of the chosen single cell model $G$. For computational efficiency, we employ a leaky integrate-and-fire (LIF) neuron model, though the NEF can be applied for arbitrary neuron models. Equation (4) is referred to as an encoding equation because it describes how a vector space, in this case $x$, is encoded into neural spikes. The NEF assumes a least-squares optimal linear decoding to reconstruct x or any nonlinear function thereof, $\mathrm{f}(\mathrm{x})$. Thus, we must find the decoders $d_{i}^{f}$, such that

$$
\begin{equation*}
E=\frac{1}{2} \int\left[f(x)-\sum_{i} a_{i}(x) d_{i}^{f}\right]^{2} d x \tag{5}
\end{equation*}
$$

is minimized. Finding the decoders in this manner then provides us with a way to estimate any vector $\mathrm{f}(\mathrm{x})$ given the activities from the encoding equation. We can write this as the decoding equation:

$$
\begin{equation*}
\widehat{f(x)}=\sum_{i} a_{i}(x) d_{i}^{f} \tag{6}
\end{equation*}
$$

where N is the number of neurons in the group and $\widehat{f(x)}$ is the estimate of $f(x)$ where $x$ is the input driving the neurons. Recall that our purpose in defining the representation of a vector space in a neural population is to use it to compute a function between two populations. If we define the encoding and decoding for groups A and B using equations (4) and (6), we can substitute the decoding of $A$ into the encoding of $B$, thereby deriving connection weights. In addition, if the function we wish to compute is linear, we can include the relevant linear operator in the weight equation. The weight equation for computing any combination of linear and nonlinear functions is then:

$$
\begin{equation*}
\omega_{i j}=d_{i}^{f} \alpha_{j} L e_{j} \tag{7}
\end{equation*}
$$

where $i$ indexes the neurons in group A and $j$ indexes the neurons in $\mathrm{B}, \mathrm{f}$ is any nonlinear function and L is any $D_{B} \mathrm{x}$ $D_{A}$ linear operator, where $D_{A}$ and $D_{B}$ are the dimensionalities of the two vector spaces.

It is worth noting that these representations and computations can be implemented to any desired precision, by adding enough neurons. Specifically, the root mean-squared-error goes down as $1 / \mathrm{N}$ (Eliasmith \& Anderson, 2003). One of the main concerns of this paper is to demonstrate that the operations required for representing human-scale lexical structure can be done with a reasonable number of neurons.

It is straightforward to use the NEF to create networks of spiking neurons for computing the inverse and circular convolution operations (Eliasmith, 2005). However, neurally implementing an associative memory requires a specific application of these methods, which we will outline in the next section.

## Neural Associative Memory

There are several ways in which associative memories can be implemented (see (Lansner, 2009) for a review). Recently, (Stewart et al., 2010) used the NEF to construct an efficient, fast autoassociative (a.k.a. cleanup) memory out of spiking neurons, and this approach can be trivially extended to construct an associative memory. Moreover, they demonstrate that this approach significantly outperforms a linear associator, a direct function approximator and a standard multi-layer perceptron. However, that paper only considers lexicons up to 10,000 items, and does not discuss any actual lexical processing, as is our focus here.

Given a noisy version of an ID-vector as input, we want our associative memory to output a clean version of the corresponding semantic pointer. A simple algorithm that achieves this is to take the dot product of the input vector with each of the ID-vectors in the vocabulary, threshold these values (set to 0 all values below some fixed threshold), multiply each semantic pointer vector by its corresponding thresholded value, and add all the resultant vectors together to obtain a single D dimensional vector. If the input vector is only similar to one of the ID-vectors, then all of the dot products will be thresholded except for one and the output vector will be equal to the correct semantic pointer.

We can use the NEF to implement this algorithm in spiking neurons as follows. Assign each synset a small ( $\sim 20$ ) population of neurons. Then we set the preferred direction vector of each neuron equal to the ID-vector for the synset that the neuron is assigned to. Equation (4) shows the activities of each population can be seen as encoding the similarity between the input vector and the population's assigned ID-vector. To determine the weight matrices between these populations and the output population, we first minimize equation (5) with $f$ set to a thresholding function to find optimal decoders, and then substitute these into equation (7) with $L$ set to semantic pointer of the population's assigned synset. Thus, the output of a population with ID-vector $e$ and semantic pointer $s$ is a neural reconstruction of $\operatorname{threshold}\left(x^{T} e\right) \cdot s$. Summing the output of all the association populations is implicitly performed by the dendrites of the neurons in the output population.

## The Model

The core of the model is a network of spiking neurons, constructed using the techniques outlined above, which, given a semantic pointer corresponding to a WordNet synset and a query vector corresponding to a relation type, returns the semantic pointer corresponding to the target of the relation. This network can be used to traverse the WordNet hierarchy by running it recursively, with the output of the last run used as input on the next run. The tasks of moving the output into the input, controlling which relation goes into the query vector population, etc, are not investigated here as they are peripheral to our central concern of representing human-scale structured knowledge in a biologically plausible manner.

A schematic diagram of the model is depicted in Fig-

Figure 1: The network of spiking neurons that traverses the WordNet graph. Assume $S=R \circledast T_{I D}+U \circledast V_{I D}$ where R, $T_{I D}$, U , and $V_{I D}$ are all ID-vectors and T is the semantic pointer corresponding to $T_{I D}$. All nodes represent neural populations.
ure 1 . The nodes correspond to populations of spiking neurons which represent and manipulate 512-dimensional vectors. All neurons employ the leaky integrate-and-fire neuron model. Each time the model was run to perform a single edge traversal, it was simulated for 100 ms with a simulation timestep of 1 ms , after which the vector represented by the Output population was taken to be the output of the model. The Binding node, which performs a circular convolution between two vectors, contains 51,400 neurons, and each of the other 4 nodes outside the associative memory contain 25,600 neurons. The associative memory contains 117,659 populations, one for each WordNet synset, with 20 neurons each, resulting in a grand total of $2,506,980$ neurons. This is equivalent to approximately $14.7 \mathrm{~mm}^{2}$ of cortex, much smaller than previous neural approaches to structured representation, which required on the order of $500 \mathrm{~cm}^{2}$ cortex (as there are about 170,000 neurons per $\mathrm{mm}^{2}$; (Eliasmith, in press)).

## Experimental Results

We performed three experiments on the model to test different aspects of its performance. For each experiment, a trial consists of using the network to answer a single question about the WordNet graph (the question is different for each experiment). A run consists of a group of trials. For each experiment we perform some number of runs, calculate the performance on each run as the percentage of trials on which the model answered correctly, and report the mean performance over all the runs. We employ a bootstrapping method to obtain $95 \%$ confidence intervals on the mean performance. This data can be seen in Table 1. The model was perfectly successful on Experiment 1, and nearly so on Experiments 2 and 3.

## Experiment 1: Decoding Accuracy

This test investigates how many of the 117,659 concepts in the WordNet can be accurately decoded. For this experiment, we present the model with a semantic pointer corresponding to a randomly chosen synset and an ID-vector corresponding to a relation type, and see if the model returns the semantic pointer corresponding to the target of that relation. For example, we might present the network with the semantic pointer for $\mathbf{d o g}$ and the ID-vector for the relation isA and see if the
network returns the semantic pointer for canine. To be considered correct, the returned vector must have a larger dot product with the correct semantic pointer than with any incorrect semantic pointer in the vocabulary, and this dot product must pass a threshold of 0.7. We ran 20 runs, each of which consisted of 100 trials, amounting to 2000 edge traversals.

## Experiment 2: Hierarchy Traversal

This experiment is designed to test the model's ability to traverse the network to arbitrary depth. To that end, we use the model to answer the following question: given two synsets and a relation type, can the second synset be reached from the first synset solely by following links of the specified type? We present the model with the semantic pointer corresponding to the first synset as well as the ID-vector for the given relation type. Then we run the model, and compare the output vector to the semantic pointer for the second synset. If they are the same (their normalized dot product is above a fixed threshold), then the model responds with a Yes. If not, we feed the output vector back into the model as the new semantic pointer and run the model again. This process is repeated until the model returns a vector with a norm below a fixed threshold. If the model reaches this point, it responds with a No. Here it is especially important that the decoded semantic pointer be very similar to the correct semantic pointer since we recursively use the output, and large errors would build up with successive edge traversals. Our tests were performed using only the isA relation type as it is the most prominent in WordNet and permits the deepest traversals. We ran 20 runs, each consisting of 20 positive examples (the second synset could be reached in the actual WordNet graph), and 20 negative examples.

Table 1: Experimental Results

| Experiment | \% correct | 95\% CI |  |
| :--- | :--- | :--- | :--- |
|  |  | $10 w e r$ | upper |
| 1. Decoding Accuracy | 100.0 | 100.0 | 100.0 |
| 2. Hierarchy Traversal | 95.5 | 94.3 | 96.9 |
| 3. Sentence Encoding | 99.6 | 99.3 | 99.8 |

## Experiment 3: Sentence Encoding

The final experiment we performed was designed to confirm that this method of knowledge representation is flexible enough to allow concepts to bind to arbitrary roles while still encoding the thousands of relationships between themselves. To this end, we test whether the network can accurately decode a crude approximation of a sentence, consisting of synsets bound to one of six different roles. To build a sentence, we randomly choose roles for inclusion, each with a different probability, and then synsets are randomly chosen to fill the selected roles. Each role type is assigned an ID-vector, in the same way that ID-vectors are assigned to relation types. A semantic pointer for the sentence is created by binding synset ID-vectors to role ID-vectors in the usual way. We then present the network with the semantic pointer for the sentence and the ID-vector for a role, and see if the vector it outputs is the same as the semantic pointer for the concept filling that role in that sentence. To determine the correctness of a particular decoding, we used the same criteria as in Experiment 1. We ran 20 runs, each of which consisted of constructing 30 sentences and asking the model about each role therein, amounting to 2411 edge traversals.

## Conclusion

These empirical results demonstrate that our spiking neural network can accurately represent structured knowledge representations approaching the scale of those found in an adult human. Moreover, our's is the only approach with neural resource requirements that fall within the range of biological plausibility.

#### Abstract

Recent research has sought to examine how learners are able to track the co-occurrence of words and objects across moments in time, a behavior commonly termed crosssituational statistical learning. The current experiment was designed to examine if learners can simultaneously determine word-referent pairings while engaging in other cognitive processes that support language learning, such as distinguishing phonologically overlapping words. Participants were presented with a cross-situational statistical learning task with pairs of words in four categories: non-minimal pairs, near minimal pairs, vowel minimal pairs, and consonant minimal pairs. The results revealed that participants were able to simultaneously learn word-referent pairings while distinguishing all four categories of word pairings. However, learners experienced the most difficulty learning vowel minimal pairs. This work demonstrates that learners are able to simultaneously engage in multiple cognitive processes that support language learning.

Keywords: cross-situational statistical learning; statistical learning; word learning; phonologically minimal pairs; bilingualism

## Introduction

In one moment in time, the world presents learners with a seemingly infinite amount of information. Across several fields of study, including cognitive psychology, developmental psychology, computer science, and linguistics, a large research pursuit has been to characterize how it is that learners acquire, store, and later retrieve such a large data set of information. Indeed, this task has historically been characterized as theoretically impossible (e.g., Quine, 1960), but yet learners appear to acquire a great deal of information with ease.

A more recent trend in research has been to examine how it is that learners acquire, store, and later retrieve information across several moments in time. For example, in the domain of language learning and development, research has sought to determine how learners resolve
ambiguity in word-referent pairings across moments in time. This phenomenon is most commonly termed crosssituational or statistical word learning (e.g., Fazly, Alishahi, \& Stevenson, 2010; Frank, Goodman, \& Tenenbaum, 2009; Smith \& Yu, 2008; Vlach \& Sandhofer, 2011; Yu \& Smith, 2007, 2011).

In a typical experiment, learners are presented with a series of ambiguous learning events, which include multiple words and multiple objects. After a series of learning events, adult participants are presented with a forced-choice test in which they are asked to infer object-label pairings, while infants are presented with a preferential-looking task. This body of work has revealed that infants (e.g., 12- and 14-month-olds; Smith \& Yu, 2008) and adults (e.g., Yu \& Smith, 2007) are able to learn word mappings by tracking co-occurrence probabilities across learning events.

Cross-situational statistical learning research has focused on questions examining learners' ability to determine wordreferent pairings. However, in real-world language learning environments, learners are faced with the challenge of determining word-referent pairings while simultaneously engaging in other cognitive processes that support language learning. For example, learners must simultaneously determine word-referent pairings while parsing words that overlap phonologically.

To date, experiments have primarily used words that contain gross phonological differences, that is, words that differ in multiple sound segments, such as "beat" and "rule". However, many words, especially in English, contain the same sounds with the exception of one segment, either a vowel or a consonant. In other words, they form phonologically minimal pairs such us "beat"-"bit" or "bet""debt". Consequently, it is unknown whether learners are able to simultaneously learn cross-situational statistics while distinguishing phonologically minimal pairs.

Adults have difficulty in learning phonologically minimal pairs. For example, Dutch and Spanish listeners were presented with a word learning task in which they were explicitly taught twelve pseudo-words together with their corresponding visual referents (Escudero, Broersma, \& Simon, 2012). The words followed Dutch phonotactic
probabilities and were produced by a Dutch female speaker. Their visual referents were pictures of novel objects. At test, the native Dutch listeners made more errors for words that formed a minimal pair (e.g. "pax"-"pix") than when they formed a non-minimal pair (e.g. "beeptoe"-"pix"). Spanish listeners demonstrated an even greater difficulty in this task for minimal pairs that contained Dutch vowel contrasts that are not present in Spanish (e.g. "piex"-"pix", "pax"-"paax").

Can learners simultaneously learn cross-situational statistics and distinguish phonologically overlapping words? The current study examined whether phonologically overlapping words or minimal pairs can be successfully learned within a typical cross-situational statistical learning paradigm. In this experiment, learners were exposed to eight novel English words and eight picture referents with no explicit instructions. To examine the effect of word-pair similarity on word learning, the experiment presented learners with monosyllabic words such as "bon" and "deet" that when paired, formed four different levels of phonological overlap: (1) non-minimal pairs (nonMP), (2) near minimal pairs (nearMP), (3) vowel minimal pairs (vowelMP), and, (4) consonant minimal pairs (consMP).

## Method

## Participants

Participants were 71 undergraduates at the University of Western Sydney. A language background questionnaire revealed that 31 participants were monolingual English speakers, whose age range was 17.85 years to 52.19 years ( $\mathrm{M}=26.52$ years, $\mathrm{SD}=10.21$ years; 10 males), while 40 participants spoke two or more languages and ranged in age from 17.73 years to 28.94 years ( $\mathrm{M}=20.70$ years, $\mathrm{SD}=3.18$; 7 males). English was the dominant language of all participants.

## Stimuli

Eight monosyllabic nonsense words were recorded by a female native speaker of Australian English. Figure 1 shows the eight spoken words (in phonetic symbols) together with their randomly assigned picture referents. Four of the words were minimally different in their first consonant (left), while the other four differed in their vowel (right).

The novel words followed English phonotactic probabilities and were chosen from those included in previous studies with infant learners (see Curtin et al., 2009 for the words differing in vowels, and; Fikkert, 2010 for those differing in consonants). The female speaker produced a number of tokens of each word with child-directed intonation contours. These words and speech style were chosen to enable direct comparison of adult and infant responses to the same stimuli (Escudero, Mulak \& Vlach in preparation-a).

Two tokens of each of the eight spoken words were selected to be used in the experiment such that intonation contours were comparable across words. The visual
referents for the words were colorful pictures of novel items previously used in studies of cross-situational word learning (e.g., Vlach \& Sandhofer, 2011).

Figure 1. The eight novel words and their novel object referents.

Stimuli were presented in pairs, with four types of phonological overlap between the two spoken words that were the names of the pictures within a pair: (1) nonminimal pairs (nonMP), where the two words in the pair differed in all three sounds (e.g. /dit///pon/); (2) near minimal pairs (nearMP), where the words overlapped in one sound (e.g. /dっn/-/dit/); (3) vowel minimal pairs (vowelMP), where the words only differed in their vowel (e.g. /dit/-/dit/), and, (4) consonant minimal pairs (consMP), where the words differed in only their consonant (e.g. /bon/-/don/).

## Procedure

Participants were presented with the cross-situational learning tasks in two phases: a learning phase and a subsequent test phase.

During the learning phase, stimuli were presented via Tobii Studio on a 17 -inch screen, and the spoken words played from two speakers positioned below the screen. In each learning trial, two of the eight pictures of novel items appeared on the screen while two novel words for the pictures were spoken, such that pictures were either named left to right, or right to left. The pairings of the words and pictures were randomly assigned. The word for each picture was played once with 500 ms between them.

Trial 1: /ditt/, / bon /

Trial 2: /don/, / dit /

Trial 3: /bon/, / pon /

Figure 2. Examples of the word learning trials.

Participants were instructed to watch the pictures and listen to the words and were not told that the words were names for the pictures, nor were they asked to try and discover which word was associated with which picture.

Across the learning phase, there were a total of 36 learning trials, presented in a counterbalanced order. As mentioned above, stimuli were presented in pairs, with each trial consisting of two different pictures and two different words. There were 18 nonMP trials, and 6 each of nearMP, vowelMP, and consMP trials presented during the learning phase. Figure 2 shows examples of nonMP, nearMP and consMP trials, respectively.

After the learning phase, two testing phases were presented, though only one is reported here. In the first testing phase, stimuli were presented through Tobii Studio, as in the training phase. This phase followed immediately after the testing phase and participants were not given any additional instruction. Participants' eye-gaze was recorded without them having to make any overt response. This was done to later compare these adult data to infant eye-gaze to the same training and testing trials (Escudero, Mulak \& Vlach in preparation-a).

Here we report the results of the second testing phase which was performed immediately after the first. During the second test phase, participants performed a forced-choice inference test, which required learners to infer word-picture pairings by clicking on the corresponding computer key. Stimuli were presented through a laptop computer with a 15-inch monitor, which was set up next to the monitor for the training and first test phase. Stimuli presentation was controlled with E-Prime and participants listened to the stimuli through headphones.

During the test phase, participants saw a pair of pictures and heard four repetitions of the word that always co-
occurred with one of the pictures during the learning phase. The word was presented using two alternating repetitions of the same two tokens of that word used in the training phase, with a 500 ms interval between repetitions. Participants were asked to select whether the word corresponded to the left or right picture. There were 36 test trials in total with the same picture pairs as in the training, but the left/right positions of the pictures were randomized once for the test trials.

## Results

The current experiment sought to determine if learners could simultaneously acquire cross-situational statistics in order to learn word-referent pairings, and parse phonologically minimal pairs. Figure 3 shows the percentage of correct word-referent pairings chosen during the testing trials, separately for the four different types of phonologically overlapping pairs. Percentages for monolingual and multilingual participants are presented separately. This is because it has been shown that bilingualism affects language processing, especially word retrieval (Fennell, Byers-Heinlein, \& Werker, 2007; Bialystok, Craik, \& Luk, 2008)

Figure 3. Percentage of correct word-referent pairings for the different pair types in monolingual and multilingual listeners.

The first set of analyses examined learners' overall performance on the testing trials. Accuracy was above chance for all pair types and in both participant groups ( $M=65-76 \%, t=15-23$, all $p \mathrm{~s}<.001$ ). These results suggest that, despite the additional challenge of distinguishing phonologically overlapping words, learners
are able to learn and infer word-referent pairings during cross-situational statistical learning.

Further, a repeated measures ANOVA on the percentage of correct word-referent pairings chosen on testing trials, with pair type as the within-subject factor and language group as a between-subjects factor, revealed a main effect of pair type $(F(3,69)=3.009, p=.031)$, which indicates that both groups of listeners had lower performance for some pair types than for others. Neither the main effect of language group $(F(1,69=0.360, p=.550)$ nor the interaction of pair type * language group $(F(1,69=0.31$, $p=.942$ ) yielded statistical significance. These results suggest that, although there were not differences across groups of learners, overall participants' performance differed across the word pair types.

To follow up the effect of pair type, a series of planned comparisons were conducted between the pair types, with Bonferroni corrections for multiple comparisons: four comparisons (2-tailed). The results of these tests revealed that participants were less accurate on vowelMP than on nonMP $(t(70)=-2.53, p=.014)$ and consMP $(t=-2.44$, $p=.017$ ), while no difference was found between consonants and nonMP $(t(70)=0.189, p=.850)$ or nonMP and nearMP $(t(70)=1.468, p=.147)$. In sum, learners demonstrated the lowest performance on the vowel minimal pairs.

## Discussion

The results demonstrate that young adults can successfully learn monosyllabic nonsense words in a statistical crosssituational paradigm and without explicit instruction of word-referent pairings. Specifically, learners are able to simultaneously acquire cross-situational statistics and parse phonologically minimal pairs when learning novel words. Thus, the present study extends the findings of previous cross-situational studies (e.g., Fazly et al., 2010; Frank et al., 2009; Smith \& Yu, 2008; Vlach \& Sandhofer, 2011; Yu \& Smith, 2007) by demonstrating that a more challenging set of word-referent pairings can still be learned through the tracking of co-occurrence and statistical probabilities.

The current experiment also demonstrates that vowel minimal pairs are more difficult to learn because participants' accuracy for vowel minimal pairs was lower than that of non-minimal and consonant minimal pairs. This finding is consistent with the numerous studies that demonstrate that consonant information is more important than vowel information for lexical processing (e.g., Berent \& Perfetti, 1995; Lee, Rayner, \& Pollatsek, 2001; Perea \& Carreiras, 2006; Perea \& Lupker, 2004) and lexical acquisition (Bonatti, Peña, Nespor, \& Mehler, 2005; Nazzi \& New, 2007; Nazzi, 2005; Nespor, Peña, \& Mehler, 2003; Peña, Bonatti, Nespor, \& Mehler, 2002).

The above line of research has proposed that the main role of consonants is to signal word meaning, while vowels enable the identification of rhythm and syntactic structure (Nespor et al., 2003). Additionally, consonant information is
more critical in accessing the whole word form (see Berent \& Perfetti, 1995; Carreiras, Vergara, \& Perea, 2007; Lee et al., 2001; Lee, Rayner, \& Pollatsek, 2002; Perea \& Carreiras, 2006; Perea \& Lupker, 2004). For example, in an experiment using response time and electrophysiological measures, Carreiras et al. (2009) demonstrated that a delay in the presentation of consonant information is more detrimental for lexical processing than a delay in presentation of vowel information.

However, studies have also shown vowel information to be more important than consonant information when identifying words in fluent speech (Cole, Yan, Mak, Fanty, \& Bailey, 1996; Kewley-Port, Burkle, \& Lee, 2007). In Kewley-Port et al. (2007), the vowels or consonants were removed from sentences produced in fluent speech and it was found that vowel information had a $2: 1$ benefit over consonant information for both young normal-hearing listeners and elderly hearing-impaired listeners.

The authors argue that the reason why they find opposite results to those of the studies described above is because linguistic processing of monosyllables relies on sound-bysound, bottom-up information, while sentence intelligibility tasks incorporate considerable predictive information from top-down processing. Thus, in the context of fluent speech, we may have observed a different pattern of results. Future research should examine how acquiring cross-situational statistics and distinguishing minimal word pairs may differ in the context of fluent speech streams.

In that respect, Curtin et al. (2009) demonstrated that in lexical acquisition, infants can learn some vowel minimal pairs earlier than consonant minimal pairs, which suggests vowels may have a more lexical role than consonants in early word learning. However the authors explain that different task demands may cause the contradictory results. For example, Nazzi (2005) and Nazzi and New (2007), who found contrasting results, used a task in which infants were presented information from a real speaker, with multiple labels in the interactive communication. These task demands may thus be very different from the ones in the explicit word-referent association task in Curtin et al. (2009). Interestingly, Giezen, Escudero \& Baker (under review) suggest that these divergent results may have a developmental nature, since they found more successful vowel than consonant minimal pair learning in children, while adults exhibited the opposite bias.

Ongoing research (Escudero, Mulak \& Vlach, in preparation-a) examines infant word learning abilities using the same cross-situational word learning task as that of the present study. The results of this new study will likely shed light on the differential processing of vowels versus consonants across development.

The lack of group effects in the present study suggests that multilingualism does not influence cross-situational word learning and word retrieval immediately after learning. Interestingly, it runs contrary to studies that have demonstrated a negative influence of multiple language activation on word learning (Fennell et al., 2007) and
retrieval (Bialystok, Craik, \& Luk, 2008), and a positive influence on cognitive control (Bialystok et al., 2008; Bialystok \& Martin, 2004). Given that a bilingual processing advantage has been shown across a wide range of problem types, including both verbal and nonverbal domains, the null effect in the present study may come as a surprise. However, although word learning within a crosssituational paradigm involves intricate statistical computations and a high load on short-term memory (see Vlach \& Sandhofer, 2011, for a discussion), the 2x2 (two pictures and two spoken words per trial) learning condition may have not provided enough challenge to observe differences. It may be the case that, in the context of a crosssituational learning task with higher working memory demands, the differences between monolingual and multilingual learners will emerge.

Ongoing research (Escudero, Mulak \& Vlach, in preparation-b) is being conducted using tasks that present many words and objects in each learning event, in turn taxing working memory (e.g., in the context of $3 \times 3$ and $4 \times 4$ learning conditions). The results of this new study will likely reveal the influence of multiple language activation and cognitive control on the learning of phonologically overlapping word pairs.

On a final note, it is important to highlight that this study demonstrates the incredible capacity that human learners possess for learning language. Mapping new words to referents in the world has historically been characterized as a theoretically impossible task (e.g., Quine, 1960). However, the results of the current work demonstrate that learners can map words to referents in the world while simultaneously distinguishing phonologically overlapping sounds into words. Indeed, learners appear to accomplish multiple challenging cognitive tasks at the same time. Future research should continue to examine the cognitive processes that operate in parallel in order to support language learning and development.

## Acknowledgments

This research was funded by MARCS Institute start-up funds awarded to the first author. We would like to thank the staff at the MARCS BabyLab for their support and help during testing.

# Intuition versus Reason: Strategies that People Use to Think about Moral Problems 

Mark Fedyk (mfedyk@mta.ca)<br>Department of Philosophy, Mount Allison University<br>Sackville, NB, E4L 1G9, Canada

Barbara Koslowski (bmk2@cornell.edu)<br>Department of Human Development, Cornell University<br>Ithaca, NY, 14853, USA

#### Abstract

We asked college students to make judgments about realistic moral situations presented as dilemmas (which asked for an either/or decision) vs. problems (which did not ask for such a decision) as well as when the situation explicitly included affectively salient language vs. non-affectively salient language. We report two main findings. The first is that there are four different types of cognitive strategy that subjects use in their responses: simple reasoning, intuitive judging, cautious reasoning, and empathic reasoning. We give operational definitions of these types in terms of our observed data. In addition, the four types characterized strategies not only in the whole sample, but also in all of the subsamples in our study. The second finding is that the intuitive judging type comprised approximately $26 \%$ of our respondents, while about $74 \%$ of our respondents employed one of the three styles of reasoning named above. We think that these findings present an interesting challenge to models of moral cognition which predict that there is either a single, or a single most common, strategy - especially a strategy of relying upon one's intuitions - that people use to think about moral situations.

Keywords: Moral Judgment; Moral Reasoning; Verbal Behavior; Cognitive Strategies.

## Introduction

A significant amount of the recent and most influential research in adult moral psychology has focused on the intuitive processes that are frequently represented as the main sort of cognition that occurs when people are asked to make moral judgments about moral situations. This intuition-focused research frequently relies upon so-called "trolley dilemmas" to elicit this intuitive cognition in research participants. Trolley dilemmas are easy-tounderstand fictional moral situations that present an either/or choice between one of two ethically appealing courses of action. Participants are asked to decide one of the two courses of action, and this decision is customarily treated as a paradigmatic representation of a moral judgment. (Mikhail, Sorrentino, \& Spelke 1998, Mikhail 2012, Nichols \& Mallon 2006, Cushman \& Greene 2012)
In one of the better-known lines of research in this area, Mikhail (2007) proposes that an innate and subconscious 'universal moral grammar' determines the semantic content of people's moral judgments. The universal moral grammar is defined using the concepts of deontic logic augmented with a variety of psychological concepts like 'intentional
action'. Moreover, the computations that the universal moral grammar is hypothesized to perform and that generate moral judgment are entirely intuitive. Thus, evidence for the existence of the universal moral grammar comes from studies in which subject's intuitive decisions about trolley dilemmas are shown to be consistent with theoretical predictions about the content and logical structure of the moral grammar. (Mikhail 2008, Mikhail 2012)
Similarly, Waldmann and Dieterich (2007) argue that the content of moral judgments about trolley dilemmas and similar moral situations is determined by a different kind of intuitive knowledge, namely knowledge of a causal map. This map symbolizes causal pathways in the moral situation that a person is considering, dividing the causal pathways into those that involve agents and patients and those that do not. Agents play an active role in realizing a harmful effect, and patients experience the harmful effects caused by agents. Accordingly, the either/or choice at the heart of the situation is intuitively represented as choice between two actions (interventions), each of which can alter in different ways the causal relations that hold between agents and patients. Waldmann and Dieterich test whether a "focus on action may sometimes lead to what we call intervention myopia", such that people will focus primarily on interventions on causal pathways involving patients and agents, and focus less on interventions on causal pathways that do not involve agents and patients. (Waldmann and Dieterich 2007) Their data leads them to conclude, "the locus of intervention is one key factor contributing to moral intuitions." That may be, but the important point for our purposes is that, like Mikhail's theory, Waldmann and Dieterich's proposal is that judgments about moral either/or choices are computed by intuitive cognitive processes.
We mention these studies in some detail because we want to use them as evidence for the following claim: if you want to "nudge" subjects towards using intuitive cognitive processes to produce moral judgments about moral situations, one approach which seems likely to have this effect is to present subjects with a moral situation that embeds an explicit either/or choice - that is, a moral dilemma. After all, both studies described above are examples of experimental subjects producing moral intuitions in response to situations that contain explicit either/or choices, and there are many other studies like this. (Lombrozo 2009)

But there is another body of literature in recent moral psychology that suggests that different way of inducing intuitive responses is to ask subjects to engage with affectively salient moral situations, whether or not they are technically moral dilemmas. (Borg, Hynes, Van Horn, Grafton, \& Sinnott-Armstrong, 2006; Ciaramelli, Muccioli, Ladavas, \& di Pellegrino, 2007; Damasio, 1994; Greene, Nystrom, Engell, Darley, \& Cohen, 2004) Thus, for example, Jonathan Haidt's well-known social intuitionist model (SIM) holds that intuitively generated affective states almost always fix the content of people's moral judgment. (Haidt 2001) The basic idea is that things that we intuitively feel that we like are judged to be morally permissible, and things we intuitive feel dislike for are judged to be morally impermissible. So creating feelings along the like/dislike continuum is another potential way of encouraging uses of moral intuition; and it certainly should be if the social intuitionist model is correct.

We believe that the various lines of research that focus on the intuitive aspects of moral cognition have produced a number of novel and important scientific insights into the relationship between intuition, affect, and moral judgment. However, we are skeptical of the idea that - as per Haidt, Mikhail, and others - intuitive processes are the very nearly the only processes by which people form moral judgments. Accordingly, we present here the results of an experiment designed to identify some of the different cognitive strategies that people use when thinking about moral situations. And one of the questions we were most interested in answering was just how frequently people rely on their moral intuitions when responding to a moral situation. Because of this, our experiment was designed to maximize the likelihood that some of our participants use their moral intuitions to respond to the moral situations we asked them to consider. Our test conditions were Dilemma Non-Affect, Dilemma Affect, Problem Non-Affect, and Problem Affect, and all but the last condition was constructed so as to try to "push" subjects in these conditions towards the use of intuitive cognitive processes. Specifically, our Dilemma conditions were designed to replicate closely the trolley dilemmas discussed above by presenting our subjects with a clear either/or choice. Similarly, our Affect conditions which included language designed to elicit feelings of either disgust or sympathy - were designed to target the intuitively-mediated emotional processes that are posited by theories like the social intuitionist model. We provide a fuller description of our test conditions below - for now, we simply want to make the point that the rationale for our test conditions was our goal of trying to encourage subjects in some of our test conditions to use moral intuition. Thus, Dilemma Non-Affect targets intuitive systems like those posited by Mikhail, Waldmann, Dieterich and others; Problem Affect targets intuition systems like those posited by the social intuitionist model; Dilemma Affect targets both kinds of intuitive systems; and Problem Non-Affect acts as a control condition, insofar as it is not designed to target any specific intuitive process that has been described in the recent moral psychology literature.

Furthermore, we want stress that our aim was not to show that people are more likely to use intuitive cognitive processes in any of our test conditions. Although we designed our experiment to maximize the chances that participants in our dilemma and/or our affect conditions would be more likely to use moral intuition than those in the problem non-affect condition, our fundamental aim was to identify cognitive strategies that did not vary across our test conditions. In other words, we wanted if possible to identify any condition invariant cognitive strategies, while at the same time employing test conditions that worked against this end by making it more likely that participants in some of these test conditions would use different cognitive strategies.

## Method

We collected our data using person-to-person interviews rather than online interviews. We did this because in a separate experiment (Koslowski and Fedyk, in prep) we observed that in person-to-person interviews subjects produce a richer expression of the cognitive processes they use when responding to moral problems than they do in online-only sampling contexts.
In all of our conditions, participants were simply asked for a judgment about a moral decision faced by a character in a fictional vignette.

Participants. Participants were eighty-three undergraduate students ( $\mathrm{m}=43, \mathrm{f}=40$ ) at Cornell University. Participants were enlisted using the university's internet-based recruitment tool, and all participants received course credit for their participation.

Interview. Our interviews took place in a quiet lab room at Cornell University. No one but the interviewer and the participant was in the room at the time of the interview. Each interview was recorded using either a digital audio recorder or a tape recorder, and tapes from the latter were subsequently digitized. Data for 1 female participant was excluded from our analysis because of a tape-recorder failure that occurred during this participant's interview and thus prevented her interview from being transcribed.

Stimuli. Each participant was presented with 6 different vignettes that described a situation in which the main character in the vignette faces a moral choice. The moral situation described by our vignettes intentionally resembled the situations described by vignettes that have been used in previous research. For example, our "Smith" vignette is version of the classic runaway trolley case, albeit involving people trapped in a subway tunnel. We also used an updated version of Kohlberg's famous "Heinz" vignette, and a very simple vignette derived from Peter Singer's famous article about moral obligations towards people experiencing a devastating famine in a distant country. (Singer 1972)
All of our vignettes were written in plain English, and one of the ways in which they differed from other vignettes used by some other moral psychologists is that they described
situations that either have occurred or at least could likely occur. We did this in order to increase the ecological validity of the study, as some vignettes used by other researchers require subjects to engage in deeply counterfactual thinking. The "fat man" trolley case, for example, requires subjects to believe that, despite the laws of physics and human physiology, there exists a man fat enough to stop a runaway trolley car. (cf. Pinker 2008)
Our vignettes varied in their length, where the shortest vignette was 85 words long, and the longest 303 words long, with an average length of approximately 196 words. Each vignette introduced a main character with a gender-neutral name (like "Smith", "Davis", or "Parker") and described a situation faced by the main character that called for a moral decision.

Here are more explicit definitions of the four types of vignettes we used:

Dilemma Vignettes - for these vignettes the same language as for the Problem condition is used, except that a short phrase (like "Smith can either...") or sentence is added to the vignette that stipulates that the main character faces an either/or choice.
Affect Vignettes- in this condition, 1 or 2 short sentences were added to either the Dilemma or Problem vignettes. The sentences were designed to elicit mild feelings of either sympathy or disgust in our participants. Examples of these sentences are:
a. "The cancer is very painful, and the woman cries most days."
b. "Relief workers are trying desperately to treat children who are suffering a range of painful and eventually fatal illnesses caused by malnutrition."
c. "The boss is dirty and smells bad. He tells Adams that the sandwich he is eating is a horse-meat and pickles sandwich..."
d. "Lisa is one of the members of Smith's team. She works to support her two high-school aged children after her husband died of cancer several years ago."
Non-Affect Vignettes - for these vignettes, the sentence designed to elicit affect is omitted.
Problem Vignettes - in these vignettes, the language describing the "either/or" choice is omitted.

We constructed four test conditions by crossing these two variables: decision type (problem vs. dilemma) and affect type (affect vs. non-affect). Thus, the four test conditions were Dilemma Non-Affect, Dilemma Affect, Problem NonAffect, and Problem Affect. We did this so that - as explained in more detail above - Dilemma Affect was the condition that for theoretical reasons was most likely to push our participants towards using their moral intuitions.
Participants were randomly assigned to one of the four test conditions. Subjects therefore only ever responded to one type of vignette. Within each condition, the order in which the six vignettes were presented was random.

## Procedure

After participants had settled into the interview room and consented to participate, participants were given an unbound stack of 6 pieces of paper, where each piece of paper had written upon it one of the 6 vignettes. Participants were then asked to read along silently while the interviewer read the vignette out loud. After the interviewer was done reading the vignette, he or she then asked the participant, "What is your judgment about what X should do?", where " X " stands for the name of the main character in the relevant vignette. Participants were provided with no further instructions or feedback. They were not asked to produce any other judgments than a judgment about what the main character should do. Neither were they asked explicitly to reason about the vignettes they were presented with. Participants were therefore free to respond to our question however they wanted, which means the reasoning we observed (see below) was produced spontaneously. Once each participant concluded his or her response to our question, the interviewer moved on to the next vignette. This process was repeated until each subject had responded to all six of the vignettes.

## Coding and Analysis

The audio recordings from each of our interviews were transcribed by a professional transcription service that specializes in legal and academic work. The transcriptions were made using an "absolute verbatim" style, which means that every utterance, pause, "hmmm", and so on was transcribed and, importantly, done so using a standardized notation.
Two coders who were blind to our study's hypotheses, aims, and methods then coded these transcriptions independently. Disagreements between our coders were very infrequent, and were resolved through discussion. 82 interviews were coded, where each response to the question "What is your judgment about what X should do" was treated as an individual case. This means that our data set consisted of 492 discrete cases.

Coding Categories. We created 11 coding categories that describe easy to observe speech-acts or other kinds of verbal behavior. For example, one of our categories was "Subject asks at least one question about the vignette". Only one of our 11 categories explicitly referred to verbalized reasoning (see 4. below). The remaining 10 categories were derived from examining our transcripts for reoccurring speech-acts. We used this approach so that we did not render it a priori that our data analysis would find either an intuition / reason distinction, or find different types of reasoning in our cases. Thus, we had prior to running our analysis as much reason to expect that our analysis would sort responses into, for instance, questioning and non-questioning responses as we did for reasoned and intuitive responses.
Each of the coding categories was defined as a categorical variable, and no coding categories were treated as exclusive of any other. This permits our coding categories to nest within one another, and this property allows us to logically
construct the definitions of the cognitive strategies out of the definitions of our coding categories.

Analysis. We used a two-step cluster analysis algorithm to find natural clusters formed in the cases that comprise our observational data. Specifically, we looked for clusters that occurred in all of the different populations of cases that we could create by sorting according to gender or test condition. We used the two-step algorithm because it is able to find natural clusters in categorical variable data.
The algorithm looks for cases that have the same coding category values, and creates a preliminary cluster out of any set of cases that have the same values. It then scores a number of different "models" of the clusters identified in first step of the analysis according to their Bayesian Information Criteria (BIC). Importantly, this second step is able to resolve any borderline cases: if a particular case $c$ is similar to those cases in a group of cases $G$ which all have exactly the same values, and $c$ is also different than many other cases that, in the first step, the algorithm did not put into any clusters, the algorithm may then put $c$ into G if the model which places $c$ in G has the best BIC score. However, if the case data is too heterogeneous - as may occur if there are nearly as many clusters as there are cases -then the algorithm in the second step will delete some or all of the preliminary clusters. Because of this, it is also possible that two-step cluster analysis will find no natural clusters in some data sets. (cf. Norušis 2011)
We examined combinations of 11 different coding categories applied to 11 different populations of cases (see below). More explicitly, we looked for a combination of coding categories which the two-step algorithm was able to use to find clusters that (a) occurred in all 11 populations of cases we analyzed and that (b) had a silhouette coefficient greater than 0.6 . We also wanted to identify a set of clusters that (c) were the only natural clusters in all 11 populations of cases.
The 11 populations of cases we analyzed were: all participants, male / female participants, participants in each of the four test conditions (Dilemma Affect, Dilemma NonAffect, Problem Affect, Problem Non-Affect), and participants in each of the types of situations used to construct our test conditions (Dilemma, Affect, Problem, Non-Affect). Thus, we used the two-step algorithm to determine if the coding category "Subject says what the main character should do" picked out any natural clusters in the populations listed above. We also used the cluster analysis algorithm to determine if the two coding categories "subject says what the main character should do" and "subject asks for more information about the vignette" together picked out any natural clusters in the 11 populations of cases above And we also asked the cluster analysis algorithm to determine if the three coding categories consist of the previous two plus "subject uses moral language in their response" together picked out any natural clusters of cases in the 11 populations of cases listed above. And so on.
Thus, we supplied approximately 121 different
combinations of coding categories to the two-step algorithm. As we said, we were searching for clusters of cases that occurred in all 11 populations of cases and which scored a high silhouette coefficient (>0.6). Any such clusters would therefore represent types of responses that were invariant across conditions and populations.

## Results

We found 4 such clusters. Specifically, we found that a combination of 4 coding categories defined four different natural clusters that occurred in all 11 populations listed above. What's more, these 4 clusters were the only natural clusters in 9 of the 11 populations. The coding categories that define these clusters are:

1. Subject says what the main character should do.
2. Subject uses the word "might" or "probably" or a similar word to express hesitation when verbalizing their judgment.
3. Subject says something indicating that they are imagining themselves in the situation of the main character of the vignette (such as "Well, what I would do in that situation is..." or "If it was me there, I think that I...").
4. Subject expresses at least one inference when making their response (such as "if ... then ..." or ".... because ....").

Because these were treated as categorical variables, each of these coding categories can take the only the values "true" or "false". Each of our 492 cases will therefore have a value of "true" or "false" for each of these categories. This means that there are 16 logically possible clusters that the cluster analysis algorithm could have found using these coding categories, although it is also possible that the algorithm find could have found no clusters at all.
Here are the clusters that the algorithm found. Note that each cluster is operationally defined out of logical values for the four coding categories listed directly above:

Simple Reasoning $=$ subject expresses a judgment and expresses an inference, but does not use language indicative of hesitation and does not imagine themself in the position of the main character.
Intuitive Judging = subject expresses a judgment, and does not express an inference, does not use language indicative of hesitation and does not imagine themself in the position of the main character.
Cautious Reasoning $=$ subject expresses a judgment, expresses an inference, and does use language indicative of hesitation, but does not imagine themself in the position of the main character.
Empathic Reasoning = subject expresses a judgment and expresses an inference and imagines themself in the position of the main character, but does not use language indicative of hesitation.

We think that these four natural clusters - or, if you prefer, types of response - represent four cognitive strategies that people use to respond to moral situations. And just to be clear, these are not types of people; they are cognitive
strategies that occurred in all of our test conditions.
Figure 1 presents the proportions of these clusters in our total respondents - that is, for all 492 cases taken together. For this population, the cluster analysis algorithm placed every case into one of the four clusters, meaning that no case was excluded. Importantly, there was no significant variation in the relative proportion of these four clusters across all of the populations of cases that we analyzed. This means that the ratio of reasoners to intuitors was approximately $3: 1$ in all of our populations. It also means that the proportion of the four clusters in, for instance, the male population of cases looks very similar to the proportion of clusters in our total population of cases; for illustration, please see Figure 2.

## Proportion of Four Clusters (or Cognitive Strategies) in Total Population of Cases

Figure 1: The proportion of four natural clusters found in the population consisting of all 492 of our cases. Each of the 492 cases was placed into one of these four clusters. Proportion is expressed as a percentage, rounded to the nearest whole number. (Silhouette measure of cohesion and separation $=0.7$ )

## Proportion of Four Clusters (or Cognitive Strategies) in only Male Cases.

Figure 2: The proportion of four natural clusters found in the population consisting of only our male cases. As in Figure 1, each case was placed into one of these four clusters. Proportion is expressed as a percentage, rounded to the nearest whole number. (Silhouette measure of cohesion and separation $=0.7$ )

As we indicated above, we also found that these clusters were the only natural clusters that were present in 9 of the 11 case populations we analyzed. The two exceptions were the subpopulation of cases in the Problem Non-Affect condition (where these four clusters accounted for $75 \%$ of the natural clusters in the population) and the female respondents (where these four clusters accounted for $85 \%$ of
the natural clusters in the populations). Remember, the algorithm can resolve borderline cases by placing statistically similar though not identical cases together in the same cluster, but borderline cases will not always be resolved in the same way across different populations of cases. This is because the treatment of a borderline depends partly on what the statistical properties of other borderline cases in the population under analysis.
Finally, we would like to report that that the coding category "subject uses moral language" failed to figure in any of the condition invariant natural clusters. We find this result particularly intriguing.

## Impact of the Conditions and Other Objections

A natural worry with our claim that the four cognitive strategies that we observed are condition invariant is that our test conditions simply failed to have any experimentally meaningfully impact on our subjects - even though three of our four test conditions were designed on theoretical grounds to try to push subjects in those conditions towards intuitive responses.
So as a control for this possibility, we analyzed the cases in the different test conditions for any significant differences, and we found several. For instance, subjects in the two affect conditions were more likely to ask our interviewer for information about the vignette than subjects in the two nonaffect conditions ( $x^{2}=6.54, \mathrm{p}=0.0105$ ). We also found that, when we scored the coherency of the reasoning on a 7 point scale derived from a grading rubric used in a critical reasoning course, the coherency of reasoning of the subjects in the Problem Non-Affect condition was significantly higher than all other conditions (e.g., for Problem NonAffect versus Dilemma Affect, $\left.x^{2}=19.05, \mathrm{p}=0.0019\right)$. These data indicate that our test conditions did have different psychological effects, and this speaks to the strength of the clusters we found in our data.
We would also like to speak to the assumption that differences in people's verbal responses can be read without further experimental constructs as evidence of differences in the underlying cognitive processes. This assumption is often implicit in the analysis of experimental data in moral psychology, and it is most prominent in the work of researchers who have taken the view that moral cognition is largely driven by intuition processes (cf. Haidt 2001). Our position is that this assumption is warranted as a premise in an abductive inference for our conclusion - namely, that the best explanation of the differences we observed in our subject's verbal responses is that these differences reflect different underlying cognitive strategies.
In sum, we claim that the four natural clusters we defined above represent four different cognitive strategies that people use to respond to moral situations. Sometimes people are simple reasoners, intuitive judgers, cautious reasoners, or empathic reasoners - and, importantly, these four strategies are used whether or not people are asked explicitly to think about an either/or dilemma, and whether or not they read a vignette designed to induce mild feelings of either disgust or sympathy.

## Discussion

Some of the categories we used in our analysis did not yield any condition invariant clusters, and this result provides an interesting independent confirmation of some of the claims made by the social intuitionist model. The operational definition of "intuitive judger" above is nearly identical to the theoretical definition of an "intuitive judgment" given by Haidt (2001). And because in our experiment there was no a priori reason to think that the intuitive judging cluster would be one of the four clusters found in all of our test conditions, our observation that a large number of our respondents behaved in a way that very nearly exactly satisfies the social intuitionists' definition of "intuition" is therefore evidence of the accuracy of their theoretical definition for the concept. This result, moreover, comports very well with dual-process approaches to cognition.
However, we failed to observe significantly more intuitive judgers in the three conditions designed to induce intuitive moral cognition. The ratio of intuitive judgers to reasoners held steady across all of our test conditions. Remember: participants were given no explicit instruction to reason about the moral situations we read to them; we asked each participant for only a judgment about what the main character in the vignette should do. So the fact that we were unable to "push" subjects in some conditions to rely more frequently on moral intuition is a challenging result to intuition-based models of moral cognition like the social intuitions model and Mikhail's universal moral grammar. Despite our attempts to maximize the likelihood that participants would use intuitive cognitive processes in some of our test conditions, participants were in all of our conditions at least three times more likely to use some kind of reasoning than to use intuition.
This finding is relevant to the methodology of moral psychology. Moral intuition is often defined as the absence of reasoning, and reasoning is a normative ability the manifestation of which varies according to the skill and epistemic context of a subject. By setting the range of permitted reactions to an either/or choice or recording agreement with a proposition on a Likert scale, many moral psychological experiments are automatically designed not to record any reasoning. Yet, these constructs do not cause subjects to not reason during the experiment; they only proactively "screen-off" the expression of any underlying reasoning that may or may not occur. Our experiment was designed to see what subjects would do when this screen was removed, and our findings suggest that reasoning is a very common cognitive strategy used to arrive at moral judgments. But the deeper lesson implied by our findings is that there is more than a single concept of moral intuition employed in contemporary experimental moral psychology. Let an experimental intuition be any judgment recorded in an experiment where the subject is prevented from expressing any reasoning that may or may not occur in the production of the judgments, and let a psychological intuition be any judgment that is not produced on the basis of any immediately prior reasoning. Our findings suggest that many moral psychologists are studying only
experimental intuitions - for exactly the same reason that our "intuitive judging" category might capture only experimental, not psychological, intuitions.

#### Abstract

Languages around the world share a number of commonalities known as language universals. We investigate whether the existence of some recurrent patterns can be explained by the learner's preference to balance the amount of information provided by the cues to sentence meaning. In an artificial language learning paradigm, we expose learners to two languages with optional case-marking - one with fixed and one with flexible word order. We find that learners of the flexible word order language, where word order is uninformative of sentence meaning, use significantly more case-marking than the learners of the fixed word order language, where case is a redundant cue. The learning outcomes in our experiment parallel a variety of typological phenomena, providing support for the hypothesis that communicative biases can shape language structures.

Keywords: Language acquisition; learning biases; language universals; efficient communication.

## Introduction

In his seminal paper, the American linguist Joseph Greenberg (Greenberg, 1963) noticed that the vast majority of patterns that recur in apparently unrelated languages, also known as language universals, take the form of implicational statements: If a language has property $A$, then it will most likely have property $B$. Language universals point towards constraints on the space of structures possible in natural language since some of the theoretically possible feature combinations are cross-linguistically observed more frequently than others.

The nature of these recurrent patterns has sparked a debate in the cognitive sciences: Are language universals due to constraints specific exclusively to language which are not shared by other aspects of human cognitive systems (Chomsky, 1965), or are they due to general cognitive constraints such as constraints on perception, memory and learning (Hawkins, 2004; E Newport, 1981; Slobin, 1973)?

In this work, we explore the long-standing hypothesis that domain-general pressures associated with human communication can shape languages over time (Bates \& MacWhinney, 1989; Slobin, 1977; Zipf, 1949). Support for this hypothesis comes from recent studies that apply mathematical theories of communication to the study of language structures. This work has found that speech has many properties that strike an efficient balance between successful and fast communication (Jaeger, 2010). Recent cross-linguistic studies have further found that languages
across the world share many properties that facilitate such efficient information transfer (S.T. Piantadosi, H Tily, \& E Gibson, 2011; S.T. Piantadosi, H. Tily, \& E. Gibson, 2011; Qian \& Jaeger, 2012).

The study of language universals has primarily relied on typological and diachronic data, which has several major limitations. First, typological and diachronic studies suffer from data sparsity since only a small fraction of 6909 known languages (Lewis, 2009) have been sufficiently documented. This led some researchers to suggest that there is no evidence for language universals once common ancestry and geographical proximity between languages are taken into account (Dunn, Greenhill, Levinson, \& Gray, 2011). Second, typological and diachronic studies do not provide an insight into the mechanism of how the hypothesized constraints come to shape language over time.

The aim of this study is three-fold. First, we set out to provide direct behavioral evidence for the existence of cross-linguistic universals. Second, we investigate the cause of these universals. We ask, in particular, whether some typologically frequent phenomena can be explained by domain-general biases associated with considerations about human communication. Finally, we explore whether learning can provide a potential mechanism through which these biases come to shape language structures.

We employ an artificial language learning paradigm, where learners are exposed to miniature languages designed to have certain properties of interest. This method has been used to study learning biases in adults and children (Culbertson, Smolensky, \& Legendre, 2012; Hudson Kam \& Newport, 2009) and has provided behavioral evidence for typological universals (Christiansen, 2000; Culbertson et al., 2012; Finley \& Badecker, 2008; E. Newport \& Aslin, 2004). Of particular interest is a recent study by Fedzechkina, Jaeger, and Newport (2012), who have used this paradigm to investigate the impact of learners' communicative preferences on language structure and shown that language learners are biased towards efficient case systems.

Here we focus on the correlation in a language between the flexibility of word order and the presence of a case system. It has long been observed that languages with rich case-marking typically allow more word order freedom than languages with no case-marking (Blake, 2001; Sapir, 1921). Languages like Russian or Latin, which allow sentential subjects and objects to be placed in a variety of positions
with respect to each other and the verb, tend to have rich case systems. However, languages that enforce strict order of subject and object (e.g., English and French) typically have no or only rudimentary case-marking.

Additional evidence for the correlation between word order flexibility and the presence of case-marking comes from studies of language change. For instance, Old English allowed the permutation of subject and object while having rich case-marking. This relationship between word order and case-marking substantially changed during the history of English, and Modern English became a language with a fixed word order and no case-marking.

We explore whether this correlation between word order freedom and the presence of a case system in a language can result from a trade-off between the information content of a cue and a the amount of effort necessary to produce this cue. Word order is highly informative of sentence meaning (i.e., grammatical function assignment can be successfully recovered based on word order alone) in a fixed word order language. Case-marking is thus redundant in such language and can be omitted to conserve effort without hindering robust communication. In a flexible word order language, however, word order is less informative of grammatical function assignment, and situations can occur when sentence meaning cannot be successfully recovered based on the linear order of elements alone. The relative lack of informativity of word order is compensated for by casemarking, which, when present, provides crucial information about grammatical function assignment.

We expose learners to languages with optional casemarking that have either fixed or flexible word order. If learners indeed balance the amount of information provided by cues to sentence meaning, we predict that the relative lack of one cue will make it more likely that learners recruit alternative cues. In particular, we expect learners of the flexible word order language to use significantly more casemarkers than the learners of the fixed word order language.

## Experiment

## Participants

Participants in the experiment were monolingual native English speakers recruited from the undergraduate students at the University of Rochester or their age-matched peers from the surrounding community. All participants were compensated $\$ 25$ for their time. Participants were pseudorandomly assigned to one of the two languages: variable word order or fixed word order language (described below). Recruitment continued until the number of participants who successfully learned the language reached 20 in each of the two languages. 52 volunteers participated in the experiment. 12 participants were excluded from the analysis for the following reasons: failure to achieve $65 \%$ accuracy on unambiguous trials during the comprehension test (10 participants in the flexible word order language, see below), computer error (1 participant), or being a bilingual (1
participant). This left 40 participants for analysis, 20 in each of the two languages.

## The Languages

Lexicon Verbs There were four verbs (geed, kleidum, shen, zamper) that denoted simple transitive actions (HUG, KNOCKOVER, ROCK, KICK). All verbs occurred equally frequently in the input overall and with each word order variant allowed by the language.

Nouns There were six nouns (glim, flugit, bliffen, norg, spad, melnawg), all of which denoted male referents (MOUNTIE, CHEF, REFEREE, CONDUCTOR, HUNTER, BANDIT). There were no restrictions on nouns. All nouns occurred equally often as subjects and objects of each of the four verbs.

Case-marker There was one case-marker ('kah') that optionally marked the object of the action.

Grammar There were two language conditions in the experiment.

Fixed word order language did not contain word order variation - subject-object-verb (SOV) occurred in $100 \%$ of the input sentences. The language had optional casemarking $-67 \%$ of the input sentences contained a casemarker that marked the object of the action.

Since grammatical function assignment could be unambiguously identified by word order in this language, case-marking added little information to successful recovery of sentence meaning.

Flexible word order language contained word order variation - subject-object-verb (SOV) and object-subjectverb (OSV) word orders occurred equally frequently in the input. The language contained optional case-marking - 67\% of sentential objects were case-marked regardless of sentence word order.

In this language, word order was uninformative about grammatical function assignment. Case-marking, when present, provided important information about sentence meaning.

Head-final languages were chosen for both language conditions since they are cross-linguistically more likely to have case-marking systems (Greenberg, 1963).

## The Procedure

The procedure builds on the method developed by Hudson Kam and Newport (2009). Participants were trained and tested on one of the two languages during three 30-35 minute visits to the lab spread over three consecutive days, with at most one day between the visits. The same procedure was used on all three visits. During each session, participants were presented with a mixture of training and test blocks that fell into two broad categories: noun training and sentence training.

Noun Exposure and Tests During noun exposure participants were presented with pictures of each of the characters accompanied by their label in the novel language
(12 trials total). Participants were instructed to repeat the names of the characters aloud to help them learn. The initial noun presentation was followed by a noun comprehension test where participants were presented with pictures of two characters and asked to choose the correct match for the name they heard (12 trials total). Feedback was provided after each trial. After completing the noun comprehension test, participants were presented with the noun production test where they were asked to provide the name of the character shown on the screen (6 trials). Feedback on performance was provided after each trial. The three noun training blocks were repeated immediately upon completion of the noun production test. On Day 1 noun exposure and noun production blocks were also presented before the sentence production test. On Days 2 and 3 participants were only given the noun production block before the sentence production test. Noun exposure and comprehension blocks were also shorter on Days 2 and 3 ( 6 trials each).

Sentence Exposure and Tests During the sentence exposure phase, participants viewed short computergenerated videos and heard their descriptions in the novel language. Participants were asked to repeat the sentences out loud to facilitate learning. On all days, exposure sentences were presented in sets of two training blocks (24 trials each). During the first sentence exposure block on Day 1 participants were allowed to replay the videos and sounds as many times as they wanted; replay was disabled for all other exposure blocks throughout the study. Sentence exposure was followed by a sentence comprehension test ( 24 trials total). Participants were shown two videos involving the same action where the order of the doer and undergoer was reversed and were asked to choose the video best matching the sentence they heard. No feedback on performance was provided during the sentence comprehension test. After the sentence comprehension test, participants completed two more sentence exposure blocks and one more sentence comprehension block. Each experimental session ended with a sentence production test (48 trials) where participants were asked to describe a previously unseen video using the provided verb prompt. No feedback on performance was provided.

## Scoring

In the comprehension test, participants' responses were scored as 'correct' if they matched the intended sentence interpretation. This was based only on case-marked (unambiguous) trials for both languages. Participants who failed to achieve $65 \%$ accuracy were excluded from all analyses. The results reported below still hold, however, if these participants are included as well.

In the production test, we scored the word order used in the sentence, the presence of case-marking on the object as well as lexical (using the wrong word for a referent or an action) and grammatical mistakes (using a word order not allowed by the grammar or using the case-marker incorrectly). If the name of only one referent was incorrect
and it was still possible to determine sentence word order, productions were scored as overall correct but containing a lexical error. Such productions were included in the analyses below. Productions containing grammatical errors were excluded from all analyses. The results presented below still hold if productions containing lexical errors are excluded as well.

## Results

Accuracy of Acquisition Both languages were acquired with a high degree of accuracy. On the final day of training learners of the fixed word order language made less than $1 \%$ lexical mistakes and no grammatical mistakes, while learners of the flexible word order language made $1.6 \%$ lexical mistakes and $6.2 \%$ grammatical mistakes in their productions. These data suggest that the task was feasible for our participants.

Word Order Use in Production One way learners of the flexible word order language can ensure robust communication is by fixing word order and dropping casemarking. Thus we first analyzed participants' word order use in the flexible word order condition, asking whether there was a tendency to regularize word order. If learners of the flexible word order language behave just like fixed word order learners who use SOV in all their productions, there will be little reason to expect differential case-marker use between the two language conditions.

Overall, learners of the flexible word order language maintained word order flexibility: There was no word order regularization in participants' productions on any day of training (Day 1: 49\% SOV word order in production, not significantly different from the $50 \%$ input proportion [ $\left(\chi^{2}\right.$ (1)=.15, $\mathrm{p}=.7, n s]$; Day 2: $45 \%$ SOV word order in production, not significantly different from the input [ $\chi^{2}$ $(1)=2.66, \mathrm{p}=.1, n s]$; Day 3: $49 \%$ SOV word order in production, not significantly different from the input $\left[\left(\chi^{2}\right.\right.$ (1) $=.17, \mathrm{p}=.7, n s]$ ).

Case-Marker Use in Production We now turn to our main question: Do learners balance the amount of cues to the meaning of the sentence, recruiting additional cues in those cases when existing cues do not provide enough information to successfully decode the intended meaning?

We used a mixed logit model to predict the use of casemarking in participants' productions based on language condition (flexible/fixed word order language) and day of training $(1,2,3)$ as well as the interactions between these two factors. The model included the maximal random effects structure justified by the data based on model comparison. The results reported below hold when the model with the full random effects structure was used. There was a significant main effect of language (see Figure 1): Learners of the flexible word order language used significantly more case-markers in their productions than the learners of the fixed word order language throughout the experiment ( $\beta=1.45, \mathrm{z}=2.24, \mathrm{p}<.05$ ). There was a significant
interaction between Day 2 of training and language condition ( $\beta=.46, \mathrm{z}=3.4, \mathrm{p}<.001$ ) and Day 3 of training and language condition ( $\beta=.25, \mathrm{z}=2.75, \mathrm{p}<.01$ ). Simple effects test shows that learners of the flexible word order language used significantly more case-markers than the learners of the fixed word order language on Day $2(\beta=1.65, \mathrm{z}=2.5$, $\mathrm{p}<.05$ ) and Day 3 ( $\beta=1.94, \mathrm{z}=2.72, \mathrm{p}<.01$ ) of training.

As expected under our hypothesis, then, learners used significantly more case-marking when they learned a language where word order was uninformative of grammatical function assignment (flexible word order language) as compared to the language where referent-to-grammatical-function assignments were reliably identified by word order (fixed word order language).

Figure 1: Case-marker use in production
What is driving the observed difference in case-marker use between the two language conditions? Under our hypothesis, we expect learners of the fixed word order language to gradually lose case-marking, producing fewer case-markers than the input proportion, since case-marking is a redundant cue to sentence meaning in a language that does not allow word order variability. Given the design of our flexible word order language, learners could take advantage of case-marking to facilitate successful decoding of the intended meaning in two ways. First, learners could regularize case-marking in the language overall and use more case-markers in their own productions than in the input. Alternatively, learners could condition case-marking on word order and use significantly more case-markers with one word order variant than with the other. Both possibilities will increase successful recovery of the intended meaning, but the latter will minimize effort at the same time (since not all sentential objects will need to be case-marked) and would thus be a more efficient option. In the following sections, we explored these predictions in more detail.

## Case-Marker Use in the Fixed Word Order Language

Do learners of the fixed word order language deviate from the input they receive and reduce the amount of casemarking in the newly acquired language? Indeed, they showed a strong tendency to drop case-marking and used
significantly fewer case-markers in their own productions compared to the input starting on the first day of training (Day 1: 50\% case-marking in production, significantly lower than the $67 \%$ input proportion $\left[\left(\chi^{2}(1)=23.51\right.\right.$, $\mathrm{p}<.001]$; Day 2: 45\% case-marking in production, significantly lower than the input $\left[\left(\chi^{2}(1)=40.6, \mathrm{p}<.001\right]\right.$; Day 3: $41 \%$ case-marking in production, significantly lower than the input $\left[\left(\chi^{2}(1)=61.87, \mathrm{p}<.001\right]\right)$.

The behavior of the majority of individual subjects followed our prediction. Out of 20 participants, 14 participants produced fewer case-markers than the input on the final day of training; 8 of these did not use case-marking at all in their own productions; and only 3 participants produced substantially more case-markers than the input proportion (see Figure 2).

Figure 2: Individual preferences in case-marker use in the fixed word order language on the final day of training. The dashed line indicates the input proportion of case-marking.

Case-Marker Use in the Flexible Word Order Language Next we took a closer look at the learning outcomes in the flexible word order language. Do learners increase communicative success by favoring robustness but sacrificing efficiency and regularize case-marking in the language overall? Or do they favor efficiency to achieve the same goal, conditioning case-marking on sentence word order?

Learners of the flexible word order language did not use case-markers significantly more frequently than in the input language (Day 1: 55\% case-marking in production, significantly below $67 \%$ input proportion $\left[\left(\chi^{2} \quad(1)=9.5\right.\right.$, $\mathrm{p}<.01]$; Day 2: $72 \%$ case-marking in production, not significantly different from the input $\left[\left(\chi^{2}(1)=1.78, p=.18\right.\right.$, $n s]$; Day 3: $71 \%$ case-marking in production, not significantly different from the input $\left[\left(\chi^{2}(1)=.89, p=.3, n s\right]\right)$.

There was a significant tendency to condition casemarking on sentence word order throughout the experiment (see Figure 4): Learners overtly marked objects with case significantly more often if sentence word order was OSV ( $\beta=1.11, \mathrm{z}=17, \mathrm{p}<.001$ ). A significantly higher proportion of
object case-marking in OSV sentences compared to SOV sentences was observed on every individual day of training (Day 1: $(\beta=1.53, \mathrm{z}=12.6, \mathrm{p}<.001)$; Day 2 ( $\beta=.9, \mathrm{z}=8.6$, $\mathrm{p}<.001$ ); Day 3 ( $\beta=.91, \mathrm{z}=8.23, \mathrm{p}<.001)$ ).

Figure 3: Individual preferences in case-marker use in the flexible word order language on the final day of training. The dashed line indicates the input proportion of casemarking.

Figure 4: Case-marker use by sentence word order in production (flexible word order condition)

Learning outcomes in each language condition thus support our hypothesis. As expected, learners of the fixed word order language tend to gradually drop case-marking as they acquire the novel language. Learners of the flexible word order language maintain case-marking in the language they acquire and make efficient use of it by conditioning case-marking on sentence word order.

## Discussion

Our results provide experimental evidence that some of the typological properties observed cross-linguistically can stem from learners' biases towards communicatively efficient systems. We found that language learners have a bias to balance the amount of information provided by two cues to sentence meaning (case and word order) and tend to use an
additional cue significantly more often in those cases when the other cue does not provide sufficient information to successfully parse the sentence.

Importantly, our results parallel synchronic and diachronic typological data from natural languages. We presented learners with languages that contained the same amount of case-marking, but the learning outcomes consistently differed depending on the amount of word order flexibility allowed in the input language. While learners of the flexible word order language retain casemarking in their own productions, as do Russian, Latin and other free word order languages, learners of the fixed word order language tend to lose case-marking as they acquire the new language, mimicking fixed word order languages such as English and French.

The learning outcomes in our experiment also parallel diachronic phenomena such as the evolution of English from Old English to Modern English. Our data, however, does not speak to whether word order fixing was a result of the loss of case-marking or whether case-marking became a redundant cue and was lost after English word order became fixed for independent reasons. Under our hypothesis, both processes will yield the same outcome.

We found that learners of the flexible word order language did not regularize case-marking uniformly across the two possible word orders. Instead they restructured the language to make efficient use of case-marking by conditioning it on sentence word order, using significantly more case-markers when sentence word order was OSV.

Why do learners preferentially case-mark objects in sentences with OSV word order and not the other way around? This behavior could be reflective of a cognitive bias to mark the atypical, somewhat resembling the crosslinguistically common phenomenon known as 'word order freezing' (Lee, 2001). Many flexible word order languages (Turkish, Russian, German, Hindi, Japanese, etc.) enforce default word order for sentences in which case-marking is uninformative (e.g., in the absence of case-marking or in the presence of case syncretism) and require direct objects to be overtly case-marked if sentence word order deviates from the dominant one. For instance, the Russian example in (1) with case-syncretism can only be interpreted as SVO, although Russian generally allows both SVO (dominant) and OVS orders (non-dominant).

$$
\begin{align*}
& \text { Mat' ljubit doch'. }  \tag{1}\\
& \text { Mother-NOM/ACC loves daughter-NOM/ACC } \\
& \text { 'Mother loves daughter' }
\end{align*}
$$

Even though SOV and OSV are equally likely both in the input and in participants' productions in our experiment, OSV word order is typologically rare and is almost always a non-default word order cross-linguistically and thus might attract a higher proportion of case-marking.

The second possibility is that learners prefer to put more informative cues earlier in the sentence to allow for faster processing, as has been hypothesized by Hawkins (2004)
and Nichols (1986). Preliminary support for this hypothesis comes from Fedzechkina et al. (2012), who found that learners of a language with object case-marking preferred to use more case-marking in OSV sentences, whereas learners of a language with subject case-marking used significantly more case-marking in SOV sentences. That is, in both cases, learners preferred case-marking on the sentence-initial argument, thereby providing the disambiguating cue as early as possible in the sentence.

## Conclusions

We used an artificial language learning paradigm to ask whether language structures are shaped by communicative biases. We find that the cross-linguistically common correlation between word order flexibility and the presence of case-marking can be at least partially explained by domain-general learning biases stemming from a preference to balance the amount of information provided by the cues to sentence meaning.

#### Abstract

Language learners tend to regularize unpredictable variation and some claim that is due to a language-specific regularization bias. We investigate the role of task difficulty on regularization behavior in a non-linguistic frequency learning task and show that adults regularize variable input when tracking multiple frequencies concurrently, but reliably reproduce the variation they have observed when tracking one frequency. These results suggest that regularization behavior may be due to domain-general factors, such as memory limitations.

Keywords: frequency learning; regularization; probability matching; Bayesian models;

## Introduction

Languages contain very little unpredictable variation (Chambers et al., 2003) and language learners tend to regularize the inconsistent input they encounter (Reali \& Griffiths, 2009; Hudson Kam \& Newport, 2009, Smith \& Wonnacott, 2010). For example, English contains two forms of the indefinite article $a$ and $a n$, but a deterministic rule (based on the initial phoneme of the following noun) governs the use of these two variants. Why are languages regular, and what drives learners to eliminate free variation in language? Some have suggested that we come to the task of language learning with the expectation that languages are regular and that this expectation takes the form of a language-specific innate bias (Bickerton, 1984; DeGraaff, 1999; Lumsden, 1999; Becker \& Veenstra, 2003). Others claim that linguistic regularization can be explained by domain-general learning mechanisms, such as the effects of memory limitations on the type of variation that learners produce (Hudson Kam \& Newport, 2005, 2009; Hudson Kam \& Chang, 2009). Hudson Kam and Newport $(2005,2009)$ have shown that children tend to regularize free variation, whereas adults maintain it by probability matching, and attribute this difference to children having lower working memory capacity than adults. Newport (1990) demonstrated that children have more of a limited ability to learn from inconsistent input and Hudson Kam and Chang (2009) showed that adults probability matched more when word retrieval was made easier and regularized more when it was difficult, further corroborating their claim that memory limitations can lead to regularization, although see Perfors (2012) for an account of restricted memory encoding that does not lead to regularization.

A similar effect of memory limitations can be found in a non-linguistic tasks. In a study with adults, Kareev et al. (1997) reported an effect of individual differences in working memory capacity (as determined by a digit-span test) on participants' perception of the correlation of two probabilistic
variables. Participants with lower capacity overproduced the most common variant, whereas participants with higher capacity did not. Regularization is also modulated by the number of variables in a task; adults regularized slightly more when predicting which of three lights will flash next than when predicting for two lights (Gardner, 1957).

In this paper, we explore the effect of tracking single versus multiple frequencies on the regularization behavior of adults in a non-linguistic task. We show that participants probability match when tracking a single frequency, but regularize when tracking six frequencies concurrently. Because concurrent frequency learning is a prominent aspect of language learning (Saffran, Alin \& Newport, 1996), and also elicits regularization in a non-linguistic task, this is consistent with a domain-general account of the observed regularization bias in language, possibly attributable to limited working memory.

## Frequency learning experiment

Participants 381 participants were recruited via Amazon's Mechanical Turk crowdsourcing platform and completed our experiment online. 37 participants were excluded on the basis of the following criteria: failing a color vision test (2), self-reporting the use of a pen or pencil during the task (14), not reporting their sex or age (2), or having previously participated in any of our experiments, as determined by their user ID with MTurk (19). More participants were recruited than necessary with the expectation that many would be excluded by these criteria. Once the predetermined number of participants per condition was met, data from the last participants was excluded, totaling 24 participants across all conditions and tasks. All excluded participants received the full monetary reward for the task. The average monetary reward per participant, converted to an hourly rate, was $\$ 2.64$. Of the final 320 participants, 184 are female, and the mean age is 36 $(\min =18, \max =69)$, with a standard deviation of 12 years.
Materials The experiment was coded up as a java applet that ran in the participant's web browser in a 600x800-pixel field. Photographs of 6 different containers (a box, pouch, jar, bowl, bucket, and basket) and graphically generated images of marbles in 12 different colors (blue, orange, brown, grey, black, yellow, red, teal, olive, pink, purple, and lime) served as stimuli.

One-item task This experiment consisted of a training phase in which participants observed a series of 10 marble draws from a bag, and a testing phase in which participants were asked to produce another several likely draws from the

Figure 1: Each pane displays the percentage of participants that responded with a given output frequency of the minority marble $(m)$ during testing. Columns are the input ratio of $m: M$ during training. Dashed lines mark the input frequency of $m$. In the one-item task, participants probability matched, reproducing the input ratio with high fidelity. This task was between-subjects; each participant was trained on one input ratio only. In the six-item task, participants were more likely to regularize than to reproduce the input ratio. This task was within-subjects; each participant was trained on all six input ratios concurrently.

Figure 2: Training and testing trials for the six-item task.
same bag. In each training trial, a picture of the bag was displayed for 1000 milliseconds and then a marble (blue or orange) appeared over the bag for 2000 milliseconds. There were 10 training trials, with no break between trials. In each testing trial, the bag was displayed with the two marble colors below. Participants mouse clicked on a marble to make their choice of one draw from the bag. Their choice was displayed above the bag for 2000 milliseconds and then the next testing trial began. There were 10 testing trials with no breaks between trials. Locations (left or right) of the blue and orange marbles were held constant across test trials for each participant, but counterbalanced across participants.

A fixed ratio of blue to orange marbles was shown in the training phase. Each participant was randomly assigned to one of 6 training conditions based on this ratio. The color of the training ratio's minority marble ( m ) and majority marble $(M)$ was counterbalanced across participants. All possible ra-
tios of $m: M$ were tested and will be referred to as the $0: 10$, 1:9, 2:8, 3:7, 4:6, and 5:5 conditions. 192 participants took part in this task, with 32 in each condition.

Six-item task This task is based on the word frequency learning task from Reali and Griffiths (2009). Participants observed 10 marble draws each from six different containers, totaling 60 marble draws (see Figure 2). Each container was associated with 2 unique marble colors ( 12 unique marble colors were therefore used). Training and testing trials were identical to the one-item task. Each container was uniquely associated with one of the possible ratios specified by condition $0: 10,1: 9,2: 8,3: 7,4: 6$, and 5:5 above. Thus, the six-item task is a within-subject version of the one-item task, with the addition that training and testing trials from all six conditions are interleaved. Assignments of a ratio and marble colors (in predefined color pairs) to each container was randomized per participant. 64 participants took part in this task. Two additional versions of this experiment were also run; one where all 6 bags were in condition 0:10 (each container was mapped to one color only) and one where all 6 containers were in condition 5:5. Each of these versions was completed by 32 new participants.

## Experiment results

Participants in the six-item task were more likely to regularize their responses per container than participants in the oneitem task. Here, we refer to regularization as the production of a more extreme ratio than that observed during training,

Figure 3: Difference in mean entropy scores between tasks, for each input ratio. Each participant's sequence of marble draws during testing was converted into an entropy score. Lower scores denote greater regularity within a response. Participant responses were significantly more regular in the six-item task than in the one-item task for input ratios 3:7, 4:6, and 5:5. Error bars show the standard error of the mean.
where $0: 10$ and 10:0 are the most extreme ratios and 5:5 is the least extreme. The distributions of participant responses are shown in Figure 1. Each pane displays the percentage of participants that responded with a given output frequency of $m$, per input frequency and per task. In the one-item task, participants probability matched; the mode of the population is on the input frequency of $m$, meaning that the most common response was perfect reproduction of the ratio observed during training. In the six-item task, visual inspection suggests that participants did not reproduce the training ratios with as high fidelity. Most participants regularized by overproducing the majority marble (all mass in the bars to the left of the dotted line) and a large number of responses are fully regular, meaning the output frequency of $m$ is 0 or 10 .

To better assess the different degrees of regularization between tasks, we calculated the entropy of each participant's sequence of test choices. This quantifies the amount of variation (in bits) with a value between 0 and 1 ; where 0 denotes a completely regular sequence (i.e. a series of all blue marble draws) and 1 denotes a maximally variable sequence (i.e. a series of 5 blue and 5 orange draws, in any order). This allows us to refine our definition of regularization as the overproduction of one marble, such that the entropy of the participant's testing choices is lower than that of their training observations. The mean entropy scores of participant responses per input frequency are shown in Figure 3.

A linear mixed effects regression analysis showed a significant effect of task on entropy scores, $t(34)=-7.226, p<$ .001, and a significant effect of input frequency on entropy scores, $t(34)=-10.832, p<.001$. This means the two tasks elicited different amounts of regularity within participants’

## Six-item task <br> 

Figure 4: Distribution of participant responses for two additional versions of the six-item task, where all items contained the same input ratio of $m: M$. One group of participants was trained on all 0:10 ratios and another group was trained on all 5:5 ratios.
responses and that participants' responses were modulated by training frequencies; they noticed differences in the input frequencies and this affected their responses. A significant interaction of task and input frequency on entropy scores was also obtained, $t(34)=4.570, p<.001$; participants responded differently to different input frequencies, and this pattern of responses also differed by task.

There was a significant difference in mean entropy scores between tasks for input frequencies 3:7, 4:6, and 5:5 ( $W=$ $1427.5, p=.001 ; W=1714, p<.001 ; W=1585.5, p<$ .001 ), respectively. ${ }^{1}$ The difference in mean entropy between tasks was not significant for input frequencies $0: 10$, $1: 9$, and $2: 8(W=894, p=.228 ; W=1184.5, p=.192 ; W=$ $1264, p=.054^{2}$ ), respectively.

Two additional experiments were conducted to explore the possibility that regularization in the six-item task is due to interference between containers, such that ratios learned for one container get confused with ratios learned for another container. We eliminated this type of interference by training participants on 6 containers with identical ratios. Figure 4 shows participant responses when trained on all 0:10 ratios (left) and all 5:5 ratios (right). The average entropy for the all $0: 10$ task is significantly lower than that of the $0: 10$ condition in the six-item task ( $W=5061, p=.004$ ), but not significantly different than the $0: 10$ condition in the one-item task ( $W=2900.5, p=.466$ ). Tracking multiple 0:10 ratios is no different than tracking one 0:10 ratio, but it is different from tracking one $0: 10$ ratio concurrently with other ratios. This means interference may account for the errors participants make in the original six-item task when producing draws for the container they observed as $0: 10$. However, for the all 5:5 task, the average entropy was not significantly different from

[^59]the $5: 5$ condition in the six-item task $(W=5892.5, p=.617)$. Participants still produced 0:10 and 10:0 responses in the absence of observing these ratios during training. Therefore, interference may account for some of the differences between the one-item and six-item tasks, but this isn't the sole cause of the regularization behavior observed in the six-item task.

## Frequency learning models

What cognitive processes cause regularization? So far our analyses have quantified the difference in regularity between participants' training and testing responses. In this section, we turn our focus to an internal force that can affect a learner's behavior; an inductive bias favoring certain ratios of marbles.

## Bayesian model

Bayesian models provide a way to quantify inductive biases and understand their effect on behavior. We fit a betabinomial Bayesian sampler model to participants' responses, following Reali and Griffiths (2009), and ask what prior expectation for regularity a Bayesian rational learner would need to have in order to produce the data that our participants produced.

A Bayesian rational learner uses Bayes' rule, $P(h \mid d) \propto$ $P(d \mid h) P(h)$, to infer what proportion of marbles generated the draws that they observed. Here, each proportion is a hypothesis and the observed draws are the data. Bayes rule combines the prior probability of a hypothesis, $P(h)$, with the likelihood of the data under that hypothesis, $P(d \mid h)$, to arrive at a posterior probability of that hypothesis given the data, $P(h \mid d)$. The prior is a beta distribution over all hypotheses, $\operatorname{Beta}\left(\frac{\alpha}{2}, \frac{\alpha}{2}\right)$, where the parameter $\alpha$ determines whether the learner expects to see regular draws or variable draws. A learner with $\alpha<2$ will tend to regularize their productions, a learner with $\alpha=2$ is unbiased toward any particular proportion of draws, and a learner with $\alpha>2$ is biased towards variability in draws. The likelihood of drawing $N$ marbles in ratio $k:(N-k)$ from a container of marbles in proportions $p:(1-p)$ follows a binomial distribution (Equation 1).

$$
\begin{equation*}
P(k \mid p, N)=\binom{N}{k} p^{k}(1-p)^{N-k} \tag{1}
\end{equation*}
$$

Once the posterior probability over all hypotheses has been determined, the learner must choose a hypothesis to generate testing responses from. We take the case where learners sample a hypothesis from the posterior distribution, and then sample data from this hypothesis according to its likelihood (as if the learner were randomly drawing marbles from the hypothesized proportion, with replacement, as in Equation 1).

This model defines the probability of generating all testing proportions (output states) from all training proportions (input states) and can be visualized as a transition matrix between all possible states in the system. Because our experiment covers all possible training proportions for 10 draws from a bag, we can also construct an empirical transition matrix from participant responses in each task. From here on,
we switch to visualizing our data in terms of marble $1\left(m_{1}\right)$ and marble $2\left(m_{2}\right)^{3}$. Figure 5 (top row) shows the two empirical transition matrices and three model matrices for different values of the prior parameter $\alpha$. Each value of $\alpha$ defines a unique transition matrix, and thus a unique pattern of behavior. For example, if a Bayesian learner observes 1 draw of $m_{1}$ and 9 of $m_{2}$, and if their prior is $\alpha=0.01$, they are most likely to produce 0 draws of $m_{1}$ and 10 of $m_{2}$, regularizing their productions. If their prior is $\alpha=2$, they are most likely to produce 1 draw of $m_{1}$ and 9 of $m_{2}$, probability matching their productions. And if their prior is $\alpha=10$, they are most likely to produce 3 draws of $m_{1}$ and 7 of $m_{2}$, increasing variation in their productions. Thus, the prior used here intuitively captures a range of human behaviors in frequency learning.

The model fitting task at hand is to determine which model transition matrix most resembles the empirical transition matrix, by assigning the most likelihood to the empirical data. The prior associated with the best-fit model is the one that best explains participant behavior and gives us an idea of what biases our participants may have.

The best-fit bias in the one-item task is $\alpha=1.55$ with a $\log$ likelihood of -413 , which is equivalent to correctly predicting $20 \%$ of participant responses in this task ${ }^{4}$. This prior shows an expectation for a slight amount of regularity in the data set. For the six-item task, the best-fit bias is $\alpha=1.21$ with a log likelihood of -1186 , equivalent to $9 \%$ response prediction. This prior shows a stronger bias toward regularity in the six-item task than in the one-item task.

Prediction percentages are lower for the six-item task because participant responses are more variable in the this task than in the one-item task. Only deterministic processes (with one output per input) can be predicted with $100 \%$ accuracy. The ceiling on model prediction for each task was determined by fitting each data set to itself, yielding a maximum of $32 \%$ accuracy for the one-item task and $16 \%$ accuracy for the sixitem task. Relative to these ceilings, the best-fit models account for $61 \%$ and $56 \%$ of participant responses in the oneitem and six-item tasks, respectively.

## Bootstrap model

An input-based random sampling model was also fit to the data. This model defines the transition matrix that would be obtained if participants produced their testing responses by randomly sampling 10 draws from their training observations, with replacement. In this case, each row would be a binomial where $p$ equals the training proportion of $m_{1}$. It is important to note that this transition matrix defines the dynamics of drift in one generation and may be used as a baseline for the loss of variation that can occur in the absence of a regularization bias.

[^60]

Figure 5: Transition matrices (top row) and their associated stationary distribution (bottom row) for the experimental results of the two frequency learning tasks, and for the Bayesian model showing three example bias strengths $(\alpha=0.01,2,10)$. Transition matrices give the probability of moving from each input frequency (the number of training trials showing marble 1) to each output frequency (the number of testing trials in which participants produced marble 1) ${ }^{3}$. The stationary distribution shows how often the transition matrix will produce each output frequency of marble 1.

For this model, the log likelihood of the one-item task data is -259 , equivalent to $25 \%$ response prediction, and is a better fit than the best-fit beta-binomial sampler model ${ }^{5}$. Thus, of the models explored in this paper, drift provides the best account of our participants' probability matching behavior. However, a repeated measures Monte Carlo test shows that the standard deviation among participant output entropies in the one-item task data are significantly lower than that obtainable by drift: $p=.04, p=.03, p=.01, p=.003$, for conditions $2: 8,3: 7,4: 6,5: 5$, respectively. Although these data are wellaccounted for by the drift model, they still show a quantitative difference in standard deviation, meaning that the forces behind probability matching are not truly isomorphic to drift. As for the six-item task, the log likelihood is -1076 , equivalent to $6 \%$ response prediction. Here, the sampler model with a bias toward regularization is still the better fit.

## Null model

This model is the transition matrix that would be obtained if participants were randomly sampling from the two testing choices each trial (i.e. not engaging in the task). Here, every row would be a binomial distribution where $p=0.5$. For this model, the log likelihood of the one-item task data is -604 , equivalent to $4 \%$ response prediction. For the six-item task, the $\log$ likelihood is -1630 , equivalent to $1 \%$ response prediction. Of all models considered, this is the worst fit for both tasks, meaning that participants are not likely to be randomly sampling from their testing choices.

[^61]The results of these model fits strongly suggest that participants in the six-item condition are not just performing poorly at reproducing their training proportion, but they are regularizing their responses in a way that can not be accounted for by random errors.

## Learning biases and long-term behavior

In addition to comparing the transition matrices, which describe the behavior of one generation of learners, we can also look at the long-term behavior of the system, which is described by the stationary distribution of the transition matrix (Figure 5, bottom row). This distribution tells us what percent of the population we would expect to see in each state, after an arbitrarily large number of generations, if the output state of one learner served as the input state to another. Griffiths and Kalish (2007) have shown that the stationary distribution mirrors the prior distribution over hypotheses for the Bayesian sampler model utilized here. The stationary distributions of the empirical transition matrices are most interesting because these would be an estimate of our participants' regularization bias (the prior) if they were Bayesian sampler learners ${ }^{6}$. In line with this interpretation, the stationary distribution of the six-item task closely resembles that of its best-fit Bayesian model, which has a beta distribution $\operatorname{Beta}(0.605,0.605)$. However, the stationary distribution of the one-item task does not resemble that of its bestfit Bayesian model, which has a u-shaped beta distribution Beta( $0.775,0.775$ ). In general, the Bayesian model is a good fit to participant behavior in the six-item task, but does not account very well for participant behavior in the one-item task.

[^62]A close examination of the model's transition matrices and stationary distributions shows that probability matching behavior with a low standard deviation is not within this model's range of behavior.

## Discussion

We have shown that learning a single versus multiple frequencies modulates participants' regularization behavior in a non-linguistic task. When participants tracked the frequency associated with a single item, they probability matched; reproducing the variation they had observed with high fidelity. However, when tracking multiple frequencies concurrently, participants regularized their responses, usually by overproducing the most common variant.

A beta-binomial Bayesian sampler model was fit to the results of each task and showed a stronger prior bias toward regularization in the six-item task than in the one-item task. Strictly speaking, the prior represents the inductive bias of the learner, and participants should come to a marble-drawing task with a particular expectation about the ratios of marbles in containers, regardless of the difficultly of the task. The fact that we find different best-fit priors according to different task demands means that we are not revealing the inductive bias of our participants, per se, but a composite picture that characterizes more than one cognitive constraint. At least one constraint that is sensitive to task demands should be added to the model, such as a memory constraint that disproportionally forgets lower-frequency observations. Such an addition could free up the prior to more accurately reflect participants’ inductive bias. This raises a point of caution in comparing inductive biases across domains without controlling for task demands, since task demands can modulate bias strengths.

Our modeling results also suggest that human probability matching and regularization behavior do not lie on a simple continuum that can be captured by the prior alone. Although the Bayesian model accounted well for our participants' regularization behavior, it failed to account for the restricted variance of probability matching. Participants may be trying to produce a representative sample of draws, where the most likely response is the training ratio itself. Such a parameter might lead to high-fidelity reproduction of the training proportion under low memory constraints only.

If memory constraints are the cause of the regularization bias revealed when learning the frequencies of marbles in several containers, then this same domain-general factor may be the cause of regularization in tasks naturally characterized by concurrent frequency learning, such as language learning.

#### Abstract

The present study presents a novel paradigm for testing the ability for adults to rapidly learn novel morphological categories in the wake of irrelevant information: specifically number markings intermixed with irrelevant gender cues. Using an artificial language learning paradigm, participants were exposed to picture-sound pairs in which pictures of animals varied by number (singular, dual and plural), but with irrelevant gender information intermixed with the exposure items (masculine, feminine and neuter). Auditory stimuli were presented in CVCVCV forms (e.g., [zovabu]) in which the first two syllables denoted the animal (e.g., [zova] for snail) and the final syllable denoted number. (e.g., [bu] for single). Results revealed that participants were able to learn which category the suffix endings referred to, based on a two-alternative forced-choice generalization task. Implications for the learning of complex paradigms are discussed.

Keywords: statistical learning, number, morphology.

## Introduction

Languages are governed by complex sets of rules in which sentences are formed through a systematic combination of words. The rule-governed nature of sentences relies heavily on the use of morphological rules and syntactic categories. Words of the same syntactic categories (e.g., nouns and verbs) share similarities beyond meaning. For example, while verbs typically describe actions, in English verbs frequently follow a noun and precede a prepositional phrase (as in The dog sat on the carpet). In addition, syntactic categories share morphological properties, such as tense, gender and number. These morphological indicators are often present as prefixes or suffixes. The specific phonological form of these morphemes appears to be arbitrary in many languages, as in the use of $/-\mathrm{s} /$ as plural in English. However, there is some evidence that languages with complex systems of gender and number morphology such as French, German, and Hebrew may show signs of systematicity within subcategories (Brooks, Braine, Catalano, and Brody, 1993). In this paper we explore how adults are able to learn complex systems of morphology, and whether learners are sensitive to differences in the arbitrariness of morphological patterns.

This study specifically looks at learning of morphologically complex words. Morphemes are parts of words that do not break down into smaller segments with meanings. For example, the word flying contains two morphemes: fly and -ing. Morphology plays an important role in language learning (as well as in learning linguistic categories) because morphology involves both the form of the morpheme (e.g., -ing) as well as its meaning (i.e., progressive). Because morphological forms are often bound - attached to the stems of each word in the category, learners must be able to recognize morphemes within complex words. In order to learn the morphology of one's language, the learner must be able to separate words in terms of their morphological parts. This ability is referred to as morpheme segmentation.

Because all morphemes involve form and meaning, there is a question as to when both aspects of the morpheme are learned. Given that infants are exposed to complex words in speech before they know the meaning of many words, it is likely that infants are able to segment morphological information without semantics. Studies have shown that by 15 months, infants can use distributional cues to learn nonadjacent dependencies, which are necessary for learning syntactic categories (Gomez \& Maye, 2005), and by 18 months, can begin to acquire categories (Mintz, Newport, \& Bever, 2002). Gomez and Gerken (2000) suggest that some learning of categories occurs at the very earliest stages of life. These studies suggest that morpheme segmentation can occur without knowledge of the specific meaning of the words. In addition, these results also suggest the possibility that early learners are equipped with biases to learn linguistic systems using distributional cues. Because languages tend to show broad similarities with respect to the nature of complex morphological rules, it is possible that languages evolved to accommodate biases within the learner.

The nature of learning biases in young infants raises the question as to why there are differences between child and adult language learners. Any theory of learning biases, innate or otherwise, must explain how biases change (and remain the same) over time, in order to explain why children and adults show differences in language learning strategies (Newport, 1990). One hypothesis is that adults have lost the abilities for acquisition that children have (MacWhinney, 1983), but in some cases of artificial language learning, adults outperform children. Specifically, Braine, Brody, and Brooks (1990) showed higher rates of learning for adults
compared to children when learning novel suffix endings. Another hypothesis suggests adults have learned new methods for acquisition that override the initial learning biases (McWhinney, 1983).

While there are clear differences between children and adults, there is evidence that adults still show biases towards certain morphemes. For example, several studies have shown that children learn suffixes more quickly than adults, and adults learn prefixes more quickly than children (Frigo \& McDonald, 1998; MacWhinney, 1983), but research has also shown that adults can parse suffixes with no additional distributional cues (Finley, 2010). In addition, Finley and Newport (in prep) showed that adult learners are biased against typologically infrequent morphological patterns such as infixation. By studying when adults are able to learn patterns that deviate from their native language (and when they cannot), we can better understand the biases that exist for language learning, as well as to better understand how adults can better achieve native-like competence in learning a second language. If adults show biases for particular patterns that are common, but against patterns that are rare or unattested in natural language, it suggests that biases about language learning persist into adulthood that may help to shape how languages across the world are structured.

The present study focuses on how morphological patterns are learned when the pattern itself differs from the native language, and there is information in the input that is irrelevant to the morphological parsing. The question is whether adults can easily ignore the irrelevant parsing, and learn a morphological pattern that is similar to the native language (English) but differs in important respects. For example, number marking of nouns in English follows a singular-plural distinction in which singular nouns are unmarked, but plural nouns are marked with a suffix. There are also languages that have a three-way number marking system in which singular, dual and plural are marked each with a specific suffix, as in Slovene (Greenberg, 2006). This type of system poses a specific challenge for an adult learner because the participant may enter the experiment with the assumption that number marking works exactly like English, but will have to undo these assumptions in order to learn that all numbers are marked and that there is a distinction between 'two' and 'plural' that is not found in English.

Previous research has explored how adults and children learn novel category patterns. The bulk of these studies focused on the statistical properties of the items themselves, such as the frequency of presentation, the role of immediate feedback (Braine, et al., 1990), similarity of words belonging to each class (Brooks, Braine, Catalano, \& Brody, 1993) and the density and overlap between subcategories (Reeder, Newport, \& Aslin, 2013; Reeder, Newport, \& Aslin, 2009, 2010). Finley and Newport (2010; 2011) focused on the statistical cues that allow for morpheme segmentation without semantic information. In addition, it has been shown that providing visual word cues can
enhance speech segmentation of a novel language (Cunillera, Laine, Camara, \& Rodriguez-Fornells, 2010).

The present paper extends previous research by focusing specifically on morphological paradigms that relate to a specific system of form-meaning combinations that can extend to novel words as in a wug test (Berko, 1958). While Finley and Newport $(2010,2011)$ focused on learning a novel language in which all words were systematically marked by a morpheme, the morphemes had no meaning associated with them, and so it was not clear how the morphemes worked together to form a morphological system, or paradigm. A morphological paradigm is a set of morphemes that marks specific classes (e.g., three suffixes, each marking a different number, /-bu/ 'singular', /-ke/ 'dual', /-mi/ 'plural'). In this study, we test the role of distributional information in learning novel morphological systems, thus extending Finley and Newport $(2010,2011)$ to include morphologically complex systems where both form and meaning are required to learn the language. In order to understand what aspects of the system participants learn, we measured generalization to novel items. This involved measuring responses to test items that appeared in the set of training words in addition to a new set of test words.

In addition, the present study explored whether learners can cope with irrelevant cues when learning a novel pattern. For example, when exposed to a novel label, the learner must weigh many possibilities, many of which are not part of the intention of the speaker (Medina, Snedecker, Trueswell, \& Gleitman, 2011). The same is true in learning novel morphological patterns. If the word ending has a specific morphological meaning (e.g., /-ing/ in English /running/ as opposed to /-ing/ in /string/), the learner must discern whether (and when) this ending has semantic significance, and what (if any) that semantic significance is.

In the present study, participants were exposed to a novel language in which all words were nouns that marked number (singular, plural and dual). However, gender information was provided for the nouns, simulating the problem of ambiguity in learning novel instances in a controlled manner.

## Methods

The present study used an artificial language that contained a large number of stem words and fewer suffixes, mirroring the fact that many natural languages have many more open class morphemes (stems) than closed class morphemes (affixes). Participants were exposed to a miniature language with nouns marked for number, in the form of picture-word pairings. Following exposure, participants were provided with a test in order to determine whether the participant was able to discriminate between the different suffixes and their appropriate meanings.

## Participants

All thirteen participants were adult native English speakers recruited from Elmhurst College and the surrounding community. Each participant was given a $\$ 10$
gift card for participating. Some participants may have previously participated in an artificial grammar learning experiment, however no participant had been exposed to the stimuli used during the present experiment.

## Design

The experiment was designed to test the ability of adult learners to integrate learning form and meaning when the form is arbitrary. A miniature language was developed for the study that contained only words with stems and suffixes. Stems of the words were paired with a type of animal (e.g., /befa/ denotes a ladybug). Each suffix corresponded to the number of animals. The suffix /-bu/ denoted 'singular' (e.g., /befabu/ 'one ladybug'), the suffix /-ke/ denoted 'dual', (e.g., /befake/ 'two ladybugs'), and the suffix /-mi/ denoted 'plural' (e.g.. /befami/ 'more than two ladybugs').

Exposure to the language was created via picture-word pairings in which the sound of the word was paired with a picture of the appropriate number of animals. The gender of the animal varied randomly throughout, and served as irrelevant information. The gender of the animal was denoted using a bowtie for males, purses for females and no marking for unmarked gender. Examples of the picturesound pairings can be found in Table 1.

Table 1: Examples of Picture-Naming Pairings.

All stems were of the form CVCV and all suffixes were of the form CV (/-bu/, /-ke/ and /-mi/), where C is a consonant and V is a vowel. All words were therefore CVCVCV. Consonants were all from the set $[b, d, g, k, m$, $\mathrm{n}, \mathrm{p}, \mathrm{s}, \mathrm{t}, \mathrm{v}, \mathrm{z}]$ and vowels were from the set $[\mathrm{a}, \mathrm{e}, \mathrm{i}, \mathrm{o}, \mathrm{u}]$. No words overlapped with English words, and each consonant and vowel was presented equally often in each position.

Training consisted of 12 stems (each corresponding to a different animal), combined with two of the three suffixes, creating 24 total training items. Each stem and each suffix appeared with equal frequency across the 24 training items. Exposure consisted of repeating the 24 training items eight times. While each sound could be paired with three different pictures (e.g., if /ganubu/ signified a single giraffe, the appropriate picture would be for any gender: female, male and neuter), the same picture was used for each pictureword pairing for all eight cycles of the training stimuli. The irrelevant information (e.g., gender markings on the training pictures) was distributed throughout the training items.

Participants were tested on their knowledge of the language as well as their ability to generalize the suffix information to novel stem forms using a two-alternative forced-choice test. In the test, participants matched two spoken words to a single picture. Participants were told one of the words would be from the language they had been listening to and the other word would not be from the language. Participants chose which of two words correctly corresponded to the picture shown. There were twelve items in three different test conditions, described in more detail below, with examples in Tables 2-4.

Familiar Stem-Familiar Picture The first type of test item specifically tested the learner's ability to match a picture seen in training to its corresponding word. Participants heard two words with the same bi-syllabic stem. One word was heard during training, and the other word was a word not heard in training but contained the same stem as the 'correct' test item. If the participant was able to match the picture to the correct suffix, it demonstrates that the participant had learned the suffix-picture pairings. Because the two options contained the same stems, the options were highly similar, and could thus not rely on the stem to make the correct response.

Table 2: Familiar Stem-Familiar Picture Test Items

| Correct Item | Decoy <br> Item |
| :--- | :--- |
| befabu | befake |
| sufemi | sufebu |

Familiar Stem-Novel Picture The second type of test item probed the learner's ability to generalize the suffixes to the items that were not heard in training. For every stem, there were three possible suffix pairings, but only two were heard
in training. In this test condition, the picture shown corresponded to the stem+suffix pairing that was not heard in training, and the decoy item was a stem+suffix item that was heard during training. Both options had the same stem, meaning that participants had to rely on the suffix to choose the correct response. Because the decoy item was familiar to the participant, if participants chose the item that was most familiar, they would be incorrect. Examples of these test items can be found in Table 3, below.

Table 3: Familiar Stem-Novel Picture Test Items

| Correct Item | Decoy <br> Item | Picture |
| :--- | :--- | :--- |
| befake | befami | sufemi |
| ganumi | ganubu |  |

Novel Word-Novel Picture The third type of test item probed the learner's ability to generalize to novel stem items. This served as a comprehension version of a wug test. Participants heard two stem+suffix combinations, in which the stems were identical in both conditions. The picture shown corresponded to one of the suffixes. Participants could only rely on knowledge of the suffix to get these items correct, as the participants had not seen these stem items in training.

Table 4: Novel Word-Novel Picture Test Items

| Correct Item | Decoy <br> Item | Picture |
| :---: | :--- | :---: |
| pumubu | pumumi | pazike |
| pozimi | kovebu |  |

There were 12 tokens of each of the three test sets of test items. These items were presented in a random, mixed fashion. The 12 items in each test condition were balanced such that the correct response was singular, plural and dual an equal number of times (four). The items were also balanced such that all possible suffix combinations were heard an equal number of times (e.g., in a test trial where /bedemi/ is pit against /bedeke/, the two suffix options are $/ \mathrm{ke} /$ and $/ \mathrm{mi} /$. This suffix combination occurred equally often as $/ \mathrm{ke} / \mathrm{vs}$. $/ \mathrm{bu} /$ and $/ \mathrm{mi} / \mathrm{vs}$. $/ \mathrm{bu} /$ ).

All stimuli were recorded by an adult female native speaker of English in a sound attenuated booth at $12,000 \mathrm{~Hz}$ (though participants were allowed to adjust headphones to a comfortable volume during the experiment). Stress was placed on the first syllable using standard English pronunciation, with the exception that no vowels were reduced, meaning all syllables contained partial stress (as English reduces unstressed syllables). All stimuli items were normalized for intensity (set at 70dB) using Praat (Boersma \& Weenink, 2005). All phases of the experiment were run in Psyscope X (Cohen, MacWhinney, Flatt, \& Provost, 1993). Participants were given both written and verbal instructions. The entire experiment took approximately 20 minutes.

## Results

Proportion of correct responses for all three test items are given in Figure 1. We compared each test item to $50 \%$ chance via three separate one-sample $t$-tests. All three test items were significantly above chance; the Familiar StemFamiliar Picture test items had a mean of $0.88, t(12)=7.91$, $p<0.001$, the Familiar Stem-Novel Picture test items had a mean of $0.85, t(12)=75.69, p<0.001$ and the Novel WordNovel Picture test items had a mean of $0.88, t(12)=7.37$, $p<0.001$, suggesting that the participants learned the suffixation pattern.

Figure 1: Test Item Results.

Because the novel language contained contrasts and markings for number (singular-dual-plural) that are not found in English, we divided responses by number marking, to ensure that all three number markings were learned by participants. These are presented in Figure 2.

Figure 2: Number-Marking Results.

We compared the results via a $3 \times 3$ within-subjects ANOVA. There were no main effects for Test Type, $(F(2,24)=1.29$, $p=0.29)$, Number Type $(F(2,24)=1.79, p=0.19)$, and no Interaction $(F(4,48)=1.71, p=0.16)$. This suggests that all three number markings were learned equally well.

We hypothesized that the difference between dual and plural may be the most difficult to learn because dual and plural are not distinguished in English. We therefore performed planned comparisons between dual and plural test items. There were no differences between dual and plural test items for either the Familiar Word-Familiar Picture, $t(12)=0.32, p=0.75$, or the Familiar Word-Novel Picture, $t(12)=1.10, p=0.29$ test items. There was a significant difference between the dual and the plural test items for the Novel Word-Novel Picture test items, $t(12)=2.50, p=0.028$. This suggests that if there is a difference in the difficulty of learning novel number markings, that this is most likely to appear during generalization to novel stems.

The learning rates were relatively robust across participants. Of the 13 participants, only two had overall means less than $80 \%$ ( $50 \%$ and $41.67 \%$ respectively). For these two participants, the difference in number was most pronounced. These participants were most accurate on dual test items ( $70.83 \%$ correct), around chance for singular items $(45.83 \%$ correct) and below chance for plural items ( $20.83 \%$ correct). Because so few participants scored below $80 \%$ correct, no inferential statistics can be made. However, these results may indicate that those who have difficulty learning novel morphological systems may only have trouble with specific number markers.

## Discussion

The results of the present study provide important insights into how novel complex morphological systems are learned. First, consistent endings along with consistent number cues allowed the vast majority of participants to infer that the final suffix referred to number, and that this final suffix applied to novel items, both for stems heard during exposure, as well as novel items not heard during exposure. Second, this ability is very robust in adults. Of the thirteen participants, only two showed means below $80 \%$ suggesting that these relatively complex patterns are learned with ease, without any feedback from the learning paradigm. Third, the number markings in the present experiment differed from those found in English: all different numbers were marked (as opposed to only plural in English), and a distinction was created between dual and plural (as opposed to only plural in English).

The stimuli in the present experiment included irrelevant cues to gender, which the participants were able to rule out. Because both gender and number cues were provided, the paradigm allows for future research to study both gender and number markings simultaneously. It also demonstrates that learners are able to cue into the relevant aspects of novel data, and ignore irrelevant aspects.

The results showed relatively few differences between test items that probed for knowledge of the different number markings, despite the fact that the dual number marking was novel to the English speakers. This suggests that learners are adaptable to novel number markings. Interestingly, the two participants who showed poor performance overall, seemed to show differential responses to different number categories, suggesting that problems in learning novel morphology may be specific to a specific morpheme, rather than the entire morphological paradigm. Because these trends can only be made for two participants, more research is needed to understand why some learners have difficulty learning novel morphological structures, while others have little difficulty.

The present study presented a novel paradigm for exploring how adults are able to learn novel morphological systems. The results demonstrated that adults are able to rapidly and robustly learn novel number marking systems despite irrelevant gender cues. The present paradigm provides a tool for future research to explore how complex systems of form and meaning are learned and generalized to novel items. The present paradigm allows the experimenter to control for how much information is relevant to the morphological system and how much is irrelevant.

The paradigm specifically allows the researcher to explore novel questions about how complex morphological systems are learned. In many languages, the same phonological unit is used to mark multiple morphemes. For example, $/-\mathrm{s} /$ is used in English to mark both plural as well as third person singular, present tense verbs. In German, /der/ is used to mark nominative singular case, as well as plural genitive case. In these instances, the learner must sort out when each morpheme is used. The present paradigm may help to sort out what aspects of the morphological paradigm are most helpful to learning a complex paradigm. Future research will explore how phonological regularities and semantic consistency contribute to learning a novel morphological paradigm.

The present study makes use of adult participants. While studying children is often ideal when examining language learning, adult studies are also extremely useful in terms of understanding how learning biases persist into adulthood. The present paradigm is well suited to adapt to child language studies, allowing future research to easily make adult-children comparisons in learning. However, there are many reasons that using adults in the present study has theoretical importance. Throughout life, novel stimuli are presented in a language no matter how long ago the language was learned. New words come into the language (e.g., as each new generation adds to the list of slang words). Adult studies increase the knowledge about continuing language learning in the first language and learning in general. In addition, studying adults in a second language environment will help to understand the biases that adults use in second language learning, which may provide insight into making adult second language learning easier. In addition, studies of adult second language learning often
reveal deficiencies in learning the morphology of the language (Johnson \& Newport, 1989; Newport, 1990). Thus, understanding adult learning biases for morphological learning may have direct implications for understanding these deficits (and possibly finding methods to correct them).

The present study adds to the growing number of studies that demonstrate that learners are able to make use distributional cues to learn the regular (rule-based) aspects of language. When forms (e.g., suffixes) are paired consistently with a meaning, the learner infers a general rule that can apply to items that have never been seen or heard before. This is done despite additional, irrelevant cues that could potentially disrupt the learning mechanism. The fact that learners are able to sort out which cues are relevant without any direct feedback, demonstrates the enormous inferential power of the human mind.

## Acknowledgments

The authors would like to thank Matt Goldrick, Patricia Reeder, Elissa Newport, Emily Kasman, Morgan Smith and Elizabeth Jennings, members of the Aslin-Newport Lab, as well as participants at the 2012 Psychonomics Meeting for helpful comments and discussion. In addition, we would like to thank the Elmhurst College Psychology Department and the participants at Elmhurst College. S. Finley assumes all responsibility for any errors. Funding was provided by a student-faculty collaboration grant from Elmhurst College.

# Analogical Reinforcement Learning 

James M. Foster \& Matt Jones<br>james.m.foster@colorado.edu, mcj@colorado.edu<br>University of Colorado, Department of Psychology \& Neuroscience<br>Boulder, CO 80309 USA

#### Abstract

Research in analogical reasoning suggests that higher-order cognitive functions such as abstract reasoning, far transfer, and creativity are founded on recognizing structural similarities among relational systems. Here we integrate theories of analogy with the computational framework of reinforcement learning (RL). We propose a computational synergy between analogy and RL, in which analogical comparison provides the RL learning algorithm with a measure of relational similarity, and RL provides feedback signals that can drive analogical learning. Initial simulation results support the power of this approach.

Keywords: Analogy; Reinforcement Learning; Schema Induction; Similarity; Generalization

## Introduction

The goal of the present work is to develop a computational understanding of how people learn abstract concepts. Previous research in analogical reasoning suggests that higherorder cognitive functions such as abstract reasoning, far transfer, and creativity are founded on recognizing structural similarities among relational systems (Doumas et al., 2008; Gentner, 1983; Hummel \& Holyoak, 2003). However, we argue a critical element is missing from these theories, in that their operation is essentially unsupervised, merely seeking patterns that recur in the environment, rather than focusing on the ones that are predictive of reward or other important outcomes.

Here we integrate theories of analogy with the computational framework of reinforcement learning (RL). RL offers a family of learning algorithms that have been highly successful in machine learning applications (e.g., Bagnell \& Schneider, 2001; Tesauro, 1995) and that have neurophysiological support in the brain (e.g., Schultz et al., 1997). A shortcoming of RL is that it only learns efficiently in complex tasks if it starts with a representation (i.e., a means for encoding stimuli or states of the environment) that somehow captures the critical structure inherent in the task. We formalize this notion below in terms of similarity-based generalization (Shepard, 1987) and kernel methods from statistical machine learning (Shawe-Taylor \& Cristianini, 2004). In other words, RL requires a sophisticated sense of similarity to succeed in realistically complex tasks. Psychologically, the question of how such a similarity function is learned can be cast as a question of learning sophisticated, abstract representations.

This paper proposes a computational model of analogical RL, in which analogical comparison provides the RL learning algorithm with a measure of relational similarity, and RL provides feedback signals that can drive analogical learning. Relational similarity enables RL to generalize knowledge from past to current situations more efficiently, leading to faster
learning. Conversely, the prediction-error signals from RL can be used to guide induction of new higher-order relational concepts. Thus we propose there exists a computationally powerful synergy between analogy and RL. The simulation experiment reported here supports this claim. Because of the strong empirical evidence for each of these mechanisms taken separately, we conjecture that the brain exploits this synergy as well.

## Analogy

Research in human conceptual knowledge representation has shown that concepts are represented not just as distributions of features (cf. Nosofsky, 1986; Rosch \& Mervis, 1975) but as relational structures. This relational knowledge includes both internal structure, such as the fact that a robin's wings allow it to fly (Sloman et al., 1998), as well as external structure, such as the fact that a dog likes to chase cats (Jones \& Love, 2007). Theories of analogical reasoning represent relational knowledge of this type in a predicate calculus that binds objects to the roles of relations, for example CHASE(DOG,CAT). According to these theories, an analogy between two complex episodes (each a network of relations and objects) amounts to recognition that they share a common relational structure (Gentner, 1983; Hummel \& Holyoak, 2003).

At a more mechanistic level, the dominant theory of analogy is structural alignment (Gentner, 1983). This process involves building a mapping between two episodes, mapping objects to objects and relations to relations. The best mapping is one that maps objects to similar objects, maps relations to similar relations, and most importantly, satisfies parallel connectivity. Parallel connectivity means that, whenever two relations are mapped to each other, the objects filling their respective role-fillers are also mapped together. An example is shown in Figure 1. Parallel connectivity is satisfied here because, for each mapped pair of attack relations (red arrows), the objects filling the ATTACKER role are mapped together (knight is mapped to queen), and the objects filling the ATTACKED role are also mapped together (rook to rook and king to king). Thus structural alignment constitutes a (potentially partial or imperfect) isomorphism between two episodes, which respects the relational structure that they have in common. Importantly, if the search for a mapping gives little emphasis to object-level similarity (as opposed to relation-level similarity and parallel connectivity), then structural alignment can find abstract commonalities between episodes having little or no surface similarity (i.e., in terms of perceptual features).

We propose structural alignment is critical to learning of

Figure 1: An example of structural alignment between two chess positions. Both positions contain instances of the abstract concept of a FORK: black's piece is simultaneously attacking both of white's pieces. These attacking relations are represented by the red arrows. Cyan lines indicate the mapping between the two episodes. The mapping satisfies parallel connectivity because it respects the bindings between relations and their role-fillers.
abstract concepts for three reasons. First, perceived similarity of relational stimuli depends on structural alignability (Markman \& Gentner, 1993). Second, structural alignment is important for analogical transfer, which is the ability to apply knowledge from one situation to another, superficially different situation (Gick \& Holyoak, 1980). For example, a winning move in one chess position can be used to discover a winning move in a different (but aligned) position, by translating that action through the analogical mapping. Third, a successful analogy can lead to schema induction, which involves extraction of the shared relational structure identified by the analogy (Doumas et al., 2008; Gentner, 1983; Hummel \& Holyoak, 2003). In the example of Figure 1, this schema would be a system of relational knowledge on abstract (token) objects, including ATTACK(PIECE1,PIECE2), ATTACK(PIECE1,PIECE3), and potentially other shared information such as NOT_ATTACKED(PIECE1) and KING(PIECE2).

These three observations suggest that analogy plays an important role in learning and use of abstract relational concepts. The first two observations suggest that analogical transfer can be cast as a form of similarity-based generalization, as we elaborate in the next two sections. In brief, structural alignment offers a sophisticated form of similarity that can be used to generalize knowledge between situations that are superficially very different. The third observation suggests that analogy can discover new relational concepts (e.g., the concept of a chess fork, from Figure 1), which can in turn lead to perception of even more abstract similarities among future experiences.

One potential shortcoming of the basic theory of analogy reviewed here is that is it essentially unsupervised. In this framework, the quality of an analogy depends only on how well the two systems can be structurally aligned, and not on how useful or predictive the shared structure might be. For
example, one could list many relational patterns that arise in chess games but that are not especially useful for choosing a move or for predicting the course of the game. In previous work, we have found that implementing structural alignment and schema induction in a rich and structured artificial environment results in discovery of many frequent but mostly useless schemas (Foster et al., 2012). An alternative, potentially more powerful model of analogical learning would involve feedback from the environment, so that the value of an analogy or schema is judged partially by how well it improves predictions of reward or other important environmental variables. For example, the concept of a fork in chess is an important schema not (only) because it is a recurring pattern in chess environments, but because it carries information about significant outcomes (i.e., about sudden changes in each player's chances of winning). A natural framework for introducing this sort of reward sensitivity into theories of analogy is that of RL, which we review next.

## Reinforcement Learning

RL is a mathematical and computational theory of learning from reward in dynamic environments. An RL task is characterized by an agent embedded in an environment that exists in some state at any given moment in time. At each time step, the agent senses the state of its environment, takes an action that affects what state occurs next, and receives a continuousvalued reward that depends on the state and its action (Sutton \& Barto, 1998). This framework is very general and can encompass nearly any psychological task in which the subject has full knowledge of the state of the world at all times (i.e., there are no relevant hidden variables).

Most RL models work by learning values for different states or actions, which represent the total future reward that can be expected from any given starting point (i.e., from any state or from any action within a state). These values can be learned incrementally, from temporal-difference (TD) error signals calculated from the reward and state following each action (see Model section). There is strong evidence that the brain computes something close to TD error, and thus that RL captures a core principle of biological learning (Schultz et al., 1997).

In principle, this type of simple algorithm could be used to perfectly learn a complex task such as chess, by experiencing enough games to learn the true state values (i.e., probability of winning from every board position) and then playing according to those values. However, a serious shortcoming of this naive approach is that it learns the value of each state independently, which can be hopelessly inefficient for realistic tasks that typically have very large state spaces. Instead, some form of generalization is needed, to allow value estimates for one state to draw on experience in other, similar states.

Many variants of RL have been proposed for implementing generalization among states (e.g., Albus, 1981; Sutton, 1988). Here we pursue a direct and psychologically motivated form of generalization, based on similarity (Jones \&

Cañas, 2010; Ormoneit \& Sen, 2002). We assume the model has a stored collection of exemplar states, each associated with a learned value. The value estimate for any state is obtained by a similarity weighted average over the exemplars' values; that is, knowledge from each exemplar is used in proportion to how similar it is to the current state. This approach is closely related to exemplar-generalization models in more traditional psychological tasks such as category learning (Nosofsky, 1986). It can also be viewed as a subset of kernel methods from machine learning (Shawe-Taylor \& Cristianini, 2004), under the identification of the kernel function with psychological similarity (Jäkel et al., 2008).

A critical consideration for all learning models (including RL models) is how well their pattern of generalization matches the inherent structure of the task. If generalization is strong only between stimuli or states that have similar values or outcomes, then learning will be efficient. On the other hand, if the model generalizes significantly between stimuli or states with very different outcomes, its estimates or predictions will be biased and learning and performance will be poor. The kernel or exemplar-similarity approach makes this connection explicit, because generalization between two states is directly determined by their similarity. As we propose next, analogy and schema induction offer a sophisticated form of similarity that is potentially quite powerful for learning complex tasks with structured stimuli.

## Analogical RL

The previous two sections suggest a complementary relationship between analogy and RL, which hint at the potential for a computationally powerful, synergistic interaction between these two cognitive processes. We outline here a formal theory of this interaction. The next two sections provide a mathematical specification of a partial implementation of this theory, and then present simulation results offering a proof-inprinciple of the computational power of this approach.

The first proposed connection between analogy and RL is that structural alignment yields an abstract form of psychological similarity that can support sophisticated generalization (Gick \& Holyoak, 1980; Markman \& Gentner, 1993). Incorporating analogical similarity into the RL framework could thus lead to rapid learning in complex, structured environments. For example, an RL model of chess equipped with analogical similarity should recognize the similarity between the two positions in Figure 1 and hence generalize between them. Consequently the model should learn to create forks and to avoid forks by the opponent much more rapidly than if it had to learn about each possible fork instance individually.

The second proposed connection is that the TD error computed by RL models, for updating value estimates, can potentially drive analogical learning by guiding schema induction. Instead of forming schemas for whatever relational structures are frequently encountered (or are discovered by analogical comparison of any two states), an analogical RL model can be more selective, only inducing schemas from analogies that
significantly improve reward prediction. Such analogies indicate that the structure common to the two analogue states may have particular predictive value in the current task, and hence that it might be worth extracting as a standalone concept. For example, if the model found a winning fork move by analogical comparison to a previously seen state involving a fork, the large boost in reward could trigger induction of a schema embodying the abstract concept of a fork.

The proposed model thus works as follows (see the next section for technical details). The model maintains a set of exemplars $E$, each with a learned value, $v(E)$. To estimate the value of any state $s$, it compares that state to all exemplars by structural alignment, which yields a measure of analogical similarity for each exemplar (Forbus \& Gentner, 1989). The estimated value of the state, $\tilde{V}(s)$, is then obtained as a similarity-weighted average of $v(E)$. After any action is taken and the immediate reward and next state are observed, a TD error is computed as in standard RL. The exemplar values are then updated in proportion to the TD error and in proportion to how much each contributed to the model's prediction, that is, in proportion to $\operatorname{sim}(s, E)$.

Additionally, whenever the structural alignment between a state and an exemplar produces a sufficient reduction in prediction error (relative to what would be expected if that exemplar were absent), a schema is induced from that analogy. The schema is an abstract representation, defined on token (placeholder) objects, and it contains only the shared information that was successfully mapped by the analogy. The schema is added to the pool of exemplars, where it can acquire value associations directly (just like the exemplars do). The advantage conferred by the new schema is that it allows for even faster learning about all states it applies to (i.e., that contain that substructure). For example, rather than learning by generalization among different instances of forks, the model would learn a direct value for the fork concept, which it could immediately apply to any future instances. A consequence of the schema induction mechanism is that the pool of concrete exemplars comes to contain more and more abstract schemas. Thus the model's representation transitions from initially episodic to more abstract and conceptual.

Analogical RL thus integrates three principles from prior research: RL, exemplar generalization, and structural alignment of relational representations. Because each of these principles has strong empirical support as a psychological mechanism, it is plausible that they all interact in a manner similar to what we propose here. Thus it seems fruitful to explore computationally what these mechanisms can achieve when combined.

## Model

The simulation study presented below uses a variant of RL known as afterstate learning, in which the agent learns values for the possible states it can move into (Sutton \& Barto, 1998). This is a reasonable and efficient method for the task we use here-tic-tac-toe, or noughts \& crosses-because the
agent's opponent can be treated as part of the environment and is the only source of randomness. Our main proposal regarding the interaction between RL and analogical learning is not limited to this approach.

The operation of the model is illustrated in Figure 2. On each time step, the model identifies all possible actions and their associated afterstates. For each afterstate $s$, it computes an analogical similarity, $K$, to each exemplar, $E$, by structural alignment. Each possible mapping $M: s \rightarrow E$ is evaluated according to

$$
\begin{align*}
& \Phi(M)=\beta \cdot \sum_{o \in s} \operatorname{sim}(o, M(o)) \\
& +\sum_{r \in s} \operatorname{sim}(r, M(r)) \cdot\left[1+\sum_{i=1}^{n_{r}} I_{\left\{M\left(\operatorname{child}_{i}(r)\right)=\operatorname{child}_{i}(M(r))\right\}}\right] \tag{1}
\end{align*}
$$

This expression takes into account object similarity, by comparing each object $o$ in $s$ to its image in $E$; relational similarity, by comparing each relation $r$ in $s$ to its image in $E$; and parallel connectivity, by having similarity between mutually mapped relations "trickle down" to add to the similarity of any mutually mapped role-fillers (Forbus \& Gentner, 1989). The sim function is a primitive (object- and relationlevel) similarity function, $\beta$ determines the relative contribution of object similarity, $n_{r}$ is the number of roles in relation $r, \operatorname{child}_{i}(r)$ is the object filling the $i^{\text {th }}$ role of $r$, and $I_{\{P\}}$ is an indicator function equal to 1 when proposition $P$ is true. Analogical similarity is then defined as the value of the best mapping (here the $\theta$ parameter determines specificity of generalization):

$$
\begin{equation*}
K(s, E)=\exp \left(\theta \cdot \max _{M} \Phi(M)\right) \tag{2}
\end{equation*}
$$

The activation $a(E)$ of each exemplar is determined by normalizing the analogical similarities, and the estimated value of $s, \tilde{V}(s)$, is computed as a similarity-weighted average of the exemplar values $v(E)$ (Figure 2). Thus the estimate is based on the learned values of the exemplars most similar to the candidate state.

Once values $\tilde{V}(s)$ have been estimated for all candidate afterstates, the model uses a softmax (Luce-choice or Gibbssampling rule) to select what state to move into (here $\tau$ is an exploration parameter):

$$
\begin{equation*}
\operatorname{Pr}\left[s_{t}=s\right] \propto e^{\tilde{V}(s) / \tau} \tag{3}
\end{equation*}
$$

Learning based on the chosen afterstate $s_{t}$ follows the SARSA rule (Rummery \& Niranjan, 1994), after the model chooses its action on the next time step. This produces a TD error, which is then used to update the exemplar values by gradient descent (see Equations for $\delta$ and $\Delta v(E)$ in Figure 2).

The model also grows its representation in two ways. First, it begins with no exemplars, and on each trial adds the state it moves to as a new exemplar with probability inversely proportional to the number of exemplars already in the model. This recruitment policy leads the exemplar pool to grow with

Figure 2: Model operation. Each candidate afterstate is evaluated by analogical comparison to stored exemplars, followed by similarity-weighted averaging among the learned exemplar values. Learning is by TD error applied to the exemplar values. On some trials, especially useful analogies produce new schemas that are added to the exemplar pool. In the example here, $s$ and $E$ both have guaranteed wins for X by threatening a win in two ways. The induced schema embodies this abstract structure. Dots with red arrows indicate ternary "same-rank" relations. $r=$ reward; $\gamma=$ temporal discount parameter; $\alpha=$ learning rate; other variables are defined in the text.
the square root of time, which seems to give good performance.

The more important form of representation learning in the model is schema induction. Schema induction has not been implemented yet, but Figure 2 shows how it is expected to work. Following learning after each trial, the model determines how much each exemplar contributed to reducing prediction error, by comparing $\delta$ to what it would have been without that exemplar. If the reduction is above some threshold, the analogical mapping found for that exemplar (lower right of figure) produces a schema that is added to the exemplar pool (far right). The schema is given a value of $v$ initialized at $\tilde{V}\left(s_{t}\right)$. This schema value is updated on future trials just as are the exemplar values. Acquisition of new schemas in this way is predicted to improve the model's pattern of generalization, tuning it to the most useful relational structures in a task.

## Simulation

The model was tested on its ability to learn tic-tac-toe. Each board position was represented by treating the nine squares as objects of types 0 (blank), 1 (focal agent's), and 2 (opponent's), and defining 8 ternary "same-rank" relations for the rows, columns, and diagonals. Thus a player wins by filling all squares in any one of these relations. Object similarity was defined as 1 for matching object types and 0 otherwise. Similarity between relations was always 1 because there was only one type of relation. Reward was given only at the end
of a game, as +1 for the winner, -1 for the loser, or 0 for a draw. After the game ended, it moved to a special terminal state with fixed value of 0 . For simplicity, all free parameters of the model $(\beta, \theta, \alpha, \gamma, \tau)$ were set to a default value of 1 .

Three variations of the model were implemented, differing in their levels of analogical abstraction. The Featural model was restricted to literal mappings between states (upper-left square to upper-left square, etc.). This model still included generalization, but its similarity was restricted to the concrete similarity of standard feature-based models. The Relational model considered all 8 mappings defined by rigid rotation and reflection of the board. This scheme was used in place of searching all 9 ! possible mappings for every comparison, to reduce computation time. Finally, the Schema model extended the Relational model by starting with two hand-coded schemas, 111 and 022 . The first of these is a single same-rank relation bound to three instances of the player's own token. Thus moving into a state satisfying this schema produces an immediate win. Likewise, moving into a state satisfying the second schema risks an immediate loss. The model was given no information about these schemas (i.e., $v$ was initialized to 0 for both), but it was capable of learning values for them. The purpose of this model was to test the utility of having schemas that capture task-relevant structures. Logically this question is separate from that of how such schemas are acquired, although we have addressed that question elsewhere (Foster et al., 2012), and we plan to integrate a solution into the present model soon.

Each model variant was trained in blocks of 10 games of self-play followed by a pair of testing games against an ideal player (playing first in one game and second in the other). Learning occurred only during training. In testing games, the model was given one point for each non-losing move it made (i.e., moves from which it could still guarantee a draw), for a maximum of 9 points per pair of testing games.

Average learning curves are shown in Figure 3A for 50 independent copies of each model over 5000 blocks (50,000 training games). Figure 3B shows results for single copies of the Relational and Featural models over 30,000 blocks. These results show that the Featural model does eventually learn, but the Relational model learns an order of magnitude faster, and the Schema model learns another order of magnitude faster than the Relational model.

## Discussion

The results presented here constitute a proof-of-principle that analogy and schema induction can be productively integrated with a learning framework founded on RL and similaritybased generalization. This integration leads to a model exhibiting sophisticated, abstract generalization derived from analogical similarity, as well as discovery of new higher-order relational concepts driven by their ability to predict reward.

The basic modeling framework used here applies not just to analogical similarity and schema induction, but to other forms of representational learning as well. Kernel-based RL offers

Figure 3: Learning curves. A: 50 copies of each model. B: Single copies of the two slower models over extended training.
a powerful and general theory of representation learning, because it can be integrated with any form of representation that yields a pairwise similarity function. Its TD error signal can drive changes in representation via the objective of improving generalization. In previous work, we have applied this idea to learning of selective attention among continuous stimulus dimensions (Jones \& Cañas, 2010). The current model offers a richer form of representation learning, in that it acquires new concepts rather than reweighting existing features.

The analogical RL model also builds on other models of relational learning. Tomlinson \& Love (2006) propose a model of analogical category learning, with essentially the same similarity and exemplar generalization mechanisms adopted in the present model. Our model adds to theirs in that it applies to dynamic tasks and in that it grows its representation through schema induction. Van Otterlo (2012) has developed methods for applying RL to relational representations of the same sort used here, although the approach to learning is quite different. His models are not psychologically motivated and hence learn in batches and form massive conjunctive rules, with elaborate updating schemes to keep track of the possible combinations of predicates. In contrast, the present approach learns iteratively, behaves probabilistically, and grows its representation more gradually and conservatively. This approach is likely to provide a better account of human learning, but a more interesting question may be whether it offers any performance advantages from a pure machine-learning perspective.

In the present model, the activation of each exemplar elicited by a candidate state can be thought of as a feature of that state. The exemplar effectively has a "receptive field" within the state space, defined by the similarity function. This duality between exemplar- and feature-based representations is founded in the kernel framework (see Shawe-Taylor \& Cristianini, 2004). The present model takes advantage of this duality, producing a smooth transition from an episodic, similarity-based representation to a more semantic, featurebased representation defined by learned schemas.

The model as currently implemented does have several limitations. Foremost, it does not yet include a mechanism for inducing new schemas. We and others have shown how schema induction can be successfully deployed in an open-
ended model in a complex environment (Doumas et al., 2008; Foster et al., 2012). We hope that building this type of mechanism into the analogical RL framework will produce a bettercontrolled, directed system capable of autonomously discovering genuinely new abstract concepts.

A second limitation of the current model is its slowness to learn, due to the nature of gradient descent operating in a large weight space. In contrast, human learning often shows understanding of new concepts in as little as one trial (Maas \& Kemp, 2009). The theory of analogy via structure mapping seems like the best candidate for a process-level theory of such rapid learning, and we predict that the full analogical RL model with schema induction will show significant steps in that direction.

The present work is complementary to hierarchical Bayesian models that discover relational structure through probabilistic inference (Tenenbaum et al., 2011). Whereas our model builds up schemas from simpler representations, the Bayesian approach takes a top-down approach, defining the complete space of possibilities a priori and then selecting among them. The top-down approach applies to any learning model, because any well-defined algorithm can always be circumscribed in terms of its set of reachable states. This is a useful exercise for identifying inductive biases and absolute limits of learning, but it offers little insight into the constructive processes that actually produce the learning. These mechanistic questions are critical if the goal is to understand how the human mind discovers new, abstract concepts.

# Developmental and postural changes in children's visual access to faces 

Michael C. Frank, Kaia Simmons, Daniel Yurovsky, \& Guido Pusiol<br>\{mcfrank,kaias,yurovsky, pusiol\}@stanford.edu<br>Department of Psychology<br>Stanford University

#### Abstract

The faces of other people are a critical information source for young children. During early development, children undergo significant postural and locomotor development, changing from lying and sitting infants to toddlers who walk independently. We used a head-mounted camera in conjunction with a face-detection system to explore the effects of these changes on children's visual access to their caregivers' faces during an in-lab play session. In a cross-sectional sample of 4-20 month old children, we found substantial changes in face accessibility based on age and posture. These changes may translate into changes in the accessibility of social information during language learning.

Keywords: Social development; face processing; headcamera.

## Introduction

A father offers his young daughter a novel object: a bright yellow feather duster. A few moments after she accepts the toy, he remarks, "Isn't the zem funny?" Her father may still be talking about the feather duster, or he may be describing a new object. To find out she has access to a simple and reliable method: she can look to his face to infer the direction of his attention.

The ability to follow social signals like eye-gaze is an important part of early social cognition (Scaife \& Bruner, 1975) and a strong predictor of children's early language development. For example, Brooks and Meltzoff (2005) found that children who followed an experimenter's gaze better before their first birthday had larger vocabularies at 18 months. Similarly, Carpenter, Nagell, and Tomasello (1998) found that children's level of joint engagement (as well as the degree to which mothers followed the child's focus of attention in their labeling) predicted vocabulary growth in both language production and comprehension. These studies suggest that children's social environment plays a powerful supportive role in language learning.

But at the same time as children are beginning to learn their first words, their view of the world is changing radically (Adolph \& Berger, 2007). As speechless infants, they are unable to locomote independently. Before their first birthday, they begin crawling; soon after, they begin to walk independently. Infants' visual field is subject to the whims of their caregivers, but caregivers often place them in positions conducive to joint attention. In contrast, toddlers determine their own input to a much greater degree, but as a consequence they spend much of their time in a world primarily populated by knees. These postural and locomotor changes may have a profound effect on what children see.

A recent study suggests the possibility of links between motor milestones, social cognition, and language. Walle and

Campos (under review) noted robust correlations between children's ability to walk and their vocabulary, both receptive and productive. On the basis of an observational study of parent input, they speculated that the emergence of walking may change the ability of the child to access social information (because walking toddlers see more of the social world than crawling infants). Accessing more social information may in turn allow children to discover word meanings more effectively.

Recent methodological developments have the potential to provide data that would allow this hypothesis to be tested. The availability of head-mounted cameras and eye-trackers allows for the measurement of children's naturalistic environment in a way that was not previously possible. Yoshida and Smith (2008) gave the first demonstration of the radical differences between toddler and adult perspectives on the social world, with toddlers' visual field being dominated by hands and objects much more than that of adults. More recent work has used head-mounted eye-tracking methods to measure young toddlers' fixations (Franchak, Kretch, Soska, \& Adolph, 2011), also finding that children look relatively infrequently at their mothers' faces in naturalistic play.

These methods are now being applied to understand inputs to language acquisition. Work by Yu, Smith, and colleagues suggests that word learning is facilitated when parents and children create moments in which the visual field is dominated by a single object (Smith, Yu, \& Pereira, 2011; Yu \& Smith, in press). Some data even suggest that young children's restricted viewpoint may be more effective for learning words than the comparable adult perspective (Yurovsky, Smith, \& Yu, in press). Together, this body of evidence suggests that measuring infants' perspective-and how it changes in motor development-is a critical part of understanding early language learning.

In the current study we took a developmental approach to understanding the relationship between perspective and access to social information. We recorded head-camera data from a group of infants and children across a broad age range as they played with their caregivers during a brief laboratory visit. We then hand-annotated these data for the child's posture and parents' naming behavior and used face-detection algorithms to measure the frequency of faces in the child's visual field. The resulting dataset allows us to analyze changes in access to faces according to children's age, posture, and linguistic input.

Figure 1: Our light-weight, low-cost head-mounted camera with fisheye lens.

## Methods

## Participants

Participants were 20 infants and children ( $\mathrm{N}=4$ each at 4 , $8,12,16$, and 20 months, 9 females total) in an ongoing large-scale study, recruited from the surrounding community via state birth records. Participants had no documented disabilities and were reported to hear at least $80 \%$ English at home. Success rates for children wearing the camera for long enough to initiate the play session varied from $100 \%$ at 8 months to approximately $50 \%$ at 20 months.

## Head-mounted camera

Our head-mounted camera ("headcam") is composed of a small, inexpensive MD80 model camera attached to a soft elastic headband from a camping headlamp. An aftermarket fisheye lens intended for iPhones and other Apple devices is attached to increase view angle. The total cost of each camera is approximately $\$ 60$. The camera captures $720 \times 480$ pixel images at approx. 25 frames per second, and has battery life of $60-90$ minutes. Without the fisheye lens, the viewing angle for the camera is $32^{\circ}$ horizontal by $24^{\circ}$ vertical; with the fisheye, $64^{\circ}$ horizontal by $46^{\circ}$ vertical. The device is pictured in Figure 1.

The vertical field of view of the camera was considerably smaller than the child's approximate vertical field of view, which-even at 6-7 months-spans around $100-120^{\circ}$ in the vertical dimension (Mayer, Fulton, \& Cummings, 1988; Cummings, Van Hof-Van Duin, Mayer, Hansen, \& Fulton, 1988). We were therefore faced with a choice in the orientation of the camera. If we chose a lower or higher orientation, we would be at risk of truncating either the child's own hands and physically proximate objects, or the faces of the adults around the child. Yet if we chose the middle orientation, we would still be at risk of underestimating the proportion of faces viewed by the child. Thus, for the purposes of the current study-measuring visual access to faces-we chose to orient the camera towards the upper part of the visual field. ${ }^{1}$ While this orientation decreased our chances of

[^63]recording the objects being manipulated by the child, it nevertheless allowed us to capture the majority of the faces in the child's visual field.

## Procedure

After coming to the lab, families were seated in our waiting room where they signed consent documents and where children were fitted with the headcam. After a short period of play, they were escorted to a playroom in the lab where the free-play session (the focus of the current study) was conducted.

In the waiting room, the experimenter placed the headcam on children's heads after they had time to adjust to the environment. For children who resisted wearing the headcam, the experimenter used distractor techniques (presenting stimulating toys or engaging the children in hand-occupying activities) intended to keep children's focus elsewhere and prevent them from taking off the camera (Yoshida \& Smith, 2008). Once the child was wearing the camera comfortably for a period of time, child and caregiver (or caregivers: in two cases, there were two adults present) were escorted to the playroom.

In the playroom, the experimenter presented the child's parent with a box containing three labeled pairs of objects, each consisting of a familiar and a novel object (e.g. a ball and a feather duster, marked as a "zem"). Parents confirmed that the child had not previously seen the novel toys. Parents were instructed to play with the object pairs with the child, one at a time, "as they typically would" and to use the novel labels to refer to the three toys. After giving these instructions, the experimenter left the room for a period of approximately 15 minutes. During this time, a tripod-mounted camera recorded video from a corner of the room and the headcam captured video from the child's perspective.

## Data Processing and Annotation

All headcam videos were cropped to exclude the period of entry to the playroom and were automatically synchronized with the tripod-mounted videos using FinalCut Pro Software. The final sample was approx. 5 hours of headcam video (M $=12 \mathrm{~min}$, range: $2-21 \mathrm{~min}$, for a total of roughly 400,000 frames.

Posture and Orientation Annotation One major goal of our study was to understand the relationship between children's posture and their access to information from the faces of their caregiver. To investigate this relationship, we created a set of annotations for the child's physical posture (e.g. standing, sitting) and orientation of the caregiver relative to the child (e.g. in front of, behind, close, far away). For each headcam video, a coder used OpenSHAPA software to annotate both orientation and posture (Adolph, Gilmore, Freeman, Sanderson, \& Millman, 2012).

Orientation was initially categorized as having the caregiver in front, to the side, or behind the child, and close (de-

[^64]

Figure 2: Sample frames from the headcam videos for a child from each age group, selected because they featured successful face detections (green squares).
fined informally as within arm's reach) or farther away. Because of data sparsity, we consolidated this scheme into three categories: close to the caregiver with the caregiver either in front or on the side, farther from the caregiver again with caregiver either in front or on the side, and a global category of caregiver behind the child. Posture was categorized as being held/carried, lying face-up, sitting, prone (crawling or lying), standing, or other. Data from when the child was out of view of the tripod camera was marked as uncodable and excluded from these annotations.

Labeling Annotation We were also interested in the availability of social information proximate to naming events in the caregivers' speech to children. Accordingly, a human coder marked the onset time when the name of any of the six objects in the object set was used. Overall, caregivers produced a median of 35 labels in a highly skewed distribution across participants (range: 9-131).

## Face Detection

An additional goal of the study was to measure the presence of caregivers' faces in the child's field of view (as approximated by the headcam). To avoid hand-annotating the size and position of faces in every frame of video, we tested two face detection systems. Sample frames from the video with successful detections are given in Figure 2.
Face detection algorithms The first algorithm was based on freely available computer vision tools (Bradski \& Kaehler, 2008) and is described in depth in our previous work (Frank, 2012). This system had two parts. The first was the application of a set of four Haar-style face detection filters (Viola \& Jones, 2004) to each frame of the videos independently. These detectors each provide information about whether a face is present in the frame as well as size and position for any detections. In a second step, these detections are then combined via a hidden Markov model (HMM), trained on hand-annotated data (see Appendix). The HMM model (which performed nearly as well as the more complex and computationally-intensive Conditional Random Field model used in our previous work) attempted to estimate whether a face was truly present in each frame of the videos, using as its input the number of Haar detectors that were active in any given frame.

The second algorithm that we evaluated was a semiautomated adaptive tracker-by-detection (SAATD). The algorithm required manual user input (selecting a single face example per video) for its initialization, but then needed no additional training data. The tracker is based on Kalal, Mikolajczyk, and Matas (2010) which uses patches in the trajectory of an optical-flow based tracker (Lucas \& Kanade, 1981) to train and update a face detector. The optical flow tracker and the face detector work in parallel. If the face detector finds a location in a new frame exhibiting a high similarity to its stored template, the tracker is re-initialised on that location. Otherwise, the tracker uses the optical flow to decide the location of a face in the new frame. The primary advantage of the SAATD algorithm is the use of motion for face detection: Following the movement of the pixels that define a face it is possible for the algorithm to adapt to new morphologies (i.e. different face poses).

Detector evaluation To ensure that our evaluation was not biased by the relatively rare appearance of faces in the dataset, we annotated two samples, both a random sample from the data and a sample with a high-density of faces (see Appendix). We evaluated each algorithm on its precision (hits / hits + false alarms) and recall (hits / hits + misses), as well as F-score (the harmonic mean of these two measures). Results are reported in Table 1.

The HMM model obtained a relatively high level of performance for the random subsections, but performed poorly when there was a relatively high density of faces present. In contrast, SAATD performed well on both samples, giving better performance especially in cases where there was partial occlusion. Our goal in using face-detection algorithms was to provide a measurement technique that eliminated tedious and expensive hand-coding and provided acceptable results. We therefore selected the SAATD model and report detections from this algorithm as an estimate of face presence in all further analyses.

## Results

We report results from three different sets of analyses. First, we explore developmental changes in posture and orientation in our dataset. Next, we explore how these changes affect access to faces, as measured using our face-detection algorithm.

Figure 3: Proportion time in each posture, plotted by child's age (left panel). Proportion time in each orientation relative to the caregiver, again plotted by child's age (right panel). For clarity, the "other" code is not plotted in either figure. Error bars show standard error of the mean across participants.

Table 1: Model performance on gold standard generalization training set dataset. P, R, and F denote precision, recall, and F-score for each of the two samples.

|  | High-density |  |  | Random |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Model | P | R | F | P | R | F |
| HMM | .55 | .38 | .45 | .89 | .74 | .81 |
| SAATD | .86 | .78 | .81 | .93 | .76 | .83 |

Finally, we report preliminary results on the accessibility of faces during labeling.

## Changes in Posture and Orientation

Our posture coding captured typical developmental milestones (Figure 3, left). Overall, sitting was the most common posture for interactions in the caregiver play session. The youngest infants in our sample mostly sat (with parental assistance), but also lay down and were carried a significant proportion of the time. The 12-month-olds were the only group who spent a large amount of time crawling, and the 16- and 20-month-olds sat and stood in equal parts.

Similarly, our coding of orientation revealed some significant developmental changes (Figure 3, right). Younger children more frequently had the caregiver behind them, often because the caregiver was supporting the child's sitting posture (for the 4-month-olds especially). In contrast, the 12-20 month olds were able to locomote independently and so were able to spend more time further from the caregiver.

## Access to Faces

We next investigated the effects of the child's posture and orientation on the presence and size of the caregiver's face in the visual field. Figure 4 shows the proportion of frames with a positive face detection, plotted by the child's age, posture, and orientation relative to the caregiver.

Overall, there were very large differences in access to faces across age. The 4-month-olds saw almost no faces-their parents were behind them most of the time, supporting them
since they could not sit independently. In contrast, the 8-month-olds, who could sit independently, typically sat across from their caregiver and saw many faces in both the sitting and prone postures. The 12-month-olds spent a large amount of time in the prone position (typically crawling after the ball, for example) and saw almost no faces in that posture. The 16and 20-month-olds saw many faces because they were standing while their parents were sitting, putting their faces at a relatively similar level.

Across ages, the carrying and prone postures resulted in the smallest number of faces seen, while standing and sitting resulted in far more. These postures both presented opportunities for seeing faces in large part because parents were sitting or lying on the floor with children. Although far fewer faces were seen when the caregiver was behind the child, ${ }^{2}$ both the close and far positions resulted in approximately equal proportions of face detections.

## Access to Faces During Labeling

Our final analysis concerned the accessibility of caregivers' faces during labeling events. Franchak et al. (2011) found that referential speech was marginally more likely to draw toddlers' attention to mothers' faces. We were similarly interested in whether looking at faces occurred during labeling. Accordingly, we used the labeling annotations for each child to identify the 2 s before and after each labeling event. We then computed the proportion face detections within this window across ages.

The overall pattern of face accessibility closely mirrored the base rates shown in Figure 4. Although this general pattern in itself is important in assessing developmental access to social information, in the current analysis we were interested in whether there was differential access to faces around labeling instances. We thus computed difference scores between the baseline face detection rate and the rate of face detections

[^65]

Figure 4: Proportion face detections, split by age group (left panel), posture (middle panel), and caregiver's orientation (right panel). We omit the lying face-up posture due to data sparsity. Black points show individual participants and are jittered slightly on the horizontal, red lines show means and $95 \%$ confidence intervals.

Figure 5: Proportion of faces detected in a 4 s window of time centered around labeling events, plotted by age group and whether the word was familiar or novel. Error bars show $95 \%$ confidence intervals. 4-month-olds are omitted due to the limited number of total face detections for this group.
in labeling windows for each participant. Figure 5 shows the results of this analysis.

Although any conclusion must remain extremely tentative because of the small sample, we nevertheless saw an increase in label-related face access for the 20 -month-olds. This difference was robust across a variety of window sizes from 1-6 s. (8-month-olds were more variable but similarly showed some trend towards greater face access during naming.) We cannot yet make inferences about the source of these differences: They could be could be caused by children, caregivers, or a combination of the two. Nevertheless, these results converge with previous work and suggest that, in combination with face detection techniques, the headcam may be a viable
method for examining social access during language learning.

## General Discussion

Using a head-mounted camera, we explored the relationship between infants' postural and locomotor development and their visual access to social information. The use of automated annotation tools from computer vision allowed us to measure the prevalence of caregivers' faces in their children's visual field. We found systematic differences in the visual accessibility of faces based on posture, orientation, and age, as well as hints of differences in language-related changes in visual access. While these results remain preliminary given the size of our developmental sample, this work nevertheless provides an important proof-of-concept that computer vision techniques can be used as a measurement method in the developmental context.

The measures developed here have broad applicability to the study of individual and cultural differences. Since the physical circumstances of child rearing vary widely across households and across cultures, there may be important and predictable differences in children's visual experience. As suggested by the correlations between walking and vocabulary development (Walle \& Campos, under review), postural development may have substantial downstream consequences for language. For example, shifts in how infants are placed in particular postures by strollers or carriers (Zeedyk, 2008) or how their motor development is encouraged by parent practices (Bril \& Sabatier, 1986) may lead to differences in social input which in turn affect their language learning. Since our variant of the headcam method is both inexpensive and highly portable, we have been able to deploy it in children's homes with some success; it may thus be a valuable tool for investigating differences in child-rearing practices.

A deep body of work uses children's linguistic inputmeasured using audio recordings-to understand the learning mechanisms underlying vocabulary acquisition
(Huttenlocher, Haight, Bryk, Seltzer, \& Lyons, 1991; Hart \& Risley, 1995; Fernald, Perfors, \& Marchman, 2006). There have been some important initial successes in using visual input to predict language uptake ( $\mathrm{Yu} \&$ Smith, in press). Nevertheless, we have a long way to go before our knowledge about children's visual input parallels our understanding of their linguistic environment. Coming to such an understanding will require the creation of both corpus resources and automated tools such as those we have begun to develop here.

## Acknowledgments

## Appendix: Face presence annotation

We selected 1 minute of interaction for each age group, divided evenly across the four dyads at that age. For each dyad, we divided the recorded video into contiguous 1 s segments and selected 16 in accordance with two criteria. First, 8 of these segments were selected by choosing the parts of the videos highest in face detection (high density sample). To be fair to both algorithms, half of this was chosen from the segments with the most HMM detections and half were chosen from the segments with the most SAATD detections. The remaining segments were chosen by randomly sampling from segments not yet selected for coding (random sample). Segments were annotated frame-by-frame by a human coder, who marked each frame as containing a face if at least half of the face was in the child's view. Detector output for each of these frames was then compared to this gold standard. A detection was counted as correct if it overlapped a face with half of its total area. The HMM training sample was selected via the same method as this gold standard sample, but used separate set of video segments.

# The Effect of Incremental Context on Conceptual Processing: Evidence from Visual World and Reading Experiments

#### Abstract

The analysis of the internal structure of concepts reveals the presence of a substantial amount of contextual information. Even though this interaction is easily recognizable, it is not clear how contextual information is processed and included into concept representations. The aim of this paper is to shed light on this question by analyzing the effect that an increasing amount of context exerts on conceptual processing. We report a self-paced reading experiment and a visual world experiment to test two hypotheses about the integration of context information: the incremental activation hypothesis suggests that the degree of facilitation in concept processing increases with the amount of context available; and the immediate activation hypothesis states that once a sufficient amount of contextual support is reached, no more facilitation occurs. Our data are compatible with the latter account.

Keywords: incremental processing; context effects; eye movements; visual world; self-paced reading.

## Introduction

Contextual information plays an essential role in different cognitive domains, including language processing, visual processing, or reasoning. In this paper we investigate the effect that context exerts on conceptual processing (Murphy, 2002). A widely recognized way to analyze the internal structure of concepts is the use of semantic feature norms (Wu \& Barsalou, 2009; McRae, Cree, Seidenberg, \& McNorgan, 2005). In experiments eliciting feature norms, participants enumerate features associated with a target concept; these lists can then be used to shed light on the internal structure of concepts, including the role of context (Frassinelli \& Keller, 2012). However, feature norms are static, and do not allow to study the time-course of concept processing. Real-time data are required to investigate how conceptual representations are constructed, and how they interact with conceptual information. Relevant prior work includes a study by Huettig, Quinlan, McDonald, and Altmann (2006), which analyzed the activation of conceptual information over time using the visual world paradigm (Tanenhaus, Spivey-Knowlton, Eberhard, \& Sedivy, 1995). However, Huettig et al. (2006) were not interested in contextual effects and used contexts that were as neutral as possible. Frassinelli and Keller (2012) replicated this study, but also introduced contextual variability as a factor, comparing the effect of a neutral context and two biasing
contexts associated with the target concept in different ways. However, Frassinelli and Keller (2012) focused their analysis on the concept region, providing only indirect evidence regarding effects taking place in the previous part of the sentence, where contextual information is integrated.

The aim of the present paper is to study contextual constraints on the processing of context, focusing in particular on the question of how context is integrated with conceptual information. According to Federmeier and Kutas (1999), contextual facilitation effects can occur in different tasks (and affect, e.g., reading time, lexical decision times, pronunciation time); effects appear both at the level of lexical priming and at the level of the entire sentence. Based on this assumption, we aim to clarify the relation between single contextual words and the entire sentence. We constructed sentence materials that provide a differential number of context words that bias comprehension towards the target concept. This design allows us to determine how such facilitation (or bias) occurs, and to distinguish two possible hypotheses: the incremental activation hypothesis, which suggests that the degree of facilitation in concept processing increases with the amount of context available; and the immediate activation hypothesis, which states that once a sufficient amount of contextual support is reached, no more facilitation occurs.

We performed two experiments. In a self-paced reading experiment, we tested if the amount of context available has an effect on the ease of conceptual processing, measured as the reading time for the target concept. In a visual world study, we presented the target concept pictorially, allowing us to measure the degree of facilitation (i.e., the number of looks) that occurs while the context words are processed, giving us access to the time course of conceptual integration.

## Experiment 1: Self-Paced Reading

The aim of this experiment was to analyze the effect that context information has on participants' reading time for the target concept. As widely discussed in the reading literature (Morris, 1994), higher coherence between the context and the target word is reflected in lower reading time. We therefore predict that reading times for a target word representing a
concept are reduced in proportion to the number of context words presented that bias the reader towards the concept.

## Method

Materials We used the same 24 concepts as Huettig et al. (2006) (but we dropped their semantically related condition, as it is not relevant for the present experiment). We embedded these concepts into a sentential context using the following general structure:

## (1) location - actor - verb - object - target concept -spill-over region

The target word is in bold, the three context words in italics (see below for an example). For each target concept, we identified three context words which were highly related to it (high-biasing (HB) words) and three context words that were unrelated to it (low-biasing (LB) words). Of the resulting eight possible combinations of LB and HB context words, we chose four, illustrated by the following examples:
(2) All LB context (None): On the path, the man was holding a box full of mushrooms carefully.
(3) HB location context (Loc): In the forest, the man was holding a box full of mushrooms carefully.
(4) HB location and actor context (LocAct): In the forest, the picker was holding a box full of mushrooms carefully.
(5) All HB context (All): In the forest, the picker was holding a basket full of mushrooms carefully.

This resulted in 96 experimental sentences: four contexts for each of the 24 concepts.

Norming Studies In order to make sure that the context words we chose had the biasing effect we expected them to have, we conducted a series of norming studies on Amazon Mechanical Turk.

First, 20 participants performed a sentence plausibility judgment task: they assessed how plausible the experimental sentence was by rating it on a scale from 1 (completely implausible) to 7 (completely plausible). A sentence was considered plausible when the averaged rating was higher than 4. This process allowed us to identify those sentences that were not completely plausible; they were replaced and re-tested.

A sentence completion study then evaluated the predictability of the target concept from the sentence context. Twenty new participants had to complete each sentence (with the target concept removed) by typing in a noun. An Anova showed a statistically significant difference between the None ( $6.4 \%$ of correct answers) and the All (43\%) condition $(F(1,3)=1.84, p<.001)$. The Loc (19.2\%) and the Lo$\operatorname{cAct}(14.4 \%)$ were not significantly different $(F(1,3)=0.64$ and $F(1,3)=0.40)$.

Twenty-four further participants performed a word completion study: the three context words appeared on the screen
one after the other and then participants had to type a word related to the context word. The aim of this study was to exclude syntactic effects (word order, but also the effect of the verb) in the completion study. The outcome of this experiment was in line with the sentence completion experiment, despite the fact that the context words were presented in isolation rather than in a sentence.

Finally, sixty participants performed a word association study in order to test the associations between the six context words (three LB and three HB words) and the target word in the sentence. According to an Anova, the three HB context words were equally strongly associated with the target word. Furthermore, all of them were more associated with the target than the LB words.

Procedure The 96 experimental sentences were distributed over four lists of 24 items each according to a Latin square design. Twenty-seven fillers were added and the list randomized for each participant. Twenty yes/no questions about the sentence were also included.

Thirty-four native English speakers from the University of Edinburgh took part in the experiment after giving informed consent and were paid $£ 5$. Each saw one of the lists. We excluded one participant based on a low percentage of correct answers ( $<50 \%$ ) and another participant with a reading time averaging 2.5 standard deviations above the grand mean (as suggested in Hofmeister (2011)).

We used a moving-window self-paced reading procedure (Just, Carpenter, \& Woolley, 1982), in which participants read a sentence on the screen at their own pace. At the beginning of each trial, all the words in the sentence are masked with dashes and separated by spaces; participants had to press the space bar to uncover the next word and hide the previous one. For this experiment, we used the software package Linger (version 2.94) on Apple computers.

## Results

We analyze the reading times associated with the target word, which can be assumed to index the amount of effort associated with processing the target concept. Table 1 shows the mean reading times for the target concept across the four context conditions. The results indicate that reading time decreases in proportion with the number of HB words in the context. Table 2 reports a linear mixed-effects model (LME) with log-transformed reading time as the dependent variable. In the model, the factors Loc, LocAct, and All were contrast coded against the reference level None. Participant and Item were included as random intercepts, and as random slopes under Loc, LocAct, and All (thus implementing a maximal random effects structure, D. Barr, Scheepers, and Tily (2013)). The LME model shows that LocAct and All are statistically different from the None condition. After a HB context, participants spend less time reading the target concept compared to a LB context. The difference in reading time between None and the Loc does not reach significance.

| Condition | Reading Time |
| :--- | :---: |
| None | $390.1 \pm 25.2$ |
| Loc | $358.5 \pm 21.4$ |
| LocAct | $346.0 \pm 15.5$ |
| All | $336.7 \pm 10.5$ |

Table 1: Reading time (in ms) with standard errors for the target concept in the four contextual conditions.

| Predictor | Coefficient |
| :--- | :---: |
| (Intercept) | $12.771^{* * *}$ |
| Loc | -0.067 |
| LocAct | $-0.097^{*}$ |
| All | $-0.094^{*}$ |
| ${ }^{*} p<.05,{ }^{* *} p<.01,{ }^{* * *} p<.001$ |  |

Table 2: Coefficients for the mixed effects model for the reading time data in Table 1.

## Discussion

In this self-paced reading experiment, we looked at the relation between the amount of HB information in the context and the reading time of the target concept. The hypotheses we started with predict two distinct outcomes: the incremental activation hypothesis predicts that the reading time of the target concept is reduced in proportion to the number of HB context words that are present. On the other hand, based on the immediate activation hypothesis, we expect that there is a threshold on the amount of contextual information that is required before an effect of context on reading time occurs.

Descriptively, the reading times in Table 1 are compatible with incremental activation: each additional contextual concept results in a further reduction in reading time. However, the mixed model analysis in Table 2 shows significant differences only between LocAct and None and All and None; Loc on its own does not have a significant effect. Furthermore, post-hoc tests failed to show significant differences between the reading times in the three context conditions (Loc, LocAct and $A l l)$. This is a pattern that would be expected under the immediate activation hypothesis: the contextual threshold has been reached at LocAct, and additional context words do not significantly pre-activate the target concept any further.

Taken together, the results of this experiment are inconclusive. We therefore performed a follow-up experiment which directly tests our two hypotheses by measuring the amount of activation the target concept receives during the processing of each context word.

## Experiment 2: Visual World

The aim of this experiment was to test whether the activation of concepts happens gradually (more activation with every new context word, as predicted by incremental activation), or at once (the first context word triggers full activation, which
then declines, as predicted by immediate activation). In a visual world study, we measure the amount of activation for the target concept at each context word in terms of the proportion of looks received by the object corresponding to the target concept.

## Method

Materials We used visual scenes that consisted of four black and white line drawings extracted from the Snodgrass and Vanderwart (1980) collection: one target object and three distractors randomly arranged in four quadrants. (These were the same stimuli as in Frassinelli and Keller (2012), already normed by Huettig et al. (2006)). The sentence materials were the same as in Experiment 1, and the stimuli instantiated the same 24 target concepts. As an example, consider the visual stimulus in Figure 1, which corresponds to the sentences in (2)-(5).

Figure 1: Example of the scene for the target concept mushroom (the box is not shown to the participants).

Procedure The 96 sentences in the experiment were spoken by the speech synthesis system Festival (Clark, Richmond, \& King, 2007) using an HMM voice (Roger), so as to reduce possible effects of prosody or speaker variation.

In order to counterbalance order or position effects, we rotated the four objects on the screen. The resulting 384 items were distributed over 32 lists of 24 items each according to a Latin square design. Twenty-five fillers were added and the list randomized for each participant. Nine yes/no questions about the sentence were also presented.

Thirty-four native English speakers from the University of Edinburgh took part in the experiment after giving informed consent and were paid $£ 5$. Each saw one of the lists.

Participants were sat in front of a 21 " multi-scan monitor with a resolution of $1024 \times 768$ pixels and their eye movements were recorded using an EyeLink II head-mounted eyetracker with a sampling rate of 500 Hz . Only the dominant eye was tracked. At the beginning of the experiment and after every ten trials, the eye-tracker was recalibrated using a ninepoint randomized calibration. Before each trial, drift correction was performed. At the beginning of each trial the scene
appeared on the screen, and the sentence began to play at the same time; the scene disappeared 1500 ms after the end of the sentence. The experiment lasted approximately 20 minutes.

Data Analysis The analysis is based on the proportion of fixations on the target object across experimental conditions. We excluded out-of-screen fixations and blinks from the analysis.

In order to analyze the effects exerted by a context word before and after its acoustic offset, we aligned the fixation probabilities at that point ( 0 ms ). In order to exclude any overlap between two regions of analysis in the sentence we calculated the minimum amount of time between the onset and the offset of the context word ( 150 ms ) and between the offset of the context word and the onset of the following one ( 400 ms for location, actor, and concept; 150 ms for object). The vertical line shows the offset of the context word, while the horizontal dotted line indicates the probability of randomly fixating on one of the four objects depicted on the screen ( $25 \%$ of total fixations).

For each context word we report an LME analysis of the results. As suggested by D. J. Barr (2008), the dependent variable of our models is the empirical logit of the fixation probability calculated for each bin. We used a bin size of 5 ms . To compare the effects produced by HB and LB contexts, we included three factors in contrast coding: each factor encodes the differences between the reference level None (coded as -.5) and one of the three other conditions (Loc, LocAct, All; coded as .5). The continuous factor Time shows variations over time. In order to identify the minimal model that best fits our data, we used the best-path forward model selection procedure (recommended by D. Barr et al. (2013) if a model with full random effects structure fails to converge). We report only the coefficients and the significance levels for the minimal model, i.e., we show only the main effects and the interactions included during the selection procedure. All models included Participant and Item as random intercepts, as well as random slopes for Context and Time.

## Results

Location Word The first context word we analyze is location. The plot in Figure 2(a) shows the probability of fixating the target object at this context word. Before its offset, it is already possible to identify a general effect produced by the presence of a location (both HB and LB), as the fixation probabilities are higher than random. However, specific effects appear only 100 ms after the offset of the context word. The None (low biasing) condition shows a decrease over time, while an increase in fixation probability is observed in the Loc and LocAct conditions (compared to None, the reference level), which corresponds to the significant interactions Time: Loc and Time: LocAct (see Table 3, column 1). A similar effect is visible for All, but fails to reach significance.

Figure 2: Fixation probabilities aligned at the offset ( 0 ms ) of the context words.

| Predictor | Coefficient Location | Coefficient Actor | Coefficient Object | Coefficient Concept |
| :--- | :---: | :---: | :---: | :---: |
| (Intercept) | $-0.7548^{* * *}$ | $-0.6764^{* * *}$ | $-0.6215^{* * *}$ | -0.0138 |
| Time | 0.0005 | $0.0002^{* * *}$ | 0.0003 | $0.0003^{* * *}$ |
| Loc | 0.1019 | -0.7303 | 0.1955 | -0.1110 |
| LocAct | -0.0388 | 0.4809 | -0.0744 | -0.2919 |
| All | - | -0.1136 | 0.2204 | -0.0849 |
| Time:Loc | $0.0008^{* * *}$ | $-0.0011^{* * *}$ | - | $0.0003^{* *}$ |
| Time:LocAct | $0.0003^{* *}$ | - | $-0.0024^{* * *}$ | $-0.0007^{* * *}$ |
| Time:All | - | - | $0.0011^{* * *}$ | $-0.0004^{* * *}$ |
| $\quad{ }^{*} p<.05,{ }^{* *} p<.01,{ }^{* * *} p<.001$ |  |  |  |  |

Table 3: Coefficients for the mixed effects model for the data in Figures 2(a), 2(b), 2(c), 2(d). Empty cells indicate that the factor in question was not included during model selection.

Actor Word The plot in Figure 2(b) shows the fixations at the word encoding an actor. In the Loc condition, participants tend to fixate less on target object (compared to None), an effect that is more evident before the offset of the word. This corresponds to a significant negative interaction Time: Loc in the LME (see Table 3, column 2). The plot also seems to indicate an overall higher level of fixations in the LocAct condition (compared to $A l l$, which is identical at this point in the sentence). However, this difference is not significant (no main effect or interaction involving LocAct in the LME).

Object Word The next context word analyzed is the object of the sentence. Figure 2(c) shows that before the offset of the object, the HB conditions all show a higher overall fixation proportion compared to None. After the offset, the curves diverge: All shows a steeper increase than None (significant positive interaction All:Time, see Table 3, column 3). This is explained by the fact that All is the only condition with a HB object. The condition LocAct, shows a steep decrease, i.e., the significant negative interaction LocAct:Time, while Loc remains constant (no significant effects involving Loc).

Concept Word Figure 2(d) shows the number of fixations at the point when participants hear the concept associated with target object on the screen (note the different $y$-axis). At this point, global effects of different amounts of HB information across conditions should be visible. After the offset of the context word, there is an inverse relation between the amount of HB information and the slope of the curves in the Loc, LocAct, and All conditions. The more HB information is available, the sooner fixation proportions decrease. This is consistent with the pattern observed in the reading times of the concept word in Experiment 1.

On the other hand, fixation probability in the None condition increases, in particular after word offset, and remains high. The negative interactions Time:LocAct and Time:All (see Table 3, column 4) are consistent with this observation, indicating a significant decrease in fixations in LocAct and All compared to None. Furthermore, there is a significant positive
interaction Time: Loc, indicating an increase in fixation probability in this condition compared to None.

## Discussion

The aim of this experiment was to analyze the effect of incremental context information over time. The analysis of actor and object (see Figure 2(b) and Figure 2(c)) showed few interesting effects. The regions at which it was possible to identify a clear effect of contextual variability were location and concept. Location is the first context word participants are exposed to and it had a strong effect on driving their fixations towards the target concept. This is in line with previous results of visual world studies on language comprehension (Altmann \& Kamide, 1999), showing anticipatory eye movements towards a target as a result of predictive spoken language input. Less expected are the outcomes related to the concept area. We found that high-biasing contexts allows participants to identify and process the target object at an early stage: this effect is visible even at the first context word (location in our case). At the concept word itself, we then fail to observe a sustained increase in fixations to the target object. The opposite pattern was observed in the low-biasing context: were we see no increase in fixations at the context words, but a sustained increase once the concept word has been processed. In an HB context, the target word is contextually expected, and thus fixated less, while in the LB context, it is unexpected and thus fixated more.

One possible explanation for this pattern of results (i.e., a decrease in target fixations at the target word after a biasing context) is inhibition of return. This is a well-know effect in eye-movements, which manifests itself in a low probability of returning to a region once it has been fixated (Posner, Rafal, Choate, \& Vaughan, 1985). Our failure to find an increase in fixations at the concept region in the HB conditions could be due to inhibition of return, as the target had already been fixated at an earlier point in these conditions (i.e., during anticipatory processing while hearing biasing context words).

## General Discussion

The aim of this study was to test the effect that an incremental amount of contextual information exerts on conceptual processing. We ran two experiments: a self-paced reading and a visual world experiment. The former identified a reduction of the time required to read a target concept with increasing amount of biasing context. The visual world study showed increased looks to the target during the processing of the first context word (location) and at the concept word itself.

The results obtained in our visual world study corroborate the findings of Frassinelli and Keller (2012) who found that a biasing context leads to an early recognition and processing of the target concept. Moreover, the results show an expectation effect: over time, the biasing contexts produced an expectation of the target concept and this led to a reduced number of fixations to the target object when the corresponding concept word occurred (potentially involving inhibition of return as the driving mechanism behind this decrease in fixation probability).

The key novel contribution of the paper is to elucidate the time course of contextual integration. In the introduction, we proposed two possible hypothesis on how context interacts with concept processing: the incremental activation hypothesis (the degree of facilitation increases with the amount of context) and the immediate activation hypothesis (once sufficient contextual support has accrued, no additional facilitation occurs). The results of Experiment 2 allow us to evaluate these two hypotheses. We found that when participants are exposed to a low-biasing context, we see an increase of fixations to the target concept only when that concept is mentioned. In the high-biasing conditions, on the other hand, this increase occurs already at the first context word, with no further increases at the second or third context word. Also when at the concept word, only a small increase in fixations is observed. It seems that a single context word is sufficient to identify the concept on the screen. Additional context exerts only a confirmatory effect. This pattern of results is compatible with the immediate activation hypothesis: a certain amount of contextual information is sufficient to trigger conceptual processing; additional contextual information does not trigger an incremental increase in concept activation.

In more theoretical terms, these results enhance our understanding of conceptual representation. They indicate that the activation of a specific concept takes place when the overlap between its internal structure and the information extracted from the context reach a certain critical level.

# The intrinsic structure of spatial configurations and the partner's viewpoint shape spatial memories and descriptions 

Alexia Galati ${ }^{\text {a }}$ (galati@ucy.ac.cy)<br>\&<br>Marios N. Avraamides ${ }^{\text {a, }}$ (mariosav@ucy.ac.cy)<br>${ }^{\text {a }}$ Department of Psychology, University of Cyprus<br>${ }^{\mathrm{b}}$ Centre for Applied Neuroscience, University of Cyprus<br>Nicosia, Cyprus

#### Abstract

We examined how the intrinsic orientation of spatial layouts and the conversational partner's viewpoint shape how people organize spatial information in memory and subsequently describe it. In 24 pairs, Directors first studied an array with a symmetrical structure while either knowing their Matcher's subsequent viewpoint or not. When describing the array to the Matcher, the array's intrinsic orientation was aligned with the Director, the Matcher, or neither partner. Memory tests preceding descriptions revealed that Directors misaligned with the structure organized information according to a priori knowledge, being more likely to use the structure as an organizing orientation when knowing that Matchers were aligned with it. The perspective of Directors' descriptions was also influenced both by the partners' alignment with the structure and their advance knowledge of that. Altogether, speakers are guided by converging social and representational cues to adapt flexibly the organization of their memories and perspectives of their descriptions.

Keywords: perspective-taking; spatial memory; intrinsic structure; audience design; common ground; spatial descriptions

## Introduction

When people make spatial judgments they access memory representations that maintain spatial relations around a preferred direction (e.g., Mou, McNamara, Valiquette, \& Rump, 2004). This preferred direction can be influenced by egocentric preferences for organizing information, based on one's learning perspective (Shelton \& McNamara, 2001) and on representational cues like the symmetry of the spatial configuration (Mou \& McNamara, 2002; Li et al, 2011) or the geometry of the environment (Shelton \& McNamara, 2001). However, the extent to which people take into account their conversational partner's viewpoint when organizing information in memory and communicating this information is still unclear.

A study by Shelton and McNamara (2004) addressed whether describing information from the partner's viewpoint influences speakers' resulting memory representations. Indeed, after describing an array to their partner, speakers were more accurate to make spatial judgments from perspectives aligned with the one that had been occupied by their partner (vs. other perspectives). However, since speakers learned the arrays while describing them from the partner's viewpoint (following explicit
instructions), it's possible that speakers don't spontaneously represent their partner's viewpoint in spatial memory, and instead resort to egocentric preferences for organizing information.

We recently adapted Shelton and McNamara's (2004) study to ask whether in fact speakers spontaneously represent their partner's viewpoint in memory. In Galati et al. (2013), one participant (the Director) first studied a randomly configured array, while either knowing or not knowing their partner's (the Matcher's) subsequent viewpoint, which was misaligned by $90^{\circ}, 135^{\circ}$, or $180^{\circ}$. In memory tests preceding descriptions, rather than finding facilitation for the partner's viewpoint when it was available (cf. Shelton \& McNamara, 2004), we found that speakers represented that viewpoint in memory without using it as an organizing direction. Directors took longer to imagine orienting to perspectives known to be aligned with their Matcher (at least for $90^{\circ}$ and $135^{\circ}$ ) and rotated their array drawings toward the Matcher's viewpoint. Nonetheless, these findings could indicate that, under those circumstances, speakers did not have sufficient pragmatic motivation to invest the cognitive effort to organize spatial relations around a non-egocentric viewpoint, so they simply represented it and used it as needed.

In the present study, our first goal is to elucidate whether, under different circumstances, the partner's viewpoint could be used as an organizing direction in memory. In particular, we ask whether, in collaborative tasks, a given partner's alignment with the array's intrinsic structure affords sufficient pragmatic motivation to organize spatial relations around that viewpoint. Our view is that, when selecting an organizing direction, people consider a confluence of different sources of information, including egocentric cues (e.g., their own learning viewpoint), representational cues (e.g., the array's intrinsic orientation) and social cues (e.g., the partner's viewpoint). Thus, the partner's viewpoint could be used as an organizing direction if it is reinforced by additional cues, like the array's intrinsic orientation. This prediction follows the proposal that in collaboration people try to minimize their collective effort, with one partner investing greater cognitive effort to ensure mutual understanding upon appraising that the other is likely to find the interaction difficult (e.g., Clark \& Wilkes-Gibbs, 1986). In spatial perspective-taking, attributions about the partner's
ability to contribute to the task, based on social cues, should influence whether the partner's perspective is adopted.
This is in line with findings concerning the interpretation of spatial descriptions. For instance, when people believe that their partner doesn't know their viewpoint they are more likely to interpret spatial descriptions from the partner's perspective, whereas when they believe that their partner is real (vs. simulated) they are more likely to interpret them egocentrically presumably because they shift the burden of ensuring mutual understanding to the partner (Duran, Dale, \& Kreuz, 2011). Related findings come from production tasks as well. People invest the cognitive effort to describe information from their partner's perspective when the partner does not share their viewpoint (Schober, 1993), cannot provide feedback (Shelton \& McNamara, 2004), or has worse spatial abilities than them (Schober, 2009). People are also more likely to help their partners by using available environmental features, like the intrinsic axes of objects, as the basis of their descriptions' perspective, instead of their own egocentric perspective (Tenbrink, Coventry, Andonova, \& 2011), and referring to more landmarks for orienting, and navigating along fewer, larger and more prominent streets when describing routes to a partner unfamiliar with the environment (Hölscher, Tenbrink, \& Wiener, 2011).

Thus, the second goal of our study is to examine how people adapt their spatial descriptions when faced with different cues. Specifically, we aim to clarify the extent to which they rely on their memory representations when describing information. We do so by dissociating the learning of spatial arrays from their description (cf., Shelton \& McNamara, 2004). Our earlier work suggests that speakers don't merely rely on their initial representations during descriptions, but are able to use available perceptual information (i.e., their degree of misalignment from their partners) to adapt descriptions appropriately (Galati et al., 2013). Here, we examine whether advance knowledge of the partner's viewpoint guides speakers in selecting a perspective for their descriptions, depending on whether the intrinsic structure is aligned with the speaker, their partner, or neither partner during the description. If the convergence of available cues during the description strongly biases a particular perspective, then advance knowledge of the partner's viewpoint may not influence descriptions significantly. On the other hand, advance knowledge of the partner's viewpoint and its relation to the intrinsic structure may highlight alternative perspectives for both encoding and describing the array.

## Method

## Design

Directors first studied an array with an intrinsic structure, then had their memory of the array tested, and finally described the array to a partner, their Matcher, who
reconstructed the array on the basis of the Directors' descriptions. We manipulated the alignment of the array's intrinsic structure with either partner during the description phase, as well as the partners' advance knowledge of that. In a third of the pairs, Directors studied arrays while aligned with its intrinsic structure (referred to as $0^{\circ}$, see Figure 1), and later described it to Matchers who were offset by $135^{\circ}$ measured counterclockwise (Aligned with Director condition). In another third of the pairs, Directors studied arrays from $225^{\circ}$ and later described it to Matchers who were at $0^{\circ}$ (Aligned with Matcher condition). In the final third of the pairs, Directors studied arrays again from $225^{\circ}$ and later described to Matchers who were offset by $135^{\circ}$; thus both partners were misaligned with the structure (Aligned with Neither condition). Half of the Directors in each condition studied the array while knowing where their Matcher would later be, whereas the remaining half didn't.

Figure 1: The seven-object array used, indicating $0^{\circ}, 135^{\circ}$, and $225^{\circ}$ headings.

## Participants

Forty-eight undergraduate and graduate students from the University of Cyprus participated, half of them as Directors and half as Matchers, in 24 pairs. Six were female-female pairs, 6 were male-male pairs, 6 were mixed-gender pairs with female Directors, and 6 were mixed-gendered pairs with male Directors. All pairs of participants were recruited to be friends.

## Procedure

Study phase After a practice phase during which Directors were familiarized with the Judgments of Relative Direction (JRD) task (see below), Directors studied an array with an intrinsic axis of symmetry, comprising seven common objects that lacked intrinsic front-back and left-right axes, displayed on a 70 cm -diameter circular table (Figure 1).

Directors studied the array while either aligned or misaligned with its structure (from either $0^{\circ}$ or $225^{\circ}$ ), while either knowing where their Matcher would be during the
description phase or not. When the Matcher's viewpoint was known, Matchers sat at a separate, identical table next to the Director's (see Figure 2), at the position they would occupy during the description (at $0^{\circ}$ or at $135^{\circ}$ ).
Testing phase After ensuring that Directors memorized the array, Directors moved to an adjacent room to complete the memory tasks (JRDs and the drawing task). On JRD trials, Directors were instructed to imagine being at one location facing a second, constituting an imagined heading or viewpoint, and to point to a third object, the target (e.g., Imagine being at the bucket, facing the marble. Point to the candle.). Directors first read a statement in this form (i.e., "Imagine being at $x$, facing $y$ "), pressed a button on a joystick once they adopted that heading, and then responded to the second statement ("Point to $z "$ ) by deflecting the joystick in the direction of $z$ as if they were facing $y$ and pressing a button to $\log$ in their response. Sixty-four such trials were presented individually on a computer screen. They included eight imagined headings ( $0^{\circ}, 45^{\circ}, 90^{\circ}, 135^{\circ}$, $180^{\circ}, 225^{\circ}, 270^{\circ}, 315^{\circ}$ relative to the intrinsic structure) and their order was randomized.

After the JRDs, Directors did an array drawing task. They were given 20 cm -diameter grid (with 1 mm lines) and were asked to reconstruct as accurately as possible the studied array by placing seven circular transparent markers, each labeled with a name of the array's objects, on the grid.
Description phase After their testing phase, Directors returned to the original room for the description. Pairs sat at the positions prescribed by their condition of alignment with the array's intrinsic structure. Directors described the array's configuration from memory, while the Matcher used the seven objects to reconstruct the array at their table. Instructions emphasized that participants could interact freely and that they should reconstruct the array so that, given the Director's study viewpoint, objects be translated to the Matcher's table (i.e., not rotated by the Matcher's offset). Although pairs could interact freely, Directors could not look over the barrier ( 113 cm tall) separating the two tables; they could see each other's faces but not each other's tabletops. After turning on the cameras, the experimenter left the room for the description phase. After completing the description phase, pairs were debriefed and compensated for their time, if participating for payment.

## Coding of Spatial Descriptions

Each pair's interaction during the description phase was transcribed in detail, including contributions by both Directors and Matchers. We adapted our coding scheme from Galati et al. (2013) to classify spatial expressions in the Directors' turns as:
a. Director-centered, e.g., "in front of me is the marble"
b. Matcher-centered, e.g., "the vase is to your left"
c. Structure-centered, e.g., "it's on the perpendicular line. You're supposed to be on one side on the left, and I'm on one right side of the table"

Figure 2: Set-up of a study phase in which the Director was aligned with the array's intrinsic structure (at $0^{\circ}$ ), while the Matcher was misaligned with it (at $135^{\circ}$ ).
d. Neutral, capturing inter-object relations independently of a particular viewpoint, e.g., "it's close to the bucket" or "they form a triangle"
e. Other headings, not coinciding with the Director's, the Matcher's, or the structure's intrinsic orientation, e.g., "say the candle is facing the bucket; from the bucket, it's on the left"
f. Ambiguous, when expressions could be interpreted as involving more than one of coding categories
Three more categories (both-centered, environmentcentered, and object-centered) will not be considered further since they constituted less than $1.5 \%$ of all 1609 spatial expressions.
Reliability The first author coded 20 pairs, while a second coder redundantly coded 6 pairs as well as the remaining 4 pairs. Prior to comparing their judgments, the coders discussed 52 instances for which there was disagreement over the segmentation of spatial expressions (i.e., cases where one coder identified a spatial expression while the other didn't, or parsed a phrase as two spatial expressions while the other did as one). These disagreements were resolved by discussing them until consensus was reached; the remaining, non-redundantly coded dialogues were checked for consistent application of the agreed upon criteria. For the 383 spatial expressions from the redundantly coded dialogues, the two coders made identical classifications $98 \%$ of the time, Карра $=.98, p<.001$.

## Results

## Spatial Memory

Array drawings When Directors studied the array while aligned with the intrinsic structure (from $0^{\circ}$ ), all of them used the structure as the organizing direction of their drawings, whether they knew the Matcher's viewpoint $\left(135^{\circ}\right)$ or not. On the other hand, as Table 1 shows, when
they studied the array while misaligned with its structure (from $225^{\circ}$ ), the orientation of their drawings depended on whether they knew their Matcher's viewpoint. When the Matcher's viewpoint was unavailable, they were more likely to use their learning viewpoint $\left(225^{\circ}\right)$ to draw the array. But when they had known in advance that the Matcher was aligned with the array's structure, they used the structure's axis as an organizing direction more frequently. And when they had known in advance that the Matcher would also be misaligned with the structure (at $135^{\circ}$ ), half of the Directors opted for their learning viewpoint, while half used the axis of the structure as their organizing direction. The probability that the overall distribution of the drawings' orientation was observed by chance is small ( $p=.03$, Fisher's exact test).

Table 1: Proportion of Directors who drew arrays as aligned with the intrinsic structure vs. from own viewpoint, when having studied arrays from $225^{\circ}$.

|  | Aligned with <br> intrinsic <br> structure | Aligned with <br> learning <br> viewpoint |
| :--- | :---: | :---: |
| Knows Matcher <br> is at $0^{\circ}$ | .75 | .25 |
| Knows Matcher <br> at $135^{\circ}$ | .50 | .50 |
| Does not know <br> Matcher's <br> viewpoint | .25 | .75 |

Judgments of Relative Direction Analyses of JRD performance were initially conducted while ignoring the organization suggested by the Directors' drawings. However, these results were obfuscated by the fact that, as Table 1 illustrates, when misaligned with the structure, Directors were split in their preferred orientation at any given condition of availability of the Matcher's viewpoint. For instance, although most Directors preferred the structure's axes when knowing that the Matcher would be aligned with the structure, some still preferred their learning orientation. Thus, subsequent analyses of JRD performance centered on corroborating that Directors organized object relations in memory as indicated by their drawings' orientation.

As Figure 3 illustrates, the Directors' orientation latency (time to orient to an imagined heading) was consistent with the preferred orientation of their array drawings. Directors whose drawings were aligned with the structure were generally faster to orient to the structure's canonical axes $\left(0^{\circ}, 90^{\circ}, 180^{\circ}, 270^{\circ}\right)$ than to the oblique headings $\left(45^{\circ}\right.$, $\left.135^{\circ}, 225^{\circ}, 315^{\circ}\right)$. This pattern was reversed when Directors had drawn arrays from $225^{\circ}$. Indeed, the interaction between the heading from which the array was drawn and the JRD trial's imagined heading was significant, $F(7,154)=4.96, p$ $<.001$.

We examined this sawtooth pattern of performance by fitting planned contrasts with weights: $-1.625, .875,-0.625$, $1.375,-1.625,1.375,-0.625, .875$. This contrast, with the
minimums at $0^{\circ}$ and $180^{\circ}$, adequately described the orientation latencies of Directors who drew arrays aligned with the structure, $F(1,14)=10.34, p<.01$, accounting for $88 \%$ of the variance associated with the imagined heading and leaving a non-significant amount of variance unaccounted for ( $p=.98$ ). For Directors who drew arrays from their $225^{\circ}$ study viewpoint, the sawtooth contrast with the minimums at $225^{\circ}$ and its counteralinged heading (45 ) also described performance adequately, $F(1,8)=6.43, p$ $<.05$, accounting for $62 \%$ of the variance associated with the imagined heading and leaving a non-significant amount of variance unaccounted for ( $p=.82$ ).

Figure 3: Orientation latencies (in secs) across imagined headings according to how Directors had drawn arrays

The same pattern was observed for Directors' response latency (the time to point to the target after adopting an imagined heading) and their pointing error (the unsigned angular deviation of the joystick response from the veridical response). For brevity, these analyses are not reported here.

## Spatial Descriptions

Overall, Directors produced most frequently Neutral expressions in their descriptions $(48 \%$ of all spatial expressions), with Matcher-centered expressions constituting 20\%, Director-centered 15\%, Structurecentered $8 \%$, other headings $2 \%$, and ambiguous expressions $5 \%$ of all expressions.

We will focus on the distribution of Director-centered, Matcher-centered, and Structure-centered expressions, given our manipulation of the alignment of the intrinsic structure with either partner. The distribution of these three types of spatial expressions indeed depended on the partners' alignment of the intrinsic structure during the description, $F(4,36)=3.96, p<.01$. This interaction was driven by Directors using more Matcher-centered expressions than Director-centered ones when the Matchers were aligned with the structure ( $95 \% \mathrm{CI}[-.56,-.15], p<.01$ ), whereas the reverse was true when Directors were the ones aligned with the structure (though this difference was not statistically significant: $95 \% \mathrm{CI}[-.09, .32], p=.27$ ).

On its own, the availability of the Matcher's viewpoint didn't reliably affect the distribution of these spatial
expressions; this interaction was not significant, $F(2,36)=$ $1.83, p=.18$. Nonetheless, Directors used significantly more Matcher-centered expressions than Director-centered ones ( $26 \%$ vs. $7 \%$ ) when they knew the Matcher's viewpoint in advance ( $95 \%$ CI[-.36, -.02], $p<.05$ ), whereas they used comparable proportions ( $21 \%$ vs. $20 \%$ ) when they hadn't known their Matcher's viewpoint (95\% CI[-.18, .15], n.s.).

Figure 4: Proportion of Director-centered, Matchercentered, and Structure-centered expressions when the Matcher's viewpoint was available (a) or unavailable (b) at study, across the partners' alignment with the intrinsic structure.

As Figure 4 a shows, Directors who studied arrays from $0^{\circ}$ while knowing that their Matcher would be offset by $135^{\circ}$ used comparable proportions of egocentric and Matchercentered expressions in their descriptions ( $17 \%$ vs. $18 \%$; $95 \% \mathrm{CI}[-.31, .27]$, n.s.). On the other hand, as Figure 4b shows, they tended to use more egocentric expressions (34\% vs. $10 \%$ ) when their Matcher's viewpoint wasn't available at study ( $95 \% \mathrm{CI}[-.05, .54], p=.10$ ). When the Matcher was at $0^{\circ}$ during the description, Directors used predominately Matcher-centered expressions whether this information was available in advance or not. Finally, when neither partner was aligned with the structure during the description, the distribution of expressions differed depending on whether Directors knew this in advance. As Figure 4b shows, when

Directors hadn't known the Matcher's viewpoint in advance, they used numerically more egocentric than Matcher-centered expressions ( $27 \%$ vs. $10 \%$; $95 \%$ CI: [-.13, .46], $p=.25$ ), whereas as Figure 4a shows, when they had known it in advance, they used more Matcher-centered than egocentric expressions ( $29 \%$ vs. $1 \%$; $95 \%$ CI: [ $-.58, .01]$, $p=$ .06). Moreover, as suggested by the white bars across the two figures, Directors used numerically more Structurebased descriptions when they knew in advance that Matchers would also be misaligned with the structure than when they didn't (95\% CI: [-.33, .02], $p=.08$ ).

The distribution of spatial expressions that Directors used was not influenced by the pair's gender combination or the gender of the Director; the interaction of each of these factors with the type of spatial expression was not significant: $F(6,40)=.87, p=.52$, for the pair's gender combination, and $F(6,40)=.85, \mathrm{p}=.44$ for the Director's gender.

## Discussion

Our findings suggest that people consider both representational and communicative factors when organizing spatial information in memory and when selecting the perspective from which to describe that information. The preferred direction around which people organize spatial relations in memory depends on whose viewpoint is reinforced by the configuration's intrinsic orientation. This was demonstrated by the Directors' drawings and was corroborated by their performance in the JRD task. When Directors were aligned with the intrinsic structure, they defaulted to their own viewpoint as the organizing direction, regardless of what they knew about their partner's viewpoint. On the other hand, when they were misaligned with the structure during learning, knowing that their Matchers would be aligned with the structure's orientation increased the probability of using the structure's axes as an organizing direction. Moreover, knowing that the Matcher would also be misaligned with the structure increased the probability of using the structure's axes as an organizing direction compared to not knowing the Matcher's viewpoint.

These findings suggest that a given partner's alignment with the intrinsic structure affords sufficient pragmatic motivation to organize spatial relations from that orientation: when the structure's orientation is aligned with a partner's viewpoint, these converging cues influence the preferred orientation that people use. This extends our earlier findings that, when no intrinsic structure is available, people encode the partner's viewpoint in memory but don't necessarily use it as an organizing direction, likely due to insufficient pragmatic motivation to do so when they can freely interact with their partner (Galati et al, 2013).

We propose that, when selecting the preferred orientation of their spatial memories, people combine probabilistically different sources of information. When the intrinsic structure and their own learning viewpoint converge, they
use that egocentric viewpoint; when the intrinsic structure and their partner's viewpoint converge, they opt for the partner's viewpoint. This also held for how speakers adapted their spatial descriptions. When the intrinsic structure and the Director's learning viewpoint converged, Directors tended to describe spatial information from their own perspective, with Matchers having to unpack the spatial mappings of these Director-centered descriptions. When the intrinsic structure and Matcher's viewpoint converged, Directors alleviated the Matcher's cognitive burden by describing spatial information from the Matcher's viewpoint. Speakers used the available social and representational cues to adapt their descriptions in ways that minimized their collective effort (e.g., Clark \& WilkesGibbs, 1986), with the assumption here being that a perspective supported by converging cues is optimally effective.

Moreover, speakers flexibly used information that was perceptually available in the communicative setting and didn't merely rely on the organization of the memories. For instance, when Directors who studied the array from $225^{\circ}$ without knowing their Matchers viewpoint later interacted with a Matcher at $0^{\circ}$, they used overwhelmingly Matchercentered descriptions, even though most of them had used their own viewpoint as an organizing direction in memory. This is consistent with findings that, in describing spatial information, people do not always adhere to their memory's organizing direction when it conflicts with perceptual evidence (Li et al, 2011). Altogether, the adaptation we report here underscores that people use all relevant information as soon as it becomes available (whether at study or at collaboration) to make attributions about their respective ability to contribute to the task. This is in line with the view that probabilistic constraints on information processing influence perspective-taking behavior in conversation (e.g., Hanna, Tanenhaus, \& Trueswell, 2003).

Our study offers a caveat on earlier demonstrations that the misalignment between partners influences perspectivetaking (e.g., Duran, Dale, \& Kreuz, 2011; Schober, 1993), by highlighting that misalignment interacts with other representational cues. When Directors were at $0^{\circ}$ and Matchers at $135^{\circ}$, Directors overall opted for their own perspective in descriptions, presumably because reasoning from an oblique perspective was computationally more difficult (especially when not made salient at study). However, when Matchers were at $0^{\circ}$ and Directors at $225^{\circ}$ (also a $135^{\circ}$ offset), Directors readily adopted their partner's perspective in descriptions. Thus, misalignment on its own does not determine the preferred perspective of speakers' descriptions.

In sum, in collaborative spatial tasks people adapt their memory representations and linguistic behavior in nuanced ways. They consider converging communicative and representational cues, whenever they become available, to appraise whose perspective would be optimal for efficient coordination; this influences whether they encode their
partner's available viewpoint in memory and adopt it in descriptions.

#### Abstract

Research on human reasoning is dominated by demonstrations of the errors people make in various judgment and decision-making tasks. The area of social cognition is not an exception: the list of apparent errors is long and includes a number of contradictory phenomena. Here we explore a prominent example of the contradictory pairs of biases: false consensus and false uniqueness. We show in an empirical study and with simulations that the consensus in the literature about the stability of these effects may be premature, as their occurrence depends on the format of questions used to measure them.

Keywords: False consensus; false uniqueness; social circle; response formats.

## Introduction

The false consensus effect (Ross, Greene, \& House 1977) or "looking glass perception" (Fields \& Schuman 1976) describes a phenomenon that people who exhibit a certain behavior or endorse a particular view ("performers") believe that this behavior or view is more common overall than do people with different behaviors or views ("nonperformers"). For example, Democrats would judge that democratic views are more spread in the general public than Republicans would. This kind of result has been documented so often that the false consensus bias has been considered an automatic response that may be "developmental vestiges of the infantile belief that all others are like us" (Krueger \& Clement, 1994, p.609). However, an opposite bias called false uniqueness has also been documented (Frable, 1993; Mullen, Dovidio, et al., 1992). People holding a particular view sometimes tend to think that their view is less popular than do people holding a different view.

At least five different explanations have been proposed to explain false consensus effects (Marks \& Miller, 1987). First, people are likely to have selective exposure to similar others, so their estimates of larger social environments are based on biased samples. Second, their preferred view may be more salient to them than a different view, which may make them think that their preferred view has a stronger
social support. Third, people may believe that situational factors that led them to hold a particular view will affect others in a similar way, leading them to adopt the same view as well. Note that this view contrasts with another popular bias, namely the fundamental attribution error, whereby people believe that their behavior is caused by situation but others' behavior is caused by dispositional factors. Fourth, believing that others share one's view may have a motivational cause, such as fulfilling the need to validate own belief and maintain self-esteem. Fifth, false consensus is in line with a Bayesian analysis that assumes a uniform prior distribution and one's own view as the only evidence (Dawes \& Mulford, 1996).

It is more difficult to explain false uniqueness. Suls and Wan (1987) extend the motivational account and propose that false uniqueness can contribute to one's self esteem when the behavior or view in question is desirable, but find inconsistent support for this view (Suls, Wan, \& Sanders, 1988). Moore and Kim (2003) show that because people rely more on information about themselves than about others when forming judgment of prevalence of their views, effects similar to both false consensus and false uniqueness can occur. However, their measure of these effects is different than that used in most other studies: they use the difference between people's judgments and true population values rather than the difference between judgments of groups of people holding different views.

Here we investigate a so far neglected possible factor that may lead to both effects: the format of the questions used to measure these effects. Most studies investigating false consensus use one of two response formats. Either they ask about both the percentages of performers and nonperformers, for example, "What \% of your peers do you estimate would carry the sandwich board around campus? \% What \% would refuse to carry it? \% (Total should be $100 \%$ )" (Ross, Greene, \& House, 1977), or they ask only about the percentages of performers, e.g., "What percentage of students do you think agreed to wear the sign?" (Krueger \& Clement, 1994). There are no studies, however, that compare how different response formats affect estimates of the false consensus effect. For example,
it is not known whether the effect would remain the same if participants were asked about nonperformers rather than performers. It is well known from survey methodology literature that response formats can have strong effects on answers independently of people's true beliefs (Tourangeau, Rips, \& Rasinski, 2000). Similarly, research on subjective probability calibration shows that people can appear overconfident, well calibrated, or underconfident depending on the response format used (Juslin, Wennerholm, \& Olsson, 1999). This motivates us to explore these effects in the case of false consensus and false uniqueness effects.

## Method

We asked 104 participants recruited from Mechanical Turk ( $43 \%$ female, mean age $34,44 \%$ with bachelor or higher degree) three groups of questions about 10 characteristics, listed in Table 1. The questions were taken from publicly available results of large national surveys (Gallup World Poll 2011 for characteristics 1-5, Pew Center 2011 for 610); full texts are available on request. In the present study, participants first gave their personal answer to each of the 10 questions. In this way we classified them as either performers or nonperformers on a particular characteristic. Thereafter they estimated the percentage of performers and/or nonperformers in their social circle (defined as adults you were in personal, face-to-face contact with at least twice this year), and in the general population of the United States. One random half of the participants answered the questions about their social circle first, and another half about the population.

For each characteristic, a random third of performers and a random third of nonperformers gave estimates of social circle and population percentages in one of the following response formats: 1) estimating only the percentage of performers, 2) estimating only the percentage of nonperformers, and 3) estimating both percentage of performers and nonperformers. Figure 1 provides an example of the three response formats for one of the characteristics, and Table 2 lists all formats. Note that in format 3 the estimates for performers and nonperformers have to sum to 100 , but there is no such check in formats 1 and 2. Estimates for social circle and for the population were given always in the same format. The same individual could have answered questions for different characteristics in different formats, depending on whether he was a performer or nonperformer himself, and to which response format group he was randomized to.

Table 1: Characteristics used in the study, along with percentage of people answering "yes" (performers) in national surveys, and percentage of such people in the present sample.

|  | Characteristic | Population \% of performers | Sample \% of performers |
| :---: | :---: | :---: | :---: |
| 1 | No money for food in past 12 months | 19 | 18 |
| 2 | Donated to charity last month | 57 | 41 |
| 3 | Experienced theft in past 12 months | 12 | 21 |
| 4 | Religion is important part of daily life | 64 | 28 |
| 5 | Attended worship in past 7 days | 47 | 14 |
| 6 | Belief in God necessary to be moral | 53 | 13 |
| 7 | Believes in God | 70 | 54 |
| 8 | Smokes tobacco at least once/day | 15 | 24 |
| 9 | Military force sometimes necessary | 77 | 84 |
| 10 | Homosexuality should not be accepted | 36 | 18 |

Figure 1. Example of the three response formats used to elicit estimates of performers and nonperformers in general population.

Table 2: Different ways in which prevalence of performers can be inferred, depending on the response format.

| Response <br> format | Estimates about <br> prevalence of | Estimates given <br> by | Abbre- <br> viation |
| :--- | :--- | :--- | :--- |
| 1 | Performers only | Performers | P.P |
| 2 | Nonperformers only | Performers | NP.P |
| 3 | Performers and | Performers | Pnp.P |
|  | Nonperformers |  | NPp.P |
| 1 | Performers only | Nonperformers | P.NP |
| 2 | Nonperformers only | Nonperformers | NP.NP |
| 3 | Performers and | Nonperformers | Pnp.NP |
|  | Nonperformers |  | NPp.NP |

False consensus and false uniqueness can be measured in different ways. The most prevalent approach in the literature is to calculate the difference between the prevalence of performers as estimated by performers (P.P) and the prevalence of performers as estimated by nonperformers (P.NP). A positive difference P.P - P.NP is interpreted as false consensus, and a negative difference as false uniqueness. In our study, separate groups of both performers and nonperformers gave estimates in 3 different formats. This enables calculating the size of false consensus in 9 different ways, listed in Table 3.

Table 3: Different ways in which false consensus effects can be calculated, depending on the response format.

| Type of false <br> consensus | Calculation |
| :--- | :--- |
| 11 | P.P - P.NP |
| 12 | P.P - (100 - NP.NP) |
| 13 | P.P - Pnp.NP |
| 21 | $(100-$ NP.P $)-$ P.NP |
| 22 | $(100-$ NP.P $-(100-$ NP.NP $)$ |
| 23 | (100 - NP.P) - Pnp.NP |
| 31 | Pnp.P - P.NP |
| 32 | Pnp.P - (100 - NP.NP $)$ |
| 33 | Pnp.P - Pnp.NP |

## Results

How stable are false consensus effects across different response formats? If response format does not play a role, estimates of prevalence of performers should be the same for all formats, consequently resulting in same direction and size of false consensus effects. However, Figure 2 shows that the effects vary depending on response formats used to estimate prevalence of performers. The most extreme example is characteristic number 1 (no money for food), where estimates exhibit false uniqueness when performers estimate prevalence of performers (types 11-13), but false consensus when performers estimate prevalence of nonperformers (types 21-23) or when they estimate prevalence of both performers and nonperformers (types 3133). Several other characteristics show similar patterns of both false consensus and false uniqueness effects.

Figure 2: False consensus effects for nine different ways of calculating false consensus (see Table 3 for details). Small numbers denote effects for different characteristics. Full line denotes mean of the effects. Dotted lines denotes difference between performers and nonperformers in participants social circles (see text).

How can these different false consensus and false uniqueness effects for the same characteristics be explained? We propose a simple model of how estimates of prevalence of performers in the population are derived. The model has two plausible assumptions. First, people derive estimates about the general population based on the samples they have in their immediate social environment, that is their social circles (see Galesic, Olsson, \& Rieskamp, 2012, for a social circle model that accounts for people's estimates of population distributions). Support for this assumption is shown in Figure 2, where dotted line represents differences
in percentages of performers and nonperformers, calculated by different methods, in participants' social circles. They parallel the population estimates ( $\mathrm{r}=.89$ ).

Second, we assume that to derive these estimates, people attempt to recall as many individuals in their social circle belonging to the required category (e.g. performers) as they can. Because of time and effort limits, they are often not able to recall all such individuals. Consequently they may underestimate the percentage of those individuals in the population relative to what they would report had they recalled all such individuals in their social circle.

The model can be formalized for each response format separately, as follows. Recall that to estimate false consensus effects, a researcher needs estimates of prevalence of performers. When a person is asked only about performers in the general population (response format 1 , see Table 2), his estimate of population prevalence of performers can be modeled as:

$$
P_{1}=S C_{P} \times \alpha,
$$

where $P_{1}$ is the performers' population prevalence estimated in response format $1, S C_{P}$ is the percentage of that person's social circle that are performers, and $\alpha$ is a memory activation level parameter ranging from 0 to 1 . Note that according to this model people are assumed to always estimate population prevalence of performers as lower or equal than in their social circle. When a person is asked only about nonperformers in the general population (response format 2), his estimate of population prevalence of performers can be inferred from his estimate of population prevalence of nonperformers. This can be modeled as:

$$
P_{2}=100-S C_{N P} \times \alpha,
$$

where $S C_{N P}$ is the percentage of that person's social circle that are nonperformers, and the meanings of other symbols are the same as above. Note that if prevalence of nonperformers is underestimated $(\alpha<1)$, then the inferred prevalence of performers in this response format will be overestimated relative to the true percentage in the social circle.

Finally, when a person is asked to estimate the percentage of both performers and nonperformers (response format 3), his estimate of population prevalence of performers can be modeled as:

$$
P_{3}=100 \times\left(\frac{S C_{P} \times \alpha}{S C_{P} \times \alpha+S C_{N P} \times \alpha}\right)=S C_{P}
$$

where meanings of symbols are the same as above. Because in this response format percentages of performers and nonperformers have to sum to 100 , the denominator serves to normalize the sum of prevalence estimates of performers and nonperformers, which would be lower than 100 if $\alpha<1$. That is, it is assumed that people recall a subset of performers and nonperformers from all performers and nonperformers in memory, and then estimate the percentage
of each group in the sum of both groups. If their recall of performers and nonperformers is unaffected by other factors (see Discussion for more comments on this possibility), then their population estimate of performers equals the percentage of performers in their social circle $\left(S C_{P}\right)$.

Note that for simplicity we do not model the fact that reports of social circles are similarly affected by response formats as the population estimates. However we believe that modeling this would only make estimated parameters larger, but would not change relative differences between estimates in different formats.

To check whether this simple model could reproduce the pattern of results in Figure 2, we simulated estimates of prevalence of performers for 10 different fictitious characteristics with social circle prevalence ranging from $1 \%$ to $91 \%$ in steps of 10 percentage points. We modeled population estimates using the formulas above and different values of $\alpha$. For all values of $\alpha$ lower than 1 the pattern of false consensus effects is very similar to the empirical results in Figure 2. Figure 3 shows an example for $\alpha=8$.

Figure 3: Simulated patterns of false consensus and false uniqueness effects, for $\alpha=.8$. Full line denotes results assuming the same social circles for performers and nonperformers. Dotted line denotes results assuming that performers know relatively more performers than do nonperformers.

As visible in Figure 3, the pattern of false consensus and false uniqueness effects in this fictitious data set is very similar to the empirical pattern shown in Figure 2. The full line represents false consensus estimates assuming that performers and nonperformers have the same percent of performers in their social circles. However, in reality each group typically knows more individuals similar to themselves. Therefore we observe stronger false uniqueness effects in the simulation than in the empirical data. However, if we assume a small difference in social circles so that nonperformers have 20 percentage points fewer performers in their social circles than do performers, all
effects shift towards stronger false consensus. This is shown as a dotted line in Figure 3.

## Discussion

The pattern of false consensus and false uniqueness effects seems to be a product, to a large extent, of the way questions are asked and the samples people take from their social environments.

If both performers and nonperformers are asked about their own groups (false consensus type 12), then false uniqueness effects are likely to occur. This is so because imperfect recall of nonperformers about the members of their own group leads to inflated estimates of the prevalence of performers. More generally, when nonperformers are asked about their own group rather than about performers (types 12, 22, and 32), we see a reduction of false consensus that in some cases turns into false uniqueness.

In contrast, when nonperformers are asked about performers (types 11, 21, and 31), the imperfect recall alone will lead to underestimation of performers' prevalence. If there is no difference between social circles of performers and nonperformers, then the false consensus effect for type 11 will be zero (see the point 11 of the full line in Figure 3). If there is a difference, then the false consensus effect will occur, as in the point 11 of the dotted line in Figure 3 and in empirical results in Figure 2). In all other conditions where nonperformers answer about performers, false consensus effects are most likely.

The two response formats that are most often used in the literature, where performers and nonperformers answer about performers only (type 11) or about both performers and nonperformers (type 33), produce very similar false consensus effects. This may contribute to the wide-spread consensus in the literature about the robustness of the false consensus effect. However as our findings show, false uniqueness and false consensus can occur for the same characteristics, depending on how the question is asked. Therefore false consensus may not be such a robust bias as previously assumed.

Note that the simple model described here neglects effects of frequency of contact on recall, and does not specify how the percentage estimates are formed in the first place. This model cannot explain the empirical fact that population estimates often resemble smoothed versions of one's social circle (Galesic et al, 2012), that is performers report smaller proportion of performers and larger proportion of nonperformers in population than in their social circle. A more elaborate model would describe how people sample from their social circle, for example based on frequency of contact, and how they estimate the percentage of performers based on that sample. The final estimates are likely to be shaped by both, effects of question format, and other sampling and estimation processes.

A common approach to explaining apparent errors in social judgments is to look at the human mind and search for motivational and cognitive processes that deviate from
normative rules of reasoning. Here we show that properties of social environments as well as of memory processes, and their interplay with the way questions are asked, can produce apparent false consensus and false uniqueness effects on its own. This work does not diminish the potential importance of other explanations of origins of these effects, but provides a baseline for the part of these effects that are artifacts rather than a cognitive bias.

# The Role of Feedback in Aligning Perspectives in Referential Communication 

Timothy M. Gann (tgann@ucmerced.edu)<br>Sierra Nevada Research Institute and Cognitive and Information Sciences, University of California, Merced 5200 North Lake Rd. Merced, CA 95343 USA

#### Abstract

Successful dialogue frequently requires that interlocutors construct and align their conceptualizations of referents. This study presents data from a referential communication experiment the manipulates contextual factors such as the availability of feedback and role constancy in order to investigate how conversational partners reconcile their perspectives in the face of mutual uncertainty about what constitutes common ground. The results show that speakers tend to incorporate information about the addressee's perspective, and that this information tends to come through direct feedback rather than through indirect channels such as turn-taking.

Keywords: Psycholinguistics; language production; audience design; perspective taking.

## Introduction

When deciding how to describe an object, people must first categorize it in a way that is useful to themselves them and ultimately for their partners. Sometimes, the taxonomic, established categorization is not well suited to the task and interlocutors may be forced to develop an ad hoc, or socially emergent category that is more suited to achieving their current conversational goals (Barr \& Kronmüller, 2007; Barsalou, 1991). For example, when two people are discussing where they wish to go out to eat, they may form a category of acceptable restaurants on the spot. This category emerges over the conversation and is neither pre-existing in memory nor particularly enduring (unless they frequently go out together). This socially emergent conceptualization then becomes the foundation for future exchanges. What this means is that early on in a conversation, taxonomic categories are going to be activated more often and attract more attention. However, as time goes by and speakers learn to put more emphasis on shared information, and other types of information are found to be in conflict with the goal of successfully referring to an object, the socially constructed categories should be used more often. These socially emergent categories would probably demonstrate some degree of being person-specific (Horton \& Gerrig, 2005), but that would not preclude their activation and propagation to new conversational partners if they were useful (Garrod \& Doherty, 1994).

The development of new conceptualizations during conversation should also lead to changes in how attention is allocated. Rehder and Hoffman (2005) conducted an experiment in which participants had to do a category learning task while having their eyes tracked. At the beginning of the experiment, participants would overtly attend to each of the features in the display and consider them all before making a decision. By the end of the experiment, participants learned to overtly attend only to those features that were necessary for the task of choosing which category was represented by the display.

Similarly, in a referential communication context involving perspective taking, as time passes and socially emergent categories become more dominant, attention should shift away from privileged competitors. By the end of a conversation they should be attended to about as little as an object unrelated to the target. This shift should also happen in situations in which the speaker does not initially have access to what the listener knows. As evidence about listener's knowledge, or lack of knowledge, becomes available they should gradually begin to focus on the stimuli that are most consistent with the listener's perspective.

The question then becomes, what factors influence the rate of learning during conversation? One possibility is the potential for feedback. Closely related to feedback are the roles of the interlocutors: Are they in a didactic situation in which the roles are fixed, or is it a fully interactive dialogue in which there is turn taking? Unrestricted feedback can come in many forms. First, speakers can receive pragmatic feedback in the form of knowledge about the success or failure of the listener in establishing joint attention to a target object. It is implicitly accepted that pragmatic feedback is necessary for learning to happen, with positive feedback leading to a reinforcement of the speaker's current conceptualization, and negative feedback encouraging re-conceptualization. Second, the listener can give signals to the speaker, who can make inferences about the listeners confidence about an interpretation. For example, Barr (2003) found that listeners will use speakers' confidence as a cue that the current referent is either a typical or atypical member of a category. In principle, speakers should also similarly use the listener's confidence in their selection of a target as a cue to how well their message was received.

Finally, listeners can give direct verbal feedback to the speaker. Schober and Clark (1989) conducted an experiment in which a participant acted as a non-interactive observer to a conversation. This participant attempted to do the same task the actual listener was doing, but without the ability to give feedback to the speaker.They found that the observers never aligned as closely to the speaker because they were unable to provide feedback and have the speaker adjust to or correct their interpretations. The lack of verbal feedback can also make the speakers prone to give more information as a hedge against possible misunderstandings (Gann \& Barr, 2012). For example, Krauss and Weinheimer (1966) found that when listeners were unable to give feedback, speakers were not inclined to simplify their utterances.Instead they kept utterances long so they could minimize the possibility of giving too little information. While it is possible for alignment to happen without it, direct verbal feedback likely serves to speed up the
process. Without it, speakers may not be able to easily settle on a shared perspective and fully acquire a socially emergent category that corresponds to the intersection of their knowledge with their partner's.

Role switching may serve a similar function. In a natural conversation, both participants are speakers and listeners. These participants both offer their respective conceptualizations of the referents they are bringing to each others attention, and both are able to interactively sculpt each others understanding. Even simply priming from ones partners utterances may serve to make dimensions more salient than the other might be from an individuals egocentric perspective (Pickering \& Garrod, 2004). In addition, in situations where one person is the primary speaker, there might be less incentive for that individual to align, and thus, the speaker might rely on the listener to align to align to speaker knowledge.

In many referential communication experiments that manipulate common ground, knowledge is asymmetric in one direction. Specifically, the speaker knows more than the listener, or the listener knows more than the speaker. This experiment focuses on a case in which the speaker and listener both must learn to account for this difference in knowledge. The major question is whether or not conversational partners in such a situation tend to reconceptualize the stimuli in a way that is consistent with a union of their perspectives, thus taking into account both their sets of privileged information, or an intersection of their perspectives, focusing only on that information that is mutually shared. If in a particular circumstance, speakers tend towards reconceptualizing the referent in terms of an intersection between their knowledge and their partner's, will speakers then begin to ignore competitors that are not relevant to that overlap? Additionally, is their tendency to adopt one scheme or another influenced by the form of feedback they experience: either explicit feedback, or implicit feedback through role switching? Direct feedback should allow addressees to clearly indicate to the speaker what their informational needs are, and should thus be associated with rapid alignment between the interlocutors. Learning about a partner's perspective in the role switching condition presumably relies on more indirect learning, and may not have the same impact as direct feedback.

## Method

## Participants

The participants were all native English speakers, drawn from a pool of undergraduates at the University of California, Riverside. A total of 32 students participated in the study, forming 16 dyads. For half of the dyads, the participants were assigned to either the role of the director or the matcher. The other half of the dyads did not have fixed roles, but rather switched roles after each trial of the experiment.

## Apparatus

An ISCAN ETL-400 table-mounted eye-tracker, sampling at a rate of 60 Hz , was used to track the director's gaze through-
out the experiment. The experimental stimuli were displayed for the participants on two LCD monitors. Each participant's screen was only visible to themselves. The director was given a set of headphones through which instructions could be given without the knowledge of the matcher.

## Materials

The experimental stimuli consisted of 32 sets of five items. Each stimulus item was a $300 \times 300$ pixel colored bitmap of an object placed on a black background. The sets were constructed such that there was a target object, three competitor objects that are typically referred to by the same name, and an unrelated filler item. The competitor objects contrasted with the target object along the dimensions of size, openness, and material (or color). The target was always consistently open and larger; each of those two dimensions were visible to only one of the participants. Material differed from object to object; this dimension was always shared between the participants. So for example, one participant may have seen a target that was a large open trashcan, a smaller identical competitor, a plastic trashcan, and an unrelated fourth object. The other participant would see the same target, the plastic trashcan, the same unrelated competitor, but would have a closed competitor that is otherwise as physically similar to the target as possible. See Figure 1 for an example.

## Procedure

Participants were assigned to either the role of director or matcher by having one of the participants choose a face down card at random that specified a role. If the dyad was participating in the condition in which their roles would switch throughout the experiment, it was explained to them that they were picking an initial role. For the switching participants, the participant who was eye-tracked was always the initial director.

The experiment was described to the participants as a simple communication game that they would be playing together in which the director would be describing a target object such that the matcher could pick out which object on their screen. They were shown a set of example stimuli demonstrating the perspective of both partners. The sample stimuli did not include competitors that varied along the privileged dimensions, only one that contrasted along the shared dimension. The participants were instructed that the target would be indicated to the current director with a red border. The matcher would listen to the director's description and select the object being referring to on their screen by selecting it with their mouse.

## Design

The experimental variables manipulated in the design of the experiment included whether the partners switched roles or not, and level of feedback ( $2 \times 2$ between-subjects design). The dependent variables are accuracy (whether the addressee chooses the right target), speech onset time, use of an adjective corresponding to the speaker's privileged perspec-

Figure 1: Each of the displays above corresponds to the perspective of one participant. In this example, the target would be the closed metal trashcan in the upper left corners. The display on the left contains a competitor based on openness. The display on the right shows a competitor based primarily on material/color. Each display has a competitor in common based on size.
tive/dimension, use of an adjective corresponding to the addressee's privileged perspective, use of an adjective corresponding to the shared perspective, and the proportion of time the speaker spent gazing at the shared and privileged competitors prior to speech onset.

## Analysis

The director's speech was recorded, transcribed, and coded for accuracy, speech onset, and the use of modifiers matching each of the three dimensions on which the competitors contrasted with the target. The eye-tracking data were coded as number of frames (sampled at 60 hz ) that the director spent looking at each object prior to speech onset. Eye-tracking data for trials in which the participants switched roles was removed from the data set due to the inability to make an apples to apples comparison across the condition due to the current director only contributing eye-data for half the trials in the switching condition.

The analyses were conducted using linear mixed effects models with random effects included for subjects and items. Models were fit within R using the lmer function within the package lme4 version 0.999375-39 (Bates \& Maechler, 2010). Appropriate link functions were chosen depending on the distribution of the outcome variable of interest. The significance of the fixed effects were assessed using a $\chi^{2}$ model comparisons approach in which a model without the variable of interest is compared with the full model (Barr, Levy, Scheepers, \& Tily, 2013).

## Results

Thirteen of 512 ( $2.5 \%$ ) trials were dropped from the analyses because of experimenter and procedural errors. Across all conditions the listener correctly identified the referent in $72.55 \%$ of trials (Figure 2 shows accuracy plotted by condition). There were significant effects of feedback $\left(\chi_{(1)}^{2}=\right.$ $30.431, p<0.01)$ and trial order $\left(\chi_{(1)}^{2}=11.709, p<0.01\right)$, with the presence of feedback and increasing trial order being
associated with greater accuracy. However, a three-way interaction of these factors with role switching $\left(\chi_{(1)}^{2}=5.214, p<\right.$ 0.05 ) showed that while the feedback effect was stable in both switch conditions, order only had an effect when there was no role switching and it interacted positively with feedback when there was role switching $\left(\chi_{(1)}^{2}=6.034, p<0.05\right)$.

## Speech Analysis

Potentially, speakers could refer to three dimensions in their descriptions of the referent corresponding to the contrasts between the referent and the shared competitor, the speaker's privileged competitor, and the listener's privileged competitor. At the beginning of the experiment speakers are much more likely to use the first two by virtue of their lack of access to the third, but as the experiment progresses and evidence for that dimension becomes available it should be seen to rise. The use of adjectives associated with these dimensions speaks to the underlying scheme the speaker has about what information is necessary to identify the target. Because the common competitor is always necessary (and indeed, is referred to in $88 \%$ of trials) its use is a useful check when it comes to assessing whether a speaker understands and is faithfully attempting to do the task. However, because the underlying hypotheses are focused on how speakers reconcile their privileged knowledge with that of their listeners, how they used modifiers related to the two privileged contrasts is more theoretically interesting.

Use of a modifier relating to the speaker's privileged competitor was influenced by whether or not the participants were switching roles $\left(\chi_{(1)}^{2}=6.500, p<0.05\right.$; see Figure 3). For the non-switchers, use of the speaker's privileged competitor stayed relatively close to ceiling over the course of the experiment whereas its use dropped over time for partners who switched roles. This may be because, for a speaker in the no-switch condition, their privileged competitor was always salient to them, whereas in the switching condition speakers experienced trials in which its presence was not linked to pro-

Trial

Figure 2: Proportion of targets correctly selected by the addressee.
duction. Because the use of the privileged competitor was not strongly associated with accuracy ( $\bar{r}_{\phi}=-0.028, \mathrm{p}=0.595$ ), there was not necessarily a strong reason to reduce its salience to speakers in the non-switching condition in the absence of another role.

On the other hand, the speaker had more substantial motivation to learn and use the listener's privileged competitor because its use was strongly associated with success in the task ( $\bar{r}_{\phi}=0.310, p<0.01$ ). In their use of modifiers that matched the listener's privileged competitor, speakers were significantly influenced by trial order (using more over time; $\left.\chi_{(1)}^{2}=26.866, p<0.01\right)$ and an interaction between the feedback and switching conditions ( $\chi_{(1)}^{2}=6.899, p<0.01$ ), such that the effect of feedback was larger when there was no role switching. It is interesting that there doesn't appear to be an additive effect between the two routes to getting partner feedback associated with the two factors, with the greatest degree of use of the listener's privileged competitor being when there was no role switching (see Figure 4). It's possible that the switching condition in this case reduced the pressure on the speaker to unilaterally integrate the perspective of their partners that is granted primarily through the channel of direct feedback. Indirect feedback about their partner's knowledge may not figure into their subsequent production in the switching conditions. This is because some of the information is coming during trials in which they do not have to integrate this information into an utterance themselves, and for which it is unnecessary from their perspective, thus reducing its salience.

Speech onset offers a window into feedback's anticipatory effect in regards to how much planning speakers have to do when they are aware of the possibility that their addressee can make a clarification request. Planning (time to onset of speech) was influenced by the opportunity for feedback $\left(\chi_{(1)}^{2}=10.235, p<0.01\right)$ with planning time decreasing with the presence of feedback. This is likely due to reduced pressure on the speaker to carefully craft their utterances due to
the lack of a chance for correction. Time needed for planning showed a significant decreasing trend over the course of an experimental session $\left(\chi_{(1)}^{2}=34.045, p<0.01\right)$, which is consistent with a general increase in familiarity with the task.

## Gaze Analysis

One of the primary claims of the hypotheses motivating this experiment is that patterns of gaze during planning may reflect the underlying categorical structure a speaker is considering. Rehder and Hoffman (2005) found that in category discrimination tasks participants learned to only attend to the features in a display that are required for discriminating category membership for the pattern as a whole. Likewise, it was hypothesized that gaze in a referential communication task would demonstrate the shifting category membership status of the objects under consideration by the speaker. For these analyses, due to the absence of eye-tracking data for the second participant in the switching group, and the inclusion of trial order as a factor in the analyses, only the first sixteen trials of the non-switching group were analyzed and compared with the performance of the eye-tracked partner in the switching group.

Attention directed to the privileged competitor (measured here as the proportion of pre-onset fixation time) does not appear to be influenced by the same factors that influence the use of the privileged competitor. In this case, the only factor of influence is feedback ( $\chi_{(1)}^{2}=4.820, p<0.05$ ), with feedback being associated with increased attention being directed to the privileged competitor. Theoretically, attention to the shared competitor should be relatively insensitive to condition due to its constant use regardless of circumstance, but it appears to be more heavily influenced by experimental factors than attention to the privileged competitor. This is demonstrated by a three-way interaction between switching, feedback, and trial order $\left(\chi_{(1)}^{2}=4.777, p<0.05\right)$, in which feedback led to more attention to the shared competitor at the beginning of the experiment, but less at the end. This may be due to feedback initially bringing a greater focus to the

Trial

shared competitor as parters in the role switching condition acclimated to the task.

## Discussion

Speakers and their addressees tend to align their conceptual and semantic representations over the course of a conversation. However, the final form that these representations takes may depend on the characteristics and constraints under which the interaction is undertaken. In this experiment, each participant had information that was privileged and the goal was to determine what effect conversational constraints, such as role constancy and the opportunity (and actuality) of feedback, had on the nature of the interlocutors' apparent representations as evidenced by the form of their utterances. These changed representations are supposed to reflect the creation of socially emergent categories that arise out of the alignment process.

Interestingly, the most successful descriptions included the listener's privileged competitor. This is why performance was lowest by far in the most feedback-impoverished condition. This is notable because the task was, in principle,
solvable if the addressee aligned to the speaker by realizing that they could not see the addressee-privileged competitor. Just as the speaker had the opportunity to learn what the listener's perspective was through feedback, the listener could infer the speaker's perspective through their speech. However, the speaker's use of their own privileged perspective had relatively little bearing on the outcome of an individual trial.

Speakers seemed to acquire information about the addressee's perspective most effectively through direct, corrective feedback. Despite the opportunity to model their partner's knowledge, or at least benefit from priming, when they occupied the directing role in the role switching condition, speakers appeared to primarily acquire this information through direct feedback such as the listener asking about their privileged dimension. However, the significant role switching by feedback interaction speaks to a boosted effect of feedback when partners did not switch roles. This is interesting because it suggests that perhaps it is more beneficial to have role constancy and consistent feedback than to experience both roles and be in their partner's shoes. A participant who is consistently the director may feel it is part of their
role to adapt to their partners needs, whereas partners who switched roles may have been less sure about which partner should be aligned to. On the other hand, a speaker's use of their own privileged competitor seemed to be sensitive only to role switching, with use staying at a constant, high rate when partners have stable roles, but declined steadily when they switch roles. One possible explanation is that addressee feedback is more likely to be about communicating the dimension that is salient to them, and is not used to elicit clarifications about the superfluous (from their perspective) dimension used by the speaker. An impoverished description is potentially more damaging, than over-specification, but is amenable to feedback correction (Gann \& Barr, 2012). Direct feedback could put an upward pressure on the use of the addressee's perspective, but be neutral in regards to the speaker's. Thus salience from the speakers perspective is a sufficient reason for a speaker to include information in a given description, even if it has no apparent communicative value to the addressee.

Thus, when speakers are role switching and have feedback, they are likely to align in a way that favors aligning to the addressee through the speaker's increasing use of the listener's privileged dimension. This suggests these participants are moving toward a conceptualization of the shared perspective that is a "union" of their perspectives: The speaker makes use of adjectives related to both partners privileged dimensions. The adaption that results in this union is driven by the structure of the task, and the quality of the feedback experienced. Additionally, as seen in previous experiments such as Wardlow Lane, Groisman, and Ferreira (2006), anything that raises the salience of a particular competitor is likely to increase mention of that competitor, which might explain why the privileged competitor continues to be used despite it only being relevant from the speaker's perspective. Because its use doesn't seem to have a negative effect, there is little pressure to reduce its use absent another factor.

The online measures paint a more mixed picture. The effect of speech onset in regards to feedback seemed to mirror that which was seen in the prior experiment. When speakers were not permitted the opportunity for direct advance feedback, they took a little longer to plan their utterances. The eye-tracking data were less clear. At the outset it was anticipated that the attention paid to the competitors would help reveal the underlying conceptual structure the speaker was consulting in order to formulate her utterances (Rehder \& Hoffman, 2005). However, because the listener's competitor is never visible to the speaker, there was no way to match up eye-movements with its consideration, except for perhaps if the speaker preferentially fixates nothing when considering their partner's knowledge (which is one potentially interesting future analytical direction). In addition, the relative salience of the competitors on the screen was under different selective pressures than the features in the categorization task of Rehder and Hoffman (2005), as additional decisions had to be made about how to describe the contrast rather than
making a simple judgment of category membership.

#### Abstract

When referring to an object using a description, speakers need to select properties which jointly distinguish it from any potential distractors. Previous empirical and computational work addressing this content selection process has highlighted the role of both (i) the discriminatory power of properties of a referent, i.e. how many of the distractors in a domain each property excludes; (ii) how inherently salient or preferred a property is. To date, there has been no attempt to systematically investigate the trade-off between these two potentially competing motivations. This paper investigates experimentally the extent to which speakers take discriminatory power versus preference into account during content selection for reference production. Our results suggest that discriminatory power in fact plays a relatively unimportant role. We discuss the implications of this for computational models of reference production. Keywords: Referring expressions, language production, psycholinguistics, computational modelling

## Introduction

Referring expressions such as the large bottle are an essential feature of communication. Without the ability to refer, it would be difficult to ground our communicative efforts in the physical and mental world. The processes underlying reference production have been the object of intensive study by researchers in Computational Linguistics (see Krahmer \& van Deemter, 2012, for an extensive review) and Experimental Psycholinguistics (e.g. Levelt, 1989; Arnold, 2008). Many researchers agree that the primary aim of a referring expression is to identify an object for an interlocutor, a position that is rooted in a long tradition of philosophical work on the subject (e.g. Searle, 1969).

Consider a situation in which a speaker needs to identify an object (the target referent), which has not been introduced earlier in the discourse and which is visually co-present for both speaker and listener. Here, the speaker needs to perform content selection, to determine which properties of the target referent to mention in a description. This process is non-trivial because objects have several properties to choose from; moreover, the goal of identification entails choosing a set of properties
that jointly exclude all the distractors in the domain with which a listener might confuse the target. The speaker has to tread a fine line between efficiency on the one hand and sufficient detail on the other. Thus, it would seem desirable to avoid producing an overspecified description which contains more properties than required, or an underspecified one, which does not succeed in identifying the target. Both constraints would seem to follow to the extent that speakers observe Grice's Maxim of Quantity (Grice, 1975).

To take an example, the bottle with the black border in Figure 1 has three properties that are potentially distinguishing, namely, its colour, its size and the fact that it is marked with a black diamond (hereafter referred to as its pattern). On its own, none of these properties is sufficient to distinguish it from the distractors, the other bottles in the domain. Closer inspection reveals that this target minimally requires two properties (in fact, any two of these three) for successful identification. For example, the large bottle with a diamond would do the trick without overspecifying.

Figure 1: Example domain: the target's diamond pattern excludes 4 distractors, while its green colour excludes the 3 blue bottles on the bottom row

## Models of content selection

What process would best model speakers' content selection procedure? It is widely accepted that, since speech production is incremental (cf. Levelt, 1989; Pechmann,
1989), properties would be selected one after the other. The main question is: on what basis is the choice made at each point? One possibility would be for the speaker to weigh each property in terms of its discriminatory power. For instance, looking at Figure 1, it is easy to see that starting with the target's pattern would eliminate four distractors, while either of the other two properties would eliminate only three. Hence, a possible strategy for a speaker might be to always select the most discriminatory property, given the state of the domain and the description. In this case, once a pattern is chosen, either one of the remaining two properties (colour or size) would suffice to completely distinguish the target, since their discriminatory power is equal. This strategy is embodied in a well-known computational algorithm for the automatic generation of referring expressions, the Greedy heuristic (Dale, 1989). In the psycholinguistic community, it has been proposed most explicitly in the theoretical work of Olson (1970). Olson suggested that speakers 'specify the object to the level required by the listener to differentiate the intended referent from the alternatives' (p. 244-5). One way of interpreting this, assuming an incremental procedure, is that the speaker weighs the contribution of each available property to the ultimate goal of identification, choosing the one that is most likely to help in achieving it, as the Greedy heuristic does. ${ }^{1}$

In contrast to these models, experimental work has suggested that speakers' content selection processes tend to rely on heuristics related to the inherent salience of certain properties. The primary source of evidence for this is that some properties - notably an object's colour - tend to be used even when they do not contribute to the identification of a target, leading to an overspecified description. By contrast, other properties, such as size (or, presumably, pattern in the sense being used here), tend to be used only when absolutely required. In the case of size, its relatively dispreferred status is likely due to its being a relative property, requiring comparison to other objects in the domain.

These results are extremely robust (see Pechmann,

[^66]1989; Belke \& Meyer, 2002; Engelhardt, Bailey, \& Ferreira, 2006, among many others) and appear to persist even when the colour of an object doesn't differ too starkly from that of its distractors (e.g. the target is light green, whereas a distractor is a darker shade of green; see Viethen, Goudbeek, \& Krahmer, 2012). According to Pechmann (1989), this can be explained with reference to the fact that when speakers incrementally select properties, they initiate their descriptions before having completely scanned a domain. The preference for a property like colour - which may be related to its being an inherently salient attribute of perceived objects (e.g. Pechmann, 1989) - would make it more likely for that property to be selected before others.

In short, the evidence suggests that a property's discriminatory value is not the only consideration in content selection. In the computational literature, this evidence inspired the development of the well-known Incremental Algorithm for the generation of referring expressions (Dale \& Reiter, 1995). In contrast to the Greedy heuristic, the Incremental procedure works by selecting properties one by one on the basis of their preference rather than their discriminatory value. Given an ordering of properties by their preference, the algorithm considers each in turn. If a property excludes some distractors, it is included in the description, and the distractor set is updated, before considering the next property. Like the Greedy heuristic, this algorithm terminates when the description is fully distinguishing.

In our example domain, the Incremental Algorithm would thus start with the target's colour rather than its pattern. This excludes all the blue objects, leaving two other green objects. If, in the predefined preference ordering, pattern follows colour, this is the next property that would be considered. Since pattern excludes both remaining distractors, the description generated is the green bottle with a diamond.

Thus, there are two potentially conflicting motivations underlying content selection: discriminatory power and preference. The potential trade-off is exemplified in Figure 1, where the most discriminatory property (pattern) is not the most preferred one (colour).

In spite of the evidence for preferences stemming from overspecification, there is to our knowledge no research that explicitly tests the predictions of the two models, although some of the implications of the two strategies are evident in recent computational psycholinguistic work. Gatt, van Gompel, Krahmer, and van Deemter (2011) and van Gompel, Gatt, Krahmer, and van Deemter (2012) propose a non-deterministic model of reference production called PRO, which follows one of two different paths, each of which involves the throw of a dice, loaded to reflect the degree of preference of a set of properties. Path 1 is only followed if there exists a property that rules out all distractors (the limiting case of what
we have called discriminatory power): the output of the algorithm in this case is a description containing this one property. Should several properties rule out all distractors then the (preference-loaded) dice is thrown to choose one of them. Path 2 is followed if no such property exists (as in Figure 1). Here, properties are added incrementally to the description until all distractors have been removed. Which property is chosen next is based on a throw of the dice. Once all distractors have been removed, however, the dice is thrown again to determine whether to terminate or include one more property; if the latter decision is taken, then the dice is thrown again to decide whether to terminate after that, or continue, and so on.Thus, preference does not only govern the choice between properties, it also governs the decision whether or not to over-specify.

Although PRO was found to have an excellent fit to production data, it was compared to human-produced descriptions in very simple domains in which there were only two properties available (colour and size) and one property always sufficed to distinguish the target referent. Thus, it is an open question whether speakers computed relative discriminatory power, or more simply based their strategy on the limiting case, namely, the availability of a fully distinguishing property.

More recently, Frank and Goodman (2012) proposed a Bayesian model to predict property choice ${ }^{2}$ in very simple language games in which a speaker has to choose one property (such as blue vs. circle) to describe an object in a domain. Although this work does not explicitly address identification, it is nevertheless highly relevant to the present discussion. In this model, the speaker's choice of a property given a referent is based on utility. Letting $p$ be some property of the referent, $P$ the set of available properties, and $|p|$ stand for the number of objects of which $p$ is true, the likelihood of using $p$ is

$$
\frac{|p|^{-1}}{\sum_{q \in P}|q|^{-1}}
$$

This definition approaches the notion of discriminatory power being discussed here, because the utility of $p$ increases the fewer objects it is true of (i.e. the more distractors it eliminates). However, this model does not consider preference. A more serious shortcoming is that the model assumes that a speaker can only refer using a single property; thus, it would never overspecify. Indeed, it turns out that the utility function over-estimates speakers' tendency to underspecify. Consider a case where a referent is both large and green. Assume that there is an additional green distractor, but no other large distractors (size is fully distinguishing). In this case, the probability of using the property large works out to 0.67 ,

[^67]with a probability of 0.33 for green. In the experiment reported by Gatt et al. (2011), which contained a condition precisely analogous to this one, speakers produced size-only descriptions only $17 \%$ of the time, and overspecified with both size and colour $83 \%$ of the time, a finding that tallies with figures in the literature on overspecification. Speakers never produced an underspecified description with colour only. Thus, the model of Frank and Goodman too does not satisfactorily account for the interplay between discriminatory power and preference.

In summary, the question addressed by the present paper is: To what extent do preferences trump discrimination in the process of selecting properties incrementally? We investigate the issue experimentally, using domains such as the one exemplified above. If speakers tend to prioritise properties by discriminatory power, then a property should be more often included if it is the most discriminatory one available, than if it is not. By contrast, if speakers prioritise properties by preference, then more preferred properties should be included more often than less salient properties.

## The experiment

The experiment traded off the discriminatory power of properties against their degree of preference, which was determined on the basis of previous empirical work. Our aim was to investigate which of the two heuristics outlined in the preceding discussions - one that prioritises properties based on preference, or one that does so based on discriminatory power - best matches speakers' content selection strategies. If preferences are more important, then the frequency with which properties are used should be independent of how discriminatory they are in different conditions. By contrast, if discriminatory power is more important, then a property should be used more often in case it is more discriminatory, regardless of whether it is highly preferred (as colour is) or not.

## Participants

The experiment was conducted at the Tilburg center for Cognition and Communication. 72 native speakers of Dutch (49 female, 23 male), all undergraduate students at Tilburg University, participated in return for course credit. All had normal or corrected-to-normal vision and none reported any problems with colour perception.

## Materials and design

The experimental stimuli consisted of 36 items selected from a version of the Snodgrass and Vanderwart set of line drawings with colour and texture (Rossion \& Pourtois, 2004). The items were selected on the basis of a pretest in which seven native speakers of Dutch were asked to name greyscale versions of the pictures. For the items, we selected only those pictures for which at least 5 out of the 7 speakers agreed on the name of the object. The pictures were subsequently manipulated to create a
version of each in two different sizes (large/small) and four different colours (red, blue, green and grey), with three superimposed patterns (a circle, a diamond or a square).

The rationale for using these three properties was as follows. First, there is a lot of previous work indicating that colour is highly preferred over size (see above). Second, the choice of pattern as the third property was based on its having to be realised (in Dutch, the language of the experiment) as a post-modifier, while size and colour tend to be realised as pre-modifiers, with a relatively fixed order (see e.g. Gatt et al., 2011, for previous work manipulating colour and size with similar materials). To the extent that the syntactic linearisation of properties reflects their order of selection, this would suggest that pattern would be selected after the other two. Be that as it may, however, we wanted to ensure minimal variation in syntactic ordering of the properties involved.

For each item, a visual domain was constructed, consisting of a target referent indicated by a black border, and five distractors. In each domain, all objects (target and distractors) were of the same type (e.g. all were bottles). In every domain, the target could be minimally distinguished from its distractors via any subset of two of its properties. As an example, the bottle in Figure 1 can be distinguished from its distractors by using its colour and pattern (the green bottle with a diamond), its colour and size (the large green bottle) or its size and pattern (the large bottle with a diamond). Each item was used in one of three conditions; the difference between conditions lay in which property of the target had the highest discriminatory value. One property was designated the most discriminatory property (hereafter $\mathbf{m d} \mathbf{p}$ ): this property excluded four of the distractors. The other two properties were equally discriminatory and each excluded three distractors. For example, in Figure 1, the MDP is pattern.

Note that, regardless of which property was the MDP, two properties were always minimally needed to distinguish the target. A description which mentioned all three properties would be overspecified, while one that mentioned only one property would be underspecified. As a result, there is no length confound: distinguishing descriptions are equally long in all conditions, unless they are over- or underspecified. This setup excludes another possibility, namely that speakers are biased to select a single, fully distinguishing property if one exists. This could happen, for example, because when a target has such a property (e.g. the target is the only red object), it becomes so salient that it induces a 'popout' effect (Treisman \& Gelade, 1980). While such effects have been reported in experiments on visual search, they have recently also been found to influence reference production as well (Gatt, van Gompel, Krahmer, \& van

Deemter, 2012). Here we are interested in testing a subtler notion of discriminatory power, in a more complex domain configuration.

In each trial, objects were presented in a sparse grid. For each item, the position of the target was fixed in advance and was the same in all conditions. Both items and participants were randomly divided into 3 groups. Item and participant groups were rotated through a Latin square so that each item appeared in each condition and each participant saw all conditions, but each participant saw each item only once. The experiment consisted of 36 trials, with 108 fillers. 36 of these were constructed using the objects with the same three properties as those used in the experiment. However, the type of a target sufficed to distinguish the target. The remaining 72 fillers consisted of targets that could be distinguished from their distractors using a variety of properties (such as stripes, spots etc).

## Procedure

The experiment was run using DMDx (Forster \& Forster, 2003), and used a director-matcher paradigm. Participants were divided into 36 pairs, with one randomly assigned to the role of speaker/director and the other to the role of listener/matcher. Participants did not switch roles. The director and matcher faced each other; each had a computer screen that could not be seen by the other. The speaker used a keyboard to request an item, whereupon she identified the target for the listener, who clicked on the target on his own screen. Participants were instructed to keep the interaction to a minimum, with the listener only responding by indicating to the speaker that he had finished identifying the target. The speaker's descriptions were recorded through a headset.

## Data coding

Descriptions were transcribed and coded according to which of the three properties of a target (colour, size and/or pattern) were mentioned. This classification ignored the mention of the object's type (e.g. 'bottle'), which we assumed would be included in any case and which, in our design, had no discriminatory value. A description was further classified as follows (i) Wellspecified if it contained exactly two properties (excluding type) of the target; Overspecified if it mentioned all three properties; or (iii) Underspecified if it mentioned only one property, or only the object's type. The descriptions were further coded according to whether they included the MDP or not.

## Results

In what follows, we report results from logit mixed effects (LME) analyses with Condition as fixed effect and random intercepts for participants and items.

Table 1 displays the proportion of overspecified, wellspecified and underspecified descriptions in each condi-

| MDP | Well-spec | Overspec | Underspec |
| :---: | :---: | :---: | :---: |
| Colour | 0.699 | 0.296 | 0.005 |
| Size | 0.685 | 0.310 | 0.005 |
| Pattern | 0.676 | 0.324 | 0.000 |

Table 1: Proportion of well-specified, overspecified and underspecified descriptions, by condition
tion. The number of underspecified descriptions was minimal overall (4 in total) and the rate of overspecification does not appear to differ greatly across conditions. We recoded descriptions to indicate whether each one was overspecified or not. There was no effect of condition on the likelihood of overspecification $(Z=1.02, p>.3)$, that is, the likelihood of overspecifying did not depend on which property was the MDP.

| MDP | Colour | Size | Pattern |
| :---: | :---: | :---: | :---: |
| Colour | 0.99 | 0.73 | 0.57 |
| Size | 0.99 | 0.76 | 0.55 |
| Pattern | 0.99 | 0.73 | 0.59 |

Table 2: Proportion of descriptions containing colour, size and pattern (columns) in each condition (rows)

Table 2 displays the proportion of descriptions containing colour, size or pattern, in each condition. There are two striking facts about the data: (i) the frequency with which any of the three properties was used was largely independent of the condition, that is, whether that property was the most discriminatory one or not; (ii) there is clear evidence for preferences, with colour being used more frequently than size, and size more frequently than pattern.

An LME analysis showed a highly significant effect of condition on the likelihood with which participants used the MDP $(Z=-4.33, p<.001)$; this effect was also found when the analysis was repeated focusing only on well-specified descriptions, that is, those containing two of the three properties $(Z=4.38, p<.001)$. The results show quite unambiguously that whether or not the MDP was used turned out to depend on whether it was colour, size or pattern. This is a clear indication that preference trumps discriminatory power, not the other way round.

## Discussion

Our results suggest that speakers are insensitive to subtle differences in the discriminatory power of properties, relying on preference-based heuristics. Previous work has gleaned evidence for such heuristics from overspecification data, which is further used to argue against the notion that speakers observe a strict interpretation of the Gricean Maxim of Quantity. The present experiment manipulated both property preference (by contrasting colour, size, pattern) and discriminatory power (by orthogonally manipulating whether each of these properties is most discriminatory).

The evidence shows that preference has an effect on
how frequently a property is chosen, but speakers are relatively insensitive to subtle differences in discriminatory power. We draw this conclusion from the clear tendency to make selections on the basis of which property is involved, rather than its contrastive value. Thus, colour, for example, is highly preferred and tends to be chosen irrespective of its discriminatory power. It is possible that the marked preference for colour is due to the fact that in our domains (e.g. 1), it becomes more salient since it characterises the entire object (e.g. a bottle is green in its entirety), whereas pattern, for example, does not. However, the consistency of our results in this regard with previous work (e.g. Pechmann, 1989; Belke \& Meyer, 2002) suggests that the colour preference reflects a more general tendency.

The findings directly contradict computational models such as the Greedy heuristic (Dale, 1989), as well as proposals in the psycholinguistic literature based on theoretical work such as that of Olson (1970). In contrast, it suggests that models such as the Incremental Algorithm (Dale \& Reiter, 1995) are on the right track, insofar as they make choices based on preference. On the other hand, recent work suggests that this algorithm does not give a complete picture of human reference production either. One of its limitations is that it only selects a property if it excludes some of the (remaining) distractors at a given point in the procedure, something that has been shown not to hold of human speakers (Viethen, Dale, \& Guhe, 2011). Another is that the procedure is entirely deterministic and always produces the same output for a given input and a given preference ordering among available properties. In contrast, human speakers appear to treat the notion of preference stochastically, so that a model that interprets preferences in terms of a probability distribution fits human data better (Gatt et al., 2011).

This brings us to our earlier discussion of probabilistic models. One interesting question is raised by the PRO model of van Gompel et al. (2012). This model first tries to find a property which fully distinguishes the target referent. Additional content selection decisions are carried out probabilistically based on preference. As we have discussed, this model has been shown to have a remarkably good fit to data elicited from human speakers, albeit in much simpler domains than the ones used here. Now, a possible generalisation of this model would be one that first looks for the most discriminatory property available, rather than a fully distinguishing one. The results of the present experiment, which explicitly excluded the possibility of there being a single distinguishing property for the target, suggest that this would not improve its goodness of fit. However, it should be noted that our results are based on domains in which the difference in discriminatory power between the most distinguishing property and the others is exactly 1 . Would a greater
difference motivate speakers to select the MDP, even if it was highly dispreferred? A positive answer to this question would imply that the PRO model can indeed be generalised to look for highly discriminatory properties, but only if their discriminatory value was relatively high, making them very visually salient. Thus, sensitivity to discriminatory power might fall on a continuum.

A similar point can be made about Frank and Goodman (2012)'s Bayesian model, which estimates the likelihood of a property being used for a referent as a function of the number of potential referents of that property, and the number of properties that the referent may be distinguished by. Modulo the simplification inherent in this work, namely that referents are to be distinguished using a single property, it would be interesting to investigate to what extent this notion of utility is also gradable and impacts visual salience.

## Conclusions and future work

This paper investigated content selection in reference production. It addressed the possible trade-off between (i) the discriminatory power of a property, that is, the extent to which it is likely to help in the task of distinguishing a referent from its distractors and (ii) the extent to which a property is preferred. Our results suggest that subtle differences in discriminatory power do not influence content selection choices. One question that is left open by the present work is whether larger discriminatory power differences would alter these findings, something that we plan to investigate in future work.

# Bayesian Vector Analysis and the Perception of Hierarchical Motion 

Samuel J. Gershman ${ }^{1}$ (sjgershm@mit.edu), Frank Jäkel ${ }^{2}$ (fjaekel@uos.de), Joshua B. Tenenbaum ${ }^{1}$ (jbt@mit.edu)<br>${ }^{1}$ Department of Brain and Cognitive Sciences, MIT<br>${ }^{2}$ Institute of Cognitive Science, University of Osnabrück

#### Abstract

Scenes filled with moving objects are often hierarchically organized: the motion of a migrating goose is nested within the flight pattern of its flock, the motion of a car is nested within the traffic pattern of other cars on the road, the motion of body parts are nested in the motion of the body. Humans perceive hierarchical structure even in stimuli with two or three moving dots. An influential theory of hierarchical motion perception holds that the visual system performs a "vector analysis" of moving objects, decomposing them into common and relative motions. However, this theory does not specify how to resolve ambiguity when a scene admits more than one vector analysis. We describe a Bayesian theory of vector analysis and show that it can account for classic results from dot motion experiments. Our theory takes a step towards understanding how moving scenes are parsed into objects.

Keywords: motion perception; Bayesian inference; structure learning

## Introduction

Motion is a powerful cue for understanding the organization of a visual scene. Infants use motion to individuate objects, even when it contradicts property/kind information (Kellman \& Spelke, 1983; Xu et al., 1999). The primacy of motion information is also evident in adult object perception (Mitroff \& Alvarez, 2007). In addition to individuating and tracking objects, motion is used by the visual system to decompose objects into parts. In biological motion, for example, the motion of body parts are nested in the motion of the body. Object motion may be hierarchically organized into multiple layers: an arm's motion may be further decomposed into jointed segments, including the hand, which can itself be decomposed into fingers, and so on.

The hierarchical organization of motion presents a formidable challenge to current models of motion processing. It is widely accepted that the visual system balances motion integration over space and time (necessary for solving the aperture problem) and motion segmentation in order to perceive multiple objects simultaneously (Braddick, 1993). However, it is unclear how simple segmentation mechanisms can be used to build a hierarchically structured representation of a moving scene. Segmentation lacks a notion of nesting: when an object moves, its parts should move with it. To understand nesting, it is crucial to represent the underlying dependencies between objects and their parts.

The experimental and theoretical foundations of hierarchical motion perception were laid by the pioneering work of Johansson (1950), who demonstrated that surprisingly complex percepts could arise from simple dot motions. Johansson proposed that the visual system performs a "vector analysis" of moving scenes into common and relative motions between
objects. In the example of biological motion (see Johansson, 1973), the global motion of the body is subtracted from the image, revealing the relative motions of body parts; these parts are further decomposed by the same subtraction operation.

While the vector analysis theory provides a compelling explanation of numerous motion phenomena (we describe several below), it is incomplete from a computational point of view, since it relies on the theorist to provide the underlying motion components and their organization; it lacks a mechanism for discovering a hierarchical decomposition from sensory data. This is especially important in complex scenes where many different vector analyses are consistent with the scene. Various principles have been proposed for how the visual system resolves this ambiguity. For example, Restle (1979) proposed a "minimum principle," according to which simpler motion interpretations (i.e., those with a shorter description length) are preferred over more complex ones. Gogel (1974) argued for an "adjacency principle," according to which the motion interpretation is determined by relative motion cues between nearby points. However, there is still no unified computational theory that can encompass all these ideas.

In this paper, we recast Johansson's vector analysis theory in terms of a Bayesian model of motion perception. The model discovers the hierarchical structure of a moving scene, resolving the ambiguity of multiple vector analyses using a set of probabilistic constraints. We show that this model can account for several classic phenomena in the motion perception literature that are challenging for existing models.

## Bayesian vector analysis

In this section, we describe our computational model formally. We start by describing a probabilistic generative model of motion-a set of assumptions about the environment that we impute to the observer. The generative model can be thought of as stochastic "recipe" for generating moving images. We then describe how Bayesian inference can be used to invert this generative model and recover the underlying hierarchical structure from observations of moving images.

## Generative model

Our model describes the process by which a sequence of twodimensional visual element positions $\left\{\mathbf{s}_{n}(t)\right\}_{n=1}^{N}$ is generated, where $\mathbf{s}_{n}(t)=\left[s_{n}^{x}(t), s_{n}^{y}(t)\right]$ is the $x$ and $y$ position of element $n$ at time step $t .{ }^{1}$ Elements can refer to objects, parts or features;

[^68]

Figure 1: Illustration of how a moving scene is decomposed into a motion tree. Each node in the tree corresponds to a motion component. Each object in the scene traces a path through the tree, and the observed motion of the object is modeled as the superposition of motion components along its path.
in this paper we will simply refer to them as objects. The object positions are modeled as arising from a tree-structured configuration of motion components; we refer to this representation as the motion tree. Each motion component is a transformation that maps the current object position to a new position.

An illustration of a motion tree is shown in Figure 1. Each node in the tree corresponds to a motion component. The motion of the train relative to the background is represented by the top-level node. The motions of Spiderman and Dr. Octopus relative to the train are represented at the second-level nodes. Finally, the motions of each body part relative to the body are represented at the third-level nodes. The observed motion of Spiderman's hand can then be modeled as the superposition of the motions along the path that runs from the top node to the hand-specific node. The aim for our model is to get as inputs the retinal motion of pre-segmented objectsin this example, the motion of hands, feet, torsos, windows, etc.-and output a hierarchical grouping that reflects the composition of the moving scene.

The motion tree can capture the underlying motion structure of many real-world scenes, but inferring which motion tree generated a particular scene is challenging because different trees may be consistent with the same scene. To address this problem, we need to introduce a prior distribution over motion trees that expresses our inductive biases about what kinds of trees are likely to occur in the world. This prior should be flexible enough to accommodate many different structures while also preferring simpler structures (i.e., parsimonious explanations of the sensory data). These desiderata are satisfied by a nonparametric distribution over trees known as the nested Chinese restaurant process (nCRP; Blei et al., 2010). The nCRP generates a motion tree by drawing, for each object $n$, a sequence of motion components, denoted by $\mathbf{c}_{n}=\left[c_{n 1}, \ldots, c_{n D}\right]$, where $D$ is the maximal tree depth. ${ }^{2}$ The component assignments are drawn according to:

$$
P\left(c_{n d}=j \mid \mathbf{c}_{1: n-1}\right)= \begin{cases}\frac{M_{j}}{n-1+\gamma} & \text { if } j \leq J  \tag{1}\\ \frac{{ }_{\gamma}}{n-1+\gamma} & \text { if } j=J+1\end{cases}
$$

[^69]where $j$ indexes motion components, $M_{j}$ is the number of previous objects assigned to component $j$, and $J$ is the number of components currently in use (i.e., those for which $M_{j}>0$ ). The assignment at depth $d$ is restricted to a unique set of components specific to the component assigned at depth $d-1$. In this way, the components form a tree structure, and $\mathbf{c}_{n}$ is a path through the tree. The parameter $\gamma \geq 0$ controls the branching factor of the motion tree. As $\gamma$ decreases, different objects will tend to share the same motion components. Thus, the nCRP exhibits a preference for trees that use a small number of motion components.

Note that so far we have generated a path through a potentially very deep tree for each object. Each path has the same length $D$. Remember that each node in the tree will represent a motion component. We want each object $n$ to be associated with a node in the tree and its overall motion to be the sum of all the motion components above it (including itself). Hence, for each object we need to sample an additional parameter $d_{n} \in\{1, \ldots, D\}$ that determines to which level on the tree the object will be assigned. This depth specifies a truncation of $\mathbf{c}_{n}$, thereby determining which components along the path contribute to the observations. The depth assignments $\mathbf{d}=\left[d_{1}, \ldots, d_{N}\right]$ are drawn from a Markov random field:

$$
\begin{equation*}
P(\mathbf{d}) \propto \exp \left\{\alpha \sum_{m=1}^{N} \sum_{n>m}^{N} \mathbb{I}\left[d_{m}=d_{n}\right]-\rho \sum_{n=1}^{N} d_{n}\right\} \tag{2}
\end{equation*}
$$

where the indicator function $\mathbb{I}[\cdot]=1$ if its argument is true and 0 otherwise. The parameter $\alpha$ controls the penalty for assigning objects to different depths, and the parameter $\rho$ controls a penalty for deeper level assignments.

Each motion component, i.e. each node in the motion tree, is associated with a time-varying flow field, $\mathbf{f}_{j}(\mathbf{s}, t)=$ $\left[f_{j}^{x}(\mathbf{s}, t), f_{j}^{y}(\mathbf{s}, t)\right]$. We place a prior on flow fields that enforces spatial smoothness but otherwise makes no assumptions about functional form. In particular we assume that $f_{j}^{x}$ and $f_{j}^{y}$ are spatial functions drawn independently at each time discrete time step $t$ from a zero-mean Gaussian process with covariance function

$$
\begin{equation*}
k\left(\mathbf{s}, \mathbf{s}^{\prime}\right)=\tau \exp \left\{-\frac{\left\|\mathbf{s}-\mathbf{s}^{\prime}\right\|^{2}}{2 \lambda}\right\} \tag{3}
\end{equation*}
$$

where $\tau$ is a global scaling parameter and $\lambda>0$ is a lengthscale parameter controlling the smoothness of the flow field. When $\lambda$ is large, the flow field becomes rigid. Smoothness is only enforced between objects covered by the same node in the motion tree.

To complete the generative model, we need to specify how the motion tree gives rise to observations, which in our case are the positions of the $N$ objects over time. For each object, the dot position at the next time step is set by sampling a displacement from a Gaussian whose mean is the sum of the flow fields along path $\mathbf{c}_{n}$ truncated at $d_{n}$ :

$$
\begin{equation*}
\mathbf{s}_{n}(t+1)=\mathbf{s}_{n}(t)+\sum_{d=1}^{d_{n}} \mathbf{f}_{c_{n d}}\left(\mathbf{s}_{n}(t), t\right)+\varepsilon_{n}(t) \tag{4}
\end{equation*}
$$

where $\varepsilon_{n}(t) \sim \mathcal{N}\left(\mathbf{0}, \sigma^{2} \mathbf{I}\right)$.
This generative model contains a number of important special cases under particular parameter settings. When $\gamma=0$, only one motion component will be generated; in this case, the prior on flow-fields-favoring local velocities close to 0 that vary smoothly over the image-resembles the "slow and smooth" model proposed by Weiss \& Adelson (1998). When $\gamma=0$ and $\lambda \rightarrow \infty$, we obtain the "slow and rigid" model of Weiss et al. (2002). When $D=1$, the model will generate multiple motion components, but these will all exist at the same level of the hierarchy (i.e., the motion tree is flat, with no nesting), resulting in a form of transparent layered motion (Wang \& Adelson, 1993; Weiss, 1997).

## Inference

The goal of inference is to compute the posterior over the motion tree given a set of observations. ${ }^{3}$ Because we are mainly interested in the highest probability tree, we use annealed Gibbs sampling to search for the posterior mode. The algorithm alternates between holding the depth assignments fixed while sampling the node assignments, and holding the node assignments fixed while sampling the depth assignments. By raising the conditional probabilities to a power $\beta>1$, the posterior becomes peaked around the mode. We gradually increase $\beta$, so that the algorithm eventually settles on a high probability tree. We repeat this procedure 10 times (with 500 sampling iterations on each run) and pick the tree with the highest posterior probability. Below, we derive the conditional distributions used by the sampler.

The conditional distribution over $\mathbf{c}_{n}$ is given by:

$$
\begin{equation*}
P\left(\mathbf{c}_{n} \mid \mathbf{c}_{-n}, \mathbf{s}, \mathbf{d}\right) \propto P\left(\mathbf{c}_{n} \mid \mathbf{c}_{-n}\right) P(\mathbf{s} \mid \mathbf{c}, \mathbf{d}) \tag{5}
\end{equation*}
$$

where $\mathbf{c}_{-n}$ denotes the set of all paths excluding $\mathbf{c}_{n}$. The first factor in Eq. 5 is the nCRP prior (Eq. 1). The second factor in Eq. 5 is the likelihood of the data, given by:

$$
\begin{equation*}
P(\mathbf{s} \mid \mathbf{c}, \mathbf{d})=\prod_{t} \prod_{z \in\{x, y\}} \mathcal{N}\left(\mathbf{s}^{z}(t+1) ; \mathbf{s}^{z}(t), \mathbf{K}(t)+\sigma^{2} \mathbf{I}\right) \tag{6}
\end{equation*}
$$

[^70]

Figure 2: Johansson (1950) two dot experiment. (A) Veridical motion vectors. (B) Perceived motion. (C) Inferred motion vectors. Each color corresponds to a different component in the motion tree $(D)$, but note that a component will predict different vectors depending on spatial location.
where

$$
\begin{equation*}
K_{m n}(t)=k\left(\mathbf{s}_{m}(t), \mathbf{s}_{n}(t)\right) \sum_{j} \mathbb{I}\left[j \in \mathbf{c}_{m} \wedge j \in \mathbf{c}_{n}\right] . \tag{7}
\end{equation*}
$$

Intuitively, the covariance between two points counts the number of nodes shared between their paths, weighted by their proximity in space.

The conditional distribution over $d_{n}$ is given by:

$$
\begin{equation*}
P\left(d_{n} \mid \mathbf{c}, \mathbf{s}, \mathbf{d}_{-n}\right) \propto P\left(d_{n} \mid \mathbf{d}_{-n}\right) P\left(\mathbf{s} \mid \mathbf{c}, \mathbf{d}_{-n}, d_{n}\right) \tag{8}
\end{equation*}
$$

where $\mathbf{d}_{-n}$ denotes the level assignments excluding $d_{n}$ and

$$
\begin{equation*}
P\left(d_{n} \mid \mathbf{d}_{-n}\right) \propto \exp \left\{\alpha \sum_{m \neq n} \mathbb{I}\left[d_{m}=d_{n}\right]-\rho d_{n}\right\} \tag{9}
\end{equation*}
$$

To visualize the motion components that are given by a grouping through $\mathbf{d}_{n}$ and $\mathbf{c}_{n}$, we can calculate the posterior predictive mean for object $n$ at each component $j$ (shown here for the $x$ dimension):

$$
\begin{equation*}
\mathbb{E}\left[f_{j}^{x}\left(\mathbf{s}_{n}(t), t\right)\right]=\mathbf{k}_{n j}^{\top}\left(\mathbf{K}(t)+\sigma^{2} \mathbf{I}\right)^{-1}\left(\mathbf{s}^{x}(t+1)-\mathbf{s}^{x}(t)\right), \tag{10}
\end{equation*}
$$

where $\mathbf{k}_{n j}$ is the $N$-dimensional vector of covariances between $\mathbf{s}_{n}(t)$ and the locations of all the objects whose paths pass through node $j$ (if an object does not pass through node $j$ then its corresponding entry in $\mathbf{k}_{n j}$ is 0 ).

## Simulations

In this section, we show how the Bayesian vector analysis model can account for several classic experimental phenomena. These experiments all involve stimuli consisting of moving dots, so for present purposes $\mathbf{s}_{n}(t)$ corresponds to the position of dot $n$ at time $t$. In these simulations we use the following parameters: $D=3, \sigma^{2}=0.01, \tau=1, \lambda=100, \alpha=1, \rho=$ 0.1 . The interpretation of $\sigma^{2}$ and $\lambda$ depend on the spatial scale

Figure 3: Johansson (1973) three dot experiment. (A) Veridical motion vectors. (B) Perceived motion. (C) Inferred motion vectors. ( $D$ ) Inferred motion tree.
of the data; in general, we found that changing these parameters (within the appropriate order of magnitude) had little influence on the posterior. We set $\lambda$ to be large enough so that objects assigned to the same layer moved near-rigidly.

Johansson (1950) demonstrated that a hierarchical motion percept can be achieved with as few as two dots. Figure 2A shows the stimulus used by Johansson, consisting of two dots translating orthogonally to meet at a single point. Observers, however, do not perceive the orthogonal translation. Instead, they perceive the two dots translating along a diagonal axis towards each other, which itself translates towards the meeting point (Figure 2B). Thus, observers perceive the stimulus as organized into common and relative motions. This percept is reproduced by the Bayesian vector analysis model (Figure 2C); the inferred motion tree (shown in Figure 2D) represents the common motion as the top level component and the relative motions as subordinate components. The subordinate components are not perfectly orthogonal to the diagonal motion, consistent with the findings of Wallach et al. (1985); this arises in our model through a form of "explaining away"i.e., posterior coupling between the motion layers implied by Eq. 10.

Another example studied by Johansson (1973) is shown in Figure 3A. Here the bottom and top dot translate horizontally while the middle dot translates diagonally such that all three dots are always collinear. The middle dot is perceived as translating vertically as all three dots translate horizontally (Figure 3B). Consistent with this percept, the Bayesian vector analysis assigns all three dots to a common horizontal motion component, and additionally assigns the middle dot to a vertical motion component (Figure 3C-D).

Duncker (1929) showed that if a light is placed on the rim of a rolling wheel in a dark room, cycloidal motion is perceived (Figure 4A), but if another light is placed on the hub then rolling motion is perceived (Figure 4B). Simulations of these experiments are shown in Figure 5. When a light is placed only on the rim, there is strong evidence for a single cycloidal motion component, whereas stronger evidence for a

Figure 4: Duncker wheel. (A) A light on the rim of a rolling wheel produces cycloidal motion. ( $B$ ) Adding a light on the hub produces rolling motion (translation + rotation).

Figure 5: Simulations of the Duncker wheel. (Top) A single light on the rim produces one vector following a cycloidal path. (Middle) Adding a light on the hub produces two vectors: translation + rotation, giving rise to the percept of rolling motion. (Bottom) Placing the light on the interior of the wheel produces weaker rolling motion: the translational component is no longer perfectly horizontal.
two-level hierarchy (translation + rotation) is provided by the hub light. ${ }^{4}$ It has also been observed that placing a light in between the rim and the hub produces weaker rolling motion (i.e., the translational component is no longer perfectly horizontal; Proffitt et al., 1979), a phenomenon that is reproduced by Bayesian vector analysis (Figure 5, bottom).

So far, we have been considering qualitative characterizations of various motion phenomena, but one advantage of a computational model is its ability to make quantitative predictions. We illustrate the quantitative power of Bayesian vector analysis for the case of motion transparency. When two groups of randomly moving dots are superimposed, observers may see either transparent motion (two planes of motion sliding past each other) or non-transparent motion (all dots moving in the direction of the average motion of the two groups). Which percept prevails depends on the relative direction of the two groups (Braddick et al., 2002): as the direction difference increases, transparent motion becomes more perceptible. We computed the probability of transparent motion (i.e.,

[^71]

Figure 6: Simulations of transparent motion. Transparency increases as a function of direction difference between two superimposed groups of dots.

Figure 7: Motion contrast. (A) The velocity of the background (black) dots increases along the horizontal axis. Although A and B have the same velocity, A is perceived as moving faster than B . (B) Model simulation.
two layers in our model) for a range of relative directions using 20 dots. As the relative direction increases, the statistical evidence in favor of two separate layers increases, resulting in a smoothly changing probability (Figure 6).

Inferences about the motion hierarchy may interact with the spatial structure of the scene. The phenomenon of motion contrast, originally described by Loomis \& Nakayama (1973), provides an illustration: The perceived motion of a dot depends on the motion of surrounding "background dots" (the black dots in Figure 7A). If a set of dots moves on a screen such that the dots on the left move more slowly than dots on the right, they form a velocity gradient. Two "target" dots that move with the same velocity and keep a constant distance (the red dots in Figure 7A) can still be perceived as moving with radically different speeds, depending on the speed of the dots close by. In our model, most of the motion of the velocity gradient is captured by the Gaussian process on the top-level motion component. However, this top-level component does not capture all of the motion of each dot. The target dots (in red), in particular, are each endowed with their own motion component and move relative to the toplevel node. This relative motion differs depending on where along the gradient the target dot is located, resulting in motion contrast (Figure 7B).

How does our model scale up to more complex displays?

An interesting test case is biological motion perception: Johansson (1973) showed that observers can recognize human motions like walking and running from lights attached to the joints. Later work has revealed that a rich variety of information can be discriminated by observers from point light displays, including gender, weight and even individual identity (Blake \& Shiffrar, 2007). We trained our model (with the same parameters) on point light displays derived from the CMU human motion capture database. ${ }^{5}$ These displays consisted of the 3 -dimensional positions of 31 dots, including walking, jogging and sitting motions. The resulting motion parse is illustrated in Figure 8: the first layer of motion (not shown) captures the overall trajectory of the body, while the second and third layers capture more fine-grained structure, such as the division into limbs and smaller jointed body parts. Note that the model knows nothing about the underlying skeletal structure; it infers body parts directly from the dot positions. This demonstrates that Bayesian vector analysis can scale up to more complex and realistic motion patterns.

## Conclusion

How does the visual system parse the hierarchical structure of moving scenes? In this paper, we have developed a Bayesian framework for modeling hierarchical motion perception, building upon the seminal work of Johansson (1950). The key idea of our theory is that a moving scene can be interpreted in terms of an abstract graph-the motion tree-encoding the dependencies between moving objects. Bayesian vector analysis is the process of inferring the motion tree from a sequence of images. Our simulations demonstrated that this formalism is capable of capturing a number of classic phenomena in the literature on hierarchical motion perception.

Two limitations of our theory need to be addressed. First, the generative model assumes that motion components combine through summation, but this is not adequate in general. For example, a better treatment of the Duncker wheel would entail modeling the composition of rotation and translation. In its current form, the model approximates rotation by inferring motion components that are tangent to the curve traced by the rotation. We are currently investigating a version of the generative model in which motion transformation compose with one another, which would allow for nonlinear interactions. Second, although we described an algorithm for finding the optimal motion tree, Bayesian vector analysis is really specified at the computational level; our simulations are not illuminating about the mechanisms by which the vector analysis is carried out. Nor does it commit to any particular neural implementation. More work is needed to connect all these levels of analysis. Grossberg et al. (2011) have described a detailed theory of how vector analysis could be performed by the visual cortex, and their efforts offer a possible starting point.

We view hierarchical motion as a model system for study-

[^72]

Figure 8: Analysis of human motion capture data. Each color represents the assignment of a node to a motion component. All nodes are trivially assigned to the first layer (not shown). In addition, all nodes were assigned to the second layer ( $A$ ). A subset of the nodes were also assigned components in the third layer $(B)$. Unfilled nodes indicate that no motion component was assigned at that layer. The skeleton is shown here for display purposes; the model was trained only on the dot positions.
ing more general questions about structured representations in mind and brain. The simplicity of the stimuli makes them amenable to rigorous psychophysical and neurophysiological experimentation, offering hope that future work can isolate the neural computations underlying structured representations like motion trees.

#### Abstract

How are space and time related in the brain? This study contrasts two proposals that make different predictions about the interaction between spatial and temporal magnitudes. Whereas ATOM implies that space and time are symmetrically related, Metaphor Theory claims they are asymmetrically related. Here we investigated whether space and time activate the same neural structures in the inferior parietal cortex (IPC) and whether the activation is symmetric or asymmetric across domains. We measured participants' neural activity while they made temporal and spatial judgments on the same visual stimuli. The behavioral results replicated earlier observations of a space-time asymmetry: Temporal judgments were more strongly influenced by irrelevant spatial information than vice versa. The BOLD fMRI data indicated that space and time activated overlapping clusters in the IPC and that, consistent with Metaphor Theory, this activation was asymmetric: The shared region of IPC was activated more strongly during temporal judgments than during spatial judgments. We consider three possible interpretations of this neural asymmetry, based on 3 possible functions of IPC.

Keywords: ATOM, Metaphor, Space, Time, fMRI, Parietal lobe

## Introduction

It is clear that spatial and temporal magnitudes interact in the brain and mind, but the exact nature of this interaction is a matter of debate. According to one account, A Theory Of Magnitude (ATOM; Walsh, 2003), space, time and other prothetic domains (i.e. that can be experienced as more or less in magnitude) interact because they are represented by a common metric, located in the inferior parietal cortex (IPC; Walsh 2003; Bueti \& Walsh 2009). Support for this model comes from behavioral experiments showing cross-dimensional interference between different prothetic dimensions, as well as from neuroimaging studies showing that magnitude processing in various dimensions activates overlapping areas of IPC, mainly in the right hemisphere (see Bueti \& Walsh 2009 for review). According to ATOM, these different magnitudes share a representational substrate because they need to be integrated for successful execution of actions: Bueti and Walsh (2009) note that, "There is no such thing as getting to the right place at the wrong time" (pg. 1832). Like Locke (1689/1995) before them, ATOM theorists imply that space and time are symmetrically related. Indeed, if different prothetic domains are represented by the same metric, there is no a priori reason to assume that one domain should depend asymmetrically on another.

According to a second theoretical proposal, Metaphor Theory (MT), space and time are asymmetrically related: Temporal representations depend on spatial representations, more than vice versa. This asymmetry is fundamental to MT, which posits that representations of abstract concepts depend, in part, on representations of more concrete, perceptible domains (Lakoff \& Johnson, 1980; 1999). Since time is an abstract entity that we can never see or touch, it is argued to rely on spatial representations for conceptual scaffolding. Evidence for this asymmetric relationship comes from psychophysical studies showing asymmetric cross-dimensional interference between distance and duration: Task-irrelevant spatial magnitude influences temporal judgments more than task-irrelevant temporal magnitude influences spatial judgments (Bottini \& Casasanto, 2010; Casasanto \& Boroditsky, 2008; Casasanto, Fotakopoulou, \& Boroditsky, 2010; Merritt, Casasanto, \& Brannon, 2010; see also Boroditsky, 2000).

These cross-domain asymmetries were predicted by MT but not by ATOM. Yet, the available data leave open a possibility: Perhaps spatial and temporal magnitudes are encoded symmetrically. The observed asymmetry could arise subsequently, as magnitudes are re-represented during retrieval or response planning. If so, this finding would help to reconcile ATOM and MT, suggesting that initial stages of magnitude processing may be ATOMic even if later stages are metaphoric.

To test this proposal, we used fMRI to measure neural activity during spatial and temporal magnitude reproduction tasks. First, we compared activity during the encoding of spatial and temporal magnitudes to establish whether space and time interact at this stage, and whether they do so in the IPC. Second, by defining this area of overlap as a Region of Interest (ROI) and by comparing neural activity during the encoding of space and of time, we contrasted predictions of MT and ATOM. Both theories predict that encoding space and time should activate overlapping areas: On the basis of previous findings, we assume areas within IPC. MT predicts that this common area will be activated more by time than by space, because people involuntarily encode more irrelevant spatial information during temporal encoding than vice versa. ATOM does not predict any cross-domain asymmetry in the region of overlap.

## Methods

## Participants

18 healthy native English speakers (16 right-, 1 lefthanded, 1 ambidextrous, 9 male, mean age $=23.7$, range: 20-31) took part in the current experiment. All participants provided informed consent and were compensated for their participation.

## Materials

Lines of varying lengths were presented for varying durations. Durations ranged from 1000 ms to 4000 ms in 600 ms increments. Displacements ranged from 100 to 400 pixels in 60 pixel increments. The six durations were fully crossed with the six spatial displacements, producing 36 unique lines. Half of the lines were red and half were blue. Color was randomly assigned and counter-balanced across conditions and participants. Lines grew horizontally across the screen from left to right, along the vertical midline. The starting position of the lines was, on average, at 337 pixels from the left border of the screen, with the starting point randomly jittered ( $\pm 25$ pixels) so the monitor could not be used as a reliable reference frame for spatial estimations. Participants responded with a joystick (Current Designs, Philadelphia, USA; model: HHSC-JOY-1). Participants used their right hand to control the joystick for cursor movement and their left index finger for button responses.

## Procedure

Participants engaged in four different tasks: spatial reproduction, temporal reproduction and two color identification control tasks. Each trial started with a white cue that was presented for 1 second and indicated which dimension participants would need to reproduce for this trial (an " X " for space, an hourglass for time, and different colored squares for the two control conditions). This cue was followed by a single growing line that stayed on the screen until it reached its maximum spatial and temporal extent and then disappeared. After a period of 5 sec . ( $+/$ random jitter; range $=0-1$ sec.), a response cue and a cursor appeared until participants performed the required task or until a time-out period of 12 seconds had elapsed.

In the space condition (S), the X-icon appeared in either the upper- or lower-left corner of the screen (location counterbalanced across participants). To reproduce the distance that the line had traveled, participants moved the cursor from the center of the screen to the center of the icon, clicked once, moved the cursor rightwards in a straight line and then clicked a second time. The distance between the clicks represented the estimated displacement of the line. In the time condition (T), the hourglass-icon appeared in the lower- or upper-left corner of the screen (i.e. in the corner opposite the space cue). To reproduce duration, participants moved the cursor to the center of
the icon, clicked once, waited for the amount of time the line had been on the screen, and clicked a second time in the same spot. The time between the two clicks represented the duration of the line (procedure adapted from Casasanto \& Boroditsky, 2008).

Finally, two color identification conditions were included as controls: the "color half" (CH) and "color-full" (CF) conditions provided a low level visual control for the target lines, and also allowed us to subtract out activity due to motor preparation prior to responses. Each color condition required the same motor response as one of the target conditions. In the "color-half" condition (CH), participants saw two squares appear, each consisting of a red and a blue half. The left square was presented in the same corner in which the spatial response cue was presented for that participant and the second square was presented 250 pixels to the right of the left one. Participants first moved the cursor to the half of the left square that matched the color of the line, clicked once, moved the cursor rightwards in a straight line to the half of the right square that matched the color of the line and clicked again. Both squares were identical within a given trial (e.g. 2 red-blue squares), but the order of the colored halves was counterbalanced across trials ( $50 \%$ red-blue; $50 \%$ blue-red). In the "color-full" condition (CF), participants saw a blue and a red square appear in the upper- and lower-left corners of the screen (square position was counterbalanced across trials) and clicked twice on the square that had the color of the presented line.

Before entering the scanner, participants read the instructions and performed 3 practice trials of each condition. While in the scanner, participants performed each of the four tasks for each of the 36 unique lines $(4 \times 36=$ 144 trials in total). Lines were presented randomly within condition, and the order of conditions varied pseudorandomly (maximum of 3 trials of the same condition in a row).

## fMRI Data Acquisition

fMRI data were acquired on a Siemens Avanto 1.5 T MRI system (Siemens, Erlangen, Germany) using a standard birdcage head-coil for RF transmission and signal reception. T2*-weighted BOLD-sensitive images were acquired using a gradient EPI sequence (Echo Time (TE) = 40 ms ; Repetition Time (TR) $=2.28 \mathrm{~s} ; 32$ axial slices in ascending order; voxel size $=3.3 \times 3.3 \times 3.0 \mathrm{~mm}^{3}$ ). For each subject we also acquired a T1-weighted high-resolution anatomical scan ( $\mathrm{TE}=2.95 \mathrm{~s}, \mathrm{TR}=2.25 \mathrm{~s}$, voxel size $=$ $1.0 \times 1.0 \times 1.0 \mathrm{~mm}^{3}, 176$ sagittal slices, field of view $=256$ ).

## fMRI Data Analysis

Functional data were preprocessed and analyzed with SPM8 (http://www.fil.ion.ucl.ac.uk/spm/). Preprocessing involved the removal of the first 5 volumes to allow for T1 equilibration effects. Images were spatially realigned
with rigid body registration, temporally realigned to the middle slice (slice 17), co-registered to each participant's structural scan, normalized to a standard EPI template in MNI space and resampled at an isotropic voxel size of 2 mm . To remove baseline-drifts and low frequency signal changes, a $1 / 128 \mathrm{~Hz}$ temporal high-pass filter was applied. The normalized images were then smoothed with an isotropic 8 mm FWHM Gaussian kernel.

The preprocessed data were analyzed on a subject-wise basis using an event-related approach. The time series were entered into a GLM with separate regressors for the encoding and response phase for each condition (respectively modeled at one second before stimulus offset and response onset for $\mathrm{S}, \mathrm{T}, \mathrm{CH}$ and CF ), which were then convolved with a canonical hemodynamic response function. Although response phase regressors were added to the model for completeness, they were not analyzed further and will not be discussed. Finally, nuisance regressors were added to account for disturbances caused by small head movements.

To examine neural activity specific to spatial and temporal encoding, we computed two contrast images for each participant individually ([S-CH] and [T-CF]). These were then entered into separate second level random effects analyses to compute the space- and time-specific activations on the group level. Each of these two analyses consisted of a one-sample t-test to reveal activations significantly different from zero across the contrast images from all participants. A double threshold was applied to protect against Type I errors: only voxels with a $p<.001$ (uncorrected) and a volume exceeding 41 voxels (328 $\mathrm{mm}^{3}$ ) were considered (volume sizes were defined by Monte Carlo Simulation, $\mathrm{p}<.001$, Slotnick, 2011).

To reveal the neural overlap between spatial and temporal encoding, we performed a conjunction analysis on the 2 second-level contrast images ([S-CH] $\cap$ [T-CF]). Based on our a priori hypothesis, bilateral clusters of IPC activity that emerged from the conjunction were extracted and defined as our ROI's. From these ROI's, we extracted separate contrast values for the [S-CH] and the [T-CF] contrasts for each subject, using the MarsBaR package (Brett, Anton, Valabregue, \& Poline, 2002; http://marsbar.sourceforge.net, v.042).

## Results

## Behavioral Results

First we tested whether spatial and temporal reproduction was affected by variation in the task-irrelevant stimulus dimension. The spatial and temporal extents of the stimuli and responses were normalized, so that slopes could be compared across domains ${ }^{1}$. We calculated the normalized

[^73]slopes of the effect of irrelevant spatial information on duration reproduction (ST) and the effect of irrelevant temporal information on spatial distance reproduction (TS) for each participant separately (Fig. 1). The results showed significant cross-dimensional interference effects: The spatial extent of stimuli predicted the variation in the temporal responses $\left(\right.$ Wald $\left.\mathrm{X}^{2}(1)=23.55, p=.001\right)$ and the duration of stimuli predicted the variation in spatial responses $\left(\right.$ Wald $\left.\mathrm{X}^{2}(1)=12.21, p=.001\right)$. Importantly, these effects were asymmetric: Spatial information affected duration reproduction more than temporal information affected distance reproduction (Wald $\mathrm{X}^{2}(1)=8.00, p=$ .01).

Figure 1: Cross-domain interference effects. TS (Blue): Effect of line duration on spatial distance reproduction. ST (Red): Effect of line displacement on duration reproduction. Error bars indicate SEM.

To investigate within-domain performance, we used the normalized stimulus and response values to calculate the normalized slopes of the effect of spatial variation on spatial reproduction (SS) and temporal variation on temporal reproduction (TT), for each participant separately. Although the results show strong effects both of actual space on estimated space (SS: Normalized slope $=0.98$; Wald $\left.\mathrm{X}^{2}(1)=10139, p=.001\right)$ and of actual time on estimated time (TT: Normalized slope $=0.88$ Wald $\mathrm{X}^{2}(1)=$ $1465, p=.001)$, they also show a significant difference between within-dimension effects: participants were significantly better at spatial than at temporal reproduction (Difference of normalized slopes $=0.10$ Wald $\mathrm{X}^{2}(1)=$ 20.41, $p=.001$ ).

This difference in within-domain performance between space and time is potentially problematic for the interpretation of the between-domain asymmetry. If performance in one domain is nearly perfect, estimates in this domain may be less susceptible to interference than estimates in
the other domain (Bottini \& Casasanto, 2010). To rule out this concern, we re-ran the regression model after equating for within-dimension performance. Following Casasanto, et al. (2010), we excluded the data from participants with low TT-slopes until the within-dimension performance was the same for Space and Time (i.e. until SS $=\mathrm{TT} ; \mathrm{N}=7$ ). Even after equating within-dimension performance, a strong space-time asymmetry persisted: the spatial extent of stimuli predicted the variation in the temporal responses more than vice versa (Wald $X^{2}(1)=$ 12.56, $p=.001$ ), as in previous experiments (e.g., Casasanto \& Boroditsky, 2008; Merritt et al., 2010).

## Imaging Results

Patterns of Activation As the ROI analysis was our main point of focus, we provide only a cursory overview of the whole-brain results. During spatial encoding ([S-CH]), we observed bilateral activations in parietal areas (including the IPC, intraparietal sulcus (IPS) \& superior parietal gyrus), extrastriate visual cortex (extending into the inferior temporal gyrus) and frontal areas (precentral gyri, IFG, anterior insulae (AI), middle frontal gyri, SMA \& medial superior frontal gyri). During temporal encoding ([TCF]), we found activations in the parietal cortex (bilateral IPC, IPS, \& supramarginal gyri; right angular gyrus), left dorsal extrastriate cortex and a range of bilateral frontal activations (precentral gyri, AI, DLPFC, SMA, anterior cingulate and medial superior frontal gyri). Additional activity was observed in bilateral superior temporal gyri, right inferior temporal gyrus and subcortical areas (thalamus and basal ganglia).

To reveal neural activations common to spatial and temporal encoding, we performed a conjunction analysis on both aforementioned contrasts ([S-CH] $\cap$ [T-CF]; Fig. 2, left). Overlapping activations were found in bilateral parietal cortex, ranging from lateral IPC into the IPS and including part of the supramarginal gyrus in the right hemisphere. Additional clusters of activity included the left extrastriate cortex, just anterior to the cuneus, and a posterior part of the right inferior temporal gyrus. Frontal activations included bilateral DLPFC and parts of both precentral gyri (extending ventrally into the IFG and AI). Furthermore, we observed right-lateralized dorsal activation of the posterior middle and superior frontal gyri, extending into the superior frontal sulcus. Finally, the conjunction revealed medial frontal activations comprising the SMA, the medial superior frontal gyri and the middle and anterior cingulate.

ROI Analysis To investigate whether space and time encoding activated the bilateral IPC clusters revealed by the conjunction analysis symmetrically or asymmetrically, we defined the left and right IPC clusters as our two ROI's and extracted the contrast values per subject for each con-
dition of interest. These contrast values were entered into a regression model, with Condition (Space; Time), Hemisphere (Left; Right) and their interaction (Condition*Hemisphere) as within-subject factors and Subject as a repeated random effect. The IPC was activated more strongly by temporal encoding than by spatial encoding (main effect of Condition: Wald $\mathrm{X}^{2}(1)=4.65, \mathrm{p}=.03$ ). Furthermore, both domains activated the right IPC more than the left IPC (main effect of Hemisphere: Wald $\mathrm{X}^{2}(1)$ $=6.79, \mathrm{p}=.01)$, but the relationship between spatial and temporal activation did not differ between hemispheres (Condition*Hemisphere interaction: Wald $\mathrm{X}^{2}(1)=.073$, p $=.79$ ). Since previous studies have tended to implicate the right IPC in magnitude processing, we analyzed the ROI in each hemisphere separately. The main effect of Condition was significant in the right hemisphere ( $\mathrm{T}>\mathrm{S}$, Wald $\mathrm{X}^{2}(1)=5.14, \mathrm{p}=.02$, and marginally significant in the left-hemisphere $\left(\mathrm{T}>\mathrm{S}\right.$, Wald $\left.\mathrm{X}^{2}(1)=3.49, \mathrm{p}=.06\right)$ (Fig. 2, right).

Figure 2: Left: IPC activated by both space and time. Yellow: areas activated by spatial encoding ([S-CH]); Red: areas activated by temporal encoding ([T-CF]); Orange: areas activated by both ([S-CH] $\cap$ [T-CF]).
Right: Contrast values for space and time for the left and right IPC clusters.

Although these findings demonstrate that the IPC was differentially activated by spatial and temporal encoding, we must consider a skeptical account of this neural asymmetry. Our behavioral results indicated that, for some participants, temporal encoding was less accurate than spatial encoding, and may therefore have been more effortful. In principle, a difference in cognitive effort could be responsible for the observed cross-domain asymmetry in the IPC. If the observed asymmetry were due to more effort during temporal vs. spatial encoding, then adding a measure that reflects this difference in effort to the regression model as a covariate should reduce or eliminate the main effect of Condition.

To address this possibility, we calculated the difference between the normalized slopes of within-dimension performance in the space and the time condition (SS-TT) for each participant and included this difference score in the model. Even when cognitive effort was controlled for, we observed the same robust cross-domain asymmetry effects. Both IPC clusters were still activated more by tem-
poral than by spatial encoding (main effect of Condition: Wald $\mathrm{X}^{2}(1)=4.19, p=.04$ ), with stronger overall right hemisphere activation (main effect of Hemisphere: Wald $\mathrm{X}^{2}(1)=4.24, p=.04$ ). The main effect of this behavioral measure of cognitive effort, however, was not significant (Wald $\mathrm{X}^{2}(1)=2.42, p=.12$ ), nor was its three-way interaction with Dimension and Hemisphere (Wald $\mathrm{X}^{2}(1)=$ $1.60, p=.66$ ). These analyses show that the cross-domain asymmetry in BOLD activity in the IPC ROIs cannot be attributed to the observed differences in within-domain performance (i.e., to the finding that temporal estimates were less accurate, and potentially more effortful, than spatial estimates).

## Discussion

This study investigated whether representations of space and time interact at encoding and, if so, whether their relationship is symmetric or asymmetric. Consistent with both ATOM and MT, we observed that encoding spatial and temporal magnitudes activated overlapping clusters of a widespread neural network, most notably in the bilateral IPC. Of primary interest, our behavioral and ROI data provide converging support for an asymmetric relationship between these two domains, as predicted by MT. The behavioral findings indicated that when people reproduced duration they incorporated task-irrelevant spatial information, more so than they incorporated taskirrelevant temporal information when reproducing spatial extent. Our fMRI results showed that this behavioral asymmetry corresponded to a neural asymmetry: the IPC was more active during temporal encoding than during spatial encoding. The asymmetry between space and time is already present during encoding of spatial and temporal stimuli.

Further interpretation of the asymmetric IPC activation requires addressing the question of what exactly is being represented in the IPC. On one possibility, the IPC is the locus of a domain-general magnitude metric that accumulates undifferentiated bits of information (Bueti \& Walsh, 2009, Walsh, 2003), in any prothetic domain. In our task, the activation of the IPC might reflect the degree to which this metric accumulates bits from both domains simultaneously. Our behavioral results indicated that taskirrelevant spatial information was being encoded during time trials, more than task-irrelevant temporal information was being encoded during space trials. Hence, the IPC metric would have accumulated more task-irrelevant magnitude information (along with the task-relevant magnitude information) during time trials than during space trials, resulting in the increased BOLD signal. This account can potentially reconcile ATOM with MT: It is compatible with ATOM's claim of an IPC-based general magnitude representation, and is also consistent with MT, as the asymmetric IPC activation indicates an asymmetric interaction between space and time.

A second possibility is that magnitudes from different domains are represented independently in different parts of the brain (Cohen Kadosh et al. 2008), and that the IPC hosts a mechanism by which cross-domain magnitude representations are selected and integrated according to contextual demands.

A range of empirical data supports this interpretation. Several studies have shown that, during magnitude judgments, the activation of parietal areas around the IPS is modulated by the degree of interference from irrelevant dimensions (Ansari, Fugelsang, Dhital, \& Venkatraman, 2006; Cohen Kadosh, Cohen Kadosh \& Henik, 2008; Pinel, Piazza, Le Bihan, \& Dehaene, 2004; Cohen Kadosh, Cohen Kadosh, Linden, et al., 2007; Kaufmann et al., 2005). Moreover, studies of magnitude-irrelevant visual processing find that the IPC is activated by the need to suppress task-irrelevant distractors (Friedman-Hill, Robertson, Desimone, \& Ungerleider, 2003; Marois, Chun, \& Gore, 2000; Wojciulik \& Kanwisher, 1999). These processes are mostly right-lateralized (Chun \& Marois, 2002; Marois, Chun, \& Gore, 2000; 2004) and they are independent from task difficulty (Marois et al., 2000; Wojciulik \& Kanwisher, 1999).

Our task required participants to selectively attend to the relevant dimension of the stimuli and filter out the irrelevant dimension (i.e., space or time), which varied orthogonally. The greater IPC activation we observed during temporal encoding could reflect the increased demands posed on the 'magnitude selector/integrator' to filter out the task-irrelevant spatial information. Whereas this interpretation is consistent with MT, it contradicts one of the core claims of ATOM by positing that spatial and temporal magnitude representations are distinct: What is in common is the process of selecting and integrating relevant magnitude information.

Finally, on a third possibility, encoding space and time activated nearby but separate neural populations in the IPC, but the low spatial resolution of fMRI does not allow us to separate them (see Shuman \& Kanwisher 2004 for similar arguments). On this view, spatial encoding would have mainly activated the spatial representations, whereas temporal encoding would have activated both temporal and spatial representations. Not only could this account for the BOLD asymmetry (the combined activation of the two separate neural populations in same voxels during time processing leads to a higher BOLD signal), it could also explain the behavioral pattern. If temporal encoding activates neural populations that code for space more than vice versa, due to the "source domain-target domain" link posited by metaphor theorists, there should be more opportunity for crosstalk during time encoding than during space encoding. This notion of separate but closely interacting neural representations of space and time is consistent with MT, but argues against ATOM's claim of a shared representational basis of all prothetic magnitudes.

In summary, here we show a neural asymmetry between space and time that underlies the behavioral asymmetry found here and in multiple previous studies of distance and duration estimation. We consider three possible interpretations of these behavioral and neural asymmetries, all of which are consistent with MT, but only the first of which is compatible with ATOM. If the first account is correct and the IPC is the locus of a domaingeneral magnitude metric, ATOM and MT can be reconciled and the apparent contradiction in behavioral data resolved. The two other proposals are only consistent with MT and argue directly against ATOM's main claim of a shared IPC-based magnitude metric. Rather, they suggest that space and time are represented by distinct but closely interacting neural structures, either in the IPC, or in the form of a broadly distributed network. Further studies are needed to decide among these possibilities and clarify the role of the IPC in representing or integrating magnitudes.

# Modeling Dynamic Control in Normal Aging 

Brian D. Glass (b.glass@qmul.ac.uk)<br>Biological and Experimental Psychology Centre, School of Biological and Chemical Sciences, Queen Mary College, University of London, Mile End, London E1 4NS, UK.<br>Magda Osman (m.osman@qmul.ac.uk)<br>Biological and Experimental Psychology Centre, School of Biological and Chemical Sciences, Queen Mary College, University of London, Mile End, London E1 4NS, UK.

#### Abstract

Complex and dynamic decision making environments are common throughout life, but little is known about how normal aging influences performance on these types of scenarios. To determine performance differences associated with normal aging, we test older and younger adults in a dynamic control task. The task involves the control of a single output variable via multiple and uncertain input controls. A computational model is developed to determine the behavioral characteristics associated with normal aging in a dynamic control task. Older adults exhibit a positivity effect, congruent with previous research. Model based analysis demonstrates a unique performance signature profile associated with normal aging.

Keywords: dynamic decision making; learning; normal aging; computational modeling

## Introduction

Normal human aging is associated with cognitive changes that lead to differences in the way older adults approach and perform in decision making tasks. Specifically, older adults appear to suffer from executive control deficits (Braver, et al., 2001; Kray, Li, \& Lindenberger, 2002; Ortega, et al., 2012). However, emerging evidence suggests that older adults can utilize compensatory strategies to return performance to or beyond baseline levels (Glass, et al., 2012; Huang, et al., 2012; Worthy, et al., 2011).

While previous research has focused on classic paradigms such as category learning, task switching, and singleresponse choice procedures, little is known about normal aging in dynamic control tasks for which the participant controls multiple input variables in an integrative and uncertain task environment. Such complex dynamic environments are analogous to many real-life situations. For example, we make several distinct health choices on a daily basis which influence our overall health and wellbeing in uncertain ways. These types of environments are often noisy and the specific influence of the various choices is often unclear or unspecified.

The present research contrasts older adult and younger adult performance in a dynamic control task designed to simulate such real-life dynamic decision making environments (Osman \& Speekenbrink, 2011). A novel computational modeling technique is developed to assess individual
behavioral characteristics and strategies in the dynamic control task.

## Method

## Procedure

In the present dynamic control task, the participant attempts to control a single outcome value towards a goal. To do so, on each trial the participant chooses values for three separate cues. These cue values are then combined via the dynamic control equation (Equation 1) then summed with the outcome value plus some normally distributed random noise (standard deviation $=8$ ). In this way, the participant's cue selections guide the outcome value. The outcome value is initialized at 178 with a goal value of 62 and a "safe range" ( $\pm 10$ around the goal value)

$$
y(t)=y(t-1)+0.65 x_{1}-0.65 x_{2}+e
$$

Equation 1.
where $y(t)$ is the outcome on trial $t, x_{1}$ is the positive cue, $x_{2}$ is the negative cue, and $e$ is an error term randomly sampled from a normal distribution with a mean of 0 and SD of 8 .

The dynamic control equation was designed such that one cue has a positive impact on the outcome value, one cue has a negative impact, and a third cue has no impact. The impact of the cue is not labeled or available to the participant, thus the participant must learn to control the outcome value based solely on the resulting movement of the outcome value on each trial. After each trial, the cue input values are reset to 0 . The participant can then freely select input values for each of the three cues before confirming the choices.

A critical feature of this control task is that the outcome value can swing below the target, meaning the participant must dynamically adapt in order to maximize performance. After an initial learning phase, the participants completed 2 Test blocks of 20 trials each. The first Test block was a Congruent Test in which the starting value and goal criterion were equivalent to the learning phase. The second Test block was a Transfer Test with a different starting value and goal value than the earlier phases. At the beginning of each block, the control task was reset to the initial state.

## Participants

27 younger participants aged 18 to 25 ( $\mathrm{M}=22.3$, $\mathrm{SD}=5.4$ ) and 15 older participants aged 61 to $75(\mathrm{M}=67.92, \mathrm{SD}=$ 5.03) participated in the dynamic control task. The younger participants were recruited from the Queen Mary, University of London undergraduate community and paid $£ 6$ (\$9.50). The older participants were recruited via the National Hospital for Neurology and Neurosurgery. The older adults were recruited as a healthy control group via the National Hospital for Neurology and Neurosurgery. To qualify for the healthy adult participation pool, the older adults completed the. Beck Depression Inventory-II (BDI-II; Beck, et al., 1996) and Mini-Mental State Examination (MMSE) (Folstein, et al., 1975). All scores fell within the normal cutoff range for both the MMSE (greater than 27) and BDI-II (less than 18). None of the HCs had a history of neurological or physical or psychiatric illness, head injury or drug or alcohol abuse.

## Computational Model

A computational model of behavior in the dynamic control task was constructed to determine behavioral characteristics of individual participants. The model is based on memory trace reinforcement learning. After each trial, a reinforcement history for each of the three cues is updated according to whether the cue choices resulted in the discrepancy between achieved outcome value and goal value increasing or decreasing. On the following trial, the reinforcement history becomes the basis for a probabilistic action selection function using Luce's choice. Previous research has found that participants often vary the value of more than one cue on each trial. Thus, the model includes an inter-cue gating mechanism which allows each cue value selection to take into account the action selection probabilities of the other two cues.

The resulting model features four free parameters: an exploitation parameter governing the action selection function, an inter-cue gating parameter, and two memoryupdating reinforcement strengths (one for successful trials, and one for unsuccessful trials). To evaluate the model, the model's probability of selecting the human participant's cue choice are combined across all trials and all three cues into a single model fit value. The model is fit to an individual participant's responses by an optimization procedure that determines the parameter values which maximize the fit value.

## Memory-Updating Reinforcement Strengths

After each trial, the computational model determines whether the cue values it selected resulted in the outcome value moving towards or away from the goal. For each cue, a Gaussian curve with a mean equal to the chosen cue is constructed (Equation 2).

$$
P_{\text {update }}(v)=\frac{1}{\sigma \sqrt{2 \pi}} e^{-\frac{1}{2}\left(\frac{v-v_{p}}{\sigma}\right)^{2}}
$$

Equation 2.
where $P_{\text {update }}(v)$ is the probability of selecting a value of $v$ when the previous selected value was $v_{p}$.

This curve is then summed (successful trial) or subtracted (unsuccessful trial) to the cue's former reinforcement history. A free parameter (one for successful trials, one for unsuccessful trials) determines the relative weight of the updating summation. For example, if the memory-updating positive reinforcement strength is 0.8 , then the reinforcement history is updated such that $80 \%$ of the new reinforcement history reflects the current cue value choice and $20 \%$ reflects the previous reinforcement history (Equation 3).

$$
\begin{aligned}
& P_{\text {History }}(v)=
\end{aligned} \quad\left[\left(1-\gamma_{s}\right) P(v)\right] \text {. } \quad+\left[\operatorname{sign}(R) \cdot \gamma_{s} \cdot P_{\text {update }}(v)\right] \text {. }
$$

Equation 3.
where $P_{\text {History }}(v)$ is the cue selection probability history for cue value $v, \gamma_{s}$ is the memory-updating reinforcement strength for feedback $s$ (positive or negative), and $R$ is the change in the outcome value's distance to the goal from the previous trial.

In summary, there are two memory-updating reinforcement strengths, one for positive outcomes and one for negative outcomes. Each strength represents the weight with which current choices impact choice history (see Figure 1).

Figure 1: Sample probability density curves of selecting a given value for a given cue. Over the course of a block, the curves will alter in various ways depending on the model parameters, trial success, and uncertainty inherent in the outcome value.

## Inter-cue Parameter

Before the final probabilistic selection of the cue value occurs, for each of the three cues, the reinforcement history of the two other cues are taken into consideration. The level of this consideration is controlled by an inter-cue parameter. This parameter determines the strength at which the reinforcement history of other two cues will influence the action selection of the cue at hand. This is done using a gating equation which weights the alternate cues using the inter-cue parameter (Equation 4).

$$
\begin{aligned}
P_{\text {Intercue }}\left(v_{c_{A}}\right)= & {\left[\left(1-\frac{2 \beta}{3}\right) P_{\text {History }}\left(v_{c_{A}}\right)\right] } \\
& +\left[\frac{\beta}{3} \cdot P_{\text {History }}\left(v_{c_{B}}\right)\right] \\
& +\left[\frac{\beta}{3} \cdot P_{\text {History }}\left(v_{c_{C}}\right)\right]
\end{aligned}
$$

## Equation 4.

where $P_{\text {Intercue }}\left(v_{c A}\right)$ is the probability of selecting value $v$ for cue $c_{A}$ (e.g., cue 1 ), $\beta$ is the inter-cue parameter, and $c_{A}$ and $c_{B}$ are the other two cues (e.g., cue 2 and 3 ). As the inter-cue parameter approaches 1 , the computational model is more likely to pick similar cue values for all three cue inputs. As the inter-cue parameter approaches 0 , the model is less likely to select an action for one cue based on the reinforcement history of the other two. In this way, the computational model can vary the strength in which cue values vary together in the action selection state of the decision process.

## Exploration Parameter

On each trial, the computational model evaluates the reinforcement history of each cue to generate the probability of selecting each of the 100 cue value options. From these options, a single value is chosen using the Softmax decision rule (Equation 5). The equation's exploitation parameter, $K$, determines the level of determinism in the choice process (Daw \& Doya, 2006). As $K$ approaches $\infty$, the process is more likely to choose the most probable option. As $K$ approaches 0 , the equation is more likely to pick a less probable option.

$$
P_{\text {Final }}\left(v_{i}\right)=\frac{e^{\left[P_{\text {Intercue }}\left(v_{i}\right) \cdot K\right]}}{\sum_{j=0}^{100} e^{\left[P_{\text {Intercue }}\left(v_{j}\right) \cdot K\right]}}
$$

Equation 5.
where $P_{\text {Final }}\left(v_{i}\right)$ is the final probability of selecting cue value $v_{i}, K$ is the exploitation parameter, and $v_{j}$ are all the cue values from 0 to 100 for given cue.

## Results

## Task Analysis

By considering the optimal cue actions that will maximize the outcome value's movement toward the target, the optimal selections can be computed for each trial (Equation 5). The difference between the optimal selections and the actual chosen selections results in an optimality score for each participant. Figures 2 and 3 shows that the Younger group tended to select more optimal responses in both Test blocks, although the difference was not statistically significant.

## Optimality - Congruent Test

Figure 2: Optimality scores for Congruent Test block

## Optimality - Transfer Test

Figure 3: Optimality scores for Transfer Test block
At first blush, it may seem that the Older group performed similarly to the Younger group. However, further analysis of the strategies used by both groups demonstrates critical differences in the way the Older adults completed the dynamic control task. The strategy analysis considered four different types of cue changes: varying none, varying one cue, varying two cues, and varying all three cues. Figures 4
and 5 illustrate the cue varying strategies for both groups on both the Congruent Test and Transfer Test. A 2 (Older, Younger) x 2 (Congruent, Transfer) x 4 (Strategy Type) repeated measures ANOVA reveals an Age by Block by Strategy interaction, $F(3,120)=2.95, p<0.05, \eta=0.07$. There was also a main effect of strategy, $F(3,120)=24.42$, $p<0.001, \eta=0.38$. No other main effects of interactions were statistically significant.

Figure 4. Cue varying strategies for Congruent Test
Cue Strategies - Transfer Test
$\square$ OlderAdults YoungerAdults

Figure 5. Cue varying strategies for Transfer Test
Not only did the Younger and Older groups differ in their cue varying strategies, they also differed in the values selected for the cues. Figures 6 and 7 report the mean cue values (between 0 and 100) selected for each of the three Cue Types. A 2 (Older, Younger) x 2 (Congruent, Transfer) x 4 (Strategy Type) repeated measures ANOVA revealed a
main effect of Cue Type, $F(2,80)=5.11, p<0.01, \eta=$ 0.11 , as well as an interaction of Age and Cue Type, $F(2$, $80)=3.51, p<0.05, \eta=0.08$. This suggests that the Older group tended to select higher values for the Positive and Null cues

## Cue Values - Congruent Test

$\square$ OlderAdults $\quad$ Younger Adults

Figure 6. Cue values selected for Congruent Test

Figure 7. Cue values selected for Transfer Test
Taken together, analyses of surface level behavior suggest the Older group differed from the Younger group in completing the dynamic control task. However, the nature of the underlying cognitive processes which led to these patterns of behavior remains elusive using basic task analysis. In order to distill psychologically relevant characteristics of the processes involved in the dynamic decision making task performance, a computational reinforcement learning model of the dynamic control task was fit to individual participant data.

## Model Based Analysis

Task behavior was fit to the computational model using an optimization procedure that attempted to minimize the difference between observed trial-by-trial cue value selections and the expected cue value selections as determined by the model. This was done by considering the probabilities given to the various cue values for each cue on a given trial. The optimization procedure attempted to determine best fitting free parameters (exploitation parameter, inter-cue parameter, positive and negative reinforcement sensitivity parameter) that maximized the probability that the model would select the same cue values as the human participant on a given trial.

Inter-Cue Parameter

Figure 9. Inter-Cue Parameter

Pos. Sensitivity Parameter
OlderAdults YoungerAdults

Figure 10. Positive Sensitivity Learning Parameter

Figure 11. Negative Sensitivity Learning Parameter
Figures 8 through 11 reports the mean best fit parameter values for the Younger and Older groups. In the Congruent Test, those in the Older groups were best fit with a lower exploitation parameter $(t[40]=-2.37, p=0.02)$, a higher positive reinforcement strength parameter $(t[40]=3.17, p=$ 0.003 ), and a lower inter-cue parameter ( $t[40]=-2.35, p=$ 0.02 ). There was no significant difference in the negative reinforcement strength parameter between the two groups, $t(40)=-0.29, p=0.85$. In the Transfer Test, the Older adults continued to be better fit by a higher positive reinforcement parameter than Younger adults, $\mathrm{t}(40)=2.74, \mathrm{p}<0.01$. In short, in the Congruent Test, the Older group's performance was better fit with parameters associated with higher exploration, higher positive feedback sensitivity, and lower inter-cue selection. In the Transfer Test, the Older group
continued to be better fit by model parameters associated with higher positive feedback sensitivity.

## Discussion

The present study examined the role of normal aging in a dynamic control task using a novel computational modeling technique. Standard behavioral analysis revealed older adults potentially utilized an alternative strategy in completing the dynamic control task than younger adults. A computational model of the task revealed specific behavioral characteristics associated with normal aging. In the Congruent block, older adults demonstrated more exploratory behavior, less inter-cue behavior, and more reliance on recent and positive success. On the Transfer block, older adults did not differ from younger adults in their exploratory and inter-cue behavior, but continued to demonstrate more reliance on recent and positive success.

One possible interpretation of this pattern of results is that older adults were able to achieve the final performance profile of younger adults (as measured by deviation from optimal responses) by relying on compensatory mechanisms to engage the task. Specifically, in the congruent goal test, the older adults were more exploratory, relied less on the reinforcement history of alternative cues when determining cue values, and were more influenced by trials on which they received positive feedback. During the transfer goal test, the older adult's compensatory strategy gave way to a closer performance signature exhibited by younger adults. However, they remained more influenced by positive feedback. This interpretation is supported by previous research which has shown that older adults are able to achieve the performance levels of younger adults via a compensatory strategy (Glass, et al., 2012;Worthy \& Maddox, 2012).

Another interpretation of the current results is that older adults approached the task by utilizing alternative mechanisms which may be enhanced in older adults. For example, older adults exhibit a positivity effect characterized by superior emotional processing of positively valenced content (Carstensen \& Mikels, 2005). This could account for the older adults' higher learning rate sensitivity parameter for positive feedback, but not for negative feedback. Thus, when older adults encountered successful trials, their learning rate parameters increased such that prior knowledge was discounted. In this interpretation, older adults differed in their overall strategy due to specific enhancements associated with normal aging. This interpretation is supported by the positive learning rate sensitivity parameter remaining higher for older adults than younger adults in both the congruent and transfer tasks. Future research should determine whether the differences in strategies used by older adults to complete the dynamic control task are simply the result of slower overall learning rates, or due to differences in underlying cognitive mechanisms associated with normal aging. Future work
should incorporate manipulations to test these interpretations, such as limiting feedback types to determine whether the aging positivity effect can account for performance differences.

## Acknowledgments

The authors thank Agata Ryterska for help with data collection for the project.

# Development of Category-Based Reasoning: Results from a Longitudinal Study 

Karrie E. Godwin (kegodwin@andrew.cmu.edu)<br>Anna V. Fisher, (fisher49@andrew.cmu.edu)<br>Bryan J. Matlen (bmatlen@cmu.edu)<br>Carnegie Mellon University, Department of Psychology, 5000 Forbes Avenue, Pittsburgh, PA 15213 USA

#### Abstract

Prior research on the development of category-based reasoning indicates a protracted developmental course of this ability as well as a high degree of individual variability. However, the sources of this individual variability as well as the sources of developmental change remain unclear. The present study aimed to examine these issues, with a focus on the role of representational change and executive function development. Across two time points spaced approximately 7 months apart, children's category-based reasoning was assessed along with a battery of executive function and representational change measures. Results replicated prior work in that only a small proportion of children exhibited spontaneous category-based reasoning at Time1, and this proportion increased with development. In addition, both executive function and representational change were found to predict the development of category-based reasoning.

Keywords: Category-based reasoning; inductive reasoning

## Introduction

Category-based reasoning is central to mature cognition and underlies much of our learning and functioning in the world (e.g., Osherson et al., 1990; Sloman, 1993). Despite early reports that even very young children spontaneously engage in category-based reasoning (e.g., Gelman \& Markman, 1986; Gelman \& Coley, 1990; Welder \& Graham, 2001), recent evidence suggests that development of category-based reasoning follows a relatively protracted developmental course (e.g., Badger \& Shapiro, 2012; Godwin, Matlen, \& Fisher, in press; Fisher, Matlen, \& Godwin, 2011; Fisher, 2010; Fisher \& Sloutsky, 2005).

One of the hallmarks of category-based reasoning is one's ability to make inferences based on the knowledge that two (or more) items belong to similar kinds in the absence of supporting perceptual information. For example, if one is shown a picture of a rock, a sponge, and another rock and asked to predict which two items have properties in common, one could rely on perceptual similarity to make an inference. Similarly, if the pictures are ambiguous (or not presented) and labels are used to indicate category membership, one could base their inference on matching labels (e.g., rock-rock), not necessarily because one understands that labels refer to kinds, but because the labels are perceptually identical (Sloutsky \& Fisher, 2004). However, one's ability to rely on semantically-similar labels (e.g., rock-stone) to make inferences is commonly interpreted as an index of category-based reasoning (e.g., Gelman \& Markman, 1986).

Several studies have documented that the ability to spontaneously engage in category-based reasoning appears between 4 and 6 years of age (e.g., Badger \& Shapiro, 2012;

Godwin, et al., in press; Fisher, et al., 2011; Fisher 2010; Fisher \& Sloutsky, 2005). However, it remains unclear what leads to the development of spontaneous category-based reasoning during the preschool years. Two classes of explanations have been put forth to explain changes in various areas of cognitive development, namely Representational Change and Executive Function development. We briefly discuss both explanations below.

## Representational Change

Representational change is "reorganization of existing knowledge or a difference in the utilization of information, rather than the acquisition of new information" (Nelson, 1977, p. 109). Representational change has been implicated as an explanatory factor in several areas of cognitive development, including analogical reasoning (e.g., Gentner et al., 1995), problem solving (e.g., Karmiloff-Smith, 1984), and numerical development (e.g., Opfer \& Siegler, 2007).

With regards to semantic development, there are several compelling sources of evidence pointing to representational change in the multidimensional scaling literature (e.g., Howard \& Howard, 1977), free association studies (e.g., Brown \& Berko, 1960), and development of semantic priming (e.g., McCauley, Weil, \& Sperber, 1976).

Furthermore, different approaches to modeling semantic cognition suggest that early conceptual organization is fairly undifferentiated (such that penguin, trout, and alligator may start out as belonging to the same cluster) with greater differentiation emerging with development (Kemp \& Tenenbaum 2008; Rogers \& McClelland 2004). At present, there is no direct empirical evidence testing these predictions, although Carey's (1985) seminal work is largely consistent with these developmental profiles.

## Executive Functions

Executive Functions (EF) are psychological processes thought to control other (typically, higher-order) psychological processes such as planning, reasoning, and problem-solving. Most researchers distinguish the following EF processes: set shifting, active maintenance of representations (sometimes referred to as working memory), and inhibitory control (Bunge et al., 2002; Carlson et al., 2002).

The EF system is traditionally associated with prefrontal cortex, which is believed to be one of the slowest brain regions to mature (e.g., Diamond, 2002). Development of EF has been implicated in developmental accounts of category learning (Sloutsky, 2010), and there is evidence that representation maintenance and inhibitory control play a role in the development of analogical reasoning (Morrison
et al., 2011). With regards to semantic cognition, regions of the PFC (specifically, ventrolateral PFC or VLPFC) have been shown to be engaged in controlled semantic access, for instance in classification or category generation tasks. While it remains unclear whether the role of VLPFC is to bias retrieval of task-relevant semantic information through maintaining task representations or to select task-relevant representations among competing activated representations (e.g., Wagner, 2002; Kan \& Thompson-Schill, 2004), prefrontal cortex clearly is important for controlled semantic access.

## The Present Study

Prior research on the development of category-based reasoning indicates not only a protracted developmental course of this ability, but also a high degree of individual variability. Specifically, results aggregated across several studies suggest that approximately $20 \%$ of 4 -year-olds spontaneously make category-based inferences with semantically-similar labels, and this proportion increases to approximately $40 \%$ and $65 \%$ among 5 - and 6 -year-olds, respectively (Fisher, 2010; Fisher et al., 2011; Godwin et al., in press). However, the sources of this individual variability as well as sources of developmental change remain unclear. The goal of the present study was to begin the exploration of these questions, with a focus on the putative role of representational change and executive functions. A battery of assessments was administered over the course of one school year. At Timel (Fall) we collected measures of children's category-based reasoning, verbal working memory, IQ, and semantic knowledge organization. At Time2 (Spring) we collected measures of children's category-based reasoning, semantic knowledge organization, inhibitory control, non-verbal working memory, sustained attention, and category generation.

## Method

## Participants

Participants in this study were 43 four-year-old children from a local preschool (Mage $=4.32$ years, $S D=0.28$ years, 20 females, 23 males).

## Design and Procedure

Each child participated in 13 sessions over the course of the school year ( 6 sessions at Timel and 7 sessions at Time2). Children were tested individually in a quiet room adjacent to their classroom by a trained research assistant. A brief description of the task battery is provided below.

## Category-Based Reasoning Task

This task included 9 label triads, 3 of which referred to artifacts, 3 to inanimate natural kinds, and 3 to animate natural kinds (see Table 1). All triads contained a target item, category-choice, and an unrelated lure (e.g., rat-mouse-fish). Visual stimuli consisted of sets of three identical doors. Children were told that objects were hiding behind doors. The objects were never revealed in order to
encourage children to rely on the category information conveyed by the labels.

Table 1: Category-Based Reasoning Task Linguistic Stimuli

| Target | Category Choice | Lure | Property |
| :---: | :---: | :---: | :---: |
| Rock | Stone | Grass | Higa |
| Alligator | Crocodile | Butterfly | Omat |
| Rug | Carpet | Window | Koski |
| Rat | Mouse | Fish | Lignin |
| Hill | Mountain | Flower | Erwin |
| Sea | Ocean | Apple | Manchin |
| Sofa | Couch | Cup | Creighan |
| Shoe | Boot | Car | Troxel |
| Lamb | Sheep | Frog | Matlen |

Children were first told what objects were hiding behind the doors and then told about a novel property of the target item (e.g., "The rock has higa inside"). Children were asked to generalize the novel property from the target item to either the category-choice or the unrelated lure. The task was administered four times (twice within each time point) in order to obtain a more stable estimate of children's performance. The delay between task administrations within a time point was one to two weeks. The trials were administered in one of two counter-balanced orders.

## Picture Identification Task

The picture identification task is similar in format to the Peabody Picture Vocabulary Test (Dunn \& Dunn, 1997). It assessed children's familiarity with the linguistic stimuli utilized in the category-based reasoning task. The task was administered at Time 1 and Time 2.

## Intelligence Test

The Wechsler Preschool and Primary Scale of Intelligence (WPPSI) provided a measure of children's general intelligence (Full-scale IQ or FSIQ), as well as an index of children's Verbal IQ (VIQ), Performance IQ (PIQ), and Processing Speed Quotient (PSQ). The WPPSI was administered at Time 1 only.

## Semantic Space Task

The semantic space task served as a measure of children's semantic organization. The stimuli entailed a game board ( 9 x 9 grid ; see Figure 1) and 2 game pieces (1" wooden cubes). Verbal stimuli included 24 animal pairs: 6 semantically-similar dyads (e.g., chick-hen), 6 dyads that share a common setting or habitat (e.g., chick-goat), 6 dyads that are unrelated (e.g., chick-goldfish), and 6 filler dyads (see Table 2). Thus, throughout the task, the target animal was paired with 3 different test items (i.e., the categorychoice, setting/habitat match, and the unrelated item). The 3 animal trials from the Category-Based reasoning task were included in the Semantic Space task.

Children were told that they were helping Zibbo the zookeeper organize his zoo. Children were instructed to put animals of the same kind close together on the board. For each trial, the experimenter put one of the game pieces on a predetermined square on the game board and told the child that the specified location was where Zibbo put the target animal (e.g., "The zookeeper put the chick here"). The child
was then asked to identify where the test item (i.e., the second game piece) should be placed (e.g., "Where do you think the goat should go?"). After each trial the child's response was recorded in order to calculate the distance between the target and the placement of the test item. Prior to playing the game, children were given two examples where the experimenter demonstrated that animals of similar kind (e.g., bunny and rabbit) should be placed close together and animals of different kind (e.g., dog and shark) should be placed far apart.

Table 2: List of Stimuli for the Semantic Space Task

| Critical Trials |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
| Target | Category <br> Choice | Setting/ <br> Habitat | Unrelated |  |
| Crocodile | Alligator | Fish | Grasshopper |  |
| Chick | Hen | Goat | Goldfish |  |
| Lamb | Sheep | Horse | Swan |  |
| Whale | Dolphin | Octopus | Elephant |  |
| Monkey | Gorilla | Parrot | Chipmunk |  |
| Mouse | Rat | Pig | Hippo |  |
| Filler Pairs |  |  |  |  |
| 1. Zebra/Turkey; 2. Bear/Snake; 3. Panther/ Turtle; |  |  |  |  |
| 4. Tiger/Butterfly; 5. Frog/Lion; 6. Giraffe/Seal |  |  |  |  |

Figure 1: Schematic depiction of the semantic space game board. Red squares mark the location of critical trials; yellow squares mark the location of filler trials. Note that none of the locations were colored when the task proper was administered.

Children's score on the semantic space task was calculated by averaging habitat dyads and unrelated dyads together in order to create a composite score for non-semantically-similar dyads. Next, the average score for semantically-similar dyads was subtracted from the non semantically-similar composite score to obtain a difference score. Difference scores approaching zero indicate that children did not differentiate the placement of semanticallysimilar and dissimilar dyads. Difference scores above zero indicate that children placed semantically-similar dyads closer than dissimilar dyads. The semantic space task was administered at Time1 and Time2.

## EF Measures

Verbal Working Memory Tasks Forward and Backward word-span tasks were administered to assess children's verbal working memory capacity. Verbal stimuli consisted of 60 common count nouns selected from the MacArthur Communicative Development Inventory (Dale \& Fenson,
1996). In the Forward-word span task, children were asked to recite the words in the same order in which they were presented; in the Backward-word span task children were asked to repeat the words in the opposite order. If a child made a mistake, they were given another opportunity to recite a different list of the same word length. Children's score was determined by the longest list length the child was able to recite correctly.
Inhibitory Control Measures Two common measures of response inhibition were included in the assessment battery: the Day-Night task (Gerstadt et al., 1994) and the Flanker task (Rueda et al., 2004). In the Day-Night Task, children were shown a set of cards depicting the sun and the moon. Children were asked to provide a verbal response that conflicts with the presented image (e.g., if the child was shown a picture of the sun, the correct response would be "night". Conversely if the child was shown a picture of the moon, the correct response would be "day"). The task consisted of 16 trials (the moon and the sun were presented 8 times each). Two presentation orders were created: The trials were randomized for order 1 and the sequence was reversed for order 2.
We used the version of the Flanker Task adapted for use with young children (Rueda et al., 2004). In this version children are presented with arrays of fish on a computer screen. Children are asked to feed the center fish by pressing either the left or right button. The correct response is dependent upon the direction the center fish is facing. The center fish is surrounded by four other fish (two on each side). The surrounding fish may be congruent (e.g., swimming in the same direction as the center fish) or incongruent (e.g., swimming in the opposite direction as the center fish). Neutral trials were also presented in which the central fish appears in isolation (i.e., not flanked by other fish). A total of 48 trials were administered: 16 neutral trials, 16 incongruent trials, and 16 congruent trials. For the purposes of the analyses reported below, we used the Flanker Accuracy Difference score (calculated by subtracting each child's accuracy for the Incongruent trials from the Neutral trials) and Flanker RT Difference score (calculated by subtracting each child's reaction time for the Incongruent trials from the Neutral trials).

## Non-Verbal Working Memory \& Sustained Attention

 The Track-It Task (Fisher et al., 2012) was used as an index of non-verbal working memory; this task also provided a measure of sustained attention. In this task children watched a set of moving objects: six distractors and one target. The objects moved randomly across a computer screen for 10 seconds, and then disappeared. On each trial, children were asked to select the location where the target object disappeared; the location questions provided a measure of sustained attention. Upon answering the location question, children were shown a laminated card that contained an array of 9 objects (the target object and 8 lures). Children were asked to point to the target object that they had been tracking; children's responses to this question provided ameasure of non-verbal working memory (WM). The Trackit task included 10 experimental trials and one practice trial.

## Results

Picture Identification The results from the Picture Identification task suggested that children were familiar with the labels used in the category-based reasoning task: Children's accuracy on this task approached ceiling levels ( $M=92 \%, S D=14 \%$ and $M=96 \%, S D=8 \%$ for Time 1 and 2 respectively). As an additional precaution, children's category-based reasoning scores were adjusted for their vocabulary knowledge to ensure that children possessed the pre-requisite knowledge to perform category-based induction. Thus, if a child missed an item on the picture identification task, this trial was removed from their category-based reasoning score.

Category-Based Reasoning Task Mean category-based reasoning scores at Time 1 a and 1 b were very similar (adjusted means: 0.63 and 0.66 , respectively) and significantly correlated ( $r=.483, p=0.001$ ). Mean categorybased reasoning scores at Time 2 a and 2 b were also similar (adjusted means: 0.73 and 0.80 , respectively) and significantly correlated ( $r=.689, p=0.0001$ ). Consequently, induction scores were averaged across Time 1 a and 1 b and across Time 2 a and 2 b to yield average category-based reasoning scores for Time1 ( $M=0.64, S D=0.22$ ) and Time2 ( $M=0.76, S D=0.21$ ).

The rate of category-based responding at Time1 ( $M=.64$ ) was above chance $(t(40)=4.08, p<.001)$ and somewhat higher than in our prior studies ( $M=.54$ across Fisher et al., 2011; Godwin et al., in press; Matlen et al., under review). However, it should be noted that in the present study the sample consisted entirely of children enrolled in a laboratory campus school at a private university, and prior studies utilized more diverse community-based samples.

The proportion of category-based responding at Time2 ( $M=.76$ ) was also above chance, $(t(41)=8.01, p<.001)$ and higher than at Time1, paired-samples $t(39)=3.53, p<.001$, Cohen's $d=.56$. Note that the latter finding cannot be attributed simply to children having experience with performing the same task, as scores were not significantly different at Time 1 a (.63) and 1 b (.66). Therefore, this finding points to a developmental increase in the propensity towards category-based reasoning.

To investigate individual patterns of responses, participants were classified as either category-based or non-category-based responders. A category-based responder was defined as a participant who gave a category-based response on at least 7 out of 9 (78\%) trials (binomial $p=0.09$ ). Analysis of the individual patterns revealed that only a small percentage of children were classified as category-based responders at Timel (27\%). In contrast, the majority of children were classified as category-based responders at Time 2 ( $67 \%$ ). The association between responder type and testing point (Time1 vs. Time2) was significant, McNemar's $\chi^{2}(1)=7.22, p<.005$.

Predicting Category-Based Reasoning We performed linear stepwise regression to identify the best predictors of category-based responding at Time1 and 2. Only predictors that were significantly correlated with category-based responding were entered into the model. Thus, three predictors were included: Semantic Space scores Timel, FSIQ, and Non-Verbal WM score. Overall, the model significantly predicted children's responses on the categorybased reasoning task, $R^{2}=.211, F(1)=11.42, \quad p=.002$. However, only one predictor was found to be significantly related to children's induction performance at Time 1 : Semantic Space scores $(\beta=.481, t(1)=3.38, p=.002)$.

For predicting category-based responding at Time2, only predictors that were significantly correlated with induction performance at Time2 were included in the model. The following predictors were entered into the model: Semantic Space Time 2 scores, Forward Word-Span, Backward WordSpan, FSIQ, Non-Verbal WM score, Sustained Attention score, and Day/Night score (VIQ was excluded from the analysis due to concerns regarding colinearity based on its high correlation with FSIQ). Overall, the two-predictor model significantly predicted children's responses on the category-based reasoning task, $R^{2}=.474, \quad F(2)=19.00$, $p<.001$. However, only two predictors were found to be significantly related to children's induction performance at Time 2: Non-verbal WM ( $\beta=.522, t(2)=4.37, p<.0001)$ and Day/Night scores $(\beta=.352, t(2)=2.95, p=.005)$.

Category-Based Reasoning: What Develops? What factors play a role in the development of category-based reasoning? Since several children performed at nearly ceiling level on the category-based reasoning task at Time 1, it was not possible to address this question using gain scores from Time1 to Time2. Therefore, to address this question we split the sample into three groups based on the children's performance on the category-based reasoning task at Time 1 and Time2 (see Figure 2). Group 1 included children who were already category-based responders at Time1 ( $27 \%$ of the sample); all of these children remained category-based responders at Time2. Group 2 included children who were not yet category-based responders at Timel but became category-based responders at Time2 ( $40 \%$ of the sample). Group 3 included children who were not yet category-based responders at either Time1 or Time2 (32.5\% of the sample). Splitting the sample in this manner allowed for analyses examining potential factors that may differentiate Groups 2 and 3 (i.e., children who became category-based responders at Time2 from children who were not yet category-based). Three children were missing scores for either Time 1 or 2 and were omitted from this analysis.

Importantly, children in Groups 2 and 3 obtained comparable FSIQ scores ( $M=108, M=100$ respectively), $t(27)=1.41, n s$. This finding suggests that performance differences between the two groups on the category-based reasoning task were not simply a result of disparities in children's general intelligence. Children in Group 1 obtained FSIQ scores $(M=118)$ that were over one standard deviation above the population mean $(M=100, S D=15$;

Wechsler, 2002). FSIQ scores of children in Group 1 were also significantly higher than children in Group 3, $t(21)=3.04, p<.01$, and marginally higher than those of children in Group 2, $t(25)=1.78, p=.088$. Based on IQ scores, the group of children who were already categorybased responders on the induction task at Time1, were cognitively advanced. However, it is important to note that children in Groups 2 and 3 were not lagging behind as they exhibited average intelligence compared to the general population.

Figure 2. Proportion of category-based responses at Time 1 and Time 2 by group.

Due to space limitations we cannot describe the performance patterns for these three groups on all administered tasks. However, it should be noted that on some measures children's performance was equivalent across groups. For example, children's Flanker Accuracy Difference scores were comparable in all three groups (MGroup1=.35, MGroup2=.38, MGroup3=.30, all $t \mathrm{~s}<.75, n s$ ). Similarly, Flanker RT Difference scores were comparable in all three groups (MGroup1=-127.37, MGroup2=-116.24, $M$ Group $3=-106.48$, all $t \mathbf{s}<.21, n s)$. The biggest performance differences were found on three measures: Semantic Space, Non-Verbal WM, and the Day/Night task.

Recall that the Semantic Space task was administered twice, once at Time1 and again at Time2. Therefore, we were able to compare children's performance on this task across time. As can be seen in Figure 3, children in Group 1 exhibited equivalently high performance on the Semantic Space task at both Time1 and Time2 ( $M \mathrm{~T} 1=2.41, M \mathrm{~T} 2=3.04$, paired-sample $t(10)=.73, n s)$. In contrast, children in Group 2 significantly improved in their performance on the Semantic Space task from Time1 to Time2 ( $M \mathrm{~T} 1=1.4$, $M T 2=3.01$, paired-sample $t(15)=2.38, p=.03$ ). Children in Group 3 exhibited relatively low performance on the Semantic Space task at both Time1 and Time2 ( $M$ T1 $=.88, M$ $\mathrm{T} 2=1.15, t(12)=.59, n s)$.

Overall, these findings suggest that children who showed consistently high performance on the Semantic Space task also showed consistently high performance on the categorybased reasoning task, and children who showed consistently low performance on the Semantic Space task also showed consistently low performance on the category-based reasoning task. Only those children who showed improved performance on the Semantic Space task also showed improved category-based reasoning.

Figure 3: Mean performance on the Semantic Space task at Time 1 and Time 2 by group.

A stark difference was observed in children's non-verbal WM performance. Children in Groups 1 and 2 demonstrated similar levels of performance on the non-verbal WM task ( $M=.70$ and $M=.62$ respectively; $t(25)=.67, n s$ ) with children in both groups demonstrating better non-verbal WM than children in Group 3 ( $M=.18$ ); all $t \mathrm{~s}>4.66, p<.0001$ ). A similar pattern of results was obtained for the Day/Night task as the mean accuracy rate was superior for Groups 1 and 2 ( $M=.71$ and $M=.79$ respectively) compared to Group 3 ( $M=.47$ ); all $t \mathrm{~s}>1.84, p<.08$.

Taken together these findings corroborate the results obtained from the regression models suggesting that developmental improvement in working memory, inhibitory control, and semantic differentiation underlies the development of category-based reasoning.

## Discussion

One potential limitation of the present study is that the assessment battery did not include a direct measure of vocabulary size. Arguably, vocabulary may be a precursor to category-based reasoning. Nevertheless, there is reason to believe that the high degree of individual variability observed in preschool children's category-based reasoning performance is unlikely to be explained by differences in vocabulary. It is important to note that FSIQ is a composite measure that includes an index of children's verbal ability. Recall that FSIQ scores were comparable between children who became category-based responders at Time 2 and children who were not yet category-based. Additionally, children's high accuracy rates on the Picture Identification task suggests that children are familiar with the labels that were utilized in the category-based reasoning task.

In line with prior work (Fisher et al., 2011; Godwin et al. in press), the present study provides additional evidence demonstrating that only a small percentage of preschool-age children spontaneously engage in category-based reasoning. Additionally, this work implicates three cognitive factors in the development of young children's category-based reasoning: representational change, working memory, and inhibitory control.

First, the strong relationship between improvements in semantic differentiation scores and induction scores suggests that representational change may be one underlying
mechanism in the development of children's ability to engage in spontaneous category-based reasoning. Second, working memory may be an important cognitive factor in the development of category-based reasoning as children need to maintain and manipulate the task-relevant information in working memory. Finally, sufficiently developed inhibitory control may be required to select taskrelevant representations among competing activated representations. These findings indicate that both general cognitive advances (EF and working memory) and changes in domain-specific knowledge (representational change) contribute to the advancement of category-based reasoning.

## Acknowledgments

We thank Malika Sinha, Laura Pacilio, Alyssa Montanaro, Anna Loiterstein, Like Li, Kayoung Joung, and Rachel Walsh for their help collecting data. We thank the children, parents, and teachers for making this work possible. # 'This is a wall' - Assigning Function to Objects 

Linn Gralla (gralla@uni-bremen.de)<br>Department of Linguistics and Literary Studies<br>Bremen University, Germany<br>Thora Tenbrink (t.tenbrink@bangor.ac.uk)<br>School of Linguistics and English Language<br>Bangor University, UK

#### Abstract

Construction tasks involve numerous demanding sub-tasks such as creating a mental model of the goal object and integrating the object parts into this model. For this purpose object parts need to be assigned a function within the overall structure. In this paper we examine the linguistic representation of this process. Participants were given 16 object parts to assemble without a manual, and were asked to think aloud while doing so. Depending on condition they were not given any specific information, or told that the goal object was a dollhouse, or shown a picture of the dollhouse. In a second study, participants were asked to instruct a partner to assemble the dollhouse. Results of our linguistic analysis of think-aloud data and instructions reveal three strategies of assigning function to objects, one of which occurred exclusively in instructions. With less specific information about the goal object, functions were more often assigned explicitly. In these cases function tended to relate to the overall structure (e.g. 'house') rather than to structural parts (e.g. 'wall').

Keywords: verbal reports, cognitive discourse analysis, function assignment, conceptual domains

## Introduction

Adults who observe children play are often amazed by their imagination. In their play a plastic cup becomes a boat that sails on the stormy sea. The existence of the boat in the children's mind can be seen as the result of a conceptual mapping process. The child performs a mapping between the domain of plastic objects (cup) and vehicles (boat). Mapping phenomena between different conceptual domains have been widely studied in research on metaphorical transfer (Lakoff \& Johnson, 1980; Croft, 1993) and analogical problem solving (Gentner, 1983). Here we address how speakers use language to assign an object's function in relation to a target domain, in a situation where this function is not self-evident and needs to be identified. This kind of conceptual domain shifting is essential for everyday reasoning. It is required whenever the 'meaning' of an object or depiction needs to be determined that represents something else, for example a symbol on a map that stands for an environmental feature. Our study sheds light on this kind of conceptual mapping by a closer look at the language used to represent it, providing both qualitative (how do speakers say this?) and quantitative (how often do they say it under different circumstances?) insights.

Our scenario concerns the construction of a dollhouse from wooden parts that bear little resemblance to their function within the dollhouse. A board, for instance, needs to be recognised as a 'wall' before it can be placed correctly to serve its function. We investigate the linguistic representation of function assignment in two set-ups: thinkaloud protocols collected while assembling the dollhouse, and verbal instructions to another person assembling the dollhouse. In particular, we analyze the referential terms that are used in reference to both of the domains involved (wooden objects with particular structural features and functional parts within the dollhouse), as well as the linguistic means by which the domains are linked. In the next section we will take a closer look at relevant previous findings on linguistic domain mapping.

## Mapping between conceptual domains

## Use of functional terminology in construction tasks

Malt et al. (1999) propose that the categorization of objects involves two levels: knowing an object vs. naming it. Object perception leads to a representation in terms of a recognition category, along with similar objects. The communication of objects, however, involves a representation in terms of linguistic categories, using conventional or new labels.

So far object categorization within construction tasks has only been studied in settings involving a real or an imagined addressee. Rieser (1996;1997), for example, studied object references in a dialogue scenario where assembler and instructor did not share the same workspace while constructing a toy airplane. As a result, they could share conceptualizations by spoken interaction only. Rieser examined the instructors' strategies of reference to facilitate identification of object parts, and found that they frequently described them in terms of their function in the conceptualized target object (i.e., the toy airplane; e.g., 'this is a horizontal stabilizer', Rieser, 1997:181). He called this phenomenon representational metonymy. The effect may be seen as a kind of reconceptualization and is based on world knowledge and the specific context. Apart from representational metonymy, the physical object itself could also be referred to in descriptive terms, based on the object's structural appearance along with conventional terms for them (e.g. 'Fünfträger' refers to a bar with five holes).

Studies of conceptual layers in construction tasks have focused on the frequency (e.g. von Stutterheim et al., 1993) or interactional purpose of usage of goal structure specific terminology (Rieser, 1997). For a task of instructing a generic addressee on assembling a TV stand, Daniel and Tversky (2012) report that lay instructors started their instruction by giving a list of objects. Although they did not analyze object reference directly, one of their examples shows that functional assignment took place at least once.

Although various authors have thus reported sporadic examples of function assignment, the phenomenon has not been studied systematically so far, and it is unclear to what extent it relates to the need to communicate. However, this kind of conceptual domain mapping is central to the ubiquitous process of recognizing what things are for. In this paper we investigate the linguistic representation of function assignment in two assembly scenarios, and we discuss the cognitive implications that are implied by different options. The next subsection gives some indications of possible linguistic forms.

## Linguistic representation of assignment of function in verbal reports

Rieser (1996; 1997) did not aim to analyze the linguistic features of representational metonymy, but the examples in these papers provide a good impression of how conceptual mapping is represented in assembly dialogues. Participants used phrases such as "das ist das Leitwerk" (this is a horizontal stabilizer) (1997:181), "diese zwei Schienen als Propeller" (those two tracks as propeller) (1997:191), and "dieses Baufix, diese Baufixschraube" (this Baufix, this Baufix screw) (1996:13).

Similar linguistic forms were found by Tenbrink and Seifert (2011) for conceptual mapping processes in a spatial problem-solving task. They analyzed written reports of participants planning holiday tours based on a map. This scenario involves two conceptual domains: that of the physically present road map, and that of the real world environment represented by the map. In their analysis of conceptual mapping processes, Tenbrink \& Seifert focused on the distribution and nature of nouns, verbs, adjectives/ adverbs, and temporal markers as indicators of either domain. If indicators for both domains were used within a single sentence, this sentence typically also contained indicators for conceptual mapping between them, such as the modal verbs could and should (e.g., 'I looked for a route that could be traveled'). Further indicators were final discourse markers (i.e. 'in order to') and the particle 'als' (as), which signaled "mapping from plan to purpose" (Tenbrink \& Seifert, 2011:116).

## Dollhouse assembly: Empirical studies

## Research goals

Gralla (in prep.) collected an explorative corpus of unconstrained language production data related to the assembly of a dollhouse from a set of wooden object parts
in various conditions (explained below). For the purposes of this paper we inspected this corpus to identify the ways in which participants spontaneously used language to assign function to objects. Based on Malt et al.'s (1999) distinction between perceiving and communicating about objects, we expected systematic differences to emerge between the two distinct discourse tasks (thinking aloud vs. instructing a partner). Furthermore, the linguistic representation of function assignment should also be affected by the amount of prior knowledge available about the goal object.

In order to systematize our insights on linguistic forms, we define a mapping phrase as consisting of the reference to a physically present object $\mathbf{x}$ that is assigned the functional term $\mathbf{y}$ by a relational term. Preliminary findings (reported in Tenbrink \& Gralla, 2009) and the examples seen in Rieser $(1996 ; 1997)$ suggest that these relational terms can vary with respect to the amount of certainty expressed. Relational verbs, as in "this is a wall", for instance, signal that the speaker is absolutely certain about the assignment, since the relation is expressed as a plain fact. The modal verb 'müssen' (must) implies a lesser but still high amount of certainty, as in "this must be a wall", whereas 'können' (can) reflects uncertainty, and 'sollen' (should) encodes a medium level (Halliday, 1985). In other cases the relational term expresses a comparison (look like, use as). This strategy implies that the speaker decides that $\mathbf{x}$ represents $\mathbf{y}$ because $\mathbf{x}$ and $\mathbf{y}$ share some features. This assignment is tentative because $\mathbf{x}$ may also be something else.

Interestingly, Tenbrink and Seifert (2011) also identified different kinds of modal verbs as markers of domain mapping for their tour planning scenario, in which certainty did not play any role as the planning process was entirely in the participants' hands. However, modal verbs also carry different connotations, which might play a role in this context. Whereas 'wollen' (want) expresses the subject's intention 'können' (can) expresses the possibility given that the subject is granted the permission (Engel, 2002), and 'sollen' (have to) signals an obligation. In our study, we aimed to shed further light on the repertory of linguistic forms used to express conceptual mapping, along with their distribution across the different conditions in the corpus.

Regarding the influence of prior knowledge, we expected that participants who were provided with unspecific information about the goal object should signal more uncertainty in their assignment of function than participants provided with a picture of the goal object. Participants asked to instruct another person (rather than think aloud while constructing the dollhouse themselves) should introduce the given objects and assign their function explicitly in mapping phrases (cf. Rieser, 1996; 1997; Daniel \& Tversky (2012).

## Methods

In the first of the studies carried out by Gralla (in prep.), think-aloud protocols were recorded while participants assembled a two-story dollhouse for themselves. 50 university students ( 22 male, 28 female; aged 19-42 years, mean age 24 years) participated for course credit or mone-
tary compensation. They were told that they would be given object parts to be assembled without a manual. Knowledge of the goal state varied between mention of "a dollhouse" (verbal goal condition), being shown a picture of the assembled dollhouse for 30 seconds (verbal and visual goal condition), and no such information (underspecified goal condition). Following the instruction, participants entered a room and saw a cardboard box, two wooden boards, and a triangular piece of wood on a table. The box contained 13 wooden parts (see picture 1 for an example of one object). Participants were instructed and reminded to think aloud while solving the task. There were no time constraints.

Picture 1: One wooden assembly piece

In the second study, verbal instructions on the assembly of the same two-story dollhouse were recorded. 16 students ( 9 male, 7 female; aged $20-28$ years, mean age 23 years) who did not participate in the previous experiment were first instructed to assemble the dollhouse for themselves. They were given the same information as in the verbal and visual goal condition but without the task to think aloud. After successful completion of the task the participants were introduced to another student (a confederate). They were asked to instruct this person to assemble the dollhouse, using a Skype-based one-way video connection that did not allow for any responses by the assembler.

## Analysis methods

Our data set contained 50 think-aloud protocols that were equally distributed between conditions (17 underspecified goal, 16 verbal goal, 17 verbal and visual goal), and 16 instructions. First, mapping phrases were identified in a qualitative analysis. They contained one object reference (either deictic or nominal, e.g. this thing) and a domain specific functional term, e.g. wall. Nouns belonging to the semantic field of the goal domain 'house' were classified as domain specific. Second, all phrases were classified either as direct mapping (use of relational verbs) or as representational mapping (use of comparison). Third, all verbs were annotated with regard to verb kind and type. Furthermore, the referential terms for the object (either deictic or nominal) as well as the functional term were annotated.

Example 1 (which refers to the object in picture 1) represents direct mapping with the verb 'sein' (be) as the relational term, and a deictic reference (this) for the object $\mathbf{x}$ that is assigned the functional term (y) wall.
(1) so das ist dann so ne Wand (so this is some wall then)

Example 2 (which refers to the roof of the dollhouse) illustrates representational mapping with the verb phrase 'aussehen wie' (look like) as the relational term, and the nominal reference red building part for the object $\mathbf{x}$ that is assigned the functional term roof.
(2) $\ldots$ das rote Baustück nen bisschen wie n Dach eines Hauses aussieht (... this red building part looks a bid like a roof of a house.)

The qualitative analysis and annotation of categories then led to the identification of quantitative frequencies in the various conditions.

## Results

131 mapping phrases were identified in the think-aloud protocols. The highest frequency ( 54 cases produced by 14 participants) was observed in the underspecified goal condition, as opposed to 44 cases produced by 14 participants in the verbal goal condition, and 33 cases produced by 11 participants in the verbal and visual goal condition. 23 cases of function assignment could be identified in 12 of the 16 instructions.

Figure 1: Distribution of mapping strategies (mean raw frequency with error bars $+/-2$ SE)

## Assignment of function in assembly

Direct mapping (108 cases) was more frequent than representational mapping ( 22 cases). The frequency of mapping strategies did not differ significantly between conditions (see Figure 1), $\chi^{2}(4, \mathrm{~N}=131)=7.12, \mathrm{p}=.130$. With respect to the linguistic representation of both mapping strategies, the verb 'be' was most frequent ( $91.51 \%$ ) in direct mapping. In representational mapping 'look like' (59.09\%) was used along with 'use as' (22.73\%).

29 modal verbs were identified in 18 protocols. They were almost equally distributed between conditions (11 in the underspecified goal condition: $\mathrm{M}=0.59, \mathrm{SD}=0.23 ; 8$ in verbal goal: $\mathrm{M}=0.50, \mathrm{SD}=0.13$; and 10 in verbal and visual goal: $\mathrm{M}=0.58, \mathrm{SD}=0.23$ ). Almost all (27) modal verbs occurred in direct mapping phrases. Three modal
verbs were used, namely could, must, and should. These were distributed between conditions as follows (figure 2). Participants in the underspecified goal condition used all three modal verbs, with could $(\mathrm{M}=0.83, \mathrm{SD}=0.31)$ and should $(\mathrm{M}=0.67, \mathrm{SD}=0.21)$ being more frequent than must $(\mathrm{M}=0.33, \mathrm{SD}=0.21)$. Participants in the verbal goal condition showed a preference for could $(\mathrm{M}=1.00, \mathrm{SD}=$ 0.26 ) whereas participants in the verbal and visual goal condition used must most frequently ( $\mathrm{M}=0.83, \mathrm{SD}=0.31$ ). However, the observed differences between conditions did not reach statistical significance, $\mathrm{L} \chi^{2}(4, \mathrm{~N}=29)=8.51, \mathrm{p}=$ .075, probably due to the low numbers and varied individual production of linguistic choices in our setting.

Figure 2: Distribution of modal verb type in mapping processes within conditions (mean raw frequency with error bars +/- 2 SE)

## Assignment of function in instructions

Besides identifying instances of direct and representational mapping, our qualitative data analysis revealed a further (unexpected) strategy of function assignment in instruction texts. Instructors used a more implicit way of assigning function, illustrated in example 3:
(3) „jeweils mit einem kurzen Stück einem ähm einem Wandelement ..." (each with a small piece a um a wall element)

In this example the object (a small piece) is assigned its function (wall element) by simply renaming it after a hesitation phase. Since there is no relational term connecting object reference and functional term, no conclusions can be drawn about the level of certainty reflected in this strategy. This type is called reframing because the speaker changes the frame of conceptualization from unspecific to specific. The distribution of mapping strategies shows that instructors used direct mapping most frequently ( $\mathrm{M}=0.63, \mathrm{SD}=0.20$ ). A closer look at the linguistic structure of direct mapping reveals that the verb 'be' was used in all cases; instructors never used modal verbs to assign function. Furthermore,
representational mapping and reframing ( $\mathrm{M}=0.31, \mathrm{SD}=$ 0.12 ) were also frequently used. The influence of discourse type on mapping strategies is significant, $\chi^{2}(3, N=141)=$ 8.37, $\mathrm{p}=.039$. Representational mapping was used more frequently in instructions $(0.44(\mathrm{SD}=0.18))$ than in think aloud protocols ( $0.40(\mathrm{SD}=0.77), \mathrm{z}=2.0, \mathrm{p}<.05$ ).

## Object reference and functional terminology in mapping phrases

A significant difference emerged between the two different discourse types (think-aloud vs. instruction) with respect to the referential term used for the object, $L \chi^{2}(6, N=154)=$ $57.73, \mathrm{p}=.000$. Participants who were thinking aloud while assembling the dollhouse mostly used deixis (e.g., this, that) rather than nominal references. Instructors, on the other hand, used nominal object references ( $0.94(\mathrm{SD}=0.85)$ ) more frequently than assemblers $(0.06(\mathrm{SD}=0.24), \mathrm{z}=7.5$, $\mathrm{p}<.001$ ), and they used deictic references ( 0.50 (SD = $0.63)$ ) less frequently than assemblers ( $2.42(\mathrm{SD}=2.54), \mathrm{z}=$ $-2.6, \mathrm{p}<.01$ ).
Five nouns or their synonyms were used most frequently to express function in the dollhouse: floor, roof, wall, story, and house. This list represents two perspectives. Some of these terms (floor, roof, and wall) highlight individual pieces of the dollhouse and are therefore part-based, while the others refer to the whole structure (house) or larger portions of it (story), which may consist of several individual pieces and are therefore structure-based, e.g. "aah das könnten auch Stockwerke sein" (aah this could also be stories). Conditions differed with respect to the distribution of these two perspectives (see figure 3). While participants in the underspecified goal condition used structure-based terminology $(\mathrm{M}=1.65, \mathrm{SD}=0.57)$ frequently, participants in all other conditions (including instruction) referred to individual parts significantly more often, $\chi^{2}(6, \mathrm{~N}=154)=$ $13.44, \mathrm{p}=.037$.

Figure 3: Functional terminology assigned to objects in mapping phrases - categorized according to perspectives (mean raw frequency with error bars $+/-2$ SE)

## Discussion

Our studies addressed the linguistic representation of function assignment in an unaided object assembly task. We presented a qualitative analysis of the different components of functional mapping phrases, i.e. relational term, object reference, and assigned functional terminology. Furthermore, we examined the relative frequencies of occurrence in different conditions, highlighting the influence of prior knowledge as well as differences between think-aloud protocols and instructions. The most striking differences were found with regard to the latter, revealing the influence of the speaker's communicative intention on the linguistic representation of function assignment. With respect to the former, lack of information appeared to lead to a more structure-based (rather than part-based) perspective, as expressed by the nouns used to refer to objects.

In our qualitative analysis, we identified three strategies of function assignment that reveal various levels of certainty. In the direct mapping strategy, the relational terms directly connect an object to a functional purpose, typically using the verb 'be', which signals a high level of certainty. Modal verbs (such as must, could) were used to modify the level of certainty by weakening it. In the representational mapping strategy, the relational terms look like, use as, etc. signal that the object is assigned to a goal-object based concept that serves a particular function. Since the relation signals representation rather than 'being', participants signal the tentative character of their assignment by choosing this strategy. In the reframing strategy, which in our study only occurred in instructions, the relational term is replaced by a hesitation marker between the reference to the object and the assigned functional term.

On the whole, participants giving instructions used mapping phrases only rarely. This can be interpreted in two ways. First, it may mean that they focused on the step-bystep procedure of the assembly, rather than attending to the goal structure as such. This explanation is supported by the finding that instructors used part-based terminology more frequently than structure-based references when assigning function. Furthermore, Daniel and Tversky (2012) found that instructors omitted explicit information on object parts and sequential order, but not on sequences of actions, when time was constrained. Second, our instructors may have believed that functional terms would not facilitate object identification, but rather result in additional cognitive load for their addressee (cf. von Stutterheim et al. 1993) because the wooden objects did not resemble their function in the goal structure in any obvious way.

Whenever instructors used mapping phrases, this happened with certainty, as reflected in the linguistic form chosen. This result straightforwardly reflects the fact that participants were already familiar with the dollhouse assembly task when they gave the instructions, and therefore did not need to assign objects to function in a tentative way. However, instructors used representational mapping more often than participants in the assembly study did. This may
be seen as an explicit strategy of emphasizing that function is assigned to an object. The instructors may have considered their addressee's situation, who could only see the wooden objects rather than their function. Explicitly highlighting the mapping process may therefore be felt as a useful supportive strategy.

The most interesting case, in our view, is the third strategy, which was found only in instructions: introducing the functional term after a marker of hesitation (reframing) rather than a relational term. Although this construction may seem accidental due to the hesitation marker, which is by its nature exclusive to spoken language, it was used by as many as 5 out of 12 participants. Arguably, Rieser's (1996:13) example cited above (this Baufix, this Baufix screw) is similarly structured, although no hesitation marker is reported.

What might lead speakers to use this function assignment strategy in instructions? In effect, the previous reference is elaborated by the first. In interactive scenarios, such an elaboration would happen frequently in response to a request for clarification, as described in the literature related to the referential communication paradigm (e.g. Clark \& Wilkes-Gibbs, 1986; Horton \& Gerrig, 2002). However, this cannot explain our observations, since our scenario did not allow any interaction between instructor and assembler. Instead, speakers apparently spontaneously felt the need to be more specific with regard to the function of the object that had just been referred to. Conceivably, the function of this particular object was so prominent in their minds that they directly reframed the sentence. Again, they started from their addressee's perception, leading over to the function of the wooden object. This suggests that the strategy is specific to the communicative goal of shared attention and object identification.

The analysis of the referential form for the physically present object provides further evidence that our participants in the instruction scenario took an addressee-centered perspective. Participants who were thinking aloud while assembling the dollhouse used deictic references more frequently than instructors, who tended to use nominal references instead. These findings highlight the influence of communicative intention on referential form and thereby support the assumption that think-aloud data reflects the speaker's thoughts that are not tailored for an addressee (Ericsson \& Simon, 1984).

A clear effect of prior knowledge emerged with respect to the perspective expressed by the functional term assigned to an object. Participants who had to construct the goal object from scratch, i.e. without prior knowledge, frequently assigned function by reference to the whole structure of the goal object, or larger portions of it, as in house or story. Participants who knew about the goal structure, on the other hand, assigned function mostly to object parts (e.g. 'wall'). This difference suggests that participants who had associations about typical parts of the goal object assigned these functions to the given objects. Participants who needed to construct a mental model of the goal object, on
the other hand, additionally seemed to assign function to the object arrangement as a whole, either to construct the model or to confirm their hypotheses about the goal object. This suggests that instances of function assignment are traces of the mental process of conceptualization of objects within the mental model of the goal object.

The consistency of using direct mapping strategies across conditions in the unaided assembly study showed that participants assigned function with a high amount of certainty in most cases, independent of the amount of prior knowledge. Some differences were observed at the level of certainty expressed by the use of modal verbs. Surprisingly, less knowledge about the goal objects appeared to result in higher certainty as expressed in mapping phrases. Specifically, participants who were provided with no specific prior knowledge or only a verbal clue tended to use mapping phrases frequently, with a preference for direct mapping using the relational term be without modification by modal verbs that signal uncertainty. This may suggest that participants who were shown the picture of the goal object may feel somewhat constrained by their expectation to match the given objects to their memory of the picture. If the provided objects do not match this memory, the matching process may be felt as less certain than in a more flexible situation where the only information given (if any) is the nature of the goal object. The verbal clue would then result in useful associations that are not too specific to constrain the participants' flexibility in assigning function to the wooden object parts.

In this paper we reported findings on explicit function assignment only (i.e., verbalizations directly assigning function to object parts). For this set of results, significant differences could be found only in the comparison of thinkaloud vs. instruction studies, but not between the three think-aloud assembly conditions. Gralla (in prep.) further considered indirect function assignment by investigating all domain-specific nominal references in the think-aloud protocols. With this larger data set, a clear influence of prior knowledge could be observed. Participants who were told about the nature of the goal object used domain specific nouns more frequently than participants in the other conditions did (Gralla, in prep.).

## Conclusion

Our study addressed for the first time how speakers assign function to objects during an explorative unaided object assembly task and in instructions. Results show influences of the situational context on the ways in which this domain mapping is made explicit, on certainty expressed in language, and on the functional term chosen for reference. Those findings encourage more controlled studies to further explore the effects of problem solving conditions on mapping processes of this kind.

# Is Feedforward Learning more Efficient than Feedback Learning in Smart Meters of Electricity Consumption? 

Mona Guath (mona.guath@psyk.uu.se)<br>Department of Psychology, Uppsala University<br>SE-751 42, Uppsala, Sweden<br>Peter Juslin (peter.juslin@psyk.uu.se)<br>Department of Psychology, Uppsala University<br>SE-751 42, Uppsala, Sweden

#### Abstract

The most popular way to improve consumers' control over their electricity cost is by providing frequent and detailed feedback with "in-home displays" (IHD). In this study, we examined alternative ways to train experimental participants to control and optimize their use of electricity by "feedforward" training to map energy consuming behaviors to costs. The participants were trained in one of four experimental conditions, one feedback ("IHD") and three feedforward conditions before they had to control the electricity consumption in a simulated household. Results showed that one of the feedforward conditions produced somewhat higher utility and as good or better satisfaction of a monthly budget than the feedback training condition, despite never receiving any feedback about the monthly cost, but the generalization to a new budget constraint proved to be slightly poorer.

## Introduction

The use of so-called "smart electricity meters" is rapidly becoming common. It has been estimated that within the European Union alone some 51 billion euro is being invested in smart meters (Faruqui, Harris, \& Hledik, 2009). In many countries, household energy consumption is still billed once a month, but smart meters can offer feedback that is detailed and more frequent with so called In Home Displays (IHDs). Intuitively, the latter kind of feedback system seems more beneficial, and, indeed, many early studies suggested energy reductions up to $15 \%$. However, more recent studies point at consumption reductions at $2-4 \%$, few of them being significant (Klopfert \& Wallenborn, 2011). In the present study, we focus at in-home displays (IHDs), which only display the electrical consumption at different time intervals, and, unlike smart meters, they do not have a two-way communication with the central system. In a previous laboratory experiment (Guath, Millroth, Elwin, \& Juslin, 2012), we investigated how feedback about electricity consumption is best presented to electricity consumers in order to control and optimize their use of electricity. To measure a participant's energy efficiency
in an experimentally controlled environment, the participants took on the role of an inhabitant in a simulated household, performing different types of energy consuming behaviors within a given budget (Figure 1). The goal of decreasing electricity consumption is often emphasized, but the participant's task is actually an optimization problem that requires an appropriate balance between the cost of the electricity consumed and the benefit or utility obtained. The problem is illustrated in Figure 2, where the utility of electricity consumption is plotted against cost. The maximum utility obtainable at a given cost, assumed to be a decelerating function of the cost, is illustrated by the curve in Figure 2. The hypothetical utility obtained at a cost by a consumer is illustrated with a dot. The task is to move closer to the line for "maximal utility", however, this is associated with two constraints: achieving sufficient utility to make life bearable and not surpassing a constrained budget.

Guath et al. (2012) showed that in a deterministic system, frequent and detailed feedback was advantageous, but in probabilistic system, feedback aggregated over time was better, because it filtered out random noise.

## The Present Study

In the present study, we wanted to evaluate if the same improvement could be obtained by feedforward training, rather than feedback training (as in most IHDs), hence, minimizing the negative effects from feedback interventions as conceptualized in Kluger and DeNisi's (1996) study. Specifically, we wanted to avoid the decrease of effectiveness when attention is moved away from the task to the self, thus, making the effects of the training short-term. Another motive was to make the mapping task more flexible, not being dependent on the simulated household (Figure 1). Detailed and frequent feedback (an IHD) was compared to three feedforward conditions. Feedforward is defined as a process where knowledge is used to act directly to control the system, thus anticipating the changes that will occur (Basso \& Olivetti Belardinelli, 2006). In the present task, partici-
pants had to control the monthly cost of electrical consumption. Feedback training involved feedback about this criterion variable of daily and monthly cost of electrical consumption from experience with the task (running the simulated household in Figure 1). Feedforward training involved no feedback about the criterion variable (monthly electricity cost), but three different training schemes in various ways teaching the participants to directly map energy consuming behaviors to their costs ("map" refers to the mathematical concept of associating each element in a set with an element of another set, here the electrical cost to a certain electrical post).

Figure 1. The computer display in the simulated household in the experiment.

Figure 2. Illustration of the two ways of obtaining maximum utility at a specific cost (the solid nonlinear function), either by saving or by optimizing the use.

The choice of feedforward conditions was, in part, inspired by Pachur and Olsson's (2012) study of how learning tasks affect performance and strategy selection. They investigated two learning tasks, direct criterion learning and learning by comparison, and how these affected performance depending on the type of test (paired-comparison, classification, estimation) and decision environment (linear vs. non-linear). Pachur and Olsson (2012) concluded that direct criterion learning invites exemplar memory processes (Nosofsky, 1986), while learning by comparison invites processes of cue abstraction. Because our task is non-linear, if anything, exemplar memory should be a more efficient process than the abstract processes involved in cue abstraction,
which are constrained to mainly capture linear and additive tasks (Juslin, Karlsson, \& Olsson, 2008).

Our first feedforward condition, metric mapping (corresponding to direct criterion learning), informed about the function that relates the consumption to its cost, as studied in research on function learning (e.g., Kalish, Lewandowsky \& Kruschke, 2004). When training function concepts, a continuous stimulus variable is associated with a continuous response variable, in this case an electricity post (e.g., inner temperature) with its monthly cost. The metric mapping consisted of learning to map a certain electricity consuming activity (e.g., using hot water $15 \mathrm{~min} /$ day) to its cost (i.e., $262 \mathrm{SEK} / \mathrm{month}$ ).

The second condition was rank-order mapping (corresponding to learning by comparison) as conceptualized in decision by sampling (DbS) (Stewart et al., 2006). In DbS , it is assumed that people do not store metric knowledge in memory but only perform ordinal comparisons. Instead frequency accumulation in pair-wise comparisons are used for evaluating a target attribute against a decision sample. Indeed, the results in Pachur and Olsson (2012) suggested that at least in linear tasks learning by pairwise comparisons was more efficient than training with metric mapping, despite that the pairwise comparisons provide no explicit metric information about the criterion. On the other hand, if people also need to store metric knowledge in our task, then metric mapping should be more efficient. The rankorder evaluations are elicited by questions concerning the relation between two electricity consuming device (e.g., Which of the following has the highest monthly cost: A: Having the lights on for 60 minutes per day or B: Having the computer on for 10 minutes per day?).

The third feedforward condition was causal mapping training, in which the participant is encouraged to experiment with the individual and total monthly cost of the electrical posts in a minimalistic computer program. The causal mapping condition is inspired by the theory of causal nets (Holyoak \& Cheng, 2011) that accounts for how people learn about strength and structure as well as direction of causal relations. In view of this literature, we expected that invitation to manipulate the system in real time and experiment by changing individual variables during training should produce a more accurate (causal) model of relationships in the system.

Given that our decision task is non-linear, where the linear and additive integration afforded by cue abstraction is less appropriate, and the results suggesting that metric mapping invites exemplar memory (Pachur \& Olsson, 2012), performance in the metric mapping condition is expected to be better than in the rank-order and the causal mapping conditions. We also looked at the ability to generalize knowledge to a new budget (from 2000 SEK á month to 1500 SEK á month).

## Method

## Participants

One-hundred-and-twenty-nine students at Uppsala University volunteered to participate and were compensated with a cinema ticket (worth approximately $\$ 10$ ) or by
course credit. The sample consisted of 89 females and 40 males, with mean age 24.5 years ( $S D=4.66$ ).

## Material and Procedure

The experiment consisted of four parts presented in the following order: pre-test, systematic learning, post-test for effects of the systematic learning and post-test for ability to generalize to a new budget. Participants were given written and verbal instructions for each part.

The participant was presented with a sketch of a home on the computer screen indicating various energy consuming appliances, in all 18 posts (Figure 1). The task was to regulate the electricity consumption in the house so that its fictive inhabitant (an avatar called "Peter") received as much utility as possible from the consumption. The avatar was a way to incorporate the two parameters of utility and cost in the task in a comprehensible way. In Pretest and Posttest 1 of all conditions, the participant regulated the energy consumption each day for a period of 30 days with the aim to maximize the utility from the energy consumption within a budget of 2000 Swedish Crowns (SEK), approximately \$300, per month (changed to 1500 SEK in Posttest 2). On each new day, the participant could adjust the indoor temperature, the number of times of use per week for the dishwasher, washing machine, and tumble drier etc. When the settings had been made, they could not be changed for that day. On each day, the previous day's settings were presented as default, but they could be changed by the participant.

The utility of consumption for each appliance was presented by a bar on the right side of the screen. A separate bar for each post increased with the utility of consumption associated with this post, and a global sum in the upper right corner increased with the overall utility of the energy consumption. The utility $u_{\mathrm{i}}\left(t_{\mathrm{ij}}\right)$ obtained by consumption $t_{\mathrm{ij}}$ of post $i(i=1 \ldots 18)$ at level $j$ was,

$$
\begin{equation*}
u_{i}\left(t_{i j}\right)=\sum_{i=1}^{18} w_{i} \cdot\left(t_{i j}^{\alpha_{i}} / r_{i}^{\alpha_{i}}\right) \tag{1}
\end{equation*}
$$

where $w_{\mathrm{i}}$ is the linear weight in the overall summed utility $\left(\Sigma w_{\mathrm{i}}=1\right), r_{\mathrm{i}}$ is a ceiling on the allowable consumption, and $\alpha_{\mathrm{i}}$ is a parameter for the curvature of the utility function for post $i$. Eq. 1 defines utility functions with diminishing marginal return, where the posts differ both in the rate of the diminishing return $\left(\alpha_{\mathrm{i}}\right)$ and in their weight in the total utility $\left(w_{\mathrm{i}}\right)$. The parameters were selected to approximate realistic utility functions.
The total utility $U$ was the sum of the utility of each of the 18 posts,

$$
\begin{equation*}
U=\sum_{i=1}^{18} u_{i}\left(t_{i j}\right) \tag{2}
\end{equation*}
$$

In pretests and posttests, feedback was presented only for utility. Participants were given no feedback regarding the cost of their settings. After the pretest, the participants were assigned to one of four learning conditions.

## Detailed and Frequent Feedback ("IHD")

In the feedback condition, participants continued with 120 days in the simulated household. Furthermore, and
most importantly, they also received feedback about the cost of their consumption. After each day the participants received a bill containing feedback on the cost of energy consumption where the feedback was presented in terms of used kWh and the cost in SEK, as based on a fixed price of 1.40 SEK per kWh. The bill showed the cost for each appliance as well as the total sum for all appliances. This detailed and immediate feedback resembles that of an IHD. If the budget was exceeded, the total cost was red-lighted; if not, it was green-lighted. A normally and independently distributed random error, with standard deviation equal to $5 \%$ of the cost, was added to the cost of each post to simulate probabilism ${ }^{1}$. The total cost $C$ was the sum of the consumption cost $c\left(t_{\mathrm{ij}}\right)$ of the individual posts:

$$
\begin{equation*}
C=\sum_{i=1}^{18} c\left(t_{i j}\right) \tag{3}
\end{equation*}
$$

## Metric mapping

For participants in the metric mapping condition, the task was to learn to map consumption of each electricity post directly to its cost. They were presented with questions such as: "What is the monthly cost for having the computer on for 15 minutes a day?" Intervals of 5, 10, 15,30 and 60 minutes were used to give the participants a broad spectrum of the cost for each appliance. Participants reported their responses for one question at a time and were then given feedback on whether the response was correct or not and, if not, what the correct answer was. The program coded answers within $\pm 20$ percent of the correct answer as correct. A stop criterion was set for three correct responses in one block of five questions (one block involved the cost for $5,10,15,30$ and 60 minutes of use). When the participants achieved the stop criterion for one appliance they continued with the next appliance, until they had gone through all appliances in the house. Electric posts for lighting and hot water (shower and tap water) was lumped together, creating 12 different appliances from the 18 electricity posts in the simulated household. For appliances that were run on a weekly basis, such as the dish washing machine, participants were asked about the cost for number of runs per week.

## Rank-order Mapping

For participants in the rank-order mapping condition the task was to learn which of pairs of electricity consuming activities that is most costly. They answered questions such as "What has the highest monthly cost? A: Having the lights on for 60 minutes per day or B: Having the computer on for 10 minutes per day?" After each guess they were provided with feedback on whether the response was correct or not. The items were sampled from a pool of questions created by crossing the 12 applianc-

[^74]es (as in the direct-mapping condition) by the five time intervals (5, 10, 15, 30, 60 minutes, except for appliances run on a weekly basis). The items were sampled randomly with one constraint: each appliance had to appear at least once during the training session. Each participant received a unique sample. The participants started with 200 items; thereafter, they continued until they answered 19 of the latest 20 questions correctly.

## Causal Mapping

For participants in the causal mapping condition the task was to learn the relationship between consumption and electricity cost by interacting with the appliances on a real time basis, in order to obtain a sense of the cause and effect relationships. Again, the participants trained on 12 appliances with the same time intervals as in the other mapping conditions ( $5,10,15,30,60$ minutes, except for appliances run on a weekly basis). Participants were presented with a program where they could manipulate the usage of appliances on slide bars. Each slide bar had five levels for the time intervals of 5,10 , 15,30 and 60 minutes. Next to each slide bar, the cost of the appliance was indicated. The cost changed simultaneously with the manipulation of the slide bar. Participants could observe the monthly cost for their current settings on the top of the screen, also changing simultaneously with the manipulation of a slide bar. All appliances were presented on the same screen. The order in which the appliances were presented on the screen was randomized for each participant. A time limit of 15 minutes was set, and the participants were told to experiment and learn as much as possible in this time, with the goal to optimize their behavior in the household.

## Posttests

After participants had finished their respective training session, they all continued with another 30 days in the simulated household, similar to the 30 days in the pretest. After that first post-test, the participants continued with another round of 30 days in the simulated household, but this time the budget constraint was set to 1500 SEK instead of 2000 SEK, with the goal of investigating participants' ability to generalize the knowledge they had acquired in the systematic learning conditions.

## Design

The experiment involved a $4 \times 2$ mixed factorial design, with learning condition (detailed and frequent feedback, metric mapping, rank-order mapping, and causal-model mapping) as between-subjects independent variable, and budget constraint ( 2000 and 1500 SEK) as the withinsubjects independent variable. The participants were randomized to one of the between-subjects conditions, resulting in app. 30 participants in each condition. Dependent measures were the cost and utility of the use of electricity, with a particular eye to the maximization of utility within the indicated budget constraints of 2000 SEK and 1500 SEK per month.

## Results

In pretest, there were no significant differences between the conditions and all conditions exceeded the budget of

67 SEK/day. All conditions reduced their median cost from the Pretest to Posttest 1 (Wilcoxon Test, $T=1135$, $Z=7.187, p<.001$ across all four conditions; the same holds separately within each condition, all $p \mathrm{~s}<.005$ ).
In Figure 3, the median utility is plotted against the median cost for Posttest 1. The rank order condition was unable to satisfy the budget. The three conditions satisfying budget performed similarly, although metric mapping produced somewhat more utility than the other two conditions, which both fell below budget, as observed previously with feedback training (Guath et al, 2012).

Figure 3. The median utility obtained across the participants plotted as a function of the median cost in Pretest and Posttest 1 in each of the four training conditions ( $N \approx 30$ ). The vertical line represents the budget, while the curve is the maximum utility obtainable as a function of the cost.

There was a significant difference between the conditions in the median cost at Posttest 1 (Kruskal-Wallis test: $H(3, N=129)=18.607 p=.003)$, where pairwise multiple-comparisons indicate a significant difference between rank-order mapping and feedback training ( $p<.001$ ) and between rank-order and causal mapping ( $p$ $=.005)^{2}$. In both cases, rank order mapping has a significantly higher cost. There was also a significant difference between the conditions in median utility at Posttest 1 (Kruskal-Wallis test: $H(3, N=129)=12.557 p=.006)$, where pairwise multiple-comparisons indicate a significant difference between rank-order mapping and feedback training ( $p=.019$ ) and between rank-order mapping and causal mapping ( $p=.009$ ). In both cases, rank-order mapping has a significantly higher utility. The main differences is between the rank-order condition and the other conditions, with small differences between the other conditions, albeit with a slight hedge for metric mapping that comes closest to optimal performance (i.e., where the lines in Figure 3 intersect).

Figure 4 reports a more strict analysis only including those participants that roughly satisfied the budget (i.e.,

[^75]fell within $\pm 5$ units of 67 SEK/day). While app. 50 \% of the participants were able to satisfy the budget with feedback training and metric mapping only a minority of participants were able to satisfy the budget with causal mapping and rank order mapping ( $27 \%$ and $12 \%$, respectively). Among the only two conditions with many participants satisfying the budget, metric mapping produced significantly more utility than feedback training (Mann Whitney: $U=75, Z=2.179, p=.029$ ). Thus, if anything, metric mapping appears to produce somewhat better performance than feedback training in Posttest 1.

Figure 4. The median utility across the participants plotted as a function of the median cost in Posttest 1 in each of the four training conditions for the participants able to (app.) satisfy the budget (cost between 62 and 72 SEK/day). The vertical line represents the budget, while the curve is the maximum utility obtainable as a function of the cost. The percentages in parenthesis refer to the proportion of participants in each condition that satisfied the budget constraint.

All training conditions reduced their cost from Posttest 1 to Posttest 2 (new budget) (Wilcoxon test: all $p$ s $<$ .001), and reduced their utility (Wilcoxon test: all $p \mathrm{~s}<$ .001). As shown in Figure 5, in all conditions the median cost exceeded the budget, especially in the rank order condition. There is again modest difference between the other three conditions, although metric mapping exceeds the budget more than the other conditions.

There was a significant difference between the conditions in median cost at Posttest 2 (Kruskal-Wallis test: $H(3, N=129)=17.606 p<.001)$, where pairwise multi-ple-comparisons indicate significant differences between rank-order mapping and feedback training ( $p<$ .001), between rank-order and causal mapping ( $p=$ .033), and between feedback training and metric mapping ( $p=.045$ ). There was also a significant difference between the conditions in median utility at Posttest 2 (Kruskal-Wallis test: $H(3, N=129)=11.800 p=.008)$, where pairwise multiple-comparisons indicate a significant difference only between rank-order mapping and feedback training ( $p=.011$ ). The differences between rank order and metric mapping ( $p=.061$ ) and between rank order and causal mapping ( $p=.050$ ), however, ap-
proach significance. Rank order mapping produced a higher utility (but exceeds the budget). The rank-order condition thus provides the poorest performance, while, among the other three conditions, metric mapping seems to suffer most going from Posttest 1 to Posttest 2.

Figure 5. The median utility across participants plotted as a function of the median cost in Posttest 2 (new budget) in each of the four training conditions $(N \approx 30)$. The vertical line represents the budget, while the curve is the maximum utility obtainable as a function of the cost.

Figure 6. The median utility across the participants plotted as a function of the median cost in Posttest 2 (new budget), in each of the four training conditions for participants that were app. able to satisfy the budget (cost between 45 and 55 SEK a day). The vertical line represents the budget, while the curve is the maximum utility obtainable as a function of the cost. The percentages in parenthesis refer to the proportion of participants in each condition that satisfied the budget constraint.

Figure 6 shows the results of a stricter analysis only including participants with a cost falling within $\pm 5$ units of the budget ( $50 \mathrm{SEK} /$ day). This figure also illustrates that metric mapping training suffered more in the generalization test, with only $22 \%$ of the participants satisfy-
ing the new budget, in contrast to $41 \%$ with feedback and $45 \%$ with causal mapping training. In sum: the rank order condition again produced poor performance, while feedback training and causal mapping appear to allow better generalization of the knowledge obtained to satisfy also a new budget, as compared to metric mapping.

## Discussion

The results indicate that at an immediate test of performance direct mapping training is as good as or better than the detailed and frequent feedback in a typical "smart-meter". It should be noted that the performance of the participants in the direct mapping condition is quite impressive, with a cost virtually exactly on the budget and higher utility, despite never receiving any feedback about the total monthly cost in the house. An objection, of course, could be that these participants did not really learn anything from the metric mapping training, they just happened to be right because their prior conceptions about electricity consumption happened to be correct in regard to the simulated household (which is intended to be "realistic"). That all training groups changed their behavior significantly from the pretest to the posttest to accommodate the budget speaks against this explanation. Participants clearly learned to satisfy the monthly budget from metric mapping training, despite that they never received any feedback about it.

The good performance with metric mapping is in line with the results in Pachur and Olsson (2012), where the participants with direct criterion learning performed better than learning by comparison in a non-linear context due to the exemplar strategy. In the context of their interpretation, this suggests that our participants relied on exemplar memory rather than cue abstraction. An obvious question, in that case, is how people generate exemplar representations of the complex stimuli used in our experiment. On plausible possibility, perhaps, is that they rely on "exemplars" in the form of partial configurations of electricity consumption that were associated with very successful (or unsuccessful) performance.

When generalizing to another budget, the feedback group performs somewhat better than the metric mapping group. This result was unexpected and we can only speculate as to what explains this difference. One possibility is that participants with metric mapping relied on a more exemplar-based strategy, which is known to offer less flexible generalization than the more analytic knowledge of cue-criterion relations. Another possible explanation could be the testing effect (Roediger \& Karpicke, 2006). Tests enhance retention more than additional study of the material, even when tests are given without feedback. In that perspective, the feedback training could be seen as a first test, and the post tests as yet another tests. Another interpretation could be that feedback training and causal mapping provided the participants with better knowledge of the underlying causes, that in turn, facilitated the generalization task.

In this task we found no evidence that people are especially apt at learning rank orders from pairwise comparison (Stewart et al., 2006), considering that the rank
order condition allowed few participants to satisfy the budget. In Posttest 1, only 27\% of the participants satisfied the budget criterion (and only $9 \%$ in Posttest 2). It might be the case that metric information is more crucial in the cost-benefit optimization task in our experiment.

To further investigate feedforward training, future experiments will explore the flexibility with which metric mapping and feedback training can adapt to new budgets and compare mapping involving different metrics (e.g., metrics instead referring to negative environmental effects). Also, it would be interesting to investigate the testing effect, and how it pertains to this context.

The results reported in this study opens for the possibility that shorter and cheaper feedforward training, for example, involving a 15 -minute session with a computer program, can be a cost effective alternative to the large scale implementation of complex information technology to monitor consumption and cost in real time.

# Fairness overrides reputation: The importance of fairness considerations in altruistic cooperation 

Şule Güney (s.guney@unsw.edu.au)<br>School of Psychology, University of New South Wales<br>Sydney, Australia<br>Ben R. Newell (ben.newell@unsw.edu.au)<br>School of Psychology, University of New South Wales<br>Sydney, Australia

#### Abstract

Behavioural findings in several strategic games indicate that people punish others if they think they are being treated 'unfairly' even at the cost of minimizing their own material payoff. We investigated the primary driving force behind such altruistic cooperation. In Experiment 1, we replicated previous findings indicating that the key mechanism contributing to the emergence of altruistic cooperation is fairness considerations. In Experiment 2, we investigated the effect of the opportunity for reputation building and future interaction on altruistic cooperation and found that these factors become effective only when fairness considerations are removed.

Keywords: altruistic cooperation; mini ultimatum game, fairness, reputation building, future interaction.

## Introduction

Human altruistic cooperation presents a puzzle from the perspectives of both the standard economic models of the 'self-interested actor' and the evolutionary models of the 'self-regarding individual' because it involves some characteristics that are difficult to reconcile with the predictions of standard game theoretical and evolutionary analyses. In particular, these characteristics are rewarding the cooperators (i.e., altruistic rewarding) and punishing the norm violators (i.e., altruistic punishment), at a personal cost, even though the probability that this cost will be repaid (either by third parties or by that specific agent in the future) is very low (Gintis et al., 2003).

Evidence for the existence of altruistic cooperation largely comes from laboratory experiments in which the respective behavioral pattern has been observed through economic games. One of the best-known economic games used to demonstrate altruistic cooperation (especially, altruistic punishment) is the Ultimatum Game (UG) (Güth, Schmittberger, \& Schwarze, 1982), in which two players are presented with a sum of money, and one of them is assigned to the role of Proposer while the other one to the Responder. The Proposer is asked to offer any portion of the given money to the Responder. If the Responder accepts the amount offered by the Proposer, the money is distributed in accordance with the proposal. If the Responder rejects the offer, both get nothing. According to standard economic theory of self-interest, a rational Proposer offers the minimum possible amount, and a rational Responder never rejects any amount unless it is zero (Binmore, 2007). The
underlying assumption in this prediction is that both parties care only about how much money they get. However, the vast majority of experimental studies has shown that the modal offers by the Proposers lie between $40 \%-50 \%$ of the total amount and the Responders frequently reject offers below 25\% (Güth et al., 1982; Roth, 1995; Henrich et al., 2005). This pattern of results has been replicated crossculturally (Henrich et al., 2005) and shown to be robust with large stakes (Cameron, 1999). The experiments reported here aimed to investigate the role of several factors (i.e., fairness considerations vs. perceived opportunity of reputation building and future interaction) that might contribute to the emergence of altruistic cooperation in experimental contexts.

## Altruistic cooperation as a function of fairness considerations

Some researchers argue that the underlying mechanism of such non self-regarding behaviors (i.e., high offers by the Proposers and frequent rejections by the Responders) in the UG is not to get as much money as possible, but to maintain fairness norms among players (Gintis et al., 2003; Fehr \& Gachter, 2002). In fact, the motivation behind the Proposers' high offers can be explained with or without the involvement of fairness considerations: They simply may not want to offer an amount that can be easily turned down by the Responder, so they are willing to distribute the money in a relatively fair way. Thus the Proposers' main concern still might be getting as much as possible in the end, rather than treating the Responders fairly (Declerck et al., 2009). However, for Responders, the role of fairness concerns is more apparent and must be stronger because they seem to accept ending up with nothing rather than being treated unfairly. Even though the Responders could have been better off by accepting any amount offered, they prefer to punish the Proposer' unfairness, at a cost to themselves. This pattern of response indicates that the Responders engage in altruistic punishment in response to the unfairness of the Proposer.
A special version of UG has been used to demonstrate how much the Responders care about unfair acts of the Proposers. The structure of the so-called Mini UG (see Table 1) is the same as the standard UG, with an exception: The Proposer is again asked to distribute an amount of money but unlike the standard UG, only in one of two ways.

Table 1. General structure of Mini Ultimatum Games.

| Mini Ultimatum Games* |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | (5/5) Game |  | (2/8) Game |  | (10/0) Game |  | (8/2) Game |  |
| Possible distributions | (8/2) | (5/5) | (8/2) | (2/8) | (8/2) | (10/0) | (8/2) | (8/2) |
| Perceived fairness of the (8/2) distribution |  | Unfair | Reason | nfair ** |  |  |  |  |

* The numbers in the parentheses denote how much the Proposer could get/how much the Responder could get.
** The Proposer seems to have an excuse for offering the more inequitable distribution (8/2), because otherwise he would be unfair to himself [i.e., by offering the (2/8) distribution, he would give 8 to the Responder, and take 2 himself].

Both players participate in four consecutive Mini UGs, and throughout all these games one way of distribution is always fixed while the alternative distribution is always different across games. The fixed distribution is a relatively inequitable one (i.e., the Proposer can take $\$ 8$ for himself, and offer $\$ 2$ to the Responder, see table 1 ).
However, the available alternative distribution varies in terms of the outcome fairness, sometimes yielding a more equitable outcome (i.e., the Proposer can take $\$ 5$ for himself, and offer $\$ 5$ to the Responder, see table 1), and sometimes yielding an even more unequal outcome (i.e., the Proposer can take $\$ 10$ for himself, and offer $\$ 0$ to the Responder, see table 1). Under the standard assumptions, rejection rates for the fixed distribution (8/2) were expected to be the same regardless of its alternatives, as its monetary value stays unchanged across games (Falk et al., 2003). However, this particular distribution was rejected much more frequently when the Proposer intentionally ignored the more equitable alternative distribution [i.e., the (5/5) distribution] than when he ignored the more unequal alternative distribution [i.e., the (10/0) distribution] (Falk et al., 2003; Sutter, 2007). Thus the rejection decisions made by the Responders seem not to be determined by the absolute amount of the offer (i.e., $\$ 2$ ), but by whether the offer is seen as relatively unfair [i.e., in comparison to (5/5) split] or fair [i.e., in comparison to ( $10 / 0$ ) split]. See table 1 for the perceived fairness of the fixed distribution (8/2) across four games.

These findings indicate that the Responders punish the unfairness of the Proposers by rejecting an amount of money in one case and appreciate the fairness of the Proposer by accepting the very same amount in another case. It has been argued therefore that fairness considerations must be the underlying motive behind altruistic cooperation (Gintis et al., 2003; Fehr \& Gachter, 2002).

## Altruistic cooperation as a function of misperceived opportunity of reputation building and future interaction

Although the importance of fairness considerations in such bargaining games has been widely accepted, the real reasons for altruistic cooperation (i.e., the Responders'
rejection/acceptance behaviors in the UG) have been a source of much debate (Declerck et al., 2009). As mentioned earlier, by rejecting a non-zero offer, the Responders seem to engage in actions that are opposite to their self-interest, in order to maintain the fairness norms between parties. Thus fairness considerations seem to override the self-regarding/rational motives. Confidence in such a conclusion mainly comes from the two critical features of the above-mentioned experiments: The identities of both players are kept hidden (i.e., anonymous) and they will never meet again in another round (i.e., one-shot encounter). These specific features, therefore, eliminate the possibility of reputation building (henceforth, RB) and future interaction (henceforth, FI) as potential sources of this seemingly fairness-driven behavior (Fehr \& Fischbacher, 2003). Any involvement of the possibility of RB and FI would be especially critical in this context because the altruistic behavior obtained in these experiments then could be explained within the boundaries of self-regarding motives: It is rational and adaptive to reject unfair offers if the possibility of re-encountering the same game partner in the future is high enough or if the possibility of building a reputation among other players is at stake. The underlying reason for this claim is that rejecting unfair offers protects the player from being offered with unequal distributions by the same game partner in the future or by third parties, and thus this behavior serves the player's self interest (Burnham \& Johnson, 2005; Hagen \& Hammerstein, 2006).

This argument goes further in the direction that people engage in altruistic cooperation in one-shot and anonymous encounters simply because they confuse the experimental settings with the more familiar environments where interactions are normally repeated and non-anonymous (Burnham \& Johnson, 2005). In fact, the participants might still be responding to implicit cues suggesting that future interaction is possible or that their reputation is at stake. One finding that supports this interpretation is that the presence of eyespots on the computer desktop, which triggers the sense that participants are being watched, leads to increased generosity in another money allocation game (Haley \& Fessler, 2005). Some other studies suggest that even the
perception of being involved in a situation where future interaction and reputation building is possible triggers altruistic cooperation in one-shot, and anonymously played economic games (Kiyanori et al., 2000). Thus behaving in an altruistically cooperative manner in the UGs might not solely result from the concern for the maintenance of fairness norms, but from the misperceived opportunity of reputation building and future interaction (Haley \& Fessler, 2005; Bateson, Nettle, \& Roberts, 2006).

## Present Experiments

Previous studies have already established that the (8/2) distribution is rejected at different levels depending on whether the alternative distributions are perceived as fair or not (i.e., highest rejections observed when the alternative was more equitable). However their findings diverge in terms of rejection rates of the $(8 / 2)$ distribution when the alternative distribution was more inequitable. More specifically, $9 \%$ of the Responders rejected the (8/2) distribution in the (10/0) game in Falk et al.'s (2003) study whereas almost $28 \%$ rejected in Sutter's (2007) study. Considering these differences in previous findings, we found it necessary to re-establish the basic phenomenon observed in the Mini UG (presented in Table 1) in our own subject pool, in Experiment 1.

In Experiment 2, we aimed to understand the combined effect of the real possibility of RB and FI in the Mini $\mathrm{UG}^{1}$. If the real reason behind the rejections in one-shot and anonymously played games is the misperceived possibility of RB and FI (and thus for maximizing the material pay-off, for the maintenance of fairness norms), then an increase in the level of altruistic cooperation should be expected when the actual possibility is added to the context. Although such an additional effect of possibility of RB and FI has not been investigated in the Mini UG, there are two main reasons for expecting such an increase. First, the importance given to equality is expected to be elevated (Rottemberg, 2008) because the fairness norm (i.e., distributing the allocated money evenly) is strengthened in presence of the possibility of RB and FI (Hertel et al., 2002). Second and more importantly, the sanctions inflicted upon the unfairness of a game partner through altruistic cooperation might be considered as an effective tool for maximizing future gains (Kiyanori et al., 2000). In addition, there were two main reasons for using the Mini UG, instead of the standard UG: First, its structure would allow us to see how the possibility of RB and FI, along with the fairness concerns, would contribute to the Responders' rejections especially when altruistic punishment (i.e., when the alternative offer yielded a more equitable distribution) is

[^76]expected to take place. Second, in the Mini UG, there is one special game [the ( $8 / 2$ ) game, see table 1] in which the Proposer has no choice, but to offer the fixed amount. This particular case would enable us to detect the sole effect of the possibility of RB and FI on the Responders' decisions when an unequal distribution was offered without any (un)fair intentions of the Proposer involved.

## Experiment 1

We expected the rejection rate of the $(8 / 2)$ distribution to be different across different Mini UGs. More specifically, the highest rejection rate expected to be in the $(5 / 5)$ game. In addition we expected to find statistically significant differences between the rejection rates of the $(8 / 2)$ distribution in the $(5 / 5)$ and the $(10 / 0)$ games.

## Method

Participants: Fifty first year psychology students ( M age $=$ 19.5, 36 female) at UNSW participated in the experiment as a part of their course requirement, and were informed that they would be paid, contingent on the outcome of their choices.
Procedure: There were 10 experimental sessions in total, and 5 participants were tested at a time in each experimental session. Participants were seated in separate rooms and their identities were kept hidden throughout the whole experiment. All participants played the Mini UG as the Responders since our main interest was to see whether we would be able to replicate the choice pattern of the Responders obtained in previous studies (i.e., Falk et al., 2003). However, each participant was told that only one participant in each group of 5 would be assigned to the Responder role and that the rest would be playing as Proposers. This procedure made them believe that the offer in each game would come from an actual but different participant (Proposer) rather than from the computer. The offers made by the computer mimicked the actual rate of proposals offered by real Proposers in the study of Falk et al. (2003). For instance, in that study, the (8/2) distribution was offered by $31 \%$ of the Proposers in the $(5 / 5)$ game, and $73 \%$ in the $(2 / 8)$ game. Thus the Responders in Experiment 1 were offered (8/2) distribution with the probability of .31 in the $(5 / 5)$ game, and that of .73 in the $(2 / 8)$ game. The participants played the games for real money, but currency was defined as Monetary Unit (MU), where 1 MU was equal to 0.5 AUD. The experiment was conducted and run with the Runtime Revolution Software.
Design: The Responders participated in all four Mini UGs presented in Table 1. They were asked to indicate their acceptance/rejection decisions for each of the two possible distributions in each game before hearing the actual distribution offered [i.e., the strategy method was used, see Falk et al., (2003) for further information regarding this method]. For example, in the (10/0) game, the Responders were asked whether they would accept or reject if the Proposer offered them the (10/0) distribution

Table 2. Rejection rates of (8/2) distribution across games in Experiment 1 and 2.

|  | Rejection rates of $(8 / 2)$ distribution |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
|  | $(5 / 5)$ Game | $(2 / 8)$ Game | $(10 / 0)$ Game | $(8 / 2)$ Game |
| Experiment 1 | $60 \%$ | $42 \%$ | $18 \%$ | $14 \%$ |
| Experiment 2* | $52 \%$ | $41 \%$ | $18 \%$ | $50 \%$ |

* Rejection rates reported for Experiment 2 were averaged across rounds.
instead of $(8 / 2)$; and they were subsequently asked whether they would accept or reject if the Proposer offered the $(8 / 2)$ distribution instead of $(10 / 0)$. If the game was ( $8 / 2$ ), they were simply asked what they would do if the Proposer had no choice but to offer the $(8 / 2)$ distribution. Once the Responders indicated their rejection/acceptance decision for each possible distribution, they simply moved on to the next game. After the completion of all four games, the Responders were informed about the overall outcomes and debriefed about the real set-up of the experiment (i.e., the offers were not made by actual proposers). The presentation order of the Mini UGs and that of the possible distributions in each game were randomized.

## Results

Table 2 (top row) shows the rejection rates of (8/2) distribution in different games. The main pattern observed in the previous studies (i.e., Falk et al., 2003; Sutter, 2007) was replicated. To test the overall rejection rate differences across four games, we ran Cochran's Q test. The test confirmed that the rejection rates of the $(8 / 2)$ distribution were significantly different across four games ( $\mathrm{p}<.0001$ ). The rejection rate of the $(8 / 2)$ distribution in the $(5 / 5)$ game was the highest among four games. McNemar change tests were performed for the pairwise comparisons and it showed that the rejection rate in the $(5 / 5)$ game was significantly higher than that of the (10/0) ( $\mathrm{p}<.0001)^{2}$. These results confirmed the previous findings that the rejections to an (unfair) offer were indeed not determined by the absolute amount of money, but by how fair or unfair that offer was perceived in comparison to the other available offers.

## Experiment 2

In order to test the effect of the possibility of RB and FI we changed the structure of the Mini UG from being oneshot and anonymously played to being iterated and nonanonymously played. We predicted that the rejection rates of the $(8 / 2)$ distribution in the Mini UG should be (i) even higher when its alternative was the $(5 / 5)$ distribution

[^77]because it is adaptive to build the reputation that one is a tough bargainer who rejects unfair offers, and (ii) even lower when its alternative was the $(10 / 0)$ distribution because it is adaptive to give the message for future interactions that one is capable to discern and will reward fair intentions.

## Method

Participants: Ninety-six first year psychology students (M age $=19.63$, 62 female) at UNSW participated in the experiment as a part of their course requirement and were informed that they would be paid depending on the outcome of their choices. Four participants were tested in each experimental session and there were 24 sessions in total.

Instructions phase: First, the participants were randomly allocated to their roles, (with 2 being Proposers, and the other 2 being Responders) and warned against revealing their allocated roles to the others. Individual players were then given detailed verbal instructions (along with a written instructions document) regarding the general structure of the game play, what their roles required them to do, and what the consequences of their accept/reject decisions would be. They were specifically informed that they would play the game for more than one round with the same partner, and that their decision would be announced to other players before they switched their partners. However, the players were not given any information about how many rounds they would play in total (i.e., in order to make the 'shadow of the future' long enough), when exactly they would switch partners (i.e., in order to make the possibility of RB stronger). In order to eliminate a potential wealth effect, the participants were told that the overall amount that they would receive would be determined by a coin flip at the end of the experiment. If the coin toss came up heads, then they would get paid the amount that they earned in the first half of the experiment, and if tails, the amount earned in the second half. Afterwards, the instructions documents were collected, and the players were taken to the separate rooms to complete a short quiz measuring whether all the instructions were understood clearly.

Design: Each experimental session consisted of 4 consecutive rounds and in each round the participants played a different Mini UG game [i.e., the (5/5) game in Round 1, the (8/2) game in Round 2 and so on. Note that the allocation of the games into particular rounds was randomized]. Each player was matched with his/her first game partner (i.e., Proposer 1 with Responder 1) before

Round 1 and played two consecutive rounds (e.g., Round 1 and Round 2) with the same partner. After the completion of Round 2, they switched their partners (i.e., Proposer 1 started playing with Responder 2) and played the following 2 rounds (Round 3 and Round 4) with their new partners. At the end of each round, decisions of both players (and the resulting outcomes) were announced to the players. These announcements were done privately (i.e., only between the pairs) after Round 1 and after Round 3; but publicly (i.e., to all players) after Round 2 and Round 4. For example, the decisions of Responder 1 and Proposer 1 were announced only to these two players after they completed Round 1, but their overall decisions in Round 1 and Round 2 were announced to all players just before they switched their partners.

Game play: In all Mini UGs, the Proposer was asked to choose one of the two available distributions (see Table 1). Simultaneously the Responder, without knowing what the Proposer actually had chosen to offer, was asked to indicate his/her acceptance/rejection decisions for each of the two possible distributions. (If the Responder had accepted the offer that the Proposer had actually chosen, the amount was distributed in accordance with the proposal. Otherwise, both got nothing). Both players were informed about the outcome right after the game was over, and then they moved on to the next game. The currency in the experiment was defined in Monetary Units (MU), where 1 MU equals . 5 AUD. The experiment conducted and run with z-Tree (Fischbacher, 2007). After the game play was over, both players received a questionnaire. The Proposers were asked to indicate why they offered the amount they offered and the Responders were asked why they rejected/accepted the (8/2) distribution.

## Results

All participants passed the quiz distributed before the game play, thus all responses were included in the analysis. Table 2 (the bottom row) presents the overall rejection rates of the $(8 / 2)$ distribution in different games. The highest rejection rate was obtained in the $(5 / 5)$ game and the lowest in the (10/0) game. These rejection rates of the (8/2) distribution were significantly different across four groups ( $\mathrm{p}=.0011$, Cochran's Q test). Interestingly, half of the participants rejected the $(8 / 2)$ distribution in the $(8 / 2)$ game. McNemar change tests indicated that the rejection rate in the $(5 / 5)$ game was significantly higher than that in the $(10 / 0)$ game, $p=.0006$ but not than those in the $(2 / 8)$ and the $(8 / 2)$ games, $p=.30$, and $\mathrm{p}=.83$, respectively ${ }^{3}$.

A cross-experimental comparison demonstrated that the rejection rates of the $(8 / 2)$ distribution between Experiment 1 and Experiment 2 did not significantly differ in the $(5 / 5)$ games $\left[\chi^{2}(1, \mathrm{~N}=98)=.62, \mathrm{p}=.43\right]$, the $(2 / 8)$ games $\left[\chi^{2}(1, \mathrm{~N}=98)=.00, \mathrm{p}=.97\right]$, and the $(10 / 0)$ games $\left[\chi^{2}(1, \mathrm{~N}=98)=.01, \mathrm{p}=.92\right]$. Contrary to our expectations, the rejection rates of the (8/2) distribution did not increase when the alternative distribution was
(5/5), and did not decrease when the alternative distribution was ( $10 / 0$ ). However, the ( $8 / 2$ ) distribution was rejected in the $(8 / 2)$ game much more frequently in Experiment 2 than Experiment 1, $\chi^{2}(1, \mathrm{~N}=98)=13.12, \mathrm{p}=$ .0003 . To explore the pattern of results obtained in the (8/2) game in detail, we examined round by round rejection rates. The rejection rates of the (8/2) distribution were especially high in Round 1 and Round 3 in which the first encounters with the game partners took place (see Figure 1). Possible reasons for this special pattern are addressed in the General Discussion section.

Figure 1. Rejection rates of (8/2) distribution in the $(8 / 2)$ game across rounds.

## General Discussion

In Experiment 1, we (re)established the phenomenon that people (negatively) respond to intentional unfairness in a Mini UG at a cost to their own material payoff. Contrary to our predictions, results of Experiment 2 indicated that the additional effect of possibility of RB and FI did not lead to an increase in altruistic cooperation [i.e., rejection rates of the $(8 / 2)$ distribution did not change especially when the Responders were expected to punish unfair offers (i.e., the $5 / 5$ game) or to reward fair offers (i.e., the 10/0 game)]. Two potential but competing explanations could be made. One possibility is that the possibility of RB and FI is indeed (mis)perceived in one-shot and anonymously played games, and thus did not lead to any differences in the pattern of responses when it was explicitly incorporated into the context (Haley \& Fessler, 2005; Bateson, Nettle, \& Roberts, 2006). The other possibility is that the explicit incorporation of the possibility of RB and FI did not have any additional effect on the responses in the presence of the influence of fairness considerations (that are already effective enough to determine the rates of rejection).

Unexpectedly high rejection rates observed in the (8/2) game in Experiment 2 provide supporting evidence for the latter explanation. The possibility of RB and FI changed the responses only in a particular game where the intention of the Proposer was not assessable (the $8 / 2$ game), but not in the other games in which the intentions were assessable (i.e., the $5 / 5$, the $10 / 0$, and the $2 / 8$ games). This pattern of results supports the governing role of fairness considerations in two ways. First, rejection rates of the ( $8 / 2$ ) distribution may have already reached a maximum level in the $(5 / 5)$ game or a minimum in the (10/0) game even in one-shot and anonymously played

Mini UG just as a result of the perceived fairness of the distribution. Thus there was no room for an additional effect induced by the possibility of RB and FI. This is an indication of how dominant the fairness concerns are in determining the level of altruistic cooperation.

Second, finding no evidence for pronounced levels of altruistic cooperation in respective games [i.e., the (5/5), $(2 / 8)$ and $(10 / 0)$ games] might be an indication of the effect of RB and FI being too weak to overcome the effect of fairness considerations. The Responders might only be taking the perceived intentions of the Proposers into consideration as a determinant of their accept/reject decisions for an unequal offer, and thus might not need to have additional reasons/concerns to change those decisions even when RB and FI are possible. However, once the fairness consideration is weakened as a result of the removal of the possible intentions behind an offer in the (8/2) game, the effect of RB and FI becomes effective in changing their responses/concerns: It makes the Responders (negatively) react against the unfairness of the outcome of the (8/2) distribution, most likely, in order to increase the possibility of being treated fairly in the future (Hertel et al., 2002; Kiyonari et al., 2000). The round-wise analysis of the (8/2) game (see Figure 1) confirmed that the increase in rejections (in response to unfair distribution) was indeed resulting from the effect of the possibility of RB and FI. Round 1 and Round 3, in which the highest rejections were observed, were particularly important for the Responders to convey their message for the future encounters. The implicit message given under such condition could be that they don't like to be offered an unequal distribution. The Responders' selfreports collected after the game play also indicate that the main purpose of the rejections in this game was indeed to tell the Proposers that 'I will reject again if you ever propose such an unequal distribution'.

The current set of studies explicitly reveals the importance of fairness considerations in determining the level of altruistic cooperation, especially in the presence of other dominant factors such as the possibility of RB and FI. Demonstrating that these other factors may become effective only in the absence of an important aspect of the fairness concerns [i.e., (un)fairness of intentions] provides a new avenue for the investigation of economic behavior in interactive environments.

# A Probabilistic Constraint Satisfaction Model of Information Distortion in Diagnostic Reasoning 

York Hagmayer (york.hagmayer@kcl.ac.uk)<br>Olga Kostopoulou (olga.kostopoulou@kcl.ac.uk)<br>Department Primary Care and Public Health Sciences, King’s College London<br>42 Weston Street, London, SE1 3QD

#### Abstract

Information distortion is a cognitive bias in sequential diagnostic reasoning. Assumptions about the diagnostic validity of later evidence are distorted in favor of the leading hypothesis. Therefore the bias contributes to a primacy effect. Current parallel constraint satisfaction models account for order effects and coherence shifts, but do not explain information distortion. As an alternative a new, probabilistic constraint satisfaction model is proposed, which considers uncertainty about diagnostic validity by defining probability distributions over coherence relations. Simulations based on the new model show that by shifting distributions in favor of the leading hypothesis an increase in coherence can be achieved. Thus the model is able to explain information distortion by assuming a need for coherence. It also accounts for a number of other recent findings on clinical diagnostic reasoning. Alternative models and necessary future research are discussed.

Keywords: Diagnostic reasoning; information distortion; parallel constraint satisfaction model.

## Information Distortion in Diagnostic Reasoning

Diagnostic reasoning is an important cognitive activity in many areas. Based on available evidence decision makers infer hidden properties or diagnoses that account for the observations made. Diagnostic reasoning is maybe most important in the clinical domain. Making accurate diagnoses is essential for physicians. Unfortunately clinical diagnostic reasoning is affected by many biases, which may result in medical error (Croskerry, 2003; Kostopoulou et al., 2008). One of these biases is information distortion. When deriving a diagnosis clinicians have been shown to bias their interpretation of newly arriving evidence to support their preferred hypothesis (Kostopoulou, Russo, Keenan, Delaney \& Douri, 2012). More precisely, clinicians alter their assumptions about the diagnostic validity of observed signs and symptoms (i.e., the likelihood of the diagnosis given the sign) so that they lend greater support to the favored diagnostic hypothesis. Similar findings on pre-decisional distortion of evidence have been reported for other professions like sales (Russo et al., 2006). Information distortion has been explained by a need for coherence (Russo, Medvec, \& Meloy, 1996). By interpreting new evidence as supportive of the leading hypothesis decision makers increase the coherence among the favored diagnostic hypothesis and the evidence. Consistency theories in turn account for the need for coherence (cf. Simon et al., 2004).

Parallel constraint satisfaction models, especially Thagard's (1989) ECHO model, have been used to implement coherence-based accounts of diagnostic reasoning (e.g., Gloeckner, Betsch \& Schindler, 2009). These models were extended to sequentially arriving evidence, which affords frequent updating of diagnostic hypotheses (Mehlhorn, Taatgen, Lebiere, \& Krems, 2011; Wang, Johnson, \& Zhang, 2006). Although these models can account for biased decision making, they cannot fully explain information distortion. Constraint satisfaction models in general assume that coherence relations among evidence and hypotheses, which represent assumptions about diagnostic validity, are stable. Research on information distortion, however, shows that decision makers are uncertain about these relations and may change respective beliefs during decision making (Kostopoulou et al., 2012; Russo et al., 1996; 2006). To account for these findings we will put forward a new, probabilistic constraint satisfaction model.

In the paper, we will first briefly describe a recent study on information distortion to exemplify methods and findings. Then we outline a standard constraint satisfaction model of sequential diagnostic reasoning and discuss its shortcomings. Next we propose a new, probabilistic constraint satisfaction model. Results from a simulation study will show that the model predicts information distortion and other findings from the literature. Finally, alternative models will be discussed and necessary future research will be pointed out.

## Exemplary Empirical Findings

Kostopoulou and colleagues (2012) recently published a study on information distortion in the clinical domain. Physicians were confronted with case vignettes presenting diagnostic evidence and asked to evaluate two competing diagnostic hypotheses A and B. Evidence was presented sequentially in a particular order. The first set of cues strongly favored Hypothesis A over B, the next set of cues equally supported both hypotheses, while the third set strongly favored Hypothesis B over A. Overall the evidence was ambiguous. Participating clinicians were asked to make two judgments after each new item: (i) to rate how much this particular item favors either hypothesis (i.e., the item's differential diagnostic validity), and (ii) to rate the likelihood of the diagnoses given all information received so far. Both ratings were made on a scale ranging from one hypothesis to the other. In addition, a control group of
physicians rated each item individually. Information distortion was calculated by computing the difference between individual cue ratings and mean control ratings. From a normative perspective, no information distortion should be expected as the diagnostic validity of individual cues should be constant. Hence, any changes in assumptions about diagnostic validity, which create additional support for the favored hypothesis, constitute a bias.

Three findings are important for the purpose of this paper (see Kostopoulou et al., 2012, for complete results). First, there was a substantial variation between clinicians with respect to the assumed diagnostic validity of cues, which indicates that clinicians were uncertain about how much each piece of evidence supported the hypotheses. Second, participants exaggerated or reduced the diagnostic validity of individual items to support the initially preferred hypothesis. This was especially true for the neutral cues. Third, a majority (56\%) kept the initially preferred hypothesis, while $38 \%$ switched to the hypothesis favored by the evidence coming in last. Only 6\% correctly judged the hypotheses as equally likely. A good model should be able to account these findings.

## Constraint Satisfaction Models of Diagnostic Reasoning

There are many cognitive models to describe sequential hypothesis testing, including Bayesian and logical accounts. We focus on parallel constraint satisfaction models here as they have been very successful in modeling sequential diagnostic reasoning. They also account directly for the frequently found primacy, recency and coherence effects (Mehlhorn et al., 2011, Wang et al., 2006). Thirdly, they are supported by consistency theories, which provide a psychological plausible explanation for why people strive for coherence (Simon et al., 2004).

Many constraint satisfaction models are based on ECHO, a connectionist model of the theory of explanatory coherence (Thagard, 1989). The theory assumes that the acceptance of a belief depends on its relations to other beliefs. By accepting and rejecting beliefs, the overall coherence of the belief set can be maximized. Roughly speaking, a set of beliefs is coherent, if (i) beliefs connected by a positive link (i.e., mutual support, consistency or entailment) are both accepted or rejected, and (ii) only one of the beliefs connected by a negative link is accepted (see next paragraph for formal details).

ECHO has been implemented as a connectionist network (see Figure 1). Hypotheses and items of evidence are represented by nodes, while coherence relations are represented as symmetrical links. Hypotheses and evidence are connected by links with positive weights if they are coherent with each other (e.g., if the evidence is a diagnostically valid indicator), by negative links if they are incoherent (e.g., if the evidence indicates the absence of the diagnosis), or they are not related if they irrelevant for each other. Evidence nodes are assumed to have a special status as their acceptance not only depends on coherence with
other beliefs but on observations. Therefore they receive external activation from a special activation unit (not shown in Figure 1). Evidence nodes in turn activate potential diagnoses. Hypotheses coherent with the evidence get positive activation, while contradicted hypotheses are negatively activated. Different hypotheses are assumed to compete in explaining the observations. Therefore they are negatively related. Activations are passed through the network and added to each other until a stable state is reached. More precisely, the activation of each unit $j$ is updated by combining its current activation $\mathrm{a}_{\mathrm{j}}(\mathrm{t})$ with the net effect (net ${ }_{j}$ ) of all the units i connected to it according to the following formalism (Thagard, 1989; see also McClelland \& Rumelhart, 1981):

$$
\begin{aligned}
& \mathrm{a}_{\mathrm{j}}(\mathrm{t}+1)=\mathrm{a}_{\mathrm{j}}(\mathrm{t})^{*}(1-\Theta)+\left(\text { net }_{\mathrm{j}} *\left[\text { max }-\mathrm{a}_{\mathrm{j}}(\mathrm{t})\right] \text {, if net } \mathrm{t}_{\mathrm{j}}>0\right. \\
& =\mathrm{a}_{\mathrm{j}}(\mathrm{t}) *(1-\Theta)+\left(\text { net }_{\mathrm{j}} *\left[\mathrm{a}_{\mathrm{j}}(\mathrm{t})-\mathrm{min}\right] \text {, if net }{ }_{j} \leq 0\right. \\
& \text { with net }{ }_{j}=\Sigma_{\mathrm{i}} \mathrm{rel}_{\mathrm{ij}} * \mathrm{a}_{\mathrm{i}}
\end{aligned}
$$

The parameter $\Theta$ represents a decay and min and max the maximum and minimum activation (usually 1 and -1 ). Final activations represent acceptance. Hence, the hypothesis, which receives the highest positive activation in the end, is the preferred diagnosis.

The coherence of a belief set can be calculated by summing up the products of final activations and relations. This measure has been called harmony (Thagard, 1989).

$$
\text { Harmony }=\Sigma_{\mathrm{i}} \Sigma_{\mathrm{j}} \operatorname{rel}_{\mathrm{ij}} * \mathrm{a}_{\mathrm{i}} * \mathrm{a}_{\mathrm{j}}
$$

To account for sequentially arriving evidence, the external activation of evidence nodes is assumed to shift towards the new arriving evidence (Wang et al., 2006). In line with findings on the limited capacity of attention, the received activation is kept constant and is decayed exponentially across items. The activation received by an item of evidence is calculated according to the following equation:

$$
\mathrm{a}_{\mathrm{ev}}=\mathrm{a}_{\mathrm{ev}}^{*} \exp (-1 * \Lambda[\text { Number of subsequent items seen }])
$$

The parameter $\Lambda$ represents how strongly the activation of an item is decayed due to later items. Little or no decay results in primacy effects, i.e., the first evidence biases decisions in favor of the initially preferred hypothesis. Strong decay leads to recency effects (Wang et al., 2006).

Figure 1. Parallel constraint satisfaction model of sequential diagnostic reasoning. Nodes represent hypotheses (HypA/B) and pieces of evidence (e.g., ProA). Solid lines represent coherent, dashed lines incoherent relations. Pieces of evidence arrive sequentially along the time line.

Figure 1 shows the structure of a constraint satisfaction network with two competing hypotheses (Hyp A, Hyp B) and nine pieces of evidence. The first three observations (ProA 1-3) support Hypothesis A (indicated by the solid lines) and contradict Hypothesis B (indicated by the dashed lines). The next observations (Ambig 1-3) support both hypotheses, while the final set favors Hypothesis B over A (ProB 1-3). This is the order of evidence clinicians received in the study by Kostopoulou et al. (2012).

This model predicts that Hypothesis A will be favored over Hypothesis B unless there is a very strong decay of the initial evidence (see simulations for respective evidence). But it cannot explain information distortion. As outlined above, information distortion means that assumptions about the diagnostic validity, i.e., the relations between evidence and hypotheses are distorted. The model presented here keeps these relations constant assuming that decision makers have stable beliefs about coherence relations. Hence the model cannot account for the findings by Kostopoulou and colleagues (2012) that participating clinicians distorted their assumptions about diagnostic validity for a particular case depending on their currently favored hypothesis.

## A probabilistic constraint satisfaction model

Decision makers may be uncertain about the coherence relations among evidence and hypotheses. Consider the medical domain. Although a particular diagnostic cue may have a positive predictive value for Diagnosis A, there will be cases in which another diagnosis will prove to be true. Standard constraint satisfaction models of diagnostic reasoning do not allow us to represent this uncertainty. This uncertainty can be captured by conceptualizing the relations connecting evidence and hypotheses as beliefs and defining probability distributions over these beliefs. Probability distributions are used to represent the uncertainty in many cognitive models, e.g., Bayesian models (Chater \& Oaksford, 2008), but they have not been used in constraint satisfaction models so far. Nevertheless, their application seems straightforward. There are three types of coherence relations: positive links, negative links, and no links (representing irrelevance). The probability distribution defines the likelihood that evidence and hypothesis are connected by a positive, a negative or no relation.

For example, to represent the assumption that a piece of evidence X almost always supports a Hypothesis A the probability of a positive link between $X$ and $A$ is set to a high value (i.e., $\mathrm{P}\left(+_{A x}\right) \approx 1$ ) while the probabilities of a negative or no link are assumed to be very small (i.e., $\mathrm{P}(-\mathrm{ax})$ $\left.\approx 0, \mathrm{P}\left(0_{\mathrm{AX}}\right) \approx 0\right)$. To derive predictions for a particular probability distribution, a set of constraint satisfactions networks is instantiated and run. Based on the resulting activations of the networks the likelihood that each hypothesis will receive the highest final activation is estimated. In addition, the mean resulting harmony is calculated to estimate the expected overall coherence.

Like standard parallel constraint satisfaction models the probabilistic models can account for primacy and recency effects by assuming differential decay of sequentially arriving information. Moreover, they may also account for information distortion. By shifting the probability distribution over coherence relations the overall coherence (i.e., harmony) may be increased. Thus a need for coherence may cause a change in beliefs about coherence relations resulting in information distortion. There is a limit however. To preserve the belief that a certain piece of evidence is coherent with a hypothesis in general, the probability distribution can only be shifted to a certain degree. To be more precise, the sign of the sum of weights of the relations multiplied with their respective probabilities has to remain the same. For example, if Hypothesis A and Evidence X are assumed to be coherent $\Sigma \mathrm{P}\left(\right.$ relation $\left._{\mathrm{AX}}\right){ }^{*}$ relation $_{\mathrm{AX}}>0$. Thus probabilistic constraint satisfaction models may predict information distortion without assuming an outright change in beliefs about the diagnostic validity of cues.

## Simulations

To explore the predictions of probabilistic constraint satisfaction models, we implemented the model shown in Figure 1 with various probability distributions over coherence relations (see Table 1). The overall relation between each piece of evidence and the two hypotheses was kept the same across all distributions. The first three pieces of evidence were generally coherent with Hypothesis A and incoherent with $B$, the ambiguous evidence supported both hypotheses, and the final set contradicted A and favored B.

Table 1: Probability distributions over coherence relations of the model depicted in Figure 1.

| Relation | $\begin{aligned} & \text { HypA - } \\ & \text { Pro A1-A3 } \end{aligned}$ |  |  | $\begin{aligned} & \text { HypB - } \\ & \text { Pro A1-A3 } \end{aligned}$ |  |  | $\begin{aligned} & \text { HypA - } \\ & \text { Amb1-Amb3 } \end{aligned}$ |  |  | $\begin{aligned} & \text { HypB - } \\ & \text { Amb1-Amb3 } \end{aligned}$ |  |  | $\begin{aligned} & \text { HypA - } \\ & \text { Pro B1-B3 } \end{aligned}$ |  |  | $\begin{aligned} & \text { HypB - } \\ & \text { Pro B1-B3 } \end{aligned}$ |  |  |

Table 2: Results of simulations. Harmony (i.e., degree of coherence of beliefs) after each new piece of evidence and distribution of finally preferred hypotheses
$\left.\begin{array}{lcccccccccccc}\text { Preferred Hypothesis }\end{array}\right)$

The first distribution (M1) was identical to standard models and assumed no uncertainty about the coherence between evidence and hypotheses. The second (M2) closely resembled the standard model and assumed the same relations with a high probability of .9. The third distribution (M3ProA) represents shift of assumptions in favor of Hypothesis A after the first three pieces of evidence. The ambiguous evidence (Amb1-Amb3) is considered less supportive of Hypothesis B, and the evidence clearly favoring Hypothesis B (ProB1-ProB3) as less contradictory for $A$ and less supportive of $B$. The forth distribution (M4ProB) represents a shift in favor of Hypothesis B. Now the ambiguous evidence is considered less supportive for Hypothesis A. If the model adequately captures the predictions of consistency theories, we should see an increase in coherence for M3 over M2 and M4.

The fifth probability distribution over coherence relations (M5) represents another set of basic assumptions. It assumes that all pieces of evidence are considered moderately supportive of the respective hypotheses. Distribution M6ProA again represents a shift of distribution M5 in favor of Hypothesis A while M7ProB represents a shift of M5 in favor of Hypothesis B. A comparison of the results for these distributions will show whether any of these shifts would increase coherence.

Model parameters were set to random values or kept constant for all simulations. Links of coherence had a weight of +.05 , incoherence links of -.05 . The incoherence link between hypotheses was set to -.2. Initial activations of hypotheses were set to random values between -.2 and +.2 . Evidence nodes were added sequentially to the network after activations settled. Resulting activations were transferred to the next step. External activations received by evidence nodes were decayed when new evidence arrived. The decay parameter $\Lambda$ was randomly set to values between 1 (strong exponential decay) and .1 (almost not decay). The activation added through the evidence nodes was kept constant at .5 for all steps. In line with previous studies we found that the qualitative pattern of activations hardly depended on the specific parameters (Thagard, 1989). Therefore only one set of results is reported here.

## Results

For each probability distribution 10.000 constraint satisfaction models were instantiated and run. The results of the simulations are depicted in Table 2. Harmony, i.e., the resulting overall coherence of the belief network, is shown for each new piece of evidence. In addition, the percentage of cases in which Hypothesis A was preferred over B is given. For six out of seven distributions, Hypothesis A was preferred over Hypothesis B. Thus a primacy effect resulted, which is in accordance to the results of Kostopoulou et al., (2012). As expected, decay had a strong impact on results. When the decay was strong ( $\Lambda=1$ ), that is, the last piece of evidence was strongly activated while previous evidence hardly received any activation, a recency effect sometimes occurred and Hypothesis B was favored. When decay was weak ( $\Lambda=.1$ ), that is, initial evidence was activated only slightly less than the latest evidence, a primacy effect resulted even when the distributions were shifted in favor of Hypothesis B. Note that recent research indicates that weak or no decay fits best with people's actual decisions (Mehlhorn et al., 2011).

A comparison of distributions M1 and M2 shows that a probabilistic network with high probabilities basically results in the same overall preferences as a deterministic network which is identical to standard constraint satisfaction models. Overall coherence was only slightly reduced when relations became uncertain. A comparison of distributions M2, M3ProA and M4ProB indicates that the coherence of beliefs increased substantially when the probability distribution over coherence relations was shifted in favor of Hypothesis A, but not when it was distorted in favor of B. Note that an increase in coherence for M3ProA already resulted for the ambiguous items of evidence, after which it stayed at an elevated level. Thus the model predicts information distortion especially for the ambiguous items of evidence. This is what has been found empirically.

A comparison of distribution M5 to distributions M6ProA and M7ProB shows a different picture. Starting from less assertive assumptions about the diagnostic validity of the evidence, more coherence could be gained by shifting
assumptions in favor of Hypothesis B. A closer analysis shows that coherence increased for the ambiguous pieces of evidence by shifting assumptions towards Hypothesis A, but that this gain evaporated when the evidence favoring Hypothesis B arrived. Interestingly, a shift towards B only yielded substantially more coherence for the last few items. Thus the model predicts that people being uncertain should be less likely to distort but more likely to end up choosing Hypothesis B. This is what Kostopoulou and colleagues (2012) found.

## General Discussion

A probabilistic constraint satisfaction model has been proposed to explain information distortion in sequential diagnostic reasoning. The model takes into account that diagnosticians may be uncertain whether a certain piece of evidence supports a diagnostic hypothesis for a particular case. To be more precise, it takes into account that people are aware of the fact that a piece of evidence may not always be present when a diagnosis is given and vice versa. Note that the model like constraint satisfaction models in general does not differentiate between the sensitivity of a diagnostic sign (i.e., the probability of the sign given the diagnosis) and the positive predictive value of the sign (i.e., the probability of the diagnosis given the sign). The model does, however, differentiate between believing a certain piece of evidence and believing that the information has diagnostic implications for a hypothesis.

The model has been implemented by using the standard formalism of ECHO (Thagard, 1989) and an exponential activation decay function to account for the sequentially arriving evidence. Uncertainty about diagnostic relations is represented by probability distributions over coherence relations among evidence and hypotheses. Belief in the observed evidence and hypotheses is represented by activations of the respective nodes.

Simulations were run to investigate the properties of the model and to find out whether it is able to predict findings reported in the literature. An analysis of the predictions of different probability distributions yielded several interesting results. First, the model shows a primacy effect which is reported frequently in the literature when people first receive several pieces of evidence favoring one hypothesis over others (Brownstein, 2003; Hogarth \& Einhorn, 1992). However, many other models predict order effects, so this prediction is not unique.

Second, the model predicts information distortion. The results show that by distorting assumptions about the diagnostic validity of the observed cues, i.e., by shifting probability distributions over coherence relations, more coherent beliefs can be achieved. Importantly, coherence can be increased without giving up general assumptions about the coherence between cues and hypotheses. Thus, the model explains how the need for coherence can drive changes in beliefs about diagnostic validity and why information distortion may result.

Crucially, the simulations also showed that not all changes in beliefs about diagnostic relations may result in higher coherence. They also indicated that a shift in beliefs has an impact on coherence at a particular point during the diagnostic process. Thus the model allows for very specific predictions once initial beliefs about diagnostic relations are known.

## Alternative Models

A number of parallel constraint satisfaction models has been proposed in the literature to account for diagnostic reasoning (e.g., Mehlhorn \& Jahn, 2009; Mehlhorn et al., 2011; Wang et al., 2006; Gloeckner \& Betsch, 2008; Gloeckner, Betsch, \& Schindler, 2009).

The parallel constraint satisfaction model of Gloeckner and colleagues (2009) was designed to account for distortions in validity in multiple-cue judgment. In their research they found that participants changed their assessments of diagnostic validity depending on the favored option for a particular case. Although the model was devised for concurrent, non-sequential decision making it may be extended to cover sequential decision making. The structure of the model is highly similar to the model depicted in Figure 1 with cues being related to two alternative options, which compete with each other. Cues are assumed to be related to an activation unit. But, relations and activations are given an interpretation that is very different from our proposed model. The relation to the activation unit is assumed to represent the general validity of the cue, while the activation of each cue is considered to represent the validity of this cue for the particular case. This model is able to account for many findings in the judgment and decision making literature (cf. Gloeckner et al., 2009). Nevertheless, the model has difficulty to account for information distortion, because it does not differentiate between the validity of a cue and the diagnostic validity of the cue for a particular hypothesis. The results on information distortion (Kostopoupou et al., 2012) show that participants may increase the diagnostic validity with respect to Hypothesis A while decreasing the diagnostic validity with respect to Hypothesis B. The activation of a node, however, cannot increase and decrease at the same time. Thus the activation may represent whether a piece of evidence is considered valid or invalid, but not whether it is considered valid with respect to a diagnosis. The probabilistic constraint satisfaction model allows for this differentiation. Assumptions with respect to diagnostic validity are represented by probability distributions over coherence links. Therefore assumptions about the diagnostic validity with respect to several hypotheses may change independently from each other. Such a probabilistic constraint satisfaction model may account for the findings of Gloeckner et al. (2009). It also predicts that participants would lower their belief in the validity of cues contradicting the preferred option, as the resulting activation for these nodes would be negative.

The constraint satisfaction model proposed by Wang and colleagues UECHO (2006) was specifically developed to capture sequential belief updating and learning with a parallel constraint satisfaction network. The structure of the model is the same as the model shown in Figure 1. As outlined above, the model accounts for sequentially arriving evidence by a decay function over the activation distributed by the special activation unit. We adopted this idea for our model. The second important novel idea of UECHO is that the strength of the coherence links may change due to learning from feedback. We did not consider this idea for two reasons. First, clinicians are very unlikely to change their generic diagnostic knowledge in experimental studies on diagnostic reasoning and information distortion. Second, assigning specific weights to coherence links violates the fundamentally qualitative notion of coherence stressed by Thagard (1989). Either some evidence is coherent or incoherent with a hypothesis, or it is irrelevant. Our probabilistic model keeps this notion by assuming that links are either positive, negative or zero, while at the same time defining a probability distribution over these links representing the idea that evidence may be found even when the coherent hypothesis turns out to be false. Learning from feedback could be added to our model by adding a Bayesian learning algorithm that updates the probability distribution over coherence links. This seems to be a viable and elegant alternative to the proposal of Wang and colleagues (2006). In principle, UECHO may be extended to account for information distortion by assuming that the weight of individual coherence links may change for a particular case (i.e., change without learning). Like we envisioned for our probabilistic model, this shift may be driven by increased overall coherence (i.e., harmony). Such a model, however, would not be able to represent the uncertainty about coherence relations like the probabilistic model does.

## Future Directions

The proposed probabilistic constraint satisfaction model shares important features with other parallel constraint models. In contrast to the other models it explains information distortion. As outlined above, the model allows for a number of specific predictions including conditions under which information distortion should not be found. However, to test these predictions, assumptions about diagnostic relations have to be assessed on an individual level and compared to later measurements of information distortion. Respective research still needs to be done. Hence, only future studies will show whether probabilistic constraint satisfaction models are able to successfully predict preferred hypotheses, information distortion and validity judgments of individual diagnosticians.

#### Abstract

The cognitive representation of a return path is a rather unexplored topic including different issues, e.g., perception, mental imagery, mental spatial processing, and language. We here investigated the return path with landmarks located on different positions (optimal, suboptimal). Participants learned a total of 24 routes and had to produce the return paths ( $N=20$ ). In a second experiment the different positions plus map learning versus verbal directions were investigated ( $N=20$ ). Both experiments reveal that the position of a landmark at an intersection (structural salience) has an influence on wayfinding performance. However, the results are somehow ambiguous. Therefore, we also present first approaches for predicting behavior (e.g., optimal route descriptions) and for modeling the perceptual and cognitive processes involved in finding the return path, including visibility, structural salience, mental representation/ transformation, and language.

Keywords: return path; structural salience; landmarks; mental transformation

## Introduction

Imagine that you are on a vacation in an unknown foreign city. After your arrival at the hotel you want to explore the surroundings and maybe visit a place of interest or a touristic feature (e.g., a famous building such as the Eiffel Tower in Paris). You may base your search on different means for successfully reaching your goal. You may want to use a verbal description that you received at the reception desk of your hotel, maybe you want to make use of a city map in your tourist guide, or, if you do not have these means at hand, you may want to ask a pedestrian on the street for giving you directions to your goal location. There is also the possibility of using a mobile navigation system. This latter example is part of the debate on "extended cognition" (e.g., Clark \& Chalmers, 1998), which is beyond the scope of this project. Here, the focus is rather on the "innate" navigation system, perceptual and cognitive processes that enable humans to navigate without getting lost (most of the times). In general, wayfinders use so-called landmarks, objects or buildings that stand out of their environment, to aid navigation (e.g., Lynch, 1960; Presson \& Montello, 1988; Caduff \& Timpf, 2008). Let us return to our initial example. One important question is whether the verbal description is on its own sufficient for reaching the
goal without being distracted or being led into a wrong direction? Or, would it be better to supplement the verbal description with a map, or maybe make only use of the map instead? This is not only a question of not getting lost (e.g., Dudchenko, 2010), but also a question about cognitive economy, namely, reaching the goal with the least cognitive or physical effort. Let us assume that we successfully reached the goal. We are now faced with a new, maybe more difficult, problem. We need to return to our hotel!
Finding a return path is an everyday problem but has rarely been investigated empirically (retrace the same route; e.g., Golledge, 1997, Büchner, Hölscher, \& Strube, 2007; Papinski, Scott, \& Doherty, 2009). We are able to manage this task, but we do not yet know the underlying cognitive and neural processes enabling us to find the return path.
One of the most important aspects for the return path is probably the structure of the environment (e.g., structural landmark salience; Sorrows \& Hirtle, 1999; Klippel \& Winter, 2005). Since we assume visual salience (or better perceptual salience) -that is how much an object stands out from its environment (e.g., Caduff \& Timpf, 2008)- and semantic salience of landmarks -that is for example its name, meaning, or function (e.g., Hamburger \& Knauff, 2011)- to be less important, we here try to control for these aspects and rather focus on the structural aspects as we have done in several previous experiments on structural salience (e.g., Röser, Hamburger, Krumnack, \& Knauff, 2012a; Röser, Krumnack, Hamburger, \& Knauff, 2012b).
There are two optimal positions for landmarks to be located on a regular/initial path: before the intersection (Klippel \& Winter, 2005) in direction of the turn and behind the intersection in direction of the turn (Röser et al., 2012a). Most important is that the landmark is located somewhere in direction of the turn (Röser et al., 2012a). But, for the return path, two different positions might be the optimal ones: the positions before the intersection in direction of the turn and behind the intersection opposite to the direction of the turn. These positions are invariant for the return path (they remain unchanged). The other two positions are variant, since they have to be mentally and verbally transformed for the return path (e.g., "before the intersection opposite to the direction of turn" becomes "behind the intersection and in direction of the turn" on the way back). Further details on
this theoretical assumption are provided in the section "Theoretical assumptions, modeling, future research".

## Experiment 1

## Method

## Participants

A total of 20 Psychology students from the University of Giessen participated (16 females). They had a mean age of 23.5 years ( $S D=4.08$ ). All participants were naive with respect to this study, provided informed written consent, and received course credits for participation. They had normal or corrected-to-normal visual acuity and were free of any preexisting psychiatric or neurologic illness (e.g., epilepsy).

## Materials

The equipment included a custom $19^{\prime \prime}$ monitor (Dell), a Personal Computer (HP Compaq 6000 Pro), and a Response Pad (RB-530 Cedrus Corporation©). For presentation and data recording SuperLab 4.0 Stimulus Presentation Software (Cedrus Corporation©) was employed.
The virtual environment (maze) was set up with Google® SketchUp 8 (compare to SQUARELAND; Hamburger \& Knauff, 2011), which in its original version is made of $10 \times 10$ cuboids, representing regular orthogonal intersections, and proofed very flexible in terms of experimental manipulations. Here, 24 routes, each with eight intersections in an egocentric perspective, were created. The directions left or right were used. Every intersection $(24 \times 8=192)$ contained one distinct landmark one of 192 different words on a white sign (Figure 1). These distinct landmark words were used to prevent interferences of previously learned landmark and direction combinations (e.g., in Route 1 you have to turn right when you see the word "horse"; in a later route you might have to turn left when you see the word "horse"). Hence, a landmark which was shown once to the participant does not appear again later in another route. We controlled for all landmarks being comparably imaginable by using familiar, everyday words. A landmark was placed on both sides of the corresponding facades of a corner, so it was visible from both directions of travel.

Figure 1: Screenshot of an intersection in the virtual maze (decision point). The landmark (word; Apfel = apple) is presented on both facades at one corner (position).

To control for direction or landmark position effects, the number of right/left turns and the position of landmarks (before or after the intersection, in or against moving direction) were balanced for single routes. This balancing applies to both the regular travel direction (forward) in the learning phase and to the return path in the wayfinding phase.

## Procedure

Participants learned a route of eight intersections via successively presented pictures of each of the intersections (Figure 1). Every intersection was shown for duration of eight seconds (learning phase). Subsequently, participants were instructed to find the same path again either in the normal (forward from origin to destination) or the reverse travel direction (backwards from destination to origin; wayfinding phase). Every intersection was presented via pictures and served as a decision point (right or left) for which direction decisions had to be made.
After one route was navigated (eight direction decisions), the learning phase of the next route started. No feedback about the decisions was given. The total of 24 routes had to be learned by each participant. Overall, half of the routes had to be found in the forward run direction, while for the other half the return path was required. Therefore, two experimental versions were used where navigation direction in the wayfinding phase was interchanged (e.g., Route 1 had to be found again in forward direction in version 1, but in the backwards direction in version 2). The order of the routes was randomized for every participant. Correct decisions and response times served as dependent variables. At the end participants were asked to indicate any strategies they had used during the experiment.

## Results

The mean correct route decisions on the return path were about $87 \%$ in this experiment (chance level 50\%).
An analysis of variance with repeated measures for the wayfinding phase was performed. Within-subject factors were navigation direction (forward/backward) and landmark position (all four possible positions). Both for correct decisions and response times a significant main effect for navigation direction (correct decisions: $F(1,19)=19.865$, $p<.001$; response times: $F(1,19)=21.571, p<.001)$, but not for landmark position (correct decisions: $F(3,57)=1.020$, $p=.391$; response times: $F(3,57)=.871, p=.461)$ could be found. Participants were better and faster in navigating the original route direction (forward) compared to the reverse direction (backwards), but the position of a landmark did not lead to any performance differences.
A wide range and variability of learning strategies was reported by the participants and different levels of selfconfidence in performance were expressed. Thus, we were interested in possible group differences. Therefore, we divided our sample in participants with an overall better ( $N=14$ ) and an overall worse performance ( $N=6$ ) with respect to mean overall performance. This mean-
performance-grouping now functioned as a between-subject factor in a re-analysis of variance with repeated measures. For response times again only a main effect for direction ( $F(1,18)=16.196, p=.001$ ), but not for landmark position $(F(3,54)=.508, p<.678)$ occurred. However, for correct decisions again a significant main effect for direction $(F(1,18)=22.322, p<.001)$ and an additional interaction of navigation direction $\times$ landmark position $\times$ group $(F(3,54)=3.895, p=.025)$ emerged. This means that the wayfinding performance with landmarks on varying positions differs with navigation direction and depends on the participant being a high or a low performer.

## Discussion

An overall effect for the wayfinding direction could be found. People were faster and better when travelling the route in the originally learned direction (forward) compared to navigating the return path, which is not very surprising but has not been investigated systematically before. No landmark position effect was found. Only the mean performance of low performers indicates that some people (maybe depending on spatial ability and learning strategy) might be affected by structural differences (positions), and that the helpfulness of a landmark might differ depending on the direction of travel (forward, backwards). Such data need to be further analyzed in future research with the focus on individual strategies (wayfinding performance vs. sense-of-direction; e.g., Kato \& Takeuchi, 2003).
In Experiment 2 we used a more realistic setup: video sequence from an egocentric perspective with approximated true physical sizes on a projection screen; only one route but with the option of going straight; two learning conditions; more than just eight intersections, etc.

## Experiment 2

## Method

## Participants

A total of 20 Psychology students from the University of Giessen participated ( 13 females). They had a mean age of 26.1 years ( $S D=9.03$ ). All participants were naive with respect to this study, provided informed written consent, and received course credits for participation. They had normal or corrected-to-normal visual acuity and were free of any preexisting psychiatric or neurologic illness (e.g., epilepsy).

## Materials

The same setup was used as in Experiment 1 but this time the routes were presented on a customary projection screen (171x238 cm) with a projector (Panasonic PT-F100NT).
For the experiment two different routes through the maze, with 20 intersections each, were created. Therefore, a total of 20 different words served as landmark objects (Figure 1). The words were derived from a catalog of pictograms which made them visually similar, realistic, and easy to imagine. In the maze the landmarks were again placed on both
facades of a corner (position), so they were visible from both directions of travel.
Videos of the two routes were generated from an egocentric perspective, with an eye height of 1.70 m and a constant walking speed of about $2 \mathrm{~m} / \mathrm{s}$. For presentation and data recording SuperLab 4.0 Stimulus Presentation Software (Cedrus Corporation©) was employed.

## Procedure

Participants were assigned to two groups: One of them learned a path with 20 intersections via a map, the other one through verbal description (allocentric vs. egocentric learning condition). After a five minute break, the learned path was shown as video in reverse order through the virtual maze, which was stopped at every intersection (decision point) for participants to indicate the path directions right, left, or straight (wayfinding phase). Learning condition (map/description) and landmark position (optimal/ suboptimal) served as independent variables while correct route decisions and response times served as dependent variables.

## Results

With landmarks being located in (assumed) optimal positions correct decisions on the return path were made in about $67.5 \%$ (chance level 33.3\%) if the initial path was learned via a route description. When the path was encoded via a map about $65 \%$ correct route decisions were made. With landmark objects being in suboptimal positions on the return path, $59 \%$ correct decisions were made for the description condition and $65 \%$ for the map condition.
For the optimal positions the response times were lower ( 3900 ms ) in the description condition, compared to the map condition ( 4960 ms ). Responses for intersections with landmarks on suboptimal positions revealed again a shorter response time for the description condition (4175ms), in comparison to the map condition ( 4825 ms ).

An analysis of variance with the within-subject factor landmark position (optimal/suboptimal) and the betweensubject factor learning condition (map/verbal description) was performed. It revealed a significantly higher performance for landmarks on optimal positions ( $F(1,18)=4.99, p=.038)$. But, the position did not reveal significant differences according to the response times ( $F(1,18)=.033, p=.858$ ). The learning conditions did neither differ significantly in the wayfinding phase with respect to correct decisions $(F(1,18)=.066, p=.800)$, nor with respect to response times $(F(1,18)=.621, p=.441)$. The three possible options of choice on the intersections (left, right, straight on) did not lead to significant differences according to correct decisions ( $F(2,38)=.818, p=.449$ ). No interactions were obtained.

## Discussion

The landmark position led to significant differences in performance (correct decisions), though this was not the case for the decision times. Consistent with the expectations
better decisions were made if landmarks were located on optimal positions. Since no decision time differences could be obtained, this effect cannot be due to longer viewing times for the landmarks. We may therefore conclude that the quality of a landmark as a point of reference for finding the return path very much depends on its position, as has previously been assumed for the "initial path" (forward run; Klippel \& Winter, 2005; Röser et al., 2012a,b).
The different learning conditions map and description (allocentric/egocentric) did not lead to a significant difference in the wayfinding phase, neither for correct decisions nor for the response times. This absence of an effect may be explained by the "dual coding theory of human wayfinding knowledge" (Meilinger, Knauff, \& Bülthoff, 2008). It assumes that environmental information is (sometimes) encoded in a spatial format alone but sometimes additionally in a verbal format. Information learned through maps (allocentric) is encoded verbally as well as information learned through descriptions (egocentric mental imagery). The similar performances after studying a map or a verbal description may be attributed to verbal representations existing for both encoding conditions (Meilinger \& Knauff, 2008).
In Experiment 2 position effects were found in comparison to Experiment 1. It is possible that Experiment 1 only tested the direction memory (memory task), while Experiment 2 represents a realistic wayfinding task. Since these results are not conclusive, more theoretically driven assumptions and empirical research are required.

## Theoretical assumptions, modeling, future research

In the following we present current ideas on how landmarks, places, and directions might be cognitively processed for the return path. As we have seen so far from our first two experiments on the return path and which role landmarks and landmark positions play in this context, more systematic empirical work is required.
As can be seen in Figure 2 we need to differentiate between an allocentric and an egocentric perspective. In the allocentric perspective (forward run) the assumed optimal position (Klippel \& Winter, 2005; Röser et al., 2012a) is position D , before the intersection and in direction of the turn. For the forward run optimal positions have been suggested theoretically/mathematically (Klippel \& Winter, 2005) and have been evaluated empirically (Röser et al., 2012a,b). For the return path the optimal positions are not yet known. We assume that position D should still be optimal, since it is before the intersection in direction of the turn (identical to the initial path), and this position is invariant independent of direction (no right/left encoding necessary). According to the findings by Röser et al. (2012a) position $C$ could be optimal as well in the egocentric perspective and A could be optimal in both perspectives, since $A$ is also invariant (opposite to the direction of the turn) as is the case for D .

Figure 2: Possible optimal (dark gray) and suboptimal (light gray) landmark positions for the forward run and the return path in the allocentric and egocentric perspective. See text for details.

Another important issue in the egocentric perspective is the so-called "visibility" (Winter, 2003; Röser et al., 2012b). This means that different locations have different visibilities depending on the observers own position (Figure 3). Visual attention is generally paid to the direction of turn. It seems that in an egocentric perspective it is important that a landmark is at least located in direction of the turn and that before and behind become less important.

Figure 3: Visibility from two different positions: initial path (left) and return path (right). $\mathrm{X}=$ position of individual; $\boldsymbol{\rightarrow}=$ walking direction. In the allocentric perspective each position is equally visible for both directions, not so for the return path. The small images on the bottom visualize the sight in the egocentric perspective. See text for details.

For the return path it is important to take this into account. This means that for the return path the optimal position in the allocentric perspective remains the same (D), since this location is still before the intersection and in direction of the turn (invariant; see central section of Figure 2). According to the above findings and the previous logic, in the egocentric perspective the optimal positions should now be C and D. However, position C was a suboptimal one on the forward run and therefore it may now be doubted that it becomes optimal on the return path, since it is a variant
position (forward run: before the intersection and opposite to the direction of the turn; return path: behind the intersection and in direction of the turn). This would require some additional mental transformation for the observer in order to correctly find the return path.
Now it is interesting to see that positions D and A are invariant for the initial and the return path, while B and C are variant locations (see right section of Figure 2). But, this is only the case if the spatial information is unspecific; that is right has to be transformed into left on the return path (direction specific), while turn into direction of $D$ or turn in the opposite direction of $A$ remain the same for the return path (direction unspecific).

According to the concept of "advanced visibility" (Winter, 2003) it is furthermore important in the egocentric perspective, whether both facades at one location at the intersection are visually identical/similar (e.g., same color, texture) or totally different (e.g., one facade is brown and the other white). This may change the recognizability on the return path in a dramatic way (Figure 3). For instance, if both facades are similar, then this information can be used for the return path, but if they differ significantly, then position D becomes useless on the return path, since it cannot be recognized anymore (only if the observer turns the head on the initial path at the intersection). From a perceptual point of view the object must be recognizable. If this condition is not fulfilled, the former optimal position D might become totally worthless (see Tables 1 and 2 for theoretical predictions; please note the lower right value, which has the most dramatic effects depending on visibility and equal appearance).

Not only the visibility represents an important issue but also language and how it is used when giving instructions, learning new pathways, and transforming them mentally (for the return path). As mentioned above, there are at least two ways of spatial directions: direction specific and direction unspecific information (Figure 4).

Table 1: Visibilities for the different landmark positions (A-D) in Figures 2 and 3 for the initial path, the theoretical return path, and for the real return path; 0 indicates that no facade is visible, 0.5 indicates that one facade in visible, and 1 means that both possible facades of a building at an intersection are visible. Here, both facades of a single building have the same characteristics/appearance. Thus, position D has a visibility of 0.5 on the return path, since the visible facade is similar to the one seen on the initial path.

| Path | Initial <br> Path | Return Path <br> (hypothetical) | Return Path <br> (real) |
| :--- | :---: | :---: | :---: |
| Position | 1 | 1 | 1 |
| A | 1 | 0.5 | 0.5 |
| B | 1 | 1 | 1 |
| C | 0.5 | 0.5 | $\underline{0.5}$ |
| D | 0.5 |  |  |

Table 2: Visibilities for the different landmark positions. In comparison to Table 1 we now assume that the two facades of each building are different in their appearance. This leads to a visibility of 0 for position D , since here the new facade on the return path does not contain any information about this position compared to the initial path.

| Path | Initial <br> Path | Return Path <br> (hypothetical) | Return Path <br> (real) |
| :--- | :---: | :---: | :---: |
| Position | 1 | 1 | 1 |
| A | 1 | 0.5 | 0.5 |
| B | 0.5 | 1 | 0.5 |
| C | 0.5 | 0.5 | $\underline{\mathbf{0 . 0}}$ |
| D |  |  |  |

Figure 4: Examples for verbal directions in the forward run and the return path. Note that the descriptions for positions D and A vary only slightly (if at all), while larger changes occur for positions C and B.

Direction specific here means that a precise direction with a single spatial word is provided, e.g., left or right. At first glance this information is easy to understand and simple to use. But, it becomes complicated if the return path has to be constructed, since then a left turn needs to become a right turn and vice versa (note that straight remains straight on the return path). Thus, an additional mental transformation is required. Additional in this sense means that it is also possible to encode directions in an unspecific way (without directions but rather based on landmark locations). In other words, the verbal direction turn in the direction of the gas station does not need to be verbally or mentally transformed if it is located on position D (the same is true for position A with the instruction turn in opposite direction of $A$ ). On the return path, both locations and unspecific directions would remain the same: in the mental representation the gas station would still either be in direction of the turn (D) or opposite to the direction of the turn (A). This would require one mental processing step less, since no transformation would
be required (left $\rightarrow$ right) resulting in less cognitive load. But, is this how wayfinders encode spatial information and spatial directions? Theoretically, direction unspecific information would be less effortful and therefore preferable over a direction specific strategy that results in higher cognitive load.
Therefore, it is important in a first step to systematically investigate how wayfinders encode given (unfamiliar) routes and how they transform them into a return path; and in a second step it is necessary to model the optimal strategies (also with respect to individual abilities) to make predictions about spatial performance.

## General Discussion and Conclusion

In this position paper we presented first empirical data on return path research and how this information is processed to aid wayfinding (unfortunately, we could not present all empirical research within this study). As can be seen from our theoretical assumptions, much more research is required within this context. We offered a few interesting issues, e.g., structural importance, visibility, language, mental transformation, which should be investigated further. So far we did not focus on brain imaging and neural correlates of wayfinding. But, investigating the cognitive processes of how we learn and encode initial pathways and how we later transform them into new routes (especially return paths) is also of relevance for the neuroscientific branch of this research. Thus, our findings and assumptions about the return path make up an interesting project for interdisciplinary future cognitive research.

# Attentional Processing in Bistable Perception is Influenced by Genetic Effects Associated with Sinistrality. 

Roeland Hancock (rhancock@email.arizona.edu)<br>Department of Psychology, 1503 E. University Blvd.<br>Tucson, AZ 85721 USA

#### Abstract

Binocular rivalry displays and ambiguous figures such as the Necker cube elicit a perceptual reversal effect mediated by attentional and perceptual processes. Perceptual dominance times are highly variable between individuals and may be partially influenced by genetic factors. This study examined the role of putative genetic effects associated with familial sinistrality, derived from a novel pedigree-based genetic model. In a continuous Necker viewing task, dominance times were significantly correlated ( $R^{2}=.36$ ) with a multifactorial estimate of genetic effects associated with non right-handedness. No association with genetic estimates was found in an intermittent viewing condition. These results suggest that genetic factors associated with functional asymmetries may also affect noisebased perceptual alternation, but not short term visual memory.

Keywords: Bistable Perception; Attention; Individual Differences; Familial Sinistrality

## Introduction

Functional cerebral lateralization has been proposed to arise from a combination of constraints on interhemispheric connectivity (Ringo, Doty, Demeter, \& Simard, 1994) and the properties, such as excitability, of neural assemblies within each hemisphere (Levitan \& Reggia, 2000). Cerebral lateralization, particularly for language, is often associated with individual hand preference as well as the handedness of close relatives (Tzourio-Mazoyer et al., 2010), suggesting a genetic contribution to functional asymmetry. Genetic effects associated with familial handedness may in turn be linked to subtle neurobiological differences, including the distribution of neurotransmitters involved in regulating neural excitability, noise or interhemispheric connectivity. We adopt a simple behavioral paradigm, the Necker cube viewing task, that may be sensitive to these factors at multiple time scales to identify possible associations between neural function and familial handedness.

A variety of ambiguous visual displays can induce bistable (or multistable) perception in observers, a state in which the subjective interpretation of the display alternates between perspectives. This can be induced through ambiguous figures (e.g. the Necker cube and Rubin's face/vase illusion), ambiguous motion or binocular rivalry displays in which different images are shown to each eye. Binocular rivalry displays allow more control over stimulus presentation and are more widely studied than ambiguous displays, but similar processes are assumed to drive alternation in both types of displays. Dominance times-the duration for which a particular interpretation is perceived-are highly variable between individuals (Aafjes, Hueting, \& Visser, 1966) and may be partially influenced by genetic factors in both binocular rivalry
and Necker cube displays (Shannon, Patrick, Jiang, Bernat, \& $\mathrm{He}, 2011$ ). Several factors, including the visual properties of the stimuli (e.g. intensity (Levelt, 1967)), eye movements and attention, have been proposed to affect perceptual reversals.

Eye movements are related to perceptual reversals, but it is not clear that eye movements directly cause reversals. Fixating on one face of the Necker cube biases perception, but does not eliminate perceptual alternation, suggesting that reversals are not merely the result of scanning different areas of the visual field (Toppino, 2003). Scotto, Oliva, and Tuccio (1990) showed Necker cube images that were partially corrected for eye-movements which resulted in an increased reversal rate over normal viewing conditions, further suggesting that bistable perception is not merely a product of scanning eye movements across the visual field. van Dam and van Ee (2005) examined the relation between perceptual reversals and eye movements and found no correlation between reported reversals and involuntary micro-saccades, however saccades and eye blinks were suppressed prior to button presses. This suppression occurred both when subjects reported perceptual flips and experimentally controlled stimulus flips. The number of blinks and saccades did not decrease prior to random button presses that were unrelated to the stimulus. Thus, bistable perception appears to be related to a cognitive process that then directs visual attention, rather than the direct result of visual field changes.

The present study investigates individual variability in Necker cube dominance times as a function of putative genetic effects associated with hand preference. Handedness and familial sinistrality are known to affect lateralization of other brain functions, notably language (Tzourio-Mazoyer et al., 2010). Familial sinistrality has also been found to influence spatial processing (e.g. Mckeever (1986)) and resting brain states (Hancock, 2012), but has not been widely studied with respect to the cognitive processes involved in bistable perception. Although Necker cube viewing is typically not a lateralized task, fMRI and EEG studies suggest that the reversal phenomenon is right-lateralized, at least initially (Pitts, Martínez, Stalmaster, Nerger, \& Hillyard, 2009; Britz \& Pitts, 2011) and dominance time is associated with grey matter volume in the right, but not left, superior parietal lobe (Kleinschmidt, Sterzer, \& Rees, 2012). Unilateral transcranial magnetic stimulation and caloric stimulation can disrupt binocular rivalry and Necker cube reversals (Miller et al., 2000), supporting bilateral contributions to bistable perception. While interhemispheric transfer across the corpus
may play some part in normal switching, it is unlikely to have a critical effect on dominance cycles (Miller et al., 2000; Pettigrew, 2001). Instead, Pettigrew suggests that a subcortical oscillatory mechanism, perhaps in the ventral tegmental area, may drive rivalry. A model of interhemispheric switching between two percepts is also difficult to reconcile with the similar dynamics found in multistable perception, including tristability (Wallis \& Ringelhan, 2013).

Factors known to influence asymmetric brain functionsuch as familial sinistrality-may have effects on bistable perception, but these likely reflect neural differences within hemispheres that could contribute to lateralization during development (Levitan \& Reggia, 2000). Specifically, we hypothesize that familial sinistrality may partially account for individual differences in neural excitability or noise, two critical parameters that determine dominance times in many models of bistable perception (e.g. Moreno-Bote, Rinzel, \& Rubin, 2007). In addition, bistable perception offers an interesting test case for identifying such effects at multiple levels of processing. The two Necker cube viewing tasks used here-a continuous viewing and intermittent viewing condition-are likely to differentially recruit perceptual processes. Bistable perception recruits a fronto-parietal network of brain regions, presumed to reflect contributions of both frontal, higherlevel attention processes and lower-level perceptual processes (Sterzer, Kleinschmidt, \& Rees, 2009). Intermittent viewing conditions extend dominance times (Leopold, Wilke, Maier, \& Logothetis, 2002), likely reflecting in increased role for visual memory processes in posterior brain regions. Functional studies suggest that brain asymmetries are multifactorial with partially independent factors controlling lateralization in brain regions associated with language, attention and vision (Liu, Stufflebeam, Sepulcre, Hedden, \& Buckner, 2009). Genetic effects associated with familial sinistrality are proposed to influence one or more of these functions, which may be observed as individual variability in the continuous Necker cube task (reflecting contributions of attention and visual processing, modulated by short-term dynamics ) or in the intermittent viewing task (reflecting primarily visual working memory or slow neural processes).

## Genetic Models of Handedness

Most studies of familial handedness effects treat familial handedness as a categorical variable, broadly classifying subjects as those reporting only right-handed relatives (FS-) or reporting at least one non right-handed relative (FS+). Considering the low heritability of handedness (20-30\%, Medland et al. (2009)), problems introduced by considering variable family sizes and family envelopes of interest (Bishop, 1990), and placing subjects who may have vastly different susceptibilities into the same group, categorical classification is likely to be an underpowered approach to studying genetic effects associated with handedness. Power can be increased substantially with the use of non-categorical measures of familial sinistrality, such as the proportion of left-
handed relatives (Corey \& Foundas, 2005), but these are not widely used. Even when more genetically informed familial handedness measures are used, these are sometimes based on a particular theory of genetic transmission and expression, thus confounding familial handedness effects with a specific, and likely incorrect, genetic model (e.g. McManus (1995)). Applying these theories to calculate the likelihood of individual genotypes (which might then be used a covariate) also requires assumptions regarding allele frequencies to be made. Recently, Karev (2011) proposed a quantitive measure of familial handedness based on weighting left-handed relatives by relatedness, finding that this measure correlates with hand preference measures.

In an effort to increase power and more robustly associate familial sinistrality effects with putative genetic effects, a standard multifactorial threshold model was used to estimate genetic load for left handedness in individual subjects. This model treats the phenotype as function of multiple genetic loci, each probably associated with small genetic effect, and multiple environmental effects. Unlike single gene models (Annett, 1985; McManus, 1991; see McManus, Davison and Armour (in press) for a multi-locus variant of the dextral chance model), this approach does not assume that the genetic component of the phenotype is controlled largely or entirely by posited genes with a given transmission probability and penetrance, however it can account for such effects when alleles make additive contributions to the phenotype (as is this case in McManus's model). This approach extends Karev (2011) by considering not only the relatedness of left-handed relatives but also their expected genetic effects. This is similar to McManus (1995), but relies only a standard multifactorial model, as opposed to a particular major gene model. The basic assumption of the multifactorial genetic model is that multiple loci additively contribute to a continuous phenotype and interact with environmental effects. For example, a multifactorial model of height would assume a set of loci with alleles at each loci adding or subtracting a small amount from the phenotype. The summed contribution of these alleles is the additive genetic effect or genetic load. The genetic effect interacts with environment, for example hormones or nutrient levels, to produce the expressed phenotype. Formally, we can consider the contribution of genes to a phenotype as being described by the linear model

$$
\begin{equation*}
y=X \beta+A a+e \tag{1}
\end{equation*}
$$

where $y$ is the measured phenotype, $X$ is a matrix of observations for fixed effects (sex and founder status, in this case), $\beta$ is the vector of fixed effects, $a$ is the vector of additive genetic effects and $e$ is a vector of environmental effects. $A$ is an $n \times n$ matrix describing how $n$ individuals are related in terms of their expected allele sharing. For example, $A_{i, j}=.5$ indicates that individuals $i$ and $j$ share (theoretically) $50 \%$ of their genes, i.e. $i$ and $j$ are siblings or a parent/offspring pair. For simplicity, we consider only autosomal effects.

We employ the Bayesian formulation of (1)

$$
\begin{equation*}
y \mid \beta, a, \sigma_{e}^{2} \sim N\left(X \beta+A a, I \sigma_{e}^{2}\right) \tag{2}
\end{equation*}
$$

with

$$
\begin{equation*}
a \mid A, \sigma_{a}^{2} \sim N\left(0, A \sigma_{a}^{2}\right) \tag{3}
\end{equation*}
$$

and an uninformative prior for fixed effects $\beta$, e.g.

$$
\begin{equation*}
\beta \sim N\left(0,10^{6}\right) \tag{4}
\end{equation*}
$$

For binary phenotypes, we assume that the observed phenotype is obtained by thresholding a latent continuous variable (the liability) (Falconer, 1965). If the liability, $\ell$, exceeds a threshold value $t_{0}$ (say $t_{0}=0$, since the liability distribution can be shifted arbitrarily), then the binary phenotype (e.g. disease or left-handedness) is expressed. The liability is distributed as in (2)

$$
\begin{equation*}
\ell \mid \beta, a, \sigma_{e}^{2} \sim N\left(X \beta+A a, I \sigma_{e}^{2}\right) \tag{5}
\end{equation*}
$$

where $\ell$ is mapped to a categorical phenotype $c=1,2, \ldots, k$ by the partition

$$
\begin{equation*}
t_{0}<t_{1}<t_{2}<\ldots<t_{k-1}<t_{k} \tag{6}
\end{equation*}
$$

so that

$$
\operatorname{Pr}\left(y_{i}=c \mid l_{i}, t_{c-1}, t_{c}\right)= \begin{cases}1 & t_{c-1}<l_{i} \leq t_{c}  \tag{7}\\ 0 & \text { otherwise }\end{cases}
$$

Fitting this model to family pedigrees provides a posterior distribution of additive effects for each individual in the pedigree that can be then be used as a covariate.

## Pedigrees

Data for fitting the model were obtained from a survey of hand preferences for blood relatives distributed to 4561 students in introductory psychology courses at the University of Arizona. Respondents were asked to report hand preferences (left, right, ambidextrous or unknown) for each parent and grandparent. For brothers, sisters, aunts and uncles, respondents were asked to provide the number of relatives in each relation with left, right, ambidextrous or unknown hand preference from the options $0,1,2$ and " 3 or more" (coded as 3 relatives). Respondents also reported their sex, hand preferences for writing, drawing and throwing a ball (on a five point scale from 'strong left' to 'strong right') and foot preference for kicking a ball. Respondents were considered righthanded if they reported a 'moderate right' or 'strong right' preference for writing hand, ambidextrous if they reported 'no preference' and left-handed if they reported a 'strong left' or 'moderate left' hand preference. Respondents were not given any criteria for determining relatives' handedness. A similar questionnaire was administered to each experimental participant.

Since the observed liability for right-handed individuals is always below threshold, purely right-handed families are uninformative with respect to random effect estimates, i.e.
the posterior distribution of additive genetic effects is fixed by the prior distribution. To improve the mixing properties of the model, effects were estimated only for individuals in FS+ families and individuals with missing data who did not form an ancestral link in a given pedigree were removed from the pedigree. For example, avuncular relatives and grandparents of unknown handedness were removed, but a parent of unknown handedness who had multiple children of known handedness would be retained. Families with fewer than three phenotype individuals were also removed. Pedigrees were pruned using the prunePed function in the $R$ MCMCglmm package (Hadfield, 2010). Phenotypes of the remaining unknown individuals were replaced at random, conditional on known family members. Convergent logit models were estimated with MCMCglmm using a slice sampling Monte Carlo Markov chain (MCMC) algorithm with block updating (Sorensen \& Gianola, 2002; Hadfield, 2010) for $2,500,000$ iterations with a burn in period of 500,000 iterations and thinning interval of 100 .

## Methods

## Participants

Nineteen participants ( 10 female) with no reported non righthanded relatives and 26 ( 14 female) participants with at least one reported left-handed relative, all native English speakers, were recruited from introductory psychology courses at the University of Arizona, Tucson, AZ, USA and received course credit for participation. Participants were screened by self report for history of brain injury, neurological and psychiatric disorders, medication, and normal vision. Research was approved by the University of Arizona Institutional Review Board.

## Procedure

A white-on-black Necker cube (Figure 1A) was presented, centered on a 15 inch LCD display at a viewing distance of 15 inches. Stimuli subtended a visual angle of approximately 4 degrees. Stimuli were presented using the MATLAB-based (Mathworks, Natick, MA) Psychtoolbox (Brainard, 1997) on Windows XP. Participants were seated at eye level with the center of the display using a chin rest to minimize movement. Participants were instructed to focus on a small cross in the center of the Necker cube, to avoid deliberately switching perspectives and to report perspective changes by pressing a key corresponding to the new perspective. The left and right arrow keys of a standard keyboard were labeled with images of the "left" (Figure 1B) and "right" (Figure 1C) perspectives, respectively. Participants were instructed to respond with the first and second fingers of their right hand and were familiarized with the two perspectives prior to the experiment. The experiment consisted of a continuous viewing condition, designed to elicit spontaneous perceptual reversals followed by an intermittent viewing condition designed to extend dominance times (Leopold et al., 2002) and recruit memory processes (Pastukhov \& Braun, 2008) or slow neural dynamics.

Figure 1: A Necker cube (A) and the perceived left (B) and right (C) perspectives.

In the continuous viewing condition, the Necker cube was continuously presented during four blocks, with self-paced breaks between each block. In each block, the complete Necker cube was shown for 200 seconds. As a check for random responses, one perspective, selected at random, of the complete Necker cube was reduced in intensity over 30 seconds to gradually produce a partially unambiguous cube and a corresponding increase in dominance time. This process began 0-30 seconds (uniformly distributed) after the end of each block, followed by a 30 second presentation of the complete Necker cube. In the intermittent viewing condition, participants saw an alternating sequence of a Necker cube followed by a fixation screen without the cube. On each intermittent trial, the Necker cube was shown for 750,1225 or 2000 ms followed by a fixation screen for 1000, 2236 or 5000 ms . All combinations of stimulus duration and inter stimulus interval (ISI) were repeated 24 times. Participants reported their perspective at the beginning of each trial and again if a reversal was experienced.

## Results

Log-transformed dominance times, defined as the time between alternate-side button presses, were analyzed using linear mixed effects models with random intercepts per subject and sex, block, perspective and genetic load as fixed effects. Likelihood ratio tests were used to select models. Reported p-values were estimated using MCMC as implemented in the languageR package (Baayen, 2007).

## Continuous Viewing

Dominance time increased for all participants during the partially disambiguated display periods $(M=11.88 \mathrm{sec}$, $S D=6.94$ ), indicating their responses were not stimulusindependent. No significant effect of sex or block was found. There was a significant positive association between additive genetic effects and dominance time ( $\beta=.68, p=.005$ ).

Dominance times were significantly shorter for the "right" perspective ( $\beta=.47, p<.001$ ).

Mean Dominance Times

Figure 2: Correlation $\left(R^{2}=.36\right)$ between continuous viewing dominance times and estimated additive genetic effects (a). FS- individuals are shown for comparison only.

## Intermittent Viewing

Intermittent viewing times were uncorrelated with continuous viewing times $(r=-.05, p=.74)$ or estimated genetic effects ( $r=.13, p=.53$; Figure 3) and were significantly longer ( $M=17.84 \mathrm{sec}, S D=17.65$ ) than continuous dominance times $(t(43)=6.70, p<.001)$.

## Discussion

Increasing estimated genetic load for non right-handedness in right-handed subjects was associated with increased dominance times in the continuous viewing condition. Although no control for differences in overall motor response speed as a function of familial sinistrality was included, the increase in dominance time during disambiguated display periods and intermittent viewing suggests that participants' responses were directly related to the perceived orientation of the Necker cube. Current models of bistable perception propose that reversals are the result of an interaction between parietal/occipital perceptual and visual working memory processes and noisy frontal attentional processes (Sterzer et al., 2009). In the context of these models (Gigante, Mattia, Braun, \& Del Giudice, 2009; Moreno-Bote et al., 2007), the dissociation between familial sinistrality effects in the continuous and intermittent viewing conditions suggests that the genetic effects of interest selectively act on frontal processes or the interaction between frontal and parietal regions.

No group differences were found when familial sinistrality was considered as a dichotomous variable. Although the FS-

Figure 3: Correlation between intermittent viewing dominance times and estimated additive genetic effects (a). FSindividuals are shown for comparison only.
group might be expected to have fewer genetic effects found in the FS+ group, and therefore show an overall group difference in dominance times, the obtained result is consistent with a gene-gene interaction model for handedness. Under this model, the estimated genetic effects, $a$, associated with phenotypic handedness may be decomposable into alleles that influence bistable perception and possibly other aspects of cognition and brain organization $\left(a_{b}\right)$ and one or more alleles $\left(a_{h}\right)$ that contribute to hand preference in the presence of $a_{b}$ effects. Thus the FS- and FS+ groups may have similar distributions of $a_{b}$ effects and dominance times while the FS- group lack the $a_{h}$ alleles needed to express non righthandedness in conjunction with $a_{b}$ alleles. With handedness as a phenotype, the $a_{b}$ effects of interest can only be estimated in conjunction with $a_{h}$ effects and not at all in the FS- group.

These findings validate the utility of applying a multifactorial genetic model of handedness to account for individual differences in cognitive behavior and support views of lateralization and related brain function as a complex trait, both in terms of phenotype and genetics. The neural mechanisms of the familial sinistrality-related increase in dominance times are unknown, but likely reflect differences in attentional processing or the coupling of attentional and visual levels of processing. The increases in dominance times could reflect changes at the local circuit or neurotransmitter level leading to decreased levels of neural noise that trigger perceptual reversals (e.g. Moreno-Bote et al., 2007) .

## Acknowledgments

This research was supported by a fellowship to R.H. from the Arizona Center for the Biology of Complex Diseases.

Ian Rios and Ankit Takyar assisted with data collection. Dr. Thomas G. Bever provided comments and laboratory resources.

#### Abstract

Little is known about the how the decision is made to terminate memory search, though there have been several recent attempts to uncover this process. In one recent study, Miller et al. (2012), re-analyzed data from a large number of free-recall experiments and identified intrusions as a factor that influenced search termination decisions. One potential problem with this re-analysis is that all the data were drawn from experiments in which it was impossible to determine if or when search was terminated. Using data from experiments in which search termination decisions were directly measured, we confirmed Miller at al.'s (2012) original findings but also demonstrated that intrusions influence the time taken to generate the final retrieval and the time between the final retrieval and search termination. The pattern of data is consistent with a simple, sample-withreplacement model in which intrusions are less active than items from the target list.

Keywords: recall; memory search termination; stopping rules

Every search of memory is eventually terminated. When an individual decides to terminate their own memory search (e.g., when they are not interrupted or given a fixed time limit for search), what factors influence this decision? The long history of memory research is relatively silent regarding this question as most memory recall experiments give participants a pre-determined amount of time to search memory (a closed-interval) and have no method of determining when or, even if, participants terminate their search before the retrieval interval expires. When participants are allowed to terminate their own search, as is the case in the open-interval design discussed below, a number of dependent variables emerge that allow the measurement of memory search termination decisions. These variables include the total time spent in search ( total time or $\mathrm{T}_{T}$ ), which is controlled by the participant in this design. The total time can be divided into the time from the beginning of search to the time of the final retrieval (time-to-last retrieval or $\mathrm{T}_{L}$ ) and the time between the final retrieval and search
termination (exit latency or $\mathrm{E}_{L}$; Dougherty \& Harbison, 2007). These variables allow for the testing of different memory search stopping rules previously proposed in the literature, with much of the available data uniquely supporting the cumulative-failures stopping rule (Harbison, Dougherty, Davelaar, \& Fayyad, 2009) proposed within the search of associative memory model (SAM; Raaijmakers \& Shiffrin, 1981). According to this rule, every retrieval attempt that does not produce a new retrieval is counted as a retrieval failure and search is terminated when the number of these failures reaches a threshold.

Recent research, however, has suggests that search termination might also be influenced by the presence of memory intrusions (Miller, Weidmann, \& Kahana, 2012; Unsworth, Brewer, \& Spiller, 2011). Miller et al. (2012) showed that memory search was more likely to be terminated after an intrusion from a previous list (prior list intrusion or PLI), an extra list intrusion (ELI), or after outputting a list word that had previously been retrieved (repetition). They suggested that the increase in the probability of stopping may be due to the effect such retrieval errors have on subsequent recall. Each retrieved word is thought to influence subsequent retrievals either by the use of the retrieved word as a cue for subsequent retrieval attempts (Kimball, Smith, \& Kahana, 2007; Sirotin, Kimball, \& Kahana, 2005) or by the retrieved item shifting the contextual retrieval cues closer to the retrieved items own context (Howard \& Kahana, 2002). Intrusions and repetitions then would decrease the probability of retrieving a new target list word. A PLI would increase the relative probability of another word from the prior list being retrieved; an ELI would increase the probability of sampling related extra-list words, and repetitions would increase the probability of retrieving other words that have already been retrieved.

One potential problem with the Miller et al. analysis is that they had to infer when participants terminated search since the experiments they used in their analysis used a closed-interval design. To determine
when participants might have terminated search, they used data from an open-interval experiment (Dougherty \& Harbison, 2007) to set an inter-retrieval time longer than participants were found to search memory before terminating search. However, the factors they identified as increasing the probability of search termination would also slow down retrieval. That is, if intrusions increase the probability of sampling non-target words, this decreases the probability of sampling target list words. When the probability of sampling a word decreases, the expected time to sample that word increases. Therefore, it might be that intrusions did not increase the probability of search termination but simply slowed retrieval sufficiently for no additional words to be output in the retrieval interval. Participants might have continued searching but to no avail.

In the present study, we used data from experiments that used an open-interval paradigm to examine whether intrusions increase the probability of search termination when participants were required to indicate when they terminated search. Second, we tested the hypothesis that the retrieval of an intrusion changes the probability of subsequent retrieval types. Third, we tested if terminating search after an intrusion changes the temporal variables of search termination $\left(\mathrm{T}_{T}, \mathrm{~T}_{L}\right.$, and $\left.\mathrm{E}_{L}\right)$. Fourth, we evaluated whether the results could be modeled using a cumulative-failures stopping rule, and if so what assumptions were needed.

## Open- vs Closed-Interval Retrieval

The difference between the standard free recall paradigm, or the closed-interval design, and the openinterval design is depicted in Figure 1. In the closedinterval design participants are given a predetermined length of time for retrieval (e.g., 60 seconds). In this design, the decision to terminate search is obscured. During the retrieval interval participants might continue to search memory throughout the entire interval, terminate search immediately after the final retrieval, or even retrieve items after terminating search (e.g., a participant might terminate search then stumble upon another list word while letting their mind wander). In contrast, the open-interval design allows participants to continue search until they decide to terminate their own search (depicted in Figure 1 with an " X "). As mentioned above, three temporal variables emerge as measures of memory search termination and it has been found that the $\mathrm{T}_{T}$ and $\mathrm{T}_{L}$ increases while the $\mathrm{E}_{L}$ decreases with the number of items retrieved (Dougherty \& Harbison, 2007; Harbison et al., 2009; Unsworth, Brewer, \& Spillers, 2011).

The open-interval design is therefore particularly useful for examining search termination decisions and provides not only a method of replicating the Miller et al. results, but also a method of extending them. Using this design it is possible to determine if search is terminated

Figure 1: Comparison of A) Closed-Interval and B) Open-Interval Experimental Designs.
more quickly if an intrusion is the final outputted word relative to when a word from the target list is the final retrieval.

We re-analyzed data from two previous experiments using the open-interval design to test for these results. Importantly, the data from these two experiments utilized what we call a multi-target cued recall paradigm. Within this paradigm, participants studied multiple separate lists of words successively, with all words from each list paired with a single cue word. After studying all the lists, participants were presented with a cue and asked to recall as many words as possible that had appeared with the cue. This aspect of the experiments is particularly useful for examining the role of intrusions on search termination because it should increase the probability of PLIs. The multi-target cue task can be contrasted with the standard procedure for list recall experiments, which is to have participants study a single list at a time and then, possibly after a filler task to clear short-term memory (e.g., solving simple math problems), prompt participants to retrieve words from the studied list.

## Analysis of Previous Experiments

As mentioned above, both experiments used a multitarget cued recall paradigm. For the first experiment (Dougherty \& Harbison, 2007), three lists were shown in each block for four total blocks of lists providing data from twelve lists per participant. For the second (Experiment 1, Harbison et al., 2009), four lists were shown in each of the four blocks providing sixteen lists per participant. The two experiments also differed in list length. There were ten words per list in the first experiment and eight words per list in the second. Both experiments used lists of high (KF i 50) and low (KF ; 10) frequency words drawn from the MRC Psycholinguistic Database (Wilson, 1988; available from http://www.psy.uwa.edu.au/mrcdatabase.uwa_mrc.htm). For the second experiment, in addition to high and low
frequency lists, two of the lists per block were a mix of high and low frequency words (four of each). One mixed-frequency list had a high frequency cue word per block and one had a low frequency cue word. In both experiments, word frequency did not have a significant effect on the memory search termination variables. Therefore, the analyses collapsed across lists of high and low frequency words.

Table 1: Mean Number Retrieved

| Source | List | PLI | ELI |
| :--- | :---: | :---: | :---: |
| Dougherty \& Harbison, 2007 | 3.40 | .25 | .18 |
| Exp 1. Harbison et al., 2009 | 2.12 | .53 | .42 |
| New Experiment | 1.84 | .32 | .06 |

Table 1 shows the mean number of list words, PLIs, and ELIs per participant per list. Note that the number of PLIs though still small made up $6 \%$ and $17 \%$ of the total number of items retrieved, respectively. Following the procedure of Miller et al. (2012), we examined the probability of terminating search as a function of both the previous retrieval type (list word, PLI, ELI) and output position. Note that for all results reported in this study statistical significance was determined by biasedcorrected and accelerated (BCa) bootstrap estimates of the $95 \%$ confidence intervals. Here, we test the differences between list words and the two types of intrusions. The results from both previous experiments were consistent with the PLIs and ELIs increasing the probability of search termination, as shown in Figure 2A, but none of these differences were significant for the Dougherty and Harbison (2007) experiment. For the Harbison et al. (2009) experiment, shown in Figure 2B, output positions two and three were significant for both ELIs and PLIs, also ELIs were significant for the first position. Therefore, these results replicated those of Miller et al. (2012).

The hypothesis for why intrusions increase the probability of search termination was also tested. As mentioned above, the explanation is that intrusions increase the probability of non-list items being sampled after an initial intrusion. These intrusions could be words from a previous list, as should be the case for PLIs, or words from outside the experiment, as should be the case for ELIs. Figure 3A and B shows the probability of list words, PLIs, ELIs, and search termination immediately after each type of retrieval. For both experiments, after a PLI participants were more likely to terminate search, less likely to output a list word, and, importantly, more likely to output another PLI relative to after they had generated a list word. In contrast, after ELIs there were only significant differences in the probability of generating list words and terminating search and this was only found to be significant in the Harbison et al. Experiment

Figure 2: Probability of terminating search as a function of the previous retrieval and output position for A) Dougherty \& Harbison, 2007; B) Harbison et al., 2009, Exp 1; and C) the new experiment.

1 data.
These results are consistent with the explanation proposed by Miller et al.(2012). Not only are PLIs associated with an increase in the probability of termination, but they are also associated with an increase in the probability of generating other words from previous lists. The support for ELIs is mixed, but still consistent with this explanation.

Overall the pattern of results using the open-interval design were consistent with those reported using the closed-interval design. Search termination was more likely after an intrusion, especially a PLI. Furthermore, the retrieval of a PLI does appear to be correlated with an increase in the probability of retrieving words from previous lists and a decrease in the probability of retrieving subsequent list words. However, the replication of difference in the probability of terminating search by type and output position was only significant for one of the two re-analyzed experiments. Therefore, to further test Miller et al.'s results a new experiment using the open-interval and multi-target cued recall was conducted.

Figure 3: Probability of retrieval type or termination as a function of the previous retrieval type.

## Experiment

103 Participants were randomly assigned to one of two conditions. Participants in one condition were given two blocks of four high frequency word lists followed by two blocks of low frequency word lists while participants in the other condition were given four blocks of low frequency word lists. This manipulation was designed to test a hypothesis about the role of individual differences in motivation on the influence of previous retrieval experience on stopping decisions (Dougherty \& Harbison, 2007) which is outside of the scope of the present study. As was found in the previous experiments, word frequency did not influence stopping decisions outside of the impact on number of words retrieved. Therefore, consistent with the previous experiments, all lists were combined for the purpose of examining stopping decisions.

## Stimuli

Both high and low frequency words were drawn from MRC linguistics database (Wilson, 1988), the same source for lists in the previous experiments, and the same criteria for high and low frequency words were used. Lists of eight to be recalled words and one cue word were random generated for each participant.

## Procedure

The same open-interval, multi-target cued recall procedure was used as in the previous experiments. During learning, participants were presented with the cue word and each list word from the first, second, third, and fourth list. The learning phase was then repeated. Thus, participants saw each list word with that list's cue word twice. Participants were then asked to retrieve the words from the first, second, third, and fourth lists, in that order. There were a total of four blocks of lists. As before, participants were provided an open-interval for retrieval. They indicated when they were finished retrieving from each list by saying "Stop" and pressing the space bar.

## Results and Discussion

The exit latency and total time results replicated the findings from previous open-interval experiments (Dougherty \& Harbison, 2007; Harbison et al., 2009; Unsworth et al., 2012). $\mathrm{E}_{L} \mathrm{~s}$ were negatively correlated with number retrieved and $\mathrm{T}_{L}$ and $\mathrm{T}_{T}$ were positively correlated with number retrieved. The mean within participant gammas of $-0.293,0.224$, and 0.472 , respectively, were each significant.
Intrusions and Search Termination As shown in Figure 2C, the results were again consistent with Miller et al. (2012). PLIs and ELIs were consistently more likely to be the final word retrieved before termination across output positions relative to target list words. However, only the output positions with the most participants contributing to them, the first three positions, were significantly different between the intrusion types (both PLI and ELI) and list words.

The shift in the probability of retrieving subsequent list items and intrusions after retrieving an intrusion was found in the present experiment, matching the results of the re-analyzed experiments. Participants were more likely to have a PLI after a PLI and more likely to terminate search while also being less likely to retrieve a target item. Likewise, after an ELI, participants were more likely to terminate and less likely to generate a target word. One difference from the results reported above is that participants were also more likely to generate an ELI after an ELI in the present experiment. This pattern is shown in Figure 3C.
Intrusions and the Time Course of Termination The open-interval design also allows for the testing of temporal effects of intrusions. Specifically, does the generation of an intrusion have a different profile in terms of exit latency $\left(\mathrm{E}_{L}\right)$, time-to-last $\left(\mathrm{T}_{L}\right)$, and total time $\left(\mathrm{T}_{T}\right)$ ? To test this, we compared temporal variables when search was terminated after both types of intrusions with instances where retrieval was terminated after a target list word was generated. Note that rate transformations were used for the purposes of the analyses and
that we again used BCa to estimate the $95 \%$ confidence intervals.

Figure 4: A) Exit Latency, B) Time to Last, and C) Total Time as a function of final retrieval type and total number retrieved.

We combined the data from the present experiment and the experiments included in the above reanalysis. The combined $\mathrm{E}_{L}, \mathrm{~T}_{L}$, and $\mathrm{T}_{T}$ results are shown in Figure 4 as a function of final retrieval type and total number retrieved. The $\mathrm{E}_{L}$ after a PLI was significantly shorter than when the final word was from the target list for four of the five cases. Furthermore, the $\mathrm{T}_{L}$ was longer after a final PLI for all five total number retrieved. The pattern of results was less clear for the differences between target list words and ELIs. The $\mathrm{E}_{L}$ was shorter for three of the five cases and the $\mathrm{T}_{L}$ was longer for two of them. The results were even less consistent for $\mathrm{T}_{T}$. The difference between list words and PLIs were significant for two output positions and the difference between list words and ELIs was only significant for one of the positions.

The temporal data add another portion of the picture of the role of intrusions in search termination. Combined, the present results suggest that participants are more likely to terminate search following an intrusion, more likely to generate a subsequent intrusion of the same type (particularly for PLIs), that the time to generate the final item is longer if it is an intrusion (par-
ticularly for PLIs), and that the time between the final retrieval and termination is shorter after an intrusion (particularly for PLIs). This pattern of data provides a new challenge for models of recall and particularly stopping rules to account for. The next section examines how well as simple sample-with-replacement model is able to account for these results.

## Stopping Rules and Intrusions

For the present simulation, we tested the explanation that intrusions have lower activations relative to list words. Like intrusions, items with lower activation are retrieved later in recall. Here we tested if items with lower activation shared the additional characteristic of intrusions. The present focus is on the sampling process itself. Therefore, for the sake of simplicity, we assumed a set of activations instead of modeling encoding and the activation process (Harbison, Hussey, Dougherty, \& Davelaar, 2012; Rohrer, 1996).

A sample-with-replacement model equipped with the cumulative failures stopping rule was used to predict search. The pattern of activations used to test the model was $(.5, .5, .5, .5,1,1,1.5,1.5,2,2)$. We ran the sample-with-replacement procedure where the probability of sampling item $i$ was determined by the act ${ }_{i}$ divided by the sum over all item activations. A retrieval attempt was successful if the sampled item had not previously been retrieved and if the activation of the sampled item was greater than the recovery threshold of 0.5 . Four unrecoverable items were included in the activation pattern. The total number of retrieval failures was tracked and once this number exceeded the stopping threshold of 30 search retrieval was terminated as prescribed by the cumulative failure stopping rule (Harbison et al., 2009). The stopping threshold was within the range tested in previous applications of the model (Harbison et al., 2012) and the activation pattern used, specifically the inclusion of four items that were not recoverable, was chosen to increase the variability in the number of items retrieved. Also to this end, for each simulation run a subset of six items was chosen at random (and with equal probability) from the complete pattern of activations. Without this, the number of items retrieved was too consistent to be at all comparable to participant data.

The results from 10,000 independent runs of list recall are presented in Figure 5. Items that were relatively less active show the same profile as intrusions. The probability of terminating search after an item with less activation was greater than for an item of greater activation, as shown in Figure 5A. Also, if items with lower activation were the final retrieved, it took longer to generate them ( $\mathrm{T}_{L}$ is greater) and search was terminated more quickly after the final retrieval ( $\mathrm{E}_{L}$ is smaller), as shown in Figure 5B. Therefore, the present results relating intrusions to search termination can be accounted for by

Figure 5: A) Probability of search termination and B) $\mathrm{E}_{L}, \mathrm{~T}_{T}$, and $\mathrm{T}_{L}$ by item activation.
a simple sample-with-replacement model equipped with the cumulative failures stopping rule as long as it can be assumed that intrusions are relatively less active than words from the target list. This seems a reasonable assumption as models taking into account multiple sources of association (context, experimental word associations, and semantic word associations) often a assume a multiplicative use of search cues (Sirotin, Kimball, \& Kahana, 2005; Kimball, Smith, \& Kahana, 2007) and intrusions should at least have a lower association strength to the target context than list words.

In contrast, the model does not account for the observed impact of intrusions on subsequent retrieval. That is, it cannot account for the greater probability of retrieving a PLI when the immediately preceding item is a PLI. Therefore, it might be necessary to assume that the retrieval of an intrusion changes the contextual landscape which determined the probability of retrieving subsequent PLIs and target list items. Provided this extra assumption, the cumulative failure stopping rule should have no trouble accounted for the present results.

## Conclusion

The results from three experiments using the openinterval design replicate the results from a large-scale re-analysis of closed-interval experiments (Miller et al., 2012) that participants are more likely to terminate search after an intrusion (either from previous list or from outside the experiment) than after a correct recall. Furthermore, search was terminated more quickly after an intrusion (smaller exit latency) and the time taken to generate an intrusion as the final output was greater (greater time-to-last retrieval). These results were found to be consistent with the predictions of a sample-withreplacement model equipped with a cumulative failure stopping rule. As such, the results suggest that the role
of intrusions in search termination is an indirect one. Intrusions could lead to a greater probability of retrieval failures, with the total number of retrieval failures still being the direct cause of search termination.

#### Abstract

The conclusion that people are optimistic concerning personal risk does not have a sound evidential basis. Following Harris and Hahn's (2011) critique of unrealistic optimism research, we consider the evidence from a recent series of high profile neuroscience papers. We demonstrate that the methods used are fundamentally flawed. A simulation and an empirical comparison of autism spectrum condition participants with typical adults confirm that we have learnt nothing about optimism from these studies.

Keywords: Optimism; human rationality; belief updating; statistical artifact

## Introduction

It is a long-established 'fact' that human judgment is biased when estimating personal risk. It has been argued that people underestimate their risk of encountering negative events (compared to their estimate of the average person's risk), and overestimate their chances of encountering positive events (e.g., Weinstein, 1980). This pattern of optimistic self-estimates has been termed 'unrealistic optimism'.

The majority of evidence for unrealistic optimism originated from research employing what we will term the 'comparison method'. Participants are asked to directly (Weinstein, 1980) or indirectly (e.g., van der Velde, van der Pligt, \& Hooykas, 1994; for a review, see Helweg-Larsen \& Shepperd, 2001) compare their chance of experiencing a negative life event with that of the average individual. It is argued that the existence of unrealistic optimism is supported by a pattern of results where the mean of participants' estimates of self-risk is significantly lower than the mean of their estimates of the average person's risk. However, a recent analysis of studies using the comparison method casts doubt over the existence of unrealistic optimism. Harris and Hahn (2011) showed that perfectly rational (non-biased) agents generated personal risk estimates that would be classified as unrealistically optimistic on the comparison method for purely statistical reasons. Unfortunately, the comparison method has been used in the vast majority of unrealistic optimism studies to date, meaning that rather than being a characteristic of
healthy human thought (e.g., Sharot, 2012; Taylor \& Brown, 1988), 'unrealistic optimism' may instead be a statistical artifact resulting from a flawed methodology.

## Identifying Optimism: A New Development

Unrealistic optimism is widely regarded as a central cognitive bias, yet the fact that almost all past research is based on the comparison method means that there is very little empirical evidence for its existence. The frailties associated with the comparison method have, however, only recently been identified, and common belief amongst both researchers and the general public is that risk estimates are characterised by an optimism bias (e.g., Sharot, 2012).

With this position as their starting point, Sharot and colleagues (Sharot, Guitart-Masip et al., 2012; Sharot, Kanai, et al., 2012; Sharot, Korn, \& Dolan, 2011) have begun an investigation into the neural underpinnings of the phenomenon. Sharot et al. (2011) claimed that people maintain an optimistic view of the future through selectively incorporating new desirable information into their beliefs more than new undesirable information. If this result is robust, it seems to shift the body of evidence back in favor of an optimistic bias in human likelihood judgments.

The Update Method We shall refer to the method introduced in Sharot et al. (2011; see also, Sharot, GuitartMasip, et al., 2012; Sharot, Kanai, et al., 2012) as the update method (Figure 1). Participants estimate their chance of experiencing each of a series of negative events. They are subsequently given the probabilities with which these negative events are experienced by the average individual (base rates). Subsequently, participants re-estimate their chances of experiencing the same negative life events. The critical variable is the degree to which participants update their personal risk estimates in light of the given information about the average person's risk. Updates are compared across two types of trial: trials where the base rate of the negative event was lower than the participant's initial estimate ('desirable information'), and trials where it was higher ('undesirable information'). Participants are found to update their estimates more in response to desirable

[^78]information, thus enabling the preservation of an unrealistically optimistic view of the future.

Figure 1: The update method.

## Overview

The present paper proceeds in two stages. In the first stage, we present a formal critique of the update method. We subsequently demonstrate (Study 1) that, as a result of the identified flaws, the update method gives rise to a seemingly optimistic pattern of belief updating in a population of rational Bayesian agents. Finally, in anticipation of a counter-argument that the demonstration of neural moderators of the effect (e.g., Sharot, Kanai, et al., 2012) provides further evidence for its existence, we present results from a study comparing autism spectrum condition (ASC) participants with typical adult (TA) controls. With a suitable addition to the update method, we demonstrate that we can infer nothing about the neural correlates of optimism from the results currently present in the literature.

## What's Wrong With the Update Method?

There are two distinct ways in which we might receive new information relevant to our individual risk. We may receive new information about the base rate, or we may receive diagnostic information that pertains to us personally (e.g., genetic vulnerability). Both types of information are relevant, both can be desirable or undesirable, and both should be combined via Bayes' Theorem to provide our best estimate of risk (e.g., Kahneman \& Tversky, 1973), as is illustrated in the following example.

Normative Risk Updating 55-year-old Tim estimates that the average 55 -year-old's risk of contracting heart disease (HD) (the base rate) is 20\%. In the absence of any other information, Tim's best estimate of his own likelihood of contracting HD is $20 \%$.

If Tim possesses any diagnostic information that differentiates his risk from the average person's, he should normatively combine the base rate with this diagnostic information. For example, if he does not have a family history of HD, his risk is lower than the average person's. Bayes' Theorem prescribes how this information should be combined (e.g., Kahneman \& Tversky, 1973):

$$
\begin{equation*}
P(h \mid e)=\frac{P(h) P(e \mid h)}{P(h) P(e \mid h)+P(\neg h) P(e \mid \neg h)} \tag{1}
\end{equation*}
$$

Bayes' Theorem prescribes the probability, $P(h \mid e)$, of experiencing an event $h$ (e.g., HD) in light of evidence $e$ (no family history of HD). The best estimate of experiencing that event is a function of the base rate of the event, $P(h)$, and the diagnosticity of the evidence - the likelihood ratio of true positives, $P(e \mid h)$, relative to false positives, $P(e \mid \neg h)$. In Tim's case, $P(e \mid h)$ reflects how likely an HD patient is to have no family history of HD, whereas $P(e \mid \neg h)$ reflects the probability of no family history of HD in those who do not contract HD. From a longitudinal study (Hawe, Talmud, Miller, \& Humphries, 2003), we can calculate $P(e \mid h)=.52$ and $P(e \mid \neg h)=.66$. Tim's estimate of $P(h)$ is $20 \%$ and therefore his best estimate of his chance of contracting HD is:

$$
\begin{equation*}
\frac{.2 \times .52}{.2 \times .52+.8 \times .66}=16 \% \tag{2}
\end{equation*}
$$

The base rate of HD is actually $33 \%$ for 55 year-old males (Bleumink et al., 2004). If Tim receives this information, he should recalculate his personal risk once more, using Bayes' Theorem, replacing his previous base rate estimate (20\%) with $33 \%$, which will result in an increased 'best estimate':

$$
\begin{equation*}
\frac{.33 \times .52}{.33 \times .52+.67 \times .66}=28 \% \tag{3}
\end{equation*}
$$

Given the two basic components to normative probability judgments - base rates and evidence - there are thus two ways to receive undesirable (desirable) new information: One can receive new, diagnostic information which suggests that one is more (less) at risk, or one may discover that the base rate is higher (lower) than previously thought.

In Equation 2, Tim knows the accurate base rate, calculates his personal risk rationally, and yet his personal risk is different from the base rate. In contrast to the central assumption of the update method, individuals should not necessarily change their estimate of personal risk simply because it lies above or below the base rate. Researchers can only prescribe what effect the new base rate information should have on a participant's risk estimate if they know the participant's previous estimate of the base rate. Without this knowledge, it is impossible to classify a particular trial as 'desirable' or 'undesirable' and therefore to say in which direction (and how much) the participant's estimate should change. Study 1 highlights the flaws in the update method by simulating optimistic data from non-biased agents!

## Study 1: A Simulation

Take a hypothetical sample of 100 Bayesian agents, 25 of whom assume base rates of $.1, .2, .3$, and .4 respectively (mean $=.25$ ) for Disease $X$, which has a true base rate of .25. Before the study, these agents receive evidence
reflecting their vulnerability to Disease X with the following characteristics: $P(e \mid h)=.5 ; P(\neg e \mid \neg h)=.9$.
$P(h) P(e \mid h)+P(\neg h) P(e \mid \neg h)$ defines the proportion who received evidence suggesting increased risk, here: . $25 \times .5+$ $.75 \times .1=.2$. Thus $20 \%$ of agents have evidence suggesting they will get the disease ('positive evidence') and $80 \%$ have evidence suggesting they will not ('negative evidence'). At each base rate, 5 agents will receive positive evidence, and 20 will receive negative evidence.

In the study (Table 1), agents calculate their initial risk estimates normatively via Bayes’ Theorem, using their subjective base rates; their second estimate recalculates Bayes' Theorem using the experimenter-provided true base rate (see Equations 2 and 3).

Agents whose subjective base rate estimates were below the true base rate (.25) truly receive undesirable information: Disease X is more prevalent than they thought. Agents whose subjective base rate estimates were above the true base rate truly receive desirable information: Disease X is less prevalent than they thought. However, the update method classifies information as 'desirable' or 'undesirable' based on the relationship between initial estimate and true base rate, thus misclassifying $30 \%$ of the sample (grey columns).

The final experimental 'result' is obtained by averaging across those agents receiving 'desirable' and 'undesirable' information (as defined by the experimenter). As each positive evidence group represents 5 agents, and each negative group 20 agents, the resulting absolute means are: Desirable Group $=0.04$; Undesirable Group $=0.03$. Thus, these rational agents show 'greater updating' in response to 'desirable' than 'undesirable' information and would be labelled optimistic - though rational by definition - simply due to incorrect classification. Although this is a somewhat small effect, it becomes much more pronounced when base rate estimates are regressive toward the midpoint of the scale, as is typical of people's probability estimates in many
contexts (see e.g., Harris \& Hahn, 2011; Moore \& Small, 2008, and references therein). If the true base rate were .21 , i.e., below the agents' mean estimate, then the seeming difference in updating rises to $8 \%$ ('desirable’ = . 084 ; 'undesirable' $=.004$ ) - easily able to account for extant experimental data. Figure 2 demonstrates that this pattern of results is not dependent on the precise parameters used in this illustrative example. The preponderance of positive differences in updating (where people update more in response to desirable than undesirable information) is clear from both Figure 2a (where mean estimates of the underlying base rate are correct) and Figure 2b (where base rate estimates are regressive, \& consequently represents more realistic simulations).

## Implications of the Update Method's Flaws

The key implication of the simulation results presented above is that a difference in participants' amount of updating in response to 'desirable' and 'undesirable' information, as defined in Sharot et al. (2011; see also, Sharot, Guitart-Masip et al., 2012; Sharot, Kanai et al., 2012), cannot be taken as evidence of optimism. As with the statistical confounds in the comparison method, however, there is a simple test that disassociates the predictions of an optimism account from a statistical artifact account: the inclusion of positive events (Harris \& Hahn, 2011). Our simulation result is blind to the valence of the events being judged. Consequently, for positive events the statistical account again predicts that updating will be greater in response to information that the base rate is lower than you originally believed your own risk to be. For positive events, which we want to experience, these would be classified as 'undesirable' trials, and hence this pattern of results would suggest pessimism. Thus, updating is undoubtedly optimistic (despite the flaws in the method) if participants update more in response to desirable than undesirable information for both negative and positive events.

Table 1: Artifactual Unrealistic Optimism in Study 1

| Those with positive evidence |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Subjective base rate | $\begin{gathered} 0.1 \\ (n=5) \\ \hline \end{gathered}$ | $\begin{gathered} 0.2 \\ (n=5) \\ \hline \end{gathered}$ | $\begin{gathered} 0.3 \\ (n=5) \\ \hline \end{gathered}$ | $\begin{gathered} 0.4 \\ (n=5) \\ \hline \end{gathered}$ | 0.1 <br> $(n=20)$ <br> 0.058 | 0.2 <br> $(n=20)$ | 0.3 <br> $(n=20)$ <br> 0.192 | $\begin{gathered} 0.4 \\ (n=20) \\ \hline \end{gathered}$ |
|  |  |  |  |  |  |  |  |  |
| Initial Estimate | 0.357 | 0.556 | 0.682 | 0.769 | 0.058 | 0.122 | 0.192 | 0.270 |
| True Base Rate | 0.25 | 0.25 | 0.25 | 0.25 | 0.25 | 0.25 | 0.25 | 0.25 |
| Experimenter-defined Desirability ${ }^{\text {a }}$ | Des | Des | Des | Des | Undes | Undes | Undes | Des |
| True Desirability ${ }^{\text {a }}$ | Undes | Undes | Des | Des | Undes | Undes | Des | Des |
| Correctly Classified? | NO | NO | YES | YES | YES | YES | NO | YES |
| Final Estimate | 0.625 | 0.625 | 0.625 | 0.625 | 0.156 | 0.156 | 0.156 | 0.156 |
| Amount of update (IE - FE) | -0.268 | -0.069 | 0.057 | 0.144 | -0.098 | -0.034 | 0.036 | 0.114 |

[^79]Furthermore, Figure 2 demonstrates how a non-selective change to a probabilistically relevant quantity (e.g., changing the perceived diagnosticity of individuals' evidence; or altering the regressiveness of their initial base rate estimates) that affects all agents equally, can lead to a seemingly selective effect: a sharp increase in the difference between updating for 'desirable' vs. 'undesirable' information. Thus, the selective effects of L-DOPA (Sharot, Guitart-Masip et al., 2012) and transcranial magnetic stimulation (TMS) (Sharot, Kanai, et al., 2012) on belief updating might be entirely unrelated to optimism, and simply reflect (for example) better learning (i.e., less conservative updating - formally equivalent to an increase in the diagnosticity of information) following receipt of L DOPA.

Figure 2: Seemingly 'optimistic' updating. Positive values in the z-axes demonstrate 'optimistic' updating for Bayesian agents receiving evidence with the properties shown in the x-axes, $P(e \mid h)$, and y-axes, $P(\neg e \mid \neg h)$. Panel a), agents estimate the base rate as either: $.1, .2, .3, .4$, and the true base rate $=.25$ (as in Table 1). Panel b), true base rate $=.21$. The mass of data points in both plots spuriously suggests optimistic updating.

## Study 2: An Experiment

The results reported above led us to run an experiment in which we followed Sharot et al.'s (e.g., 2011) method, but crucially included a selection of positive events in addition to the negative events. We were further interested in a comparison of ASC participants, with typical adult (TA) controls. Sharot et al. (2011) reported that optimistic updating was largely mediated by the medial prefrontal cortex. Given that ASC is associated with hypoactivity in this region across a range of tasks (Gilbert et al., 2008), and ASC participants have been suggested to be less susceptible to emotional biases in decision making (de Martino et al., 2008), one might predict these individuals to show less of an optimistic bias, similar to the attenuation of the effect in participants who have received TMS to the left inferior frontal gyrus (Sharot, Kanai, et al., 2012). Should this effect be observed, we are crucially interested in the results from the positive events in this study. If TAs do show a seeming pessimism bias (as predicted by the statistical account), will the individuals with ASC show more of a 'pessimism bias' (as they appear to be less optimistic than TAs with negative events), or will this effect also be attenuated - suggesting that ASC has not had a selective effect on 'optimism'?

## Method

Participants 20 male participants with a mean age of 34 years participated in return for $£ 10$. The 10 ASC participants all received diagnoses from an independent clinician. Of the 10, using the Autism Diagnostic Observation Schedule (Lord et al., 2000), 5 met the criteria for autism, and 5 for autistic spectrum disorders. The ASC and NT participants were matched for IQ (Weschler, 2011) and age, $t \mathrm{~s}<1$.

Design The experiment was a $2 x 2 x 2$ (group $x$ event type [positive/negative] $x$ information desirability) design, with event type and information desirability manipulated withinparticipants. In a departure from Sharot et al.'s (e.g., 2011) method, the base rates presented to participants were derived from participants' initial estimates of their own risk (IE1), rather than being externally sourced. This enabled the experimental manipulation of information desirability, as well as controlling for the potential differential accuracy of base rate information pertaining to negative events (for which there is plenty of information) versus positive events (for which there is a scarcity of information). Base rates were computed according to the following formula: A random percentage between $17 \%$ and $40 \%$ (uniform distribution) of IE was either added to, or subtracted from, the IE, according to trial type, and rounded to the nearest integer. Thus, for example, on positive desirable trials a random percentage of the IE was added to the IE resulting in a derived probability indicating that the positive event was more likely to occur than had previously been estimated, and on negative desirable trials a random percentage of the IE was subtracted from the IE, indicating that the negative event was less likely than had been estimated. All
probabilities were capped between $3 \%$ and $80 \%$ as participants were informed that this was the range of possible probabilities (see also, e.g., Sharot et al., 2011).

Stimuli and Procedure Eighty short descriptions of life events, many of which had previously been used in the study of unrealistic optimism (e.g., Sharot et al., 2011; Weinstein, 1980), were presented in a random order. Half of the events were positive and half negative. Very rare or very common events were avoided and all known probabilities lay between $10 \%$ and $70 \%$ ( $M=32.6, S D=18.8$; Office for National Statistics and PubMed). The procedure followed that of Sharot et al. (2011) (see Figure 1), with one addition. Following their IE, participants were asked to estimate the chance of the event occurring to the average person ${ }^{2}$. Following the main task, participants' memory for the base rates presented to them was tested, and they provided four salience ratings for each event ${ }^{3}$. Finally, a funneled debrief procedure (Bargh \& Chartrand, 2000) showed that no participants suspected that the derived base rates were inaccurate.

Scoring For each event the amount of update was calculated first by computing the absolute difference between the updated estimate in the second session and the IE, and second, coding the difference as positive when the update was in the direction of the base rate and negative when the update was away from the base rate. Mean updates for each participant in each condition were then calculated after removal of outliers ( $\pm 3 \times$ the interquartile range) and trials for which a derived probability could not be applied (e.g., when a participant's IE was already at the lowest extreme of the probability range, but the trial-type required that a lower base rate be supplied).

## Results

TA Controls For negative events, we replicated the central result from Sharot et al. (2011). Participants updated more in response to desirable information than to undesirable information, $t(9)=5.02, p=.001$ (see Figure 3). This result demonstrates that the minor changes to the update method's procedure were not consequential for the general paradigm. For positive events, however, the reverse pattern was observed, with greater updating in response to undesirable information than desirable information, $t(9)=4.71, p=$ .001. Across both event types, a significant event type x desirability interaction was observed, $F(1,9)=35.45, p<$ .001, with no main effect of event type or, crucially, information desirability ( $F \mathrm{~s}<1$ ).

TA Controls and ASC Participants Figure 3 shows that ASC participants showed significantly less asymmetry in their information updating than did TAs, with a significant group x event type x desirability interaction, $F(1,18)=$

[^80]

Figure 3: Mean updates in Study 2. Error bars are +/- 1 SE.
4.83, $p<.041$. None of the effects observed in the TAs were observed in the autistic participants ( $p \mathrm{~s}>.17$ ). The significant 3-way interaction demonstrated that updating in the ASC group was different from in the TA group, but there was no evidence that they were either more or less optimistic.

## Discussion

Sharot, Kanai et al. (2012) administered TMS to the left IFG in one group of their participants. Participants subsequently completed an update task comprised entirely of negative events. Participants who had received TMS to the left IFG were shown to exhibit less of an asymmetry in updating to desirable versus undesirable information, and it was therefore concluded that the left IFG is involved in the suppression of updating beliefs about vulnerability in response to undesirable information. Study 2 can be seen as analogous to this study, with the presence or absence of ASC the quasi-experimental variable in place of the location of TMS. Study 2 included positive events in addition to negative events. For positive events, TAs did not show an optimistic bias in belief updating, but rather a seeming pessimistic bias. This resulted in a $2 x 2$ interaction, such that TAs updated more in response to desirable information for negative events, but more in response to undesirable information for positive events. It was this interaction, rather than a specific optimism bias that was attenuated in the ASC participants. One can only speculate whether the same effect would occur with TMS of the left IFG.

## Summary

Optimism is currently a research area of much interest. Studying optimism with real-world events is complicated by our inability to know the objective probability of an event in a given individual's future (see also, Weinstein \& Klein, 1996). The very prevalent comparative method has been shown to be insufficient (Harris \& Hahn, 2011), and here
we have demonstrated that a recent ('update') method also fails as a test of human rationality, through 'demonstrating' that rational agents are irrational (Study 1)! Despite this weakness, the addition of positive events can determine whether there is evidence for an optimistic bias. With this addition, no evidence is found (Study 2). The inclusion of ASC participants in Study 2 also demonstrated the difficulties inherent in making conclusions about the effects of individual differences or experimental manipulations on optimistic belief updating, without the inclusion of both positive and negative events.

Our resulting conclusion, that there is no evidence for a general optimistic bias in human likelihood judgments, might seem surprising in the light of historical common belief. It is, however, consonant with recent results where participants overestimate the likelihood of negative events relative to neutral events in the laboratory (e.g., Bilgin, 2012; Harris, Corner, \& Hahn, 2009; Risen \& Gilovich, 2007; Vosgerau, 2010). On the basis of the extant evidence, we cannot conclude that an optimistic view of the future characterises healthy human thought (Taylor \& Brown, 1988).

#### Abstract

What psychological and linguistic processes allow one to go beyond the literal meaning of a sentence and infer what was meant but not said ("reading between the lines")? Theorists have differed as to whether these phenomena are driven by complex, online inference processes or by relatively rote rules. The present study uses ERP to explore the cognitive and neural mechanisms involved in scalar implicature (the inference that, e.g., "some" indicates "some but not all"), a test case that has been subject to considerable behavioral research but limited neuropsychological research. Our results challenge both rote-processing and rich-inference accounts. We provide the first ERP results showing that scalar implicature processing depends on context, challenging roteprocessing theories of implicature. However, we also fail to find evidence of a processing cost associated with implicature processing, as predicted by many rich-inference accounts. These results point to a novel conceptualization of pragmatic processing in scalar implicature.

Keywords: language; pragmatics; ERP; scalar implicature

## Rich vs. Rote Pragmatics

Understanding language appears to involve two broad but distinct kinds of processes: derivation of the semantic meaning (those things entailed to be true) and pragmatic inferences that go beyond this "literal" meaning (Bach, 1999; Grice, 1989; Morris, 1938). For example, given sentence (1), the fact that Gabe is the agent of the drinking event would typically be attributed to semantic decoding, while the inference that he is an inconsiderate lout who has annoyed the speaker would generally be construed as pragmatic.
(1) Gabe drank all of the milk and put the carton back in the fridge.

There is, however, considerable controversy about where semantics ends and pragmatics begins and about how to distinguish the representations and processes underlying each, as well as their interaction. One particularly contentious point is whether pragmatic inferences result from complex, rich reasoning processes (Grice, 1989; Sperber \& Wilson, 1986) or from relatively rote, automatic, almost grammatical rules (Chierchia, Fox, \& Spector, 2012; Levinson, 2000).

Perhaps the most-researched test case is scalar implicature, illustrated in (2):
(2) a. John ate some of the cookies.
b. John did not eat all of the cookies.

When we hear a sentence like (2a), we typically assume that (2b) is true as well. Although this inference is robust, it can be cancelled (3a), distinguishing it from semantic entailments, which cannot be cancelled (3b) (Hirschberg, 1991; Horn, 1972).
(3) a. John ate some of the cookies. In fact, he ate all of them.
b. *John ate some of the cookies. In fact, he ate none of them.

On the classical view (Horn, 1972), scalar implicature requires rich online counter-factual reasoning: Listeners only infer (2b) from (2a) if they believe i) the speaker knows whether John ate all the cookies, ii) it is relevant whether John ate all the cookies, and iii) assuming (a-b) hold, the speaker would tell them that John ate all the cookies. This view has been questioned, originally by Levinson (2000), who argued that scalar implicatures are triggered automatically, prior even to compositional processing (i.e., processing language at the level of phrases or sentences).

Much of the work addressing this theoretical dispute has been indirect, testing whether scalar implicatures are slow and computationally costly as a proxy for being rich and complex (Bott \& Noveck, 2004; De Neys \& Schaeken, 2007; Grodner, Klein, Carbary, \& Tanenhaus, 2010; Huang \& Snedeker, 2009). Results have been inconsistent and controversial. More problematically, the link between "slow and costly" and "rich and complex" can be disputed: Grodner and colleagues (2010) argue that scalar implicature is rich, complex, and fast; similarly nothing in principle forbids an automatic process from being slow.

A more direct route is as follows: If scalar implicature is the result of a complex inference process, it should be possible to create contexts in which scalar implicatures are more or less likely to be calculated. If, on the other hand, scalar implicature is an automatic process, it should be relatively impervious to context. A handful of behavioral
studies have reported contextual manipulations that affect scalar implicature calculation (Bergen \& Grodner, 2012; Bonnefon, Feeney, \& Villejoubert, 2009; Hartshorne \& Snedeker, submitted; Noveck, Chierchia, Chevaux, Guelminger, \& Sylvestre, 2002); we return to these in the Discussion. Nothing is known on a neuropsychological level about scalar implicature's context sensitivity, as no such studies have been reported. ${ }^{1}$ Thus, we conducted the present study in order to confirm the behavioral results and extend them to the neuropsychological level.

## Grammatical Context

We compare the ERPs elicited by carefully matched sentences that do or do not evoke scalar implicatures. Our method derives from previous findings that scalar implicatures are more likely to be calculated in declarative sentences (4a) than in the antecedent of a condition (4b).
(4) a. Addison ate some of the cookies before breakfast this morning, and...
b. If Addison ate some of the cookies before breakfast this morning, then...

This has been explained by Chierchia and colleagues (2012) as an effect of entailment context. Scalar implicature usually operates to deny the truth of a logically stronger statement. Since Addison ate all of the cookies entails that Addison ate some of the cookies, stating the latter implicates that the former is not true. In contrast, If Addison ate all of the cookies, then $Q$ does not entail but rather is entailed by If Addison ate some of the cookies, then $Q$; thus stating the latter does not implicate that the former is not true.

While this entailment manipulation is linguistic in nature, it is nonetheless difficult to account for on a strict automatic processing account like Levinson's (2000), on which scalar implicature is triggered lexically prior to any compositional processes - that is, before sentential context, which is by definition compositional, can play a role.

While intuitions that conditional sentences suppress implicature seem robust, experimental evidence consists of a single published judgment study (Noveck et al., 2002). ${ }^{2}$ Thus at best we do not know whether the entailment manipulation in (4) affects scalar implicature online.

The present study addresses this gap as follows:
(5) a. Addison ate some of the cookies before breakfast this morning, and the rest are on the counter.
b. If Addison ate some of the cookies before breakfast this morning, then the rest are on the counter.

[^81]Note that the rest is only felicitous if Addison has not eaten all of the cookies, which is exactly what the scalar implicature implies; thus, by hypothesis the rest should be more felicitous in (5a) than (5b). Thus, by testing whether the ERPs to the rest are different in (5a) and (5b), we test whether entailment context rapidly modulates scalar implicature, affecting interpretation of content later in the sentence. In addition, by comparing ERPs at some - the word that triggers the scalar implicature - we will gain valuable information about the neural processes supporting scalar implicature calculation.

One methodological concern remains: Declarative and conditional sentences differ in numerous ways, not just in how they affect scalar implicature. Thus, any differences observed may be due to implicature-irrelevant processes. Thus, we included a control version of the experiment, where some was everywhere replaced with only some, a phrase that semantically forces the subset ("not all") reading. Thus, the crucial analyses are interactions differences seen between the critical declarative and conditional sentences not seen between the control declarative and conditional sentences.

## Method

## Subjects

49 monolingual native English-speaking right-handed individuals participated. Two were excluded for equipment failure and ten for excessive artifact, leaving 19 in the experimental condition and 16 in the control condition.

## Materials and Procedure

Each participant saw 30 critical declarative sentences and 30 critical conditional sentences. Filler sentences consisted of 60 matched in structure - but not content - to the critical sentences but with continuations that did not mention "the rest" and 35 which additionally swapped the word some for all. These fillers prevented subjects from inferring that all sentences would refer to "the rest" of a previouslymentioned collection. An additional 42 filler sentences involved relative clauses and no quantifiers. Four lists were created by converting the critical declarative sentences into conditional sentences and vice versa and by reversing the order of all stimuli (except the first four stimuli, which were always the same fillers). The four experimental and four control lists were identical except that in the latter, the word some was always preceded by only.

Sentences were presented in eight blocks, with breaks in between. 61 of the sentences were followed by comprehension questions, which were not analyzed. Sentences were presented roughly one word at a time. Wherever two short words appeared consecutively, we presented them together (e.g., Sally/saw/a cat/on the/table). This allowed us to present the critical phrase the rest as a single unit, rather than in two parts which would potentially add noise to the ERP. Some was always presented singly. Stimuli were presented in the center of the screen for 350
ms with a 250 ms blank interval between words. The intertrial interval ranged from 1600 to 2000 ms , not counting any time spent on questions.

## Acquisition and Analysis

Ongoing EEG was recorded from 128 scalp locations using a geodesic sensor net (Electrical Geodesics, Eugene, OR) as subjects read the sentences silently. EEG was recorded relative to a vertex channel and later re-referenced to the average of the mastoid channels. Impedances were maintained below $100 \Omega$. Signals were recorded at 250 Hz and down-sampled to 200 Hz post-acquisition. A $0.1-30 \mathrm{~Hz}$ bandpass filter was applied. Epochs of 1500 ms were selected following the critical phrase (some or the rest) and were corrected with a 200 ms pre-stimulus baseline. Bad channels were replaced and epochs containing artifact (eye blink, eye movement, etc.) removed, both by computer algorithm. Only participants with at least 19 epochs per cell were included in analyses.

## The Bootstrap Cluster Algorithm

The previous literature has focused on the role of the N400 in processing scalar implicature violations. Because no previous study has looked for components indexing scalar implicature generation, we needed a mechanism for selecting and analyzing exactly those electrodes in those time periods with the greatest differences between conditions without allowing multiple comparisons to inflate our Type I error rate (cf Vul, Harris, Winkielman, \& Pashler, 2009). We adapted the recently developed bootstrap cluster analysis of Maris and Oostenveld (2007).

We calculated the context by condition interaction using a mixed effects model with maximal random effects for each electrode at each time point (to speed processing, we further down-sampled the data to 50 Hz ) and recorded the t-value. We then identified all clusters of data points with $t$-values greater than 1.96 or less than $-1.96 .{ }^{3}$ Clustering crossed both time (consecutive super-threshold data points on the same electrode were placed in the same cluster) and space (superthreshold data points from the same time point and belonging to neighboring electrodes were placed in the same cluster). Although data points with positive effects (positive t -values) may represent the same underlying dipole as data points with negative effects (negative $t$-values), we adopted the conservative approach of placing $t$-values of different polarities in different clusters. Clusters are assigned scores, which are the sum of their t -values; thus, clusters with larger statistical effects and/or which are extended in time and space are assigned larger scores.

Statistical significance was assessed through bootstrapping. The condition labels for the subjects (experimental/control) were shuffled, as were the context

[^82]codes (declarative/conditional) for each subject's average ERPs. The clustering algorithm was re-run, and the scores for the largest positive and negative clusters were recorded. This process was repeated 100 times. P-values for a given cluster in the actual data are estimated as the number of larger clusters from the bootstrapped data (calculated separately for positive and negative clusters).

## Results

As can be seen in Figure 1, the interaction between context and condition in the ERPs evoked by some were weak, and none of the resulting clusters were significant ( $p \mathrm{~s}>.2$ ).

In contrast, at the rest an interaction was observed, frontally distributed and lasting from approximately 400 to 1300 ms post-stimulus ( $p=.04$; see Figures $2 \& 3$ ). Inspection of the four waveforms for the four conditions revealed at this interaction was due to a positive deflection for the conditional/experimental sentences relative to the other three conditions. That the conditional/experimental sentences should be the odd one out is expected: only in that condition should the rest be difficult to process, and in fact in our norming studies, the conditional/experimental sentences were judged to be less felicitous than the other three types; this effect disappeared if the sentences were truncated prior to the rest.

Thus, we interpret the interaction at the rest to be due to a positive deflection for the conditional/experimental sentences, reflecting the infelicity of the rest, perhaps due to the difficulty assigning its reference.

## Discussion

A previous judgment study (Noveck et al., 2002) found that scalar implicatures were more likely in declarative than conditional sentences. If this is the case, and if this contextual manipulation affects processing rapidly, then the rest should be more difficult to process in (5b) than (5a). Indeed, we found that the contextual manipulation affected the ERPs to the rest. Interestingly, we did not find an effect of the manipulation on the ERPs to the scalar trigger some.

We address theoretical implications of these findings momentarily. First, we consider their robustness. Given recent concern about replicability in the cognitive sciences (Hartshorne \& Schachner, 2012), we conducted a replication closely matched to the above experiment with the following differences: EEG was recorded using $\mathrm{Ag} / \mathrm{AgCl}$ electrodes attached to an elastic cap following the extended 10-20 system (Newer et al., 1998), and blink artifact was corrected through linear regression. We coded the stimuli so that the ERPs to some in the filler sentences - which up through some are indistinguishable from the critical sentences could be included in analysis, doubling the number of trials for that analysis. Analyses were conducted in identical fashion and with the same result, demonstrating their robustness: no significant clusters were found at some ( $p \mathrm{~s}>.15$ ), but an extended, frontally-distributed cluster was found after the rest ( $p<.01$ ).

Figure 1: Bootstrap cluster analyses at some. In each panel, electrodes grouped into left-hemisphere, midline, and righthemisphere, with more anterior electrodes placed higher. Panel A: $t$-values. Panel B: clusters (distinct color for each cluster).

Figure 2: Bootstrap cluster analyses at the rest. In each panel, electrodes grouped into left-hemisphere, midline, and righthemisphere, with more anterior electrodes placed higher. Panel A: $t$-values. Panel B: clusters (distinct color for each cluster).

Figure 3: Difference waves (declarative - conditional) at the rest. Topographical plots are shown at 600 ms poststimulus. Four representative electrodes are depicted for the entire epoch. The relative negativity for the difference waves in the experimental sentences is driven by a positive deflection for the conditional sentences (see main text).

We consider first the positive results. As predicted, scalar implicatures are less likely to be calculated in the antecedents of conditionals (as evidenced by results at the rest), confirming a strong prediction of Chierchia and colleagues' Grammatical Theory. Moreover, context's effect was sufficiently rapid to affect processing of content (the rest) later in the sentence. This is difficult to reconcile with a strong lexicalist position like Levinson's (2000), on which scalar implicatures are always triggered by words like some, though they may be explicitly cancelled as in (3a). Note that not only was the implicature not cancelled in our conditional sentences, not calculating the implicature renders the sentences infelicitous.

Perhaps the most intriguing finding was the lack of any effect at the scalar implicature trigger some. This finding matches those of five self-paced reading experiments involving similar stimuli, for which Hartshorne and Snedeker (submitted) similarly report no effect: some was read no faster or slower whether a scalar implicature was calculated or not. These finding are in apparent conflict with a single experiment by Bergen and Grodner (2012), which showed slower reading times for some in implicaturepromoting conditions, which they interpreted as indexing the computational cost of scalar implicature calculation. However, Bergen and Grodner used a different
manipulation, an issue we return to shortly. ${ }^{4}$
There are at least three logically possible explanations of the result. The first is that the scalar implicature processing's effect on ERP (and self-paced reading) is quite small and thus we had insufficient statistical power to detect it. This would raise an interesting question: Why is the effect so small relative to typical language ERP effects (such as the effect we observed on the rest) which are observable with a study this size?

A second possibility is that scalar implicature is always triggered by some, and thus the ERPs were identical across conditions (Levinson, 2000). As already noted, this runs afoul of our results at the rest; we would have to stipulate that the entailment context acts to cancel the implicature in the conditional sentences. What the mechanism would be is unclear. Moreover, the effect of the cancellation should be measurable, and though we explored ERPs to several words subsequent to some, we saw no evidence of it.

A third possibility is that not computing the scalar implicature is also a complex and lengthy inference, sufficiently similar to actually computing the scalar implicature that the two could not be distinguished in our study. On the Grammatical Theory, the parser attempts to insert scalar implicatures at any appropriate insertion site, and they are retained if certain criteria are met, such as its resulting in a more informative (i.e., logically stronger) interpretation of the utterance. Presumably, the only way the grammar can know that these criteria have been met is to actually carry out the operations; thus, similar work is done whether the scalar implicature is ultimately endorsed or not. Similarly, on the Gricean account, scalar implicatures are calculated only when certain conditions are met (e.g., the speaker would make the stronger statement if it were true and the speaker knows whether the stronger statement is true). Whether these conditions are met affects whether the implicature is endorsed, not whether the complex set of conditions must be checked. In short, even if calculating a scalar implicature is costly, that does not necessarily mean that manipulations which affect whether the implicature is ultimately endorsed affect the computational cost.

Why then did Bergen and Grodner find an effect on some? While we manipulated whether the scalar implicature was appropriate, they manipulated the salience of the stronger alternative (e.g., all). Since scalar implicature processing requires a stronger alternative to get off the ground, their manipulation may have more directly affected whether processing happened at all.

## Conclusion

We find the grammatical entailment context modulates scalar implicature processing rapidly enough to affect

[^83]processing of subsequent words in the sentence. At the same time, this manipulation did not affect the EEG evoked by the scalar implicature trigger (some). These findings present a first step in uncovering the neural processes underlying the factors driving scalar implicature and also present challenges to existing theories.

# Causal model and sampling approaches to reducing base rate neglect 

Brett K. Hayes (B.Hayes@unsw.edu.au)<br>Ben R. Newell (Ben.Newell@unsw.edu.au)<br>Guy E. Hawkins (G.Hawkins@unsw.edu.au)<br>School of Psychology, University of New South Wales<br>Sydney, 2052, Australia

#### Abstract

Two studies examined how sampling of base rate information and causal explanation of false positives facilitate intuitive probability judgments. Experiment 1a varied these two manipulations factorially. Each had an additive effect on reducing base rate neglect and increasing choice of the normatively correct solution. Experiment 1 b showed that description of relevant distributional information produced similar facilitation to sequential sampling. These results indicate that causal and sampling approaches impact on different components of probability judgment.

Keywords: Causal reasoning, Sequential sampling, Base rate neglect, Bayesian judgment, Belief updating

## Introduction

One of the most commonly observed biases in human judgment is neglect of relevant base rate information (Eddy, 1982; Gigerenzer \& Hoffrage, 1995; Tversky \& Kahneman, 1974). For example, when people attempt to solve intuitive probability problems like that in Figure 1 (standard version), they typically ignore the low base rate ( $p$ (Cancer) $=.01$ ), generating probability estimates that are much higher than the normative Bayesian solution ( $p$ (Cancer $\mid$ Mammogram + ) $\approx 0.051$, see Appendix for a derivation) .

Previous work has suggested a number of solutions to the problem of base rate neglect. These include the use of frequency rather than probability formats for relevant statistics (Gigerenzer \& Hoffrage, 1995), and instructions that clarify set relations between the relevant samples (Barbey \& Sloman, 2007; Evans, Handley, Perham, Over, \& Thompson, 2000).

Two novel approaches to explaining and reducing base rate neglect have recently been proposed. The first involves consideration of the intuitive causal models that people construct when solving probability problems. Krynski and Tenenbaum (2007) outline a "causal-Bayes" account of probability judgments which assumes that errors arise when the statistics in a given problem do not readily map onto an intuitive causal model. In the standard mammogram problem for example, no causal explanation for the false positive rate (the probability of a positive mammogram in the absence of cancer) is given. According to Krynski and Tenenbaum (2007) this makes it difficult to integrate the false positive rate into Bayesian calculations, leading to inflated probability estimates. The problem can be overcome by providing a causal explanation for the relevant statistics. Krynski and Tenenbaum (2007) found that when
such an explanation was supplied (see the causal version in Figure 1) there was a marked increase in the accuracy of probability estimates.

Alternately Hogarth and Soyer (2011) suggest that people are less likely to neglect relevant statistics when they have had "experience" with the relevant sample. Specifically, they suggest that trial-by-trial sampling of the frequency of an event from the relevant probability distribution can lead to more accurate estimates in problems involving low base rates (cf. Lejarraga, 2010; Sedlmeier, 1999). Hence, Hogarth and Soyer (2011) allowed some participants to draw sequential samples of women with a positive mammogram from a distribution with a low base rate of cancer. Sampling led to more accurate probability estimates than when only a description of the base rate was provided.

## Mammogram problem

Doctors often encourage women at age 50 to participate in a routine mammography screening for breast cancer.

From past statistics, the following is known:
$1 \%$ of women had breast cancer at the time of the screening Of those with breast cancer, $80 \%$ received a positive result on the mammogram
[Standard version] Of those without breast cancer, 15\% received a positive result on the mammogram
[Causal version] 30\% of the women had a benign cyst at the time of screening. Of those with a benign cyst, $50 \%$ received a positive test on the mammogram

All others received a negative result
Suppose a woman gets a positive result during a routine
mammogram screening. Without knowing any other symptoms, what are the chances she has breast cancer? __ \%
Figure 1. The mammogram problem

## Combining causal model and sampling approaches

A key motivation for the current work was that the causal model and sampling approaches appear to address different components of intuitive probability problems. Krynski and Tenenbaum (2007), focused on incorporating information about false positive rates into a causal model of the problem. In contrast, Hogarth and Soyer's (2011) sequential sampling approach aimed at improving sensitivity to the low base
rate. The major goal of the current research was to combine these two approaches to overcoming base rate neglect. If our analysis is correct, then the causal model and sampling approaches should have additive effects on performance in intuitive probability problems.

A secondary goal was to address a number of methodological limitations of previous work using sequential sampling to overcome base rate neglect. First, Hogarth and Soyer (2011) asked participants to answer the same probability problem on three occasions; after a summary description of the base rate, after sampling experience, and a final estimate. For mammogram problems like that in Figure 1 this led to a complex pattern of results with accuracy increasing when probability problems were solved after sampling, but a marked decrease in accuracy when participants subsequently solved the same problem after reading a description of the base rate. To allow for a more straightforward assessment of the effects of description and experience, Experiment 1a used a betweensubjects manipulation in which half the participants provided an answer to the intuitive probability problem after reading a description and having relevant sampling experience, whereas the remainder answered on the basis of the description alone.

Second, Hogarth and Soyer (2011) assessed intuitive probability accuracy using a relatively liberal performance measure (participants had to choose the correct estimate from four options). This is likely to yield higher levels of accuracy than the more conventional method of requesting point estimates of probability. To facilitate comparison of the sampling and causal model approaches we therefore assessed performance using both open-ended estimates (as used by Krynski \& Tenenbaum, 2007) and forced choice questions.

Third and most importantly, we aimed to clarify the nature of the information that gives rise to improved base rate representations. Hence, in Experiment 1b participants were provided with a yoked description of sampling outcomes (e.g., out of 4 people observed, 1 person had cancer) to examine whether improved performance was a result of sequential sampling per se or simply the distributional information provided by the sample (cf. Rakow, Demes, \& Newell, 2008).

## Experiment 1a

This study examined the respective contribution of causal explanation of false positives and sampling experience to performance on the mammogram problem (Figure 1). Each factor was varied factorially and performance was assessed using both point estimate and forced choice methods. Based on the previous work of Krynski and Tenenbaum (2007) and Hogarth and Soyer (2011), we expected that providing causal information and relevant sampling experience would each lead to improved probability judgments. Based on our argument that each of these approaches addresses a different component of the task, we further predicted that these effects would be additive.

## Method

Participants. One hundred undergraduate students $\left(M_{\text {AGE }}=\right.$ 20.1 years) participated for course credit. Equal numbers were randomly allocated to the four experimental conditions.

Design and Procedure. The experiment followed a 2 (False positive information: standard vs. causal) x 2 (Base rate presentation: description only vs. description + sampling) design with both factors manipulated between subjects.

All participants were presented with the mammogram problem shown in Figure 1 (cf. Krynski \& Tenenbaum, 2007, Experiment 2). The problem was presented in either the standard or causal version, with each version administered to an equal number of participants. In both versions the Bayesian solution to the question about the likelihood of cancer given a positive mammogram was (approximately) 5\%.

In all conditions the problem description (the text in normal font in Figure 1) was first presented on a computer screen. In the Description only condition, an open-ended question asking for an estimate of the likelihood of cancer in a woman with a positive mammogram appeared after 15 s . As per Krynski and Tenenbaum (2007), the format of this estimate was a \% chance of cancer between 0 and 100. Participants were invited to use an on-screen calculator to assist in solving the problem. After a likelihood estimate was entered, the cancer estimation question was repeated together with four alternative "answers that people commonly give to this question" ( $1 \%, 5 \%, 65 \%, 80 \%$ ). Participants used a mouse to click on the option they thought was "closest to the correct answer".

Those in the sampling condition received an additional sampling phase between the problem description and the request for a likelihood estimate. In this phase they were told that to assist task completion they would be able to draw samples of women who had received a positive mammogram. Each time a participant clicked a "simulate" button they were told whether or not a sampled woman had cancer. In the standard condition the feedback for cancerabsent cases was "this woman does not have cancer". In the causal condition it was "this woman has a benign cyst". Samples were drawn randomly from a uniform distribution of 10000 cases ${ }^{1}$. There was no limit on the number of samples that could be drawn. At any time during the sampling process participants could also click an on-screen button to view a running tally of a) samples with cancer; b) samples without cancer; and c) total samples viewed. To familiarize participants with the sampling tool, prior to commencing the main experiment they were shown the outcomes of 10 samples of tossing an unbiased coin. After the sampling phase those in the sampling condition received the same open-ended and multiple choice questions as the

[^84]description only condition, but were not provided with an on-screen calculator. There was no time limit on any part of the procedure.

An on-screen version of the 4-item Berlin Numeracy Test (Cokely, Galesic, Schulz, Ghazal \& Garcia-Retamero, 2012) was also administered. Numerical ability $\left(M_{\text {CORRECT }}=2.44\right)$ did not differ across experimental conditions ( $p>.35$ ).

## Results and Discussion

As a preliminary step we examined behavior in the sampling condition. The number of samples drawn ranged from 3 to $50\left(M_{\text {SAMPLES }}=17.26, \quad \mathrm{SD}=12.22\right)$. A majority of participants experienced no positive cases of cancer (42\%) or only one positive case (34\%). The mean number of samples did not differ between the causal or standard versions of the sampling condition ( $p$ 's $>0.5$ ).

Intuitive probability - Open-ended estimates. Estimates of the likelihood of cancer were analyzed by computing the simple deviation of the estimate from the normative solution ( $5.1 \%$, see Figure 2). To examine group differences in estimate accuracy, deviation scores were entered into a 2(description vs. sampling) x 2(standard vs. causal version) analysis of variance (ANOVA). Estimates in the sampling condition ( $M_{\text {DEVIATION }}=25.69$ ) were closer to the normative solution than those in the description only condition ( $M_{\text {DEVIATION }}=39.91$ ), $F(1,96)=4.78, p=.03$, Cohen's $d=$ 0.43. There was a non-significant trend for estimates in the causal condition $\left(M_{\text {DEVIATION }}=26.87\right)$ to be closer to the normative solution than those in the standard condition $\left(M_{\text {DEVIATION }}=38.74\right), F(1,96)=3.33, p=.07, d=0.36$. There was no interaction between base rate presentation and causal factors, $p=.45 .^{2}$

As per Krynski and Tenenbaum (2007), we also tallied the frequency of estimates that could be classified as correct (estimates in the range $4 \%-6 \%$ ) or as base rate neglect (estimates $>=65 \%$ ). Binary logistic regression showed that "neglect" estimates were less common in sampling than description only ( $24 \%$ vs. $44 \%$ of responses in the respective conditions), Wald (1) $=4.36, p=.04$, and less common in causal than the standard condition ( $24 \%$ vs. $44 \%$ ), Wald $(1)=4.36, p=.04$. However, the frequency of estimates classified as normatively correct ( $M=12 \%$ ) did not differ across conditions. No interactions between the sampling and causal factors were found ( $p$ 's $>.4$ ).

Intuitive probability - Forced choice. These responses were classified as correct (a choice of 5\%), base rate overuse (1\%), or base rate neglect (a choice of 65 or $80 \%$ ). The proportion of responses in each category within each condition is given in Figure 3. Logistic regression was again used to examine changes in the proportion of each

[^85]type of response across conditions. Figure 3 shows that selection of the correct response was more common in the sampling than the description only condition, Wald (1) = $7.24, p=.007$, and in the causal than the standard condition, Wald (1) $=8.96, p=.003$. The interaction between these factors was not significant ( $p>.35$ ). Choice of the base rate neglect options was less common in the causal than the standard condition, Wald (1) $=4.87, p=.03$. These choices were unaffected by the sampling manipulation and there was no interaction with causal version ( $p$ 's > .15). Neither manipulation affected selection of the base rate overuse option, ( $p$ 's > .15).

Figure 2. Deviation scores for probability estimates (with standard error bars).

Additional analyses. In the description only condition, accessing the on-screen calculator during testing was positively correlated with the likelihood of giving the correct estimate on the open-ended test, $r(49)=0.28, p=$ .04 , and with selection of the correct alternative in forced choice, $r(49)=0.35, p=.01$. In the sampling condition, no sampling statistics (number of samples drawn, number of cancer positive cases observed, proportion of cancer positive cases observed) were correlated with any performance measures (all $p$ 's > 0.1). However, the frequency with which the summary tally was accessed was positively correlated with the likelihood of providing a correct estimate, $r(49)=0.32, p=.02$.

Summary. The accuracy of judgments of cancer probability was facilitated by an opportunity to sample instances with a positive mammogram and by causal explanation of false positives. Although correct probability estimates were rare, both causal and sampling manipulations led to a downward shift in estimates in the direction of the normative solution. Both manipulations increased choice of the correct estimate and decreased choice of the neglect option. Notably these effects were additive, supporting the view that the causal and sampling manipulations affect different components of intuitive probability judgment.

Figure 3. Experiment 1a. Proportion of forced choices.

## Experiment 1b

The beneficial effects of sampling found in Experiment 1a and in past work (Hogarth \& Soyer, 2011) could arise from a range of mechanisms. Hogarth and Soyer (2011) suggest that "across time, a person observes sequences of outcomes that can be used to infer the characteristics of the data generating process" (p. 435). However it is unclear whether sampling experience per se is critical here. Sequential sampling may be just one of many methods of obtaining information about the distribution of positive and negative cases. Other methods such as description of a frequency distribution (cf. Gigerenzer \& Hoffrage, 1995) could convey the same information, and hence may also reduce base rate neglect. Some support for this view comes from the Experiment 1 finding that use of a summary tally was correlated with estimate accuracy.

Experiment 1 b examined this possibility by presenting all participants with a summary tally of positive and negative cases of cancer from a sample of women with a positive mammogram. This 'enhanced description' presents the same base rate information that was present in the sampling condition of Experiment 1a, but without trial-by-trial sampling. To allow for close matching of the statistical information presented to participants, the sampling tallies used in this study were yoked to the outcomes of sequential sampling in Experiment 1a (see Rakow et al., 2008, for a
related manipulation). If sampling experience is crucial for gaining a more accurate representation of the problem, then the Experiment 1a sampling condition should yield superior probability estimates to enhanced description. If the critical issue is the generation of a representative distribution of positive and negative cases, then enhanced description should do as well as sequential sampling. As in Experiment 1a, descriptions of the problem included a standard or causal explanation of the false positives.

## Method

Participants
Fifty undergraduate students $\left(M_{\mathrm{AGE}}=19.3\right.$ years $)$ participated for course credit. Equal numbers were randomly allocated to causal and standard conditions.

## Procedure

The general procedure was similar to the causal and standard description only conditions in Experiment 1a, with the important exception that all participants were given an on-screen tally of positive and negative cases of cancer from samples of women with a positive mammogram. Fifty tallies were generated based on sampling outcomes in the sampling condition of Experiment 1a. For example, if a participant in the earlier study drew 20 samples containing 1 cancer positive and 19 negative instances, then a tally containing the same information was constructed for an enhanced description participant. An on-screen calculator was available to assist in answering the problem.

## Results and Discussion

Intuitive probability - Open-ended estimates. Estimation performance was again examined by calculating the deviation of estimates from the normative solution (see Figure 2). Accuracy as measured by deviation scores was not affected by causal explanation, $F(1,49)=0.2, p=.66$.

The more important issue was how estimation performance compared with the sampling and description conditions in Experiment 1a. Inspection of Figure 2 suggests that the pattern of deviation scores in enhanced description was more similar to the sampling than the description condition from the earlier study. These trends were examined using a cross-experimental task (description only, sequential sampling, enhanced description) x causal framing ANOVA. Planned comparisons compared performance in the enhanced description condition with the description only and sampling conditions respectively. The analysis confirmed that estimates in the enhanced description condition $\left(M_{\text {DEVIATION }}=16.56\right)$ were more accurate than in the description only condition, $F(1,144)=$ 14.04, $p<.001, d=0.74$, but did not differ from estimates in the sampling condition, $F(1,144)=2.24, p=.14$. No significant influence of causal framing was found. ${ }^{3}$

[^86]Intuitive probability - Forced choice. Forced choice responses in the enhanced description group are given in Figure 4. Binary logistic regression found no significant differences between the enhanced description and sampling groups for any type of response, and no interactions with causal framing, $p$ 's > .06. Correct responses were more common in enhanced description than in the description only conditions, Wald (1) $=9.66, p=.002$, and neglect responses were less common, Wald (1) $=7.93, p=.005$. Across the enhanced and description only conditions, causal framing led to a higher rate of correct responding than standard framing, Wald (1) $=4.06, p=.04$, but this effect was stronger in the description only condition, Wald (1) = 4.87, $p=.03$. The enhanced description and description only groups did not differ in base rate overuse.

Figure 4. Experiment 1b. Proportion of forced choices.
Summary. This study examined whether sampling experience is necessary to reduce base rate neglect in intuitive probability. When people were given a description of the relevant sampling information they performed as well as those in the sampling condition of Experiment 1a, and better than those in description only. It appears that what is crucial is having relevant information about the distribution of positive and negative cases; this can be obtained through sampling or a description of the frequency distribution.

A puzzling finding was that causal framing, which had a positive effect on probability estimates in Experiment 1a, had little impact on enhanced description estimates. This may have been due to the accuracy of intuitive probability estimates in the standard version of enhanced description being higher than the standard conditions in the earlier study (see Figure 1). In other words, estimates may have been approaching ceiling in the enhanced description standard group, reducing the likelihood of finding further facilitation due to causal explanation.

## General Discussion

These studies examined how providing sampling information about base rates and a causal explanation of false positives can improve intuitive probability judgments. Experiment 1a found that these manipulations led to a shift in probability judgments toward the normative response,
and away from inflated estimates that would usually be classified as base rate neglect. Moreover, each manipulation increased choice of the normative solution.

The results replicate and extend previous findings of a positive effect of causal framing (Krynski \& Tenenbaum, 2007) and sampling experience (Hogarth \& Soyer, 2011) on intuitive probability judgment. Experiment 1a, however, was the first study to combine these manipulations. An important result was that effects of sampling and causal explanation were additive. This is consistent with the view that these manipulations address different aspects of probability judgment. The sampling and enhanced description manipulations helped establish greater sensitivity to the base rate. The causal manipulation facilitated the incorporation of false positives into the problem solution.

Experiment 1b clarified the role of sampling experience in improving probability judgment. Contrary to the views of Hogarth and Soyer (2011), we found that sequential sampling was not essential for reducing base rate neglect. A similar level of facilitation was obtained when the relevant statistical information was conveyed by a description of sampling outcomes. This is consistent with other findings in the judgment and decision-making literature which show that detailed descriptions of statistical information can produce equivalent effects to sequential sampling (e.g., Rakow et al., 2008).
The causal facilitation effects in these studies are consistent with the broader perspective on probability judgments outlined by Krynski and Tenenbaum (2007). This "causal Bayesian" view suggests that encoding the relevant statistics in an intuitive probability problem will not lead to accurate judgments, unless the statistics can be incorporated into a causal model of the problem. In the current studies both standard and causal groups were given equivalent statistical information about false positives but only the latter were supplied with a cause. According to Krynski and Tenenbaum (2007) this allows those in the causal condition to construct an intuitive model with two generative nodes that provide alternative explanations for positive mammograms. More broadly, these findings are consistent with the idea that people often fail to spontaneously consider alternative causes for probabilistic outcomes but can do so when prompted (e.g., Fernbach, Darlow, \& Sloman, 2011).

It is notable that although both causal explanation and sampling shifted open-ended probability estimates in the right direction, neither manipulation increased the rate of normatively correct estimation. Similar results have been reported in previous work on base rate neglect. Krynski and Tenenbaum (2007) found that although causal explanation of false positives reduced base rate neglect, most participants in the causal condition still failed to produce a normative probability estimate. Likewise, although Gigerenzer and Hoffrage (1995) found that frequency formats for relevant statistics improved the accuracy of probability estimates, the majority of participants still gave
normatively incorrect answers to the mammogram problem. This raises the question of what additional barriers need to be overcome to produce normative probability estimates.

The causal Bayesian perspective suggests one answer. According to this view the solution of probability problems proceeds in three stages. The first involves constructing an intuitive causal model of the problem. The second involves encoding the relevant statistics and mapping these onto the various nodes of the causal model. The third stage uses Bayesian inference to update beliefs in the light of the observed statistics. Arguably, the causal and sampling manipulations in the current studies impacted on the first two stages. The finding that a majority still do not produce normative estimates suggests that people may need further assistance with the final stage of implementing Bayes' rule (cf. Sedlmeier \& Gigerenzer, 2001).

A final caveat is that although an opportunity to draw samples and description of sampling outcomes facilitated performance, sampling should not be regarded as a panacea for the problem of representing base rates. It is important to note that in the current studies and in Hogarth and Soyer (2011), samples were conditionalized on a woman having a positive mammogram. This ensured that with sufficient draws, a representative base rate was observed. However, samples outside the laboratory are not always constrained in this way. Sampling based on incorrect conditionalization (e.g., drawing samples of women with cancer and seeing whether they have a positive mammogram) can actually lead to more biased intuitive probability estimates (e.g., Fiedler, Brinkmann, Betsch, \& Wild, 2000).

These studies suggest that the causal Bayesian approach represents a useful framework for analyzing the subcomponents of intuitive probability problems, and intervening on these components to improve judgment accuracy. Our findings show that using experienced or described samples can reduce base rate neglect, and that supplying a cause for false positives increases the likelihood that these will be considered in probability judgments.

#### Abstract

We present a novel way of accounting for similarity judgments. Our approach posits that similarity ratings stem from three main sources: familiarity, priming, and inherent perceptual similarity. We present a process model of our approach in the cognitive architecture ACT-R, and match our model's predictions to data collected from a human subject experiment which involved simple perceptual stimuli. Familiarity accounts for rising ratings over time; priming accounts for asymmetric effects that arise when the stimuli are shown with different frequencies. Pure perceptual similarity also predicts trends in the results. Overall, our model matched the data with $R^{2}$ of 0.99 .

## Introduction

Similarity is a critical and pervasive part of human cognition (Medin, Goldstone, \& Gentner, 1993). Similarity measures are integral to object categorization and classification (Nosofsky, 1992). Similarity is also pervasive in problem solving (Novick, 1990), decision-making (Medin, Goldstone, \& Markman, 1995), and memory (Roediger, 1990). As with many aspects of human cognition, however, the mechanisms that determine similarity are not yet fully understood. Various theories abound, with none yet able to capture enough different types of situations to be called the winner (Rorissa, 2005).

One interesting result in this field is asymmetries that have been shown to arise when making similarity judgments, even of very simple perceptual stimuli (Tversky, 1977; Rosch, 1975). Rosch (1975) argued that such similarity is based on mapping stimuli onto one another and, intuitively, nonprototypical stimuli map more easily onto prototypical stimuli than vice versa. Tversky (1977) argued that is due to weighted feature matching, where the salience of features in the current context determines their weight; others agree with this thought in general (Medin et al., 1993; Glucksberg \& Keysar, 1990).

These two explanations, however, assume that either there is a clear prototype inherently present in the experiment (such as the more perceptually complex stimulus), or that stimuli have various features which have a clear inherent order of cognitive preference and saliency (such as symmetry). They do not, however, provide any concrete explanations for why complexity or symmetry may lead to prototypicality or saliency.

Polk, Behensky, Gonzalez, and Smith (2002) shed light on the situation by presenting an experiment that avoids the question entirely by using perceptual stimuli where the only feature was color (so there are no features to comparatively weigh), and where the color hues are fairly similar (so there is
no clear prototype). The experiment showed a striking asymmetry in similarity judgments between the different colors when they were presented with different frequencies during an irrelevant training task: colors which had been trained on less often were considered more similar to colors which had been trained on more often than the other way around. To account for these low-level results, Polk et al. (2002) implemented a neural network which simulated the asymmetry by measuring the ease with which the network switches between different activation patterns; those that are more stable (e.g., high-frequency patterns) were easier to assimilate to.

In our approach, we match the human subject data from Polk et al. (2002) while attempting to address three additional points. First, there was a second significant effect, that the ratings in general increased over time, that the above models do not address. Second, we wanted our approach to provide explicit cognitive processes for similarity ratings. Third, we believe that inherent perceptual similarity also plays a part in these types of similarity judgments (e.g., purple is inherently more similar to blue than to orange) (Smith \& Heise, 1992).

To this end, we begin our approach with the cognitive architecture ACT-R (Adaptive Characterization of Thought Rational) (Anderson, 2007). Using ACT-R, we account for similarity judgments by considering three values provided $a$ priori by the architecture. The first, familiarity, is represented as a base-level activation value of a concept, which represents its frequency and recency of use. The second, priming, is based on spreading activation, which disperses activation between different, associated concepts in declarative memory (Anderson, 1983; Harrison \& Trafton, 2010). In addition, we utilize an extension to ACT-R which provides it with a calculation for measuring color similarity (Breslow, Ratwani, \& Trafton, 2009; Breslow, Trafton, \& Ratwani, 2009).

Our model starts without any pre-existing declarative knowledge or network structures; all knowledge is created during the experiment. Over time, our cognitive model builds a network of concepts (e.g., color blocks) by learning associations between them in the form of subsymbolic connections between their representations in declarative knowledge. During each similarity judgment, the model combines its measure of perceptual similarity with base-level and spreading activation to determine its response. On the first trial of an experiment, there is no spreading activation since there is no declarative knowledge and so the judgment is based purely on base-level activation and perceptual similarity; however, over time the model builds up declarative memories that may contribute to spreading activation in later trials. This explains the two main effects found in Polk et al.'s experiment. Dur-
ing judgments made on stimuli which have been previously viewed with different frequencies, less activation is spread from high- to low-frequency color patches than from lowto high-frequency color patches because that is the direction which priming favors. In addition, base-level activation is higher at the end of the experiment than in the beginning due to increased familiarity with the colors, leading to increased ratings over time.

The primary contribution of this work is a general account for similarity which provides implemented, explicit, processlevel mechanisms for calculating similarity values. Other work has used activation for similarity in more abstract terms: the neural network written by Polk et al. (2002) relies on activation patterns; and other accounts also exist (Kozima \& Furugori, 1993; Ulhaque \& Bahn, 1992). Tversky (1977)'s discussion of salience, and Rosch (1975)'s on prototypicality can also be seen as broadly touching upon activation in similarity. Our work solidifies these accounts in a cognitive setting by positing that the abstract notion of salience (or prototypicality) translates to familiarity and priming in a cognitive model. In addition, our work is distinguished because we also account for inherent perceptual similarity. We show that our model is an excellent fit for empirical human subject data on similarity judgments on simple perceptual stimuli.

## Experiment

There were three phases to the experiment: a pre-test phase, a training phase, and a post-test phase (Polk et al., 2002). In the pre-test phase, participants viewed two patches of different colors that were the same size and were asked to rate their similarity on a scale of 0 to 9 ( 0 as highly dissimilar, 9 as highly similar). Five different hues of green and five different hues of blue were used, designated as bluel...blue5, and green $1 .$. green 5 . Greens and blues were never compared to each other; only hues of the same color were shown concurrently. During a trial, the stimuli were presented as part of a text question to emphasize the directionality of the judgment: "How similar is (color patch 1) to (color patch 2)?" The color blocks were labeled "Blue1" and "Blue2," or "Green1" and "Green 2 " as appropriate, with the label displaying below the color patches; note that this is irrespective of whether the color itself was blue1, blue5, etc. The blocks were 140X140 pixels. Once a user entered a rating, the screen was cleared for 500 ms before the next comparison appeared. Each pair of colors was presented twice in each direction for a total of four times each. The order in which the pairs were presented was randomized, except that the same hue was not present in consecutive trials. The sentence was centered both horizontally and vertically.

In the training phase, participants saw two patches of the same color but different sizes (125X125, 131X131, 138X138 and 144X144 pixels, appearing with equal probability) and were asked to specify which was larger. The key part of the experiment is that, during this phase, two of the five greens and two of the five blues were presented ten times more fre-
quently as others, 110 times instead of 11 (half the participants saw blue1, blue2, green1 and green 2 with a higher frequency, called the "1-2 group", the other saw blue4, blue5, green4 and green 5 presented more often, the " $4-5$ group").

The third phase was a second testing phase that was an exact repeat of the first phase. Forty-five participants took part in the experiment, with ten being excluded due to inaccuracy on their size judgments or self-reporting of a lack of concentration. For more details, see (Polk et al., 2002).

The experiment produced two interesting results. First, there was no significant difference between "forward" (less frequent color on the left, more frequent color on the right) and "backward" (more frequent color on the left, less frequent on the right) comparisons in the pre-test phase; however, these comparisons showed a striking asymmetry effect during the post-test phase. Specifically, forward comparisons were ranked as significantly more similar than backward comparisons during this testing phase. A second find was that similarity ratings were significantly higher in the post-test than in the pre-test. No other effects were reported as significant by the authors.

## ACT-R

At the core of our approach is the cognitive architecture ACTR (Anderson, 2007). At a high level, ACT-R is a hybrid symbolic/subsymbolic production-based system. In other words, given declarative knowledge (fact-based memories, or "chunks") and procedural knowledge (rule-based memories, or "productions"), as well as input from the world (e.g., visual), it decides what productions to fire next; these productions can either change its internal state (e.g., by creating new knowledge) or its physical one (e.g., by pressing a key on a keyboard). Knowledge has both a symbolic component, such as who was where at what time, and subsymbolic one, such as how relevant a fact is to the current situation.

ACT-R is made of up several major components. First, it has several limited-capacity buffers. Each buffer is backed by one (or more) theoretically motivated modules (e.g., declarative, visual, aural, etc.); in addition, there is the procedural module, which does not have an associated buffer. Each module represents a specific cognitive faculty and has been shown to have anatomical correspondences in the brain (Anderson, Albert, \& Fincham, 2005; Anderson, 2007).

Chunks consist of a set of slots, whose values determine the concept that the chunk represents. At any point in time, there may be at most one chunk in any individual buffer; a module's job is to decide when to put chunks into its corresponding buffer. Then, a central pattern matcher uses the contents of the buffers, if any, to match specific productions which, when fired, can modify the current buffer contents.

The relevant modules of ACT-R to this paper are the declarative, intentional, imaginal, visual and motor modules, which are associated with the retrieval, goal, imaginal, visual and visual-location, and motor buffers, respectively. The declarative module manages the creation and storage of the model's
factual memory; in addition, when requested, chunks can be accessed via the retrieval buffer. It has been shown to be an astonishingly good predictor of human declarative memory (Anderson, Bothell, Lebiere, \& Matessa, 1998; Anderson, 1983; Schneider \& Anderson, 2011). The intentional and imaginal modules provide support for task-oriented cognition. The goal buffer (associated with the intentional module) typically contains chunks that identify and placekeep the model's current goal; the imaginal module usually contains intermediate problem state representations. Finally, the visual and motor modules interface ACT-R with the world, allowing ACT-R to see objects on a computer screen (including their height and color) and press buttons on a keyboard.

To quantify the perceptual difference between the color blocks, we consider a measure of color similarity proposed by Breslow, Ratwani, and Trafton (2009). They introduced a component to ACT-R which supports high-level color processing that can detect both color similarity and brightness difference between colors. It is based on the CIEDE2000 algorithm (CIE, 2001), and has been shown to match well with human subject data. Given two color values, this color similarity component returns a numeric measure of how similar they are perceived to be by the cognitive model.

## Subsymbolic Information

A key aspect of declarative memory in ACT-R is priming, or the subsymbolic activation of chunks. Activation consists of three primary components: base-level activation, spreading activation, and noise. Base-level activation is a measure of familiarity that is learned over time and is a function of the frequency and recency of references to the chunk, where a single reference is defined as (for purposes of this paper) being added to and then removed from a buffer. It is designed to represent the activation of a chunk over longer periods of time. Spreading activation, on the other hand, is temporary and based on the current context, allowing chunks that are the focus of attention to prime related memories for short periods of time. Noise is a random component that models the noise of the human brain; since its presence would not affect our results, we ignore noise in the rest of this paper.

Spreading activation is spread along subsymbolic associative links between chunks. Links are created from a chunk $j$ to a chunk $i$ when: (1) chunk $i$ contains chunk $j$, or has chunk $j$ as one of its slot values; or (2) chunks $i$ and $j$ are both matched by the same production (called co-occurrence) (Anderson, 1983; Harrison \& Trafton, 2010). There are other ways of creating links, as well, but we do not utilize them in this model and so forgo their discussion. Once established, links have an associated strength value which affects how much activation is passed along the link from chunk $j$ to chunk $i$. Link strengths, intuitively, reflect the probability that chunk $i$ will be needed when chunk $j$ is being referred to by a production. They are a function of how many times chunks $j$ and $i$ have been referred to by a production at the same time, vs. how many times chunk $j$ was referred to by a production without chunk $i$. Note, then, that while links
stemming from co-occurrence are always present in both directions (i.e., chunk $j$ activates chunk $i$ and vice versa), the links may be of different strengths if the chunks have not always been referred to by productions at the same time, or with the same frequency.

Spreading activation sources from the goal buffer. When a chunk $i$ is in the goal buffer, the buffer's source activation is divided equally among all chunks $j$ which have an outgoing link to chunk $i$ (such as a slot value of chunk $i$, or a chunk that has co-occurred with chunk $i$ in the past). The $j$ chunks then use their source activation as the basis of spreading activation along all of their outgoing links. Note that in ACT-R, this is a one-step process; the chunks that receive spreading activation from the $j$ chunks do not, in turn, spread activation along their outgoing links (Anderson, 1983).

## Model and Fit

The model itself is fairly simple. It starts out with no declarative knowledge, but with the productions necessary to complete the experimental task. For each trial during the two testing phases, the model starts by looking at the color block on the left. Once the model has the block chunk in its visual buffer, the model requests a retrieval of the chunk of the color associated with it, and looks for the object on the right. Once the left color chunk has been retrieved, the model places it in the imaginal buffer and removes it from the retrieval buffer. Then, when it sees the object on the right, it can retrieve the color of the second color block. When that chunk has been retrieved, the model has each of the color chunks in a buffer and it can then proceed to making the similarity judgment.

The model draws similarity from three sources: how perceptually similar the two colors are to each other, how familiar the right color is, and to what degree the right color is primed. Recall that mathematically, perceptual similarity is calculated from the RGB values of two colors; familiarity is represented as base-level activation, which numerically represents the recency and frequency of use of a color; and, finally, priming is measured via the amount of spreading activation that a color receives in the current context. Therefore, the model calculates the perceptual similarity of the two colors, and looks at the total activation (both base-level and spreading) that the right color has at the time of the judgement. Note that while the right color receives spreading activation from sources other than the left color, the amount of "other" spreading activation is constant across trials, making the spreading activation from the left color the cause of asymmetry effects. After the model has these two numbers available, it presses the button corresponding to its rating, the trial is finished and the model waits for the next one to begin.

During a training trial, the model first looks at the color block on the left. It then stores the block's color as part of the goal representation in case it is later needed (such as if the subsequent visual search fails), and looks for another block of the same color. Once it sees the second color block, it retrieves the first one. Then, while thinking about the first
block and looking at the second one, it compares their heights and responds accordingly.

Subsymbolically, during each testing trial, co-occurrence links are created (or strengthened) between: each of the block chunks and the current goal chunk; each of the color chunks and the current goal chunk; and the two color chunks. Block chunks also have an incoming, containment link from their associated color chunk. During a training trial, co-occurrence links are created (or strengthened) between: the two block chunks; and each of the block chunks and the current goal chunk. The goal chunk and the block chunks also each have an incoming link from the color chunk because they contain it as a slot value. Figure 1 shows this in diagrammatic form, showing co-occurrence links as bi-directional for simplicity.

Figure 1: Subsymbolic connections between chunks at various phases of model execution. Here, the model performed two pre-test trials (with colors blue5/blue1, and bluel/blue2, respectively), and one training trial (where bluel is the color). In order to maintain clarity, this diagram is slightly simplified from the model's actual subsymbolic network (e.g., it does not contain containment links for the visual location slots of the left and right blocks, which have no bearing in the spreading activation process here).

In terms of parameters, the associative learning rate, which affects the rate at which links are strengthened, was set to 6.5 , which represents a fairly brisk rate of learning. There is no standard value for this parameter. The base level learning decay parameter was set to 0.4 instead of its default of 0.5 . All other parameters were set to their default values.

## Model Predictions

First, the model predicts that later comparisons will, overall, be more similar than earlier comparisons. Before the exper-
iment begins, the colors are not familiar to the model, and so do not have very high base-level activations. During the pre-test, those values increase as the color chunks are referenced many times. Throughout the training phase the chunks' base-level activations decay, since the color chunks are not referenced in those productions. Base-level activation values then increase again during the post-test, leading to higher familiarity with the colors in the post-test than in the pre-test. Since all colors are shown equally during the pre-test and post-test phases, base-level activation does not predict any sort of asymmetry effect. Additionally, within the pre-test and post-test conditions, our model predicts that there will be ordering effects, with later stimuli being rated as more similar than earlier stimuli; these effects, however, should average out given randomization of stimuli across participants.

As we have mentioned before, the different strengths of the subsymbolic links between two colors can cause asymmetries to arise in the degree to which they prime each other. Consider, on an intuitive level, Figure 1(b). Now, imagine that a model with this subsymbolic structure has the goal to judge how similar blue5 and bluel are. First, both color chunks receive equal source activation from the goal chunk due to their equivalent co-occurrence links with it. They then provide each other with spreading activation according to the appropriate link strength. Here, as its greater number of links implies, bluel has been needed more times than blue5; this means that the link blue $1 \rightarrow$ blue 5 is weaker than the link blue $5 \rightarrow$ bluel. Therefore, bluel will receive more spreading activation than blue5, leading to an asymmetry in their similarity rankings.

As a result of this asymmetry, priming in the model predicts different effects for the pre- and post- tests. For the pretest, the model predicts differences in similarity of forward and backward comparisons based solely on ordering effects of the stimuli. Given enough participants, these ordering effects average out over time to result in equal pre-test forward and backward comparisons. For the post-test, the model predicts that less frequently shown colors will spread more activation to more frequently shown colors than vice versa; i.e., it predicts that colors in forward comparisons will be ranked as more similar than those in backward comparisons.

Finally, our model predicts that the green ratings will be higher overall than the blue ratings, as well as that the $4-5$ group's ratings will be higher overall than the 1-2 group's ratings. This is because of the specific hues chosen and is a purely perceptual point. The color similarity values do not differ depending on the direction of the comparison, or on whether the test is a pre- or post-test.

## Model Fit

In addition to the experimental results published in the original article (Polk et al., 2002), we also examined more detailed aggregate data provided to us by the authors. The data included the averages, for each subject, of ratings for trials of each condition (e.g., the average rating for each subject of all pre-test forward trials of blue hue, etc.). Since our model
is sensitive to the order in which stimuli are presented, we would have preferred to replicate the experiment exactly, including presenting the stimuli in the same order as in the original experiment. Because this information was not available, we instead used our model to simulate data from 1000 participants, in order to allow effects to better converge on the model's true predictions.

Our measurement of the model fit is done in two steps. First, the model needs to transform the similarity measures into an overall similarity rating. We do this post-hoc by fitting a linear regression model to the data, with the perceptual similarity value and total activation as the explanatory variables and the human participants' ratings as the dependent variable. We use total activation to maintain cognitive fidelity; it is unclear whether human minds can separately consider baselevel and spreading activation values during cognitive tasks. Individual data points were the different conditions (e.g., the average rating across all participants in the 1-2 group of pretest forward trials of blue hue, etc.). The model only considers the main effects of the two variables; this is because our goal is to show that the two similarity measures are the primary components of similarity ratings in this task, not to make any claims about how they are combined by the brain into a numerical rating. We take this approach because there are very few theories or accepted practices of how to convert continuous, numerical data to a rating scale.

Second, with this step completed, we compared the model's predicted ratings with the human participants' ratings. The model does indeed produce the two main significant effects of the human subject data, showing both a directional asymmetry in post-test comparisons as well as an increase in similarity ratings overall in the post-test. Figure 2 shows graphs of the numerical results for both the model and the human subject data. Note that error bars for the human data are not available. $R^{2}$ (multiple) for these graphs across all data was 0.99 ; for blue only, 0.96 ; for green only, 0.96 ; for the 1-2 group (which saw blue1, blue2, green1 and green 2 more frequently), 0.98, and for the $4-5$ group (which saw blue 4 , blue5, green 4 and green 5 more frequently), 0.91.

For differences in color, the model's results, where blue pre-test ratings are slightly lower than green pre-test ratings, do not match well with the data's trends. The model does have overall higher ratings for the 4-5 group pre-test than the 1-2 group pre-test, but not to the extent of the data. The effects do not present a difficulty for the model, however, in large part because the experiment did not find these effects to be significant, presumably due to its small sample size of 35 .

In terms of their individual contribution to explaining the data, color alone yields an $R^{2}$ of 0.09 ; color and base-level activation produce an $R^{2}$ of 0.79 ; and color, base-level activation and spreading activation an $R^{2}$ of 0.99 . This is intuitive and consistent with our account of the data: base-level activation is responsible for the larger main effect between the pre- and post-tests, while spreading activation correlates to the more modest interaction effect of forward versus back-

ward comparisons.

## Discussion

In this paper, we have introduced an account for similarity ratings that combines familiarity, priming, and perceptual similarity into a single judgment. We match our account to human subject data involving simple perceptual stimuli from Polk et al. (2002). Our approach explains that ratings rise over time because participants become more familiar with the stimuli, in general. Priming explains the asymmetry effect found because, inherently, low frequency concepts prime high frequency concepts more than the opposite. Finally, although the experiment did not reveal any significant differences between colors, our approach predicts that different pairs of colors will be slightly more similar than others due to pure perceptual similarity. Using these mechanisms, we show an excellent match to the human data.

Our approach is significant for at least two main reasons. First, we provide explicit, process-level mechanisms for determining similarity that explain, in a sense, how others' work (Rosch, 1975; Tversky, 1977) is realized by the human mind. Second, and perhaps more importantly, the mechanisms we offer as the basis of similarity have been shown to be preexisting mechanisms in cognition that are also used for other
cognitive processes such as retrieval of memories, categorization, and problem solving (Anderson, 2007; Altmann \& Trafton, 2002). This strengthens our approach since it also explains the pervasiveness of similarity in human cognition that has been found by a plethora of other research.

Finally, it is worth noting that familiarity, priming and perceptual similarity are not intended to be characterized as the ultimate, and only, way to determine similarity ratings. While they work well with simple perceptual stimuli, and we expect that their success will also extend to more complicated perceptual stimuli and simple concepts, we recognize that more complicated mechanisms are likely at work in, for example, the similarity of complex perceptual scenes, or the similarity of two short stories. We believe that such judgments likely involve some sort of structure alignment process as others have hypothesized for similarity judgments of higher-level stimuli or concepts (Markman, 1999; Goldstone, 1994). Instead, this paper is intended to introduce familiarity, priming and perceptual similarity as the foundation for similarity which other mechanisms can augment.

## Acknowledgments

This work was supported by the Office of Naval Research, grant numbers N0001412WX30002 and N0001411WX20516 to GT. The views and conclusions contained in this document do not represent the official policies of the U.S. Navy.

Many thanks to Thad Polk for making his data available to us. We would also like to acknowledge Wallace E. Lawson and Anthony M. Harrison for their helpful discussions during this work.

# Large-Scale Empirical Analyses of the Abstract/Concrete Distinction 

Felix Hill (fh295@cam.ac.uk) ${ }^{1}$, Anna Korhonen (alk23@cam.ac.uk) ${ }^{1}$, Christian Bentz (cb696@cam.ac.uk) ${ }^{2}$<br>${ }^{1}$ Computer Laboratory, University of Cambridge<br>${ }^{2}$ Department of Theoretical and Applied Linguistics, University of Cambridge

#### Abstract

We present original evidence that abstract and concrete concepts are organized and represented differently, based on statistical analyses of thousands of concepts in publicly available datasets. First, we show that abstract and concrete concepts have differing patterns of association with other concepts. Second, we test recent hypotheses that abstract concepts are organized according to association, whereas concrete concepts are organized according to (semantic) similarity. Third, we present evidence suggesting that concrete representations are more strongly feature-based than abstract representations. We argue that degree of featurebased structure may fundamentally determine concreteness, and discuss implications for cognitive and computational models of meaning.

Keywords: Concreteness; concepts; similarity; association.

## Introduction

A large body of empirical evidence indicates important cognitive differences between abstract concepts, such as guilt or obesity, and concrete concepts, such as chocolate or cheeseburger. It has been shown that concrete concepts are more easily learned and remembered than abstract concepts, and that language referring to concrete concepts is more easily processed (Schwanenflugel, 1991). Moreover, there are cases of brain damage in which either abstract or concrete concepts appear to be specifically impaired (Warrington, 1975). In addition, functional magnetic resonance imaging (fMRI) studies implicate overlapping but partly distinct neural systems in the processing of the two concept types (Binder et al., 2005). Despite these widely known findings, however, there is little consensus on the cognitive basis of the observed differences (Schwanenflugel, 1991). Indeed, while many studies of conceptual representation and organization focus on concrete domains, comparatively little has been established empirically about abstract concepts. ${ }^{1}$

In this paper we test various theoretical claims concerning the abstract/concrete distinction by exploiting large publicly-available experimental datasets and computational resources. By analyzing thousands of abstract and concrete concepts, our approach marginalizes potential confounds more robustly than in smaller-scale behavioral studies. In Analysis 1 we show that abstract concepts are associated in the mind to a wider range of other concepts, although the degree of this association is typically weaker than for concrete concepts. In Analysis 2 we explore the basis of these associations by testing the hypothesis that similarity

[^87]predicts association for concrete concepts to a greater extent than for abstract concepts. In Analysis 3, we show that freeassociation is a more symmetric relation for abstract concepts than for concrete concepts. The findings together suggest contrasts in both the organization and representation of abstract and concrete concepts. We conclude by discussing the implications of the findings for existing theories and models of conceptual representation.

## Data

Our analyses exploit three publicly available resources compiled to assist psychological modeling and analysis.

USF Norms All three experimental analyses use the University of South Florida (USF) Free-association Norms (Nelson \& McEvoy, 2012). The USF data consists of over 5,000 words and their associates. In compiling the data, more than 6,000 participants were presented with cue words and asked to "write the first word that comes to mind that is meaningfully related or strongly associated to the presented word". For a cue word $c$ and an associate $a$, the Forward Association Probability (FAP) from $c$ to $a$ is the proportion of participants who produced $a$ when presented with $c$. FAP is thus a measure of the strength of an associate relative to other associates of that cue.

Many of the cues and associates in the USF data have a concreteness score, derived from either the norms of Paivio, Yuille and Madigan (1968) or Toglia and Battig (1978). In both cases contributors were asked to rate words based on a scale of 1 (very abstract) to 7 (very concrete). ${ }^{2}$

WordNet WordNet is a tree-based lexical ontology containing over 155,000 words produced manually by researchers at Princeton University (Felbaum, 1998). The present work used WordNet version 3.0.

Brown Corpus Word frequencies were extracted from the one million-word Brown Corpus (Kucera \& Francis, 1967), chosen because it is an American corpus compiled at a similar time to the USF data. Word tokens in the Brown Corpus are tagged for their part of speech (POS). For a word type it is then possible to extract the majority POS (the POS with which the type is most frequently tagged).

[^88]
## Analyses

Each of our analyses is motivated by characteristics of the abstract/concrete distinction proposed in theoretical and behavioral studies.

## Analysis 1: Patterns of Association

Motivation Schwanenflugel's Context Availability Model (1991) offers a theoretical basis for the aforementioned empirical abstract/concrete differences. Her exposition of the model relies on the following hypothesis: ${ }^{3}$
(H1) Abstract concepts have more (but weaker) connections (to other concepts) than concrete concepts.

Schwanenflugel presents only small-scale behavioral experiments (64 words, 40 participants) in support of H1. In Analysis 1 we test H 1 on a far larger data set.

Method We extracted those 3,255 pairs in the USF data for which the concreteness of the cue-word was known. Since cue words are connected to a finite set of associates by FAP values, we can isolate a probability distribution over associates for each cue. Since our measure of association strength (FAP) is relative, it is not possible to compare these strengths directly across cue words. Nonetheless, we can make inferences about absolute cue associate strength from properties of the FAP distributions. If a cue has many associates with little variance in the FAP distribution, each FAP value must necessarily be low (and absolute association strength intuitively weak). In contrast, for a given number of associates, higher variance implies that some FAP values are notably higher than the mean, and thus likely to be strong absolutely. Therefore, to address H1 we considered both the dimension (number of associates) and the variance of the FAP distribution for each cue word.

In an initial analysis of the data, we noted a moderate but significant negative correlation between concreteness and frequency, $r(3255)=-.16, p<.001$. Therefore, a multiple regression analysis was conducted with $\log$ (Frequency), Number of Associates and Variance of FAP as predictors, and Concreteness as dependent variable. Because the Concreteness/Frequency multicolinearity was exacerbated by high frequency abstract prepositions and verbs, a second analysis was conducted solely over cue words with majority POS 'noun' $(n=2,320)$.

Results and Discussion In both cases the regression model explained $17 \%$ of the variance of Concreteness and was statistically significant. The beta coefficients in Table 1 indicate that concreteness correlates negatively with both \#Associates and FAP Variance. Both are highly significant

[^89]predictors even when controlling for frequency as an independent predictor.

We have shown that abstract words have more associates than concrete words and lower variance in FAP distributions. This is consistent with the idea that the strength of their associates is on average weaker than for concrete words. Fig. 1 represents the strength of this effect visually. Whilst this confirmation of H 1 is consistent with Schwanenflugel's Context Availability model, it is also consistent with other theoretical characterizations of the abstract/concrete distinction (Paivio, 1986; Markman and Stilwell, 2001). We thus investigate the distinction in more detail in Analyses 2 and 3.

|  | All words |  | Nouns only |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Coeff. ( $\beta$ ) | $t$ | Coeff. ( $\beta$ ) | $t$ |
| \# Assocs | -0.04*** | -16.70 | -0.04*** | -15.97 |
| Variance | -18.01*** | -5.85 | -15.64*** | -4.41 |
| $\log$ (Freq) | -0.18*** | -14.21 | -0.12*** | -7.87 |
| $R^{2}=.17$ |  |  | $R^{2}=.17$ | $57.51^{* * *}$ |

Table 1: Multiple regression analysis of Concreteness

Figure 1: Average FAP mass at each associate rank over the 500 most abstract and concrete cue words in the USF data. Note the stronger initial associates in the concrete case and the longer tail of weak associates in the abstract case.

## Analysis 2: Distinct Conceptual Organization?

Motivation Based on recent behavioral studies of healthy and brain-damaged subjects, (see e.g. Crutch et al., 2009), Crutch and colleagues argue that abstract and concrete concepts differ "qualitatively" in how they relate to other concepts. More specifically, they propose the following:
(H2) Concrete concepts are organized in the mind according to similarity whilst abstract concepts are organized according to association.

The terms association and similarity refer to the ways the concept pairs [car, bike] and [car, petrol] are related: Car is said to be semantically similar to bike, and associated with (but not similar to) petrol. Intuitively, car and bike may be understood as similar because of their common physical features (wheels), their common function (transport), or because they fall within a clearly definable category (modes of transport). By contrast, car and petrol may be associated because they often occur together or because of the functional relationship between them. The two relations are neither mutually exclusive nor independent; bike and car are related to some degree by both association and similarity.

In support of H2, Crutch et al. (2009) asked 20 participants to select the odd-one-out from lists of five words appearing on a screen. The lists comprised either concrete or abstract words (based on ratings of six informants) connected either by similarity (e.g. dog, wolf, fox etc.; theft, robbery, stealing etc.) or association (dog, bone, collar etc.; theft, law, victim etc.), with an unrelated odd-one-out item in each list. Controlling for frequency and position, subjects were both significantly faster and more accurate if the related words were either abstract and associated or concrete and similar. These results support H2 on the basis that decision times are faster when the related items form a more coherent group, rendering the odd-oneout more salient.

Despite the consistency in these findings, each of Crutch et al.'s experiments tested a small sample of subjects ( $<20$ ) with a small ( $<20$ ) number of concepts. It is therefore possible that the observed differences resulted from semantic factors particular to the subjects and items but independent of concreteness. Analysis 2 exploits the USF data and WordNet to investigate H2 more thoroughly.

Method Because similarity and association are not mutually exclusive, H 2 can be interpreted in terms of differing interactions between these two relation types. If concrete concepts are organized in the mind to a greater extent than abstract concepts according to similarity, then the associates of a given concrete concept should be more similar to that concept than the associates of a given abstract concept. In other words, there should be greater correlation between similarity and association over concrete concepts than abstract. We test for this effect with a multiple regression over cue-associate pairs, with FAP as dependent variable and Concreteness, Similarity and their interaction as predictors. Relevant to H 2 is the presence or absence of a positive interaction between concreteness and similarity.

Following other studies of conceptual structure (Markman \& Wisniewski, 1997), we model similarity as proximity in a conceptual taxonomy, in this case, WordNet. Various measures of similarity have been developed for WordNet (see e.g. Resnik, 1995). PathSim, based on the shortest path between two senses, is perhaps the simplest,
and mirrors the manual approach taken by Markman \& Wisniewski (1997). For this experiment, SIM, a measure of the similarity of two words $w_{l}$ and $w_{2}$ on the range [0, 1], was defined as the maximum PathSim between all senses of $w_{1}$ and all senses of $w_{2}$. Since verbs, adjectives and nouns occupy separate taxonomic structures in WordNet, PathSim does not effectively measure similarity across these categories. We thus restrict our analysis to those 18,672 pairs in the FAP data for which cue concreteness and FAP are known and the majority POS for both words is 'noun'.

As a pre-test, SIM was evaluated on Rubinstein and Goodenough's (1965) similarity data for 65 word pairs, ${ }^{4}$ previously used as a benchmark for automatic similarity measures. The correlation between these judgments and SIM, $r(63)=.77, p<.05$, was comparable to other more complex WordNet metrics such as Resnik's (1995) Information Content, $r(63)=.79, p<.05$, and approaching the human replication baseline, $r(63)=.90$ (Resnik, 1995).

Results and Discussion As detailed in Table 2, the regression model was significant, $F(2,3252)=194.53$, and, as expected, SIM was a significant predictor of FAP. The interaction term SIM:Concreteness was positive, as predicted by H2, and a significant predictor of FAP.

Table 2: Multiple regression analysis of FAP over cue (noun) - associate (noun) pairs

|  | Coeff. ( $\beta$ ) | $t$-value |
| :---: | :---: | :---: |
| SIM | 0.048 | 3.66*** |
| Concreteness | 0.003 | 1.64 |
| SIM:Conc | 0.005 | 2.07* |
| $R^{2}=.03, F(3,18665)=194.53$ |  |  |

The positive interaction between similarity and concreteness in our model lends some support to H2. However, the size of this effect is small: the model explains less than .1 of a percentage point more variance in FAP than a model with no interaction term. While statistically significant, this difference is not consistent with a "qualitative difference" in conceptual organization between abstract and concrete concepts, as Crutch and Warrington (2005) propose. Rather, our analysis supports a gradual contrast in patterns of organization along a continuum from concrete to abstract. Of course, qualitative or categorical differences may exist that are too subtle to be detected by the current method. We intend to examine this possibility in future work, using the USF data and WordNet to generate appropriate items for larger-scale behavioral experiments.

## Analysis 3: Distinct Conceptual Representation?

Motivation Hypothesis H2 (Analysis 2) characterizes the abstract/concrete distinction in terms of conceptual

[^90]organization. With respect to the differences in representation that cause the H 2 effect, Crutch and Warrington offer only speculative hypotheses. For instance, they suggest that that "abstract concepts are represented in associative neural networks", whilst "concrete concepts have a categorical organization" (Crutch \& Warrington, 2005, p. 624). Weimer-Hastings and Xu (2005) address this question empirically, and find that people tend to generate fewer "intrinsic" and proportionally more "relational" properties for abstract concepts. Nevertheless, given the untimed, conscious nature of their feature-generation task, and the fact they test only 31 subjects with 36 concepts, the strength of their findings is limited in a similar way to those of Crutch et al. In Analysis 3 we test for evidence of specific representational differences that could explain H2 and the other concreteness effects detailed in the Introduction.

Although the limitations of classical theories of representation with strict binary property specifications are well known, many recent theories characterize representations as feature-based in a more dynamic sense (see e.g. Plaut \& Shallice, 1993). Indeed, the idea of concepts as complexes of conceptually basic features underlines explanations of various empirical observations, including typicality effects, category learning and categoryspecific semantic impairments (Tyler et al. 1995).

Feature-based models are not ubiquitous. Competing approaches such as spatial models (See e.g. Shepard, 1957) or associative networks (Steyvers \& Tennembaum, 2005) have also captured various established cognitive phenomena. One criticism of such models, however, is they naturally model relatedness with a symmetric operation: for all concepts $x$ and $y$, relatedness $(x, y)=\operatorname{relatedness}(y, x)$. As often observed, (Griffiths, et al., 2007; Tversky, 1977) empirical measures of conceptual promixity are in general asymmetric. For instance, it is common to find concept pairs $X$ and $Y$ for which subjects judge the statement ' $X$ is like $Y$ ' to be more acceptable than ' $Y$ is like $X$ '. This effect can be particularly evident when one concept is more salient or prototypical than the other ('Justin Bieber is like Elvis' vs. 'Elvis is like Justin Bieber'?). Asymmetries are also observed in priming effects and free-association, for instance with category name/member or whole/part pairs (Alsatian primes dog more than dog primes Alsatian).

A noted strength of feature-based models is that they naturally capture the asymmetry of semantic relations. In the Contrast Model, Tversky (1977) proposes that the similarity of conceptual representations is computed as some continuous function of their common and distinctive features. Such operations are generally asymmetric, particularly given a disparity in the number of features. For instance, suppose the concept jackal is represented with the features $\{4 L E G S, F U R, H O W L S\}$ and the concept $d o g$ with the features $\{4 L E G S, F U R, T A I L, C O L L A R, ~ L O Y A L$, DOMESTIC\}. Tversky argues that it is more natural to say that jackals are like dogs than vice versa because two thirds of jackal features are shared by dog, whereas only one third of $d o g$ features are shared by jackal. As with other theories
of representation mentioned previously, Tversky's demonstrations are typically confined to concrete words. Nevertheless, his conclusions could be aligned with H2 (Analysis 2) if the following hypothesis held:
(H3) Concrete representations have a high degree of feature-based structure. Abstract representations do not.

Indeed, the soundness of H 3 could point to a causal explanation of the H 2 effect. By H 3 , computing the similarity of abstract concepts by mapping features would be relatively hard. Alternative types of relation would thus be required to group sets of abstract concepts in the mind.

Proposals similar to H3 have been made by several researchers. Plaut and Shallice (1993) showed that integrating differential degrees of feature-based structure into connectionist simulations of dyslexia leads to more accurate replication of established concrete word advantages. Additionally, Markman and Stilwell's (2001) analysis of conceptual category subtypes is entirely consistent with H3. On this view, feature-based categories include those noun concepts typically considered very concrete, whereas abstract noun, prepositions and verbs are all relational categories. Feature-based categories are represented by some configuration of (featural) information 'subordinate to' or 'contained within' that representation (p. 330), whereas relational categories are defined by external information, such as the position of the representation in a relational structure. Finally, H3 is also compatible with the feature-generation data of Weimer-Hastings and Xu (2005).

In Analysis 3 we exploit the USF data to test a prediction of H3. If Tversky's demonstration that asymmetry derives from features is sound, there should be greater asymmetry between concrete concepts than between abstract concepts.

Method Although Tversky's reasoning pertains to a similarity relation, we use the USF data to explore asymmetries in association. Similarity is an important factor in association in general, as evidenced by the high SIM/FAP correlation (Analysis 2). We thus expect asymmetries deriving from similarity to be reflected in FAP values, noting that asymmetry of free-association has been observed previously (Michelbaker et al., 2011).

For each of the 18,668 ordered cue-associate pairs [ $c, a$ ] for which the concreteness of $c$ and $a$ is known, we calculate the (additive) asymmetry $|F A P[c, a]-F A P[a, c]|$. We define the total cue asymmetry, CueAsymm $(c)$, as the sum of the additive asymmetries over all associates of that cue. For a given cue item in our analysis, we experiment with three different measures of concreteness. The first is the cue concreteness Conc(c). Since Tversky's explanation of asymmetry relies on both concepts having a feature-based representation, for each pair $[c, a]$ we also calculate both the sum and the product of concreteness scores. We then define ConcSum(c) as the sum of the sums over all associates, $\operatorname{ConcSum}(c)=\sum_{a} \operatorname{Conc}(\mathrm{c})+\operatorname{Conc}(\mathrm{a})$, and ConcProd(c) as the sum of products $\operatorname{ConcProd}(c)=\sum_{a} \operatorname{Conc}(c) \operatorname{Conc}(\mathrm{a})$. To control for the possibility that FAP asymmetries are caused exclusively by a disparity in frequency between cue and
associate, we also define the measure FreqDisp(c); the sum of the absolute differences between the frequency of a cue word and that of each of its associates, FreqDisp $(c)=$ $\sum_{a} \mid$ Freq(a) - Freq(c)|. We analyse the relationship between CueAsymm (dependent variable) and the three measures of concreteness (predictors) in separate multiple regression models, with FreqDisp as an independent predictor in each.

Results and Discussion The results in Table 3 show a significant positive correlation between the concreteness measure and CueAsymm in all three models, confirming the prediction of H3. Moreover, the model with ConcProd ( $R^{2}$ $=13.73$ ) accounts for more of the CueAsymm variance than with ConcSum ( $R^{2}=.12$ ), which in turn accounts for more than with Conc ( $R^{2}=.08$ ). These two comparisons show that information about the concreteness of both cue and associate is important for predicting asymmetry, consistent with Tversky's explanation of the link between features and asymmetry. It is also notable that FreqDisp is a (marginally) significant predictor in only one of the three models. Therefore the predictive relationship between concreteness and asymmetry (illustrated in Fig. 2) does not derive from discrepancies in frequency between words.

Table 3: Multiple regression analyses of CueAsymm

|  | Coeff. ( $\beta$ ) | $t$ |
| :---: | :---: | :---: |
| Conc | 0.001*** | 16.28 |
| FreqDisp | -0.000 | -1.44 |
| $R^{2}=.08, F(2,3252)=135.60^{* * *}$ |  |  |
| ConcSum | 0.003*** | 21.33 |
| FreqDisp | -0.000* | -2.43 |
| $R^{2}=.12, F(2,3252)=230.92^{* * *}$ |  |  |
| ConcProd | 0.001*** | 22.60 |
| FreqDisp | -0.000 | -0.39 |
| $R^{2}=.14, F(2,3252)=258.81 * * *$ |  |  |

Table 4: USF pairs with highest and lowest asymmetry

| Cue (conc) | Associate | FAP | Backward AP | Additive asymmetry |
| :---: | :---: | :---: | :---: | :---: |

| Honor (1.75) | Courage (2.51) | 0.014 | 0.014 | 0 |
| Immoral (1.81) | Dishonest (2.63) | 0.014 | 0.014 | 0 |

In a separate analysis, we observed that the ConcProd model over pairs in which the cue word is a noun ( $R^{2}=$ 0.1325 ) fits better than the model over pairs in which the cue is a non-noun $\left(R^{2}=0.0987\right)$ or specifically a verb $\left(R^{2}=\right.$ 0.114 ). Indeed, across all 18,668 pairs, the mean additive asymmetry when both cue and associate are nouns (.071) is
significantly greater than when both are not (.066), $t$ (9351.3) $=2.78, p<.01$. Together with Tversky's analysis, these observations are consistent with Markman and Stilwell's proposal that many noun representations are feature-based whereas representations of verbs and prepositions rely on features to a lesser extent.

Figure 2: Scatterplot of CueAsymm vs. ConcProd.

## Conclusion

In this study we have reported the following effects of increasing conceptual concreteness:

## 1. Fewer, but stronger associates (Analysis 1).

2. A stronger correlation between the similarity of concepts and the strength of their association (Analysis 2).
3. Greater asymmetry of association (Analysis 3).

These findings derive from analyses of thousands of concepts and data from thousands of subjects, an approach that significantly increases their robustness in comparison with previous behavioral experiments.
Finding 3 is consistent with, and arguably suggestive of, the view that concrete representations are more strongly feature-based than abstract concepts. Instead of a strongly feature-based structure, abstract representations encode patterns of relations with other concepts (both abstract and concrete). We hypothesize that the degree of feature-based structure is the fundamental cognitive correlate of what is intuitively understood as concreteness.
On this account, computing the similarity of two concrete concepts would involve a (asymmetric) feature comparison of the sort described by Tversky. In contrast, computing the similarity of abstract concepts would require a (more symmetric) comparison of relational predicates such as analogy or structure-mapping (Markman \& Gentner, 1993). Because of their representational structure, the feature-based operation would be simple and intuitive for concrete concepts, so that similar objects (of close taxonomic categories) come to be associated. On the other hand, for abstract concepts, perhaps because structure mapping is more complex or demanding, the items that come to be associated are instead those that fill neighboring positions in
the relational structure specified by that concept (such as arguments of verbs or prepositions). Intuitively this would result in a larger set of associates than for concrete concepts, as confirmed by Finding 1. Moreover, such associates would not in general be similar, as supported by Finding 2.

If this is correct, it is likely that computational models of meaning could be improved by integrating a dimension of concreteness. For instance, models that connect words via syntagmatic co-occurrence would be particularly appropriate for modeling human association in abstract domains, whereas approaches based on taxonomies, or those measuring paradigmactic co-occurrence, would better reflect similarity and be more apt for concrete domains. In future work we plan to test these hypotheses by analyzing how concreteness is reflected in running text corpora.

# How Episodic and Working Memory Affect Rule- and Memory-Based Judgments 

Janina A. Hoffmann (janina.hoffmann@unibas.ch)<br>Bettina von Helversen (bettina.vonhelversen@unibas.ch)<br>Jörg Rieskamp (joerg.rieskamp@unibas.ch)<br>Department of Psychology, University of Basel, Missionsstrasse 62a<br>4055 Basel, Switzerland

#### Abstract

Making accurate judgments is an essential skill in everyday life. However, little is known about the basic cognitive skills required for accurate judgments. Research on judgment and categorization processes suggests that people rely on various strategies when making judgments. These strategies differ in the cognitive abilities they require. Specifically high working memory capacity may benefit rule-based judgments, whereas good long-term memory may be crucial for memory-based judgments. We investigated this hypothesis following an individual differences approach. 177 participants performed two judgment tasks that were either best solved by a rulebased or a memory-based strategy. Additionally, we measured working memory capacity and episodic memory with three tests. Consistent with our hypothesis structural equation modeling showed that working memory capacity predicted judgment accuracy in the rule-based task whereas episodic memory predicted judgment accuracy in the memory-based task. Apparently, different memory abilities are essential for successfully adopting different judgment strategies.

Keywords: Judgment and decision making; working memory; episodic memory

Long-term memory and working memory are to a varying degree engaged in many daily activities. On a shopping trip, for example, people need episodic long-term memory to remember items on the shopping list. Trying to quickly sum up the prices of a shopping basket, however, draws upon working memory. Similarly, everyday judgments, such as judging the skills of a job candidate or the suitability of an apartment, may require both working memory and episodic memory. In this paper, we investigate how memory skills relate to people's success in solving judgment tasks.

## Multiple Cue Judgments

In multiple-cue judgment tasks, people are asked to repeatedly estimate a continuous criterion such as the price of a shopping basket based on a number of cues, for instance the products in the shopping basket. To make such judgments, recent research suggests that people rely on two kinds of judgment strategies: rule-based and memory-based strategies (Juslin, Karlsson, \& Olsson, 2008; von Helversen \& Rieskamp, 2008).

Rule-based strategies assume that people try to explicitly abstract the relationship between the cues and the criterion and integrate this information in a linear additive way. To
estimate the price of a shopping basket, for instance, the shopper may try to estimate the price of each product and add up all prices. Mathematically, this integration process can be described with a linear additive model. The criterion estimate $\hat{c}_{p}$ of an object $p$ is the weighted sum of the cue values $x_{p i}$ :
$\hat{c}_{p}=k+\sum_{i=1}^{I} w_{i} \cdot x_{p i}$
where $w_{\mathrm{i}}$ are the cue weights for each cue $i$ and $k$ is a constant intercept.

In contrast, memory-based strategies assume that people judge a new object (the probe) by retrieving previously encountered objects (exemplars) from memory. For example, when estimating the price of a shopping basket people may recall how much they spent the last time they went shopping. The more similar a retrieved exemplar (previous shopping baskets) is to the probe (current shopping basket), the more this exemplar influences the probe's criterion estimate. If a shopper bought the same items last time, for instance, he may just recall this price from memory to estimate the new prize.

This judgment strategy is mathematically described with an exemplar model (Juslin, Olsson, \& Olsson, 2003). To determine the similarity, first the distance $d_{p j}$ between the probe $p$ and exemplar $j$ is calculated. This distance is the summed absolute difference of their cue values $x_{p i}$ and $x_{j i}$ on each cue $i$, weighted by a sensitivity parameter $h$.

$$
\begin{equation*}
d_{p j}=h\left(\sum_{i=1}^{I}\left|x_{p i}-x_{j i}\right|\right) \tag{2}
\end{equation*}
$$

These distances are then transformed into similarities $S(p, j)$ with an exponential decay function (Nosofsky \& Zaki, 1998):

$$
\begin{equation*}
S(p, j)=e^{-d_{p j}} \tag{3}
\end{equation*}
$$

To estimate the criterion value $\hat{c}_{p}$, the similarities are weighted with their corresponding criterion values $c_{j}$ and averaged (Juslin et al., 2003).

$$
\begin{equation*}
\hat{c}_{p}=\sum_{j=1}^{J} S(p, j) \cdot c_{j} / \sum_{j=1}^{J} S(p, j) \tag{4}
\end{equation*}
$$

Past research suggests that people shift between rulebased and memory-based judgment strategies depending on
task structure (Juslin et al., 2008; von Helversen \& Rieskamp, 2008). In linear additive judgment tasks, that is in tasks where the criterion can be approximated by a linear additive function of the cues, people generally rely on rulebased strategies. In contrast, in multiplicative judgment tasks, where the criterion can be approximated by a multiplicative function of the cues, memory-based strategies are more frequently used (Hoffmann, von Helversen, \& Rieskamp, 2013; Juslin et al., 2008). However, little attention has been paid to the cognitive abilities these strategies draw upon and how individual differences in cognitive abilities influence strategy selection and performance.

## Memory Processes in Multiple-Cue Judgments

Theories in judgment and categorization propose that rulebased and memory-based judgment strategies build on different memory abilities. For instance, Ashby and O'Brien (2005) suggested that executing simple rule-based categorization strategies requires working memory capacity, whereas exemplar retrieval involves episodic memory. In a similar vein, Juslin et al. (2008) argued that cue abstraction could be conceived as a capacity-constrained sequential process, whereas memory-based judgment strategies rely on a controlled retrieval process.

Previous research has often studied how working memory influences judgment and categorization performance. In line with a capacity-constrained abstraction process, cognitive load impairs performance in rule-based categorization tasks more than performance in implicit information-integration tasks (Zeithamova \& Maddox, 2006). Indeed, cognitive load may even induce people to shift from a rule-based to a memory-based strategy suggesting that memory-based strategies require less cognitive control (Hoffmann et al., 2013). Yet, some research also suggests that working memory may play a crucial role in learning in all judgment tasks. Indeed, performance in a range of judgment tasks can be predicted by measures of working memory and intelligence (Weaver \& Stewart, 2012). Similarly, Lewandowsky (2011) found that high working memory capacity benefitted learning in rule-based as well as memory-based categorization tasks. Thus, it is unclear whether high working memory capacity only benefits rule abstraction processes or whether it benefits performance in all kinds of judgment tasks.

Research relating episodic memory to judgment performance is scarce. Exemplar models predict a relationship between recognition and categorization and, indeed, have successfully modeled both recognition and categorization performance (Nosofsky, 1988). Consistent with a controlled retrieval process, the instruction to learn all exemplars by heart improves performance in a difficult memory-based judgment task (Olsson, Enkvist, \& Juslin, 2006). Also, memorization of single exemplars enhances recognition of these exemplars in a later recognition test (Palmeri \& Nosofsky, 1995). The importance of episodic memory for category learning, however, has been severely
disputed (Knowlton, 1999), leading to a call for more experimental studies (Ashby \& O’Brien, 2005). Taken together, although some evidence suggests that people engage in a controlled retrieval process when solving memory-based judgment tasks, the role of episodic memory in categorization and even more for judgments is still unclear.

## The Present Study

Our study investigates how episodic and working memory skills affect judgment performance in rule-based and memory-based judgments. We test the hypothesis that judgment accuracy is related to working memory capacity when people rely on a rule-based judgment strategy. Likewise judgment accuracy should be related to episodic memory when people adopt a memory-based judgment strategy. To test these hypotheses, the participants solved a linear as well as a multiplicative judgment task. In addition, we measured participants' working memory and episodic memory skills using three different tests.

## Participants

177 participants (113 female, $M_{\text {Age }}=24.1, S D_{\text {Age }}=6.2$ ) were recruited at the University of Basel. Participants received a participation fee of 20 CHF per hour (approx. 22 US-\$) and an additional bonus in the judgment tasks ( $M=$ $10.3, S D=2.4$ ). One subject was excluded from the analysis because he guessed in the judgment tasks.

## Automated Working Memory Span Tasks

Working memory span tasks were designed to measure both storage and processing of information in working memory (Redick et al., 2012). In working memory span tasks, participants process one set of stimuli while remembering another set of stimuli. For instance, in each trial of the operation span task, participants first see a simple equation. After they have solved the equation and given the answer, they see the first letter that has to be remembered. Subsequently, another equation is presented and another letter has to be remembered, until the set size (the number of presented letters) is reached. Finally, participants are asked to recall the letters in the order of their appearance. Trials with different set sizes are randomly interspersed, with each set size repeated three times. All span tasks were taken from Unsworth et al. (2009) and translated to German.

Reading Span In the reading span participants judged the plausibility of a sentence while remembering letters. Set size varied from 3 to 7 .

Operation Span Participants were asked to solve mathematical equations while remembering letters. Set size varied from 3 to 7 .

Symmetry Span Participants judged the symmetry of a chessboard picture while remembering the position of squares in $4 \times 4$ matrix. Set size varied from 2 to 5 .

## Episodic Memory Tasks

We measured episodic memory with three different tasks: a free recall task with pictures, a cued recall task with numbers, and a recognition test of verbs.

Picture Free Recall We selected 20 pictures from a picture database (Rossion \& Pourtois, 2004) that had high ratings on imagery and concreteness. Each picture was presented for 3 s on the screen and participants were asked to remember them. After a retention interval of 2 minutes participants recalled the pictures.

Cued Number Recall We assessed cued number recall with a computerized version of the Cued Number Recall task from the BIS 4 (Jäger, Süß, \& Beauducel, 1997). 15 pairs of a two- and a three-digit number were presented for 10 s each on the screen. After a retention interval of 2 minutes participants saw the cued number pair as well as four threedigit distractors and had to indicate which three-digit number was initially presented together with the two-digit number.

Verb Recognition We selected 40 verbs with 5 to 7 letters from the Hager and Hasselhorn database (1994) rated high on imagery and concreteness. Participants learned half of the verbs for 3 s each. After a retention interval of 2 minutes participants indicated whether they recognized the 40 verbs from the learning phase by classifying them as old or new.

## Judgment Tasks

Participants solved both a linear and a multiplicative judgment task. In the linear judgment task, we expected participants to use a rule-based strategy; that is, their judgments should be well described by a linear regression model. In contrast, in the multiplicative judgment task, participants should rely on a memory-based strategy (Juslin et al., 2008).

In the linear judgment task, the criterion $y$ was a linear, additive function of the cues and could thus be perfectly predicted by a rule-based strategy:

$$
\begin{equation*}
y=4 c_{1}+3 c_{2}+2 c_{3}+c_{4} \tag{5}
\end{equation*}
$$

where $c_{1}$ reflects the most important cue according to its cue weight. Each cue value varied between 0 and 5 .

In the multiplicative judgment task the function generating the criterion $y$ included a multiplicative combination of the cues:

$$
\begin{equation*}
y=\left(4 c_{1}+3 c_{2}+2 c_{3}+c_{4}+2 c_{1} c_{2} c_{3}+c_{2} c_{3} c_{4}\right) / 8.5 \tag{6}
\end{equation*}
$$

Because of the interacting cues, abstracting linear additive rules does not help solve the task. Therefore, people should switch to exemplar-based strategies and store the objects and the associated criterion values in exemplar memory (Juslin et al., 2008).

We used two different cover stories for the linear and the multiplicative multiple-cue judgment task. In the linear judgment task, participants judged how well a comic figure performed in a game on a scale from 0 to 50 . In the multiplicative judgment task, participants estimated how
toxic a bug was on a scale from 0 to 50 . The stimuli for the two cover stories consisted of pictures of either bugs or comic figures. These bugs and comic figures varied on four different continuous cues. The bugs varied on the length of their legs, their antennae, and their wings and the number of points on their back. The comic figures had different sizes of their ears and their nose, a different number of hairs and stripes on their shirt. These visual features were randomly assigned to the cues.

Both tasks consisted of a training phase and a test phase. During the training phase, participants learned to estimate the criterion values for 25 exemplars. In each trial, participants first saw a picture of a bug or a comic figure and were asked to estimate its criterion value. Afterwards they received feedback about the correct value, their own estimate and the points they earned. The training phase ended after 10 blocks. In the subsequent test phase, participants judged 15 new probes four times, but did not receive any performance feedback.

To motivate participants to reach a high performance, participants could earn points in every trial. The number of points they earned was a truncated quadratic function of the deviation of their judgment $j$ from the criterion $y$ :

$$
\begin{equation*}
\text { Points }=20-(j-y)^{2} / 7.625 \tag{7}
\end{equation*}
$$

At the end of the judgment tasks, the points earned were converted to a monetary bonus ( 1500 points $=1 \mathrm{CHF}$ ). In addition, participants earned a bonus of 3 CHF if they reached $80 \%$ of the points in the last training block.

## Procedure

Participants solved all tasks on one day with half an hour break between the two sessions. The tasks were presented in the same order to each participant. In the first session, participants began with the linear judgment task, moved on to the operation span, solved the verb recognition and the picture free recall task, and finally completed the symmetry span. The second session started with the multiplicative judgment task. Afterwards, participants completed the reading span and finally the cued number recall task.

## Results

## Task Performance

We first analyzed participants' average performance in the memory and the judgment tasks (see Table 1 for descriptive statistics). In the working memory tasks, we used the partial credit score, the sum of items recalled in the correct position, as the dependent variable (Conway et al., 2005). If a participant recalled all items correctly, he achieved a score of 75 in the operation span and the reading span and a score of 42 in the symmetry span. Overall, participants recalled more items in the operation and the reading span than in the symmetry span, replicating normative data (Redick et al., 2012). In the episodic memory tasks, we used the percentage of correctly recalled items as the dependent variable. On average, participants remembered a higher

Table 1: Descriptive statistics for the memory and the judgment tasks.

| Task | $M$ | $S D$ | Skew | Kurt |
| :--- | :---: | :---: | :---: | :---: |
| Operation Span | 57.7 | 12.3 | -1.2 | 1.7 |
| Reading Span | 57.1 | 12.2 | -1.8 | 2.3 |
| Symmetry Span | 29.6 | 7.4 | -0.6 | 0.1 |
| Recognition (\% recalled) | .87 | .09 | -0.7 | 0.5 |
| Cued Recall (\% recalled) | .42 | .19 | 0.2 | -0.2 |
| Free Recall (\% recalled) | .46 | .17 | 0.1 | -.01 |
| Linear Judgment |  |  |  |  |
| $\quad$ Last training block | 6.0 | 2.2 | 0.9 | 1.9 |
| $\quad$ Test (Mean) | 5.4 | 1.8 | 0.7 | 0.8 |
| Multiplicative Judgment |  |  |  |  |
| $\quad$ Last training block | 5.2 | 1.8 | 0.7 | 0.6 |
| Test (Mean) | 5.0 | 1.8 | 1.0 | 0.8 |

Note: Skew $=$ Skewness; Kurt $=$ Kurtosis
percentage of items correctly in the recognition task than in the cued recall or the free recall task.

Learning performance in the judgment tasks was measured with the root mean squared deviation (RMSD) between participants' judgments and the correct criterion in the last training block. The learning performance showed that on average participants learned the judgment tasks quite well. However, the multiplicative judgment task was learned more easily than the linear judgment task. Could participants generalize this good performance to judgments for new items in the test phase? We measured judgment performance in the test phase as the RMSD between the correct criterion and participants' mean judgments; that is, the judgment for each probe averaged over the four presentations in the test phase. Performance for new items in the test phase was comparable to performance in the training phase indicating that participants successfully generalized their performance to new items.

To determine which judgment strategy described participants' judgments best, we fitted a linear regression model (see equation 1) and an exemplar model (see equations 2-4) to participants' judgments in the last three training blocks and predicted participants' mean judgments in the test phase (von Helversen \& Rieskamp, 2008). We compared those models to a baseline model that simply estimated participants' mean judgment. Participants were classified as following the strategy that led to the smallest RMSD between model predictions and participants' mean judgments in the test phase. As shown in Figure 1 the judgment process of the participants was highly task sensitive: In the linear judgment task most participants were best described by a linear model, whereas in the multiplicative judgment task, most participants were best described by an exemplar model, $\chi^{2}(2)=95.3, p<.001$.

## Measurement Models

To understand which memory abilities underlie human judgment processes we followed a structural equation

Figure 1. Strategy classification of participants in the linear and the multiplicative judgment task.
modeling approach. Structural equation modeling allows detecting relationships between latent constructs while correcting for the distinct variance of the measures (for a review see Tomarken \& Waller, 2005).

We first estimated two separate measurement models for memory and judgment abilities. These models were later combined into one structural model. All models were estimated using a maximum likelihood estimator with robust standard errors (MLR) because descriptive data indicated some deviations from multivariate normality. The reported $\chi^{2}$ difference tests were performed using the Satorra-Bentler scaled $\chi^{2}$ values (Satorra \& Bentler, 2001).

Measurement Models for Memory Abilities To measure memory abilities, we hypothesized that episodic memory and working memory capacity can be conceived of as two separate latent constructs that may be correlated (Brewer \& Unsworth, 2012). We first fitted a two-factor latent variable model to the memory data assuming no correlation between working memory and episodic memory. All working memory span tasks loaded on one latent factor, while all episodic memory tasks loaded on a second latent factor. Because the residual variance of the manifest variable recognition was estimated to be negative, we fixed it to 0 . This model fitted reasonably well, $\chi^{2}(10)=16.11, p=.10$, $\mathrm{CFI}=.95, \mathrm{RMSEA}=.06, \mathrm{SRMR}=.08$. Allowing working memory capacity and episodic memory to correlate did not significantly improve model fit, $\chi^{2}(9)=14.85, p=.10$, CFI $=.95$, RMSEA $=.06$, SRMR $=.06$. Finally, a one-factor model assuming a correlation of 1 between episodic memory and working memory capacity fitted worse than the two-factor model, $\chi^{2}(10)=128.2, p<.001, \mathrm{CFI}=.01$, RMSEA $=.26$, SRMR $=.16$. In sum, memory abilities in our study were best described by assuming two separate, uncorrelated latent constructs for working memory and episodic memory.

Measurement Models for Judgment Abilities To find out whether performance depends on the judgment task, we fitted three different measurement models for judgment abilities to judgment performance in the four test blocks of the linear and the multiplicative judgment task. We first estimated a two-factor latent variable model assuming no

Figure 2: Structural equation model relating working memory capacity and episodic memory to judgment performance in the test phase. All loadings and correlations are standardized.
correlation between the factors. One factor predicted judgment performance in the linear judgment task, the second factor predicted judgment performance in the multiplicative judgment task. This model did not describe the judgment data well, $\chi^{2}(20)=38.54, p<.01, \mathrm{CFI}=.975$, RMSEA $=.07$, $\mathrm{SRMR}=.11$. Allowing a correlation between the judgment factors improved model fit, $\chi^{2}(19)=$ $28.24, p=.08, \mathrm{CFI}=.99$, $\mathrm{RMSEA}=.05, \mathrm{SRMR}=.03$. Finally, we estimated a one-factor model assuming a correlation of 1 between judgment performance in the linear and the multiplicative task. This one-factor model could not account for the judgment data, $\chi^{2}(20)=362.14, p<.001$, $\mathrm{CFI}=.54, \mathrm{RMSEA}=.31, \mathrm{SRMR}=.22$. In sum, a twofactor model with correlated factors captured performance variations within the judgment tasks best. This suggests that although performance in rule-based and memory-based judgment tasks is correlated, distinct processes may account for performance differences between the tasks.

## Linking Memory Skills to Judgment Performance

Next, we investigated the link between memory abilities and judgment performance. Based on our prediction, we estimated a structural model (depicted in Figure 2) relating working memory capacity to judgment performance in the linear task and episodic memory to judgment performance in the multiplicative task. This model provided a good fit to the data, $\chi^{2}(75)=89.93, p=.12, \mathrm{CFI}=.98, \mathrm{RMSEA}=.03$, $\mathrm{SRMR}=.08$. Allowing a correlation between working memory capacity and judgment performance in multiplicative tasks and a correlation between episodic memory and judgment performance in linear tasks did not significantly improve the fit of the structural model, $\chi^{2}$ (73) $=85.27, p=.15, \mathrm{CFI}=.99, \mathrm{RMSEA}=.03, \mathrm{SRMR}=.06$. Also, a structural model assuming that memory abilities do not predict judgment abilities could not account for the data,
$\chi^{2}(77)=107.48, p=.01, \mathrm{CFI}=.97, \mathrm{RMSEA}=.05, \mathrm{SRMR}$ $=.10$. Indeed, setting the weight from working memory to linear task performance to 0 decreased model fit, $\Delta \chi^{2}(1)=$ $4.10, p=.04$. Likewise, setting the weight from episodic memory to multiplicative task performance to 0 decreased model fit, $\Delta \chi^{2}(1)=12.67, p<.001$. Thus, while judgment accuracy in rule-based tasks was predicted by working memory capacity, judgment accuracy in memory-based tasks was predicted by episodic memory.

## Discussion

Our study sheds light on which memory abilities people rely when making judgments, a topic that has received little attention in the literature. As the first study linking memory abilities to performance in judgment tasks, we found that working memory capacity predicted judgment accuracy in a linear task, whereas episodic memory predicted judgment accuracy in a multiplicative task. Furthermore, participants relied on a rule-based strategy in the linear task and a memory-based strategy in the multiplicative task. In line with theories of judgment and categorization (Ashby \& O'Brien, 2005; Juslin et al., 2008) this suggests that the two strategies draw upon different memory abilities.

Our results suggest that working memory capacity only predicted judgment performance in rule-based judgment tasks. This result seems to contradict research linking working memory capacity to performance in rule-based and memory-based categorization tasks (Lewandowsky, 2011). One reason for these diverging results may be that our study focused on the differences between judgment tasks, namely the covariance that was not explained by a common judgment factor. Yet, Lewandowsky concentrated on the similarities among categorization tasks. Another reason for these diverging results may be that our study focused on the generalization to new items instead of the learning process.

Indeed, in Lewandowsky's study a learning parameter was strongly related to working memory capacity. Thus, while learning to apply a rule-based or a memory-based judgment strategy may require working memory capacity, only the correct execution of a rule-based judgment strategy may draw upon working memory capacity. Executing a memorybased judgment strategy may instead involve episodic memory skills.

Few studies have examined the link between episodic memory and judgment abilities. Our study clearly shows that episodic memory is related to performance in memorybased judgments. This result highlights the importance of episodic memory for judgments and resonates well with theories suggesting that exemplars are stored and deliberatively retrieved from long-term memory (Juslin et al., 2008). It is also in line with research arguing for exemplar processes in categorization (Nosofsky \& Zaki, 1998). Beyond that, our results highlight that a multitude of cognitive skills, not only working memory, is involved when people make judgments. Shifting the focus to longterm memory may open up new research questions and applications. For instance, memory-based judgment strategies may be more vulnerable to forgetting and interference. Knowledge about storage and retrieval processes in judgment may thus help improving judgments ranging from simple daily judgments such as estimating the price of a shopping basket to professional judgments such as judging the quality of a job candidate.

#### Abstract

This research demonstrates that preschoolers flexibly trust and mistrust the same individuals, as preschoolers recognize that their intentions may vary. In Study $1(N=101) 3$ - and 4-yearolds trusted speakers based on their current, rather than previous, intentions to give in/correct information. Thus preschoolers infer the meanings behind different intentions and recognize that intentions change within individuals over time. In Study $2(N=80) 3$ - to 5 -year-olds trusted speakers who were currently sincere, but previously intentionally inaccurate, rather than currently sincere, but previously ignorant, showing that preschoolers infer current knowledge from prior intentions. Preschoolers also trusted speakers who were currently knowledgeable, although previously ignorant, showing that they recognize knowledge is variable within individuals.

Keywords: Trust, Intention, Knowledge, Frame Problem, Preschoolers, Humor

## Introduction

A growing body of research suggests that children do not blindly trust just anyone; children consider whom to trust (e.g., Clément, Koenig \& Harris, 2004; Corriveau, Meints \& Harris, 2009; Koenig \& Harris, 2005). However, in a world where people have variable knowledge and intentions, an important question is whether children are prepared to trust individuals on some occasions but not others (e.g., Nurmsoo \& Robinson, 2009; Scofield \& Behrend, 2008; Shafto, et al., 2012). Thus, the question becomes not just whom to trust but also when to trust a given person. This is important not only for how we acquire information, but also for how we dismiss uninformative or irrelevant information. This is the Frame Problem (e.g., Dennett, 1984), which is still proving difficult to solve in Artificial Intelligence (AI, e.g., Ekbia \& Maguitman, 2001; Scherl \& Levesque, 2003), but which may be a relatively easy problem for preschoolers to solve.
Preschoolers consider past behaviors when deciding whom to trust. For example, when learning new words, both 3 - and 4 -year-olds trust a speaker who previously labeled familiar objects correctly over a speaker who labeled them incorrectly. Thus, children trust accurate over inaccurate speakers (e.g., Clément, et al., 2004; Koenig \& Harris, 2005). Children also trust knowledgeable over ignorant actors (Einav \& Robinson, 2011).

Our first goal was to discover whether preschoolers trust an informant's claims depending on their current intentions and not just on their previous accuracy or apparent knowledge. More specifically, we asked: (1) whether preschoolers are flexible when they trust others; (2) whether mental states, specifically intentions, play a role in trust; and (3) whether preschoolers understand that people's intentions can change over time. Most of the research to date suggests that people who were previously accurate or knowledgeable can be trusted in future, whereas people who were previously inaccurate or ignorant cannot. However people are not statically trustworthy or untrustworthy (e.g., Nurmsoo \& Robinson, 2009; Scofield \& Behrend, 2008; Shafto et al., 2012). Rather, a person can be trustworthy at times, but not at others.

Joking is a clear example of intentionally saying or doing the wrong thing (e.g., Hoicka, Jutsum, \& Gattis, 2008; Leekam, 1991), and so it is an occasion when the audience should not trust the information provided. Indeed, jokers want their audience to know about their falsehood, and they do not expect the audience to believe any part of it (e.g., Leekam, 1991). Thus, people provide cues when they are joking (e.g., Hoicka \& Gattis, 2012; Mireault, et al., 2012). In particular, parents express greater disbelief when joking as compared to acting literally (Hoicka, et al., 2008). Additionally, everyone jokes. For example, all 3-year-olds in a survey were reported by their parents to have produced novel jokes (Hoicka \& Akhtar, 2012). Therefore, joking is an ideal way to examine whether preschoolers use intent to say or do the wrong thing as a cue not to learn.

Research has started to consider whether young children understand the various contexts in which others intend to say or do the wrong thing. From 25 months, toddlers copy wrong actions marked as jokes (laughter), but correct the same wrong actions marked as mistakes ("Whoops!"; Hoicka \& Gattis, 2008). From 30 months, toddlers copy jokers who mislabel familiar objects, but they do not copy people who sincerely mislabel (Hoicka \& Akhtar, 2011). In the case of trust, children as young as 3 years understand that pretending is not a reliable cue for acquiring correct information compared to, for example, having direct experience with the relevant information (Koenig, 2012).

A critical aspect of intention is that it is not a stable mental state. People's intentions change over time (e.g.,

Cohen \& Levesque, 1990; Roy, 2009; van der Hoek, Jamroga, \& Wooldridge, 2007). According to Cohen and Levesque (1990, p. 214), people "keep (or commit to) intentions, but not forever; [they] discharge those intentions believed to have been satisfied". Thus, people can revise or complete their intentions, moving onto new intentions. When joking, the goal is to get a laugh at a moment in time, but not at everything forever.

Our first goal - examined in Experiment 1 - was to find out if children trust someone who currently intends to give correct information over someone who intends to give incorrect information, regardless of their past accuracy or intentions. A major goal of Experiment 2 was to discover whether children can infer a speaker's knowledge from his or her intention. When people intend to do or say the wrong thing, through joking, lying, or pretending (e.g., Hoicka \& Gattis, 2008), the speaker knows the correct information, but chooses not to say it (e.g., Leekam, 1991). Thus, if a joker previously said the wrong thing, he or she likely knew what the right answer was. By contrast, if an ignorant person said the wrong thing, this suggests that the person did not know the right answer. If children understand that joking is more likely to involve intentionally saying the wrong thing compared to being ignorant, then they should later trust a previous joker over a previously ignorant person when learning new information. Thus they may infer that the joker was more likely to know the information than the ignorant speaker, but withheld prior information.

## Experiment 1

Experiment 1 examined whether preschoolers base their trust on speakers' current intentions rather than their past accuracy or intentions. In the final test trials, one actor named novel objects while giving sincere cues whereas the other named them while giving joking cues. Depending on the condition, children had previously seen the actors display the same intentions (i.e., sincere versus joking), a switch in intentions, or they had had no prior exposure to the actors' intentions. The experimental question was whether children would be swayed by the actors' current intentions - as expressed in the test trials - or by their past intentions.

## Method

Participants Fifty-three 3-year-olds ( 33 females, $\mathrm{M}=3$ years, 5 months, range $=3$ years, 0 months -3 years, 11 months) and 484 -year-olds ( 25 females, $\mathrm{M}=4$ years, 4 months, range $=4$ years, 0 months -4 years, 11 months) were randomly assigned to one of three conditions: Consistent Intentions, Inconsistent Intentions, and No Prior Intentions. Children were of similar ages across conditions.

Materials The objects in the familiarization trials included a spoon, a bottle, a doll, and a brush. The objects in the action videos included a cookie, a cup, a scarf, and a hat. The objects in the test trials included a brown feathery cat toy, a
red, black and silver DIY object, a blue and white dog toy, and a red and white kitchen utensil. PowerPoint slideshows were made with each slide showing an object and/or actors, or a video (see procedure). Children's responses were videorecorded directly onto the laptop computer.

Design This study was a between-subjects design in which there were three conditions. In the Consistent Intentions condition, one actor was consistently joking and one actor was consistently sincere throughout the familiarization trials, action videos, and test trials. In the Inconsistent Intentions condition, one actor joked in the familiarization trials but was sincere in the action videos and test trials. The other actor was sincere in the familiarization trials but joked in the action videos and test trials. By showing that actors had switched intentions in the action videos, we anticipated that children would be prepared to recognize their new intentions in the test trials. In the No Prior Intentions condition, children saw the objects but not the actors in the training trials, and then participated in the full test trials. The dependent variable was whether children trusted the joker or sincere actor at test trials when learning new labels.

## Procedure

Familiarization Trials: At the start of the familiarization trials in the Consistent Intentions and Inconsistent Intentions conditions, children were shown a video of the two actors being asked to name an object (e.g., spoon). The joker laughed, named it incorrectly (e.g., duck) using a humorous intonation pattern (Hoicka \& Gattis, 2012) and said, "I'm being silly, only joking." The sincere actor labeled it correctly using a sincere intonation pattern (Hoicka \& Gattis, 2012) while smiling. After watching the video children were shown a slide with pictures of the object and the two actors who had named it and were asked, "She called it a [e.g., duck] and she called it a [e.g., spoon]. Can you tell me what it's called?" This repeated for the remaining three trials with different familiar objects. In the No Prior Intentions Condition, children were instead shown a slide with a picture of the familiar object, given two names for the object and then asked to name it. For example for the spoon, they were asked, "Is this a duck or a spoon?"

Action Videos: In the Consistent Intentions condition, the actor who had joked in the familiarization trials also joked in the action videos. Similarly, the sincere actor stayed sincere. In the Inconsistent Intentions condition, the actor who had joked in the familiarization trials became sincere during the action videos. Similarly, the actor who had been sincere in the familiarization trials became humorous.

For each action, each actor said the same line before performing an action such as, "I'm going to put this hat on". The sincere actor then did the correct action (e.g., putting the hat on her head) and the joker did the action incorrectly, (e.g., putting the hat under her arm) and saying, "I'm being silly, I'm only joking" and laughing. This continued for the other three actions. The No Prior Intentions condition did not include action videos.

Test Trials: Children watched four videos where a third actor asked the two actors what a novel object was called. The sincere actor smiled and said, e.g., "That's a mogo" with a sincere intonation pattern. The joker said, e.g., "That's a sepa" in a humorous intonation pattern, then, "I'm being silly, only joking" and laughed. Following the video the child was shown a slide with a photo of the object and the two actors and told, "She called it a sepa and she called it a mogo. Can you tell me what it's called?" This continued for the remaining three trials. In the Consistent Intentions condition, the actors played the same roles as they had for the familiarization trials and action videos. In the Inconsistent Intentions condition, the actor who had joked during the familiarization trials was now sincere (just as she had been during the action trials). By contrast, the actor who had been sincere during the familiarization trials was now joking (just as she had been during the action trials). In the No Prior Intentions condition, the test trials were the first time the children had seen the actors.

## Results

Data were analyzed with logit mixed effects models. Only significant effects and interactions are reported.
See Figure 1 for the percentage of trials on which children chose the sincere actor's label over the joker's, by Condition (Consistent Intentions, Inconsistent Intentions, No Prior Intentions) and Age. The base model was improved by Condition, $X^{2}(2)=13.91, p=.0010$, and Age, $X^{2}(1)=3.84$, $p=.0501$, as fixed effects. The resulting model (loglikelihood $=-149.17, N=340$ ) found children were significantly more likely to trust the sincere actor over the joker at test trials in the Consistent Intentions versus Inconsistent Intentions and No Prior Intentions conditions (both Odds-Ratio, $O R>2.43, p<.0256$ ). Four-year-olds were marginally more likely to trust the sincere actor than 3-year-olds ( $O R=1.78, p=.0526$ ).
When each condition was tested individually, children in the Consistent Intentions and No Prior Intentions conditions (both log-likelihood $>-59.22, \quad N=127 / 101$ ) were significantly more likely to trust the sincere actor than the joker at test trials (both $O R>2.66, p<.0012$ ). Age improved the model for the Inconsistent Intentions condition, $X^{2}(1)=6.03, p=.0141$. The overall model (loglikelihood $=-49.84, N=112$ ) found 4 -year-olds were more likely to trust the sincere actor than the joker at test trials than 3 -year-olds ( $O R=3.61, p=.0180$ ). Follow-up tests found that both 3- and 4 -year-olds (both log-likelihood $>$ $31.41, N=54 / 58$ ) were more likely to trust the sincere actor than the joker at test trials (both $O R>2.85, p<.0160$ ).

## Discussion

Across all three conditions, both 3- and 4 -year-olds were more likely to trust the actor who was sincere at test trials over the actor who was joking. This suggests children take into account the current intention of a speaker when deciding whether to learn from him or her. If the speaker's intention is sincere, children will learn. If the speaker's
intention is to joke, children will not learn. Thus, selective trust is not purely based on past experience with a speaker it is also based on a speaker's current intentions.

## Experiment 2

During the familiarization trials in both conditions in Experiment 2, one actor mislabeled familiar objects due to ignorance, while the other actor mislabeled familiar objects because she was joking. During test trials, the previously ignorant actor gave cues suggesting that she was now knowledgeable, whereas the joker continued to give joking cues (Knowledge Inconsistent condition). Alternatively, both actors gave cues that they were sincere (Knowledge Inferred condition).

The first experimental question concerned the Knowledge Inconsistent condition. Would children recognize that someone who was once ignorant could become knowledgeable, and would be better to trust than a previous joker who intended to continue saying the wrong thing? The second experimental question concerned the Knowledge Inferred condition. Would children distinguish the two types of inaccuracy during familiarization trials; more specifically, would they recognize that a previous joker was more likely to know the correct labels compared to an ignorant speaker, but chose not to say them. If so, during test trials children should trust a previous joker who becomes sincere, and intends to say the right thing, over a previously ignorant actor, who is also sincere, but is less likely to be knowledgeable.

## Method

Participants Thirty 3-year-olds ( 14 females, $\mathrm{M}=3$ years, 5 months, range $=3$ years, 1 month -3 years, 11 months), 28 4 -year-olds ( 13 females, $\mathrm{M}=4$ years, 5 months, range $=4$ years, 0 months -4 years, 10 months), and 225 -year olds ( 13 females, $M=5$ years, 6 months, range $=5$ years, 1 month -5 years, 11 months) were randomly assigned to one of two conditions: the Knowledge Inconsistent condition and the Knowledge Inferred condition. Children were of similar ages across conditions.

Materials Same as Study 1, except that there were an additional two familiarization objects (car, pig).

Design This study was a between-subjects design in which there were two conditions. In the Knowledge Inconsistent condition, one actor was ignorant during training, but knowledgeable during testing, whereas the other actor consistently joked. In the Knowledge Inferred condition, again, one actor was ignorant during training whereas the other joked. During action and test trials, both actors were sincere. Action trials were included to show a change of intentions in the joker, as in Experiment 1.

There were six training trials in both conditions. The joker joked for four trials, and was knowledgeable for two trials. The ignorant actor was ignorant for four trials, and
knowledgeable for two trials. By showing that the ignorant actor could switch knowledge states during training, we anticipated that children would be prepared to recognize the ignorant actor's new knowledge in the test trials in the Knowledge Inconsistent condition. Jokers also had two knowledgeable trials in order to keep (in)accuracy consistent between actors. Training was the same in the Knowledge Inferred condition in order to ensure conditions were comparable. The dependent variable was who children trusted when learning new labels - the previous joker, or previously ignorant actor.

## Procedure

Familiarization Trials: The task proceeded in the same way as in Experiment 1. In both conditions, the joker gave incorrect labels paired with joking cues for four out of six familiarization trials and correct labels paired with knowledge cues for two familiarization trials. The ignorant actor gave incorrect labels paired with ignorance cues for four out of six familiarization trials and correct labels paired with knowledge cues for two familiarization trials. Humorous cues were the same as in Experiment 1. For ignorance cues, the actor shrugged her shoulders and labeled the object incorrectly saying, e.g., "I don't know, that's a train?" Knowledgeable cues involved displaying their knowledge and labeling an object correctly, e.g., "I know this one. That's a spoon."

Action Videos: In the Knowledge Inferred condition only, children were shown action videos which were the same as those used in Experiment 1. The actor who had joked during the familiarization trials carried out the four sincere actions. The actor who had been ignorant during familiarization also carried out the four sincere actions.
Test Trials: The test trials were the same as in Experiment 1. In the Knowledge Inconsistent condition, the previous joker continued to joke during test trials saying, e.g., "That's a sepa, I'm being silly, only joking" and laughing, whilst the previously ignorant actor was now knowledgeable saying, e.g., "I know this one. It's a mogo". In the Knowledge Inferred condition, both actors labeled the novel object giving sincere cues, where they would smile and say, "That's a mogo" or "That's a sepa".

## Results

We built logit mixed effects models as in Experiment 1. No gender or age (over, under 4.5 years) differences were found. See Figure 2 for the percentage of trials on which children chose the previous joker over the previously ignorant actor, by Condition (Knowledge Inconsistent, Knowledge Inferred). The base model was improved by Condition, $X^{2}(1)=50.05, p<.0001$ as a fixed effect. The resulting model (log-likelihood $=-177.49, N=307$ ) found an effect of Condition ( $O R=6.21, p<.0001$ ). When each condition was tested individually, children in the Knowledge Inconsistent condition (log-likelihood $=-73.42$, $N=157$ ) were significantly more likely to trust the previously ignorant actor (now knowledgeable) versus the
previous joker (still joking) at test trials ( $O R=4.77, p<$ .0001). In the Knowledge Inferred condition (log-likelihood $=-93.02, N=137$ ) children were significantly more likely to trust the previous joker over the previously ignorant actor when both were sincere at test trials $(O R=1.40, p=.0505)$.

## Discussion

Experiment 2 shows that children consider intentions in combination with knowledge when deciding whom to trust for information. When both actors were sincere during test trials in the Knowledge Inferred condition, children were more likely to trust the previous joker than the previously ignorant actor. Because both actors were equally inaccurate during the training trials, accuracy could not be used as a cue. Moreover, children in Experiment 1 did not trust the joker, even when no previous training was given, suggesting that children do not simply prefer jokers. Thus, children inferred that despite the joker previously being inaccurate, she likely actually knew the correct information, at least compared to the ignorant actor, and would thus express the correct information when being sincere.

Another possible way to explain the results is that children avoided learning from someone who was previously ignorant. However, this cannot be the case because children chose to learn from the previously ignorant actor rather than the previous joker when she showed signs of knowledge in the test trials in the Knowledge Inconsistent condition. This demonstrates that children are flexible in their trust, and understand that people's knowledge can vary. They acknowledge that sometimes people know words, and sometimes they do not.

## General Discussion

Experiment 1 showed that children trust speakers based on the speakers' current intentions, rather than their previous intentions or accuracy. Children trusted the actor who was currently being sincere versus joking when learning new labels, even when the actors' previous intentions were different or had not been made available to the preschoolers. Thus, preschoolers recognized that when speakers joke, they intend to say the wrong thing, and so should not be trusted to provide accurate information.

Experiment 2 showed that preschoolers combine intention and knowledge states to determine whether information is trustworthy. Specifically, children inferred that when both actors were sincere at test trials, the actor who previously said the wrong thing in the context of a joke was more likely to know the correct labels compared to the actor who previously said the wrong thing due to ignorance. Thus, children recognized that a joker is more likely to know the truth compared to an ignorant speaker, but chooses not to say it. However, when the previous joker continued to joke, and the previously ignorant actor showed that she was knowledgeable at test trials, children were flexible and preferred the previously ignorant actor, recognizing a change in the ignorant actor's knowledge.

## Stable Traits

Much of the research to date has portrayed children's trust as involving the attribution of a stable trait concerning previous accuracy or knowledge (e.g., Clément, et al., 2004; Corriveau, et al., 2009; Einav \& Robinson, 2011; Koenig \& Harris, 2005). This is the first empirical research to show that children consider not only previous accuracy or knowledge, but also the speaker's past and current intentions, when deciding whom to trust. This is an important skill to have because speakers shift rapidly in their intentions, joking at one moment and being sincere the next. This adds to a body of research showing that children are flexible in their trust (e.g., Nurmsoo \& Robinson, 2009; Scofield \& Behrend, 2008; Shafto, et al., 2012).
In the case of intentionally saying the wrong thing, such as joking, it is highly unlikely that someone would always joke, even if most people do joke at certain times (e.g., Hoicka \& Akhtar, 2012) to trust them. The current findings converge with evidence from computational models, which suggest children consider intention and knowledge, and not just accuracy, when deciding whom to trust (Shafto, et al., 2012).

## Intention

Although much research has considered toddlers' understanding that people intend to do the right thing (e.g., Carpenter, Akhtar, \& Tomasello, 1998), understanding complex intentions, such as intentions to do the wrong thing, may be a more refined test of intention understanding as it involves considering why, and not just whether, someone would do something intentionally. Our experiments show that preschoolers respond appropriately to complex intentions from 3 years. Specifically, they recognize that people can intend to do different things for different reasons. They can intend to say the right thing to teach others, or they can intend to say the wrong thing to joke.

A growing body of research suggests that preschoolers understand that people can intend to do the wrong thing (Hoicka \& Akhtar, 2011; Hoicka \& Gattis, 2008; Rakoczy, Tomasello, \& Striano, 2004). The current experiments extend this prior research by showing that preschoolers can make use of this insight when learning new information. Children are thus flexible learners, accepting new information only when appropriate. Preschoolers are therefore able to solve the Frame Problem (e.g., Dennett, 1984) to a relatively sophisticated degree, tracking speakers’ prior and current accuracy, knowledge, and intentions to decide when to accept versus reject information. An important question that follows is how they solve the Frame Problem. In the current studies, social cues clearly helped. Indeed, in the case of humor and humorous intentions, parents scaffold infants' and toddlers' understanding through cues and explicit expressions of disbelief (Hoicka \& Gattis, 2012; Hoicka, et al., 2008; Mireault, et al., 2012). Thus, the Frame Problem may be solved to some extent through social cues and parental scaffolding.

## Knowledge

Analysis based in philosophy and AI shows that intention is not a stand-alone mental state. Rather, to have an intention, one must also have other mental states such as beliefs and knowledge (Cohen \& Levesque, 1990; van der Hoek, et al., 2007). Thus, for children to truly understand others' intentions, they must also understand others' beliefs or knowledge. Experiment 2 provides the first experimental evidence that children as young as 3 years infer knowledge from intentions, and use inferred knowledge to learn from a previously inaccurate person later on.

Although past research demonstrates that children can infer intentions to do the wrong thing when joking (e.g., Hoicka \& Akhtar, 2011; Hoicka \& Gattis, 2008), it was not clear from this research whether children understood that the actor actually knew the correct information. The current research shows that they consider intention alongside other mental states, specifically knowledge.
Experiment 2 also suggests that preschoolers can attribute knowledge to people who were previously ignorant if they later demonstrate cues showing knowledge. This is consistent with previous findings on perceptual access. Children did not trust an informant who could not perceive the information that they needed, but later trusted the same informant when he or she could perceive that information (Nurmsoo \& Robinson, 2009; Robinson, et al., 2011). This flexibility makes sense. For example, sometimes people forget information, but not always. Sometimes people have some knowledge in a domain, but not all knowledge, for example vocabulary, for which there is variation amongst parents (e.g., Huttenlocher, 1998). Thus, a speaker may know some labels, but not all labels. Being sensitive to cues which suggest when someone has knowledge and when they do not, even within the same domain, would thus be a useful tool in selectively trusting, and acquiring information, from others.

# When Is Language a Window into the Mind? Looking Beyond Words to Infer Conceptual Categories 

Kevin J. Holmes (kjholmes@berkeley.edu)<br>Department of Linguistics, University of California, Berkeley, 1203 Dwinelle Hall, Berkeley, CA 94720 USA<br>Phillip Wolff (pwolff@emory.edu)<br>Department of Psychology, Emory University, 36 Eagle Row, Atlanta, GA 30322 USA

#### Abstract

Language is often regarded as a rich source of evidence about the mind. However, a number of findings challenge this position, at least at the level of words: Where languages differ in their lexical distinctions, conceptual differences are not always observed. We ask here how language might serve as a window into the mind despite an apparently loose connection between words and concepts. We propose that prominent conceptual distinctions, though not necessarily captured by individual words, may be revealed by elements of meaning shared by multiple words. Testing this hypothesis in the domain of space, we show that clusters of spatial terms, identified through dimensionality reduction analyses of semantic similarity data, align with conceptual categories spontaneously accessed during the perceptual discrimination of spatial relations. These findings suggest that aspects of semantic structure beyond the level of words may provide considerable insight into the conceptual system. Implications for research on linguistic relativity are discussed.

Keywords: language and thought; word meaning; concepts; semantic structure; space; categorical perception.

## Introduction

Many cognitive scientists regard language as a window into the mind (Chomsky, 1975; Lakoff, 1987; Pinker, 2007). Complicating this view, however, is the observation that languages differ dramatically in how they partition the world by name (Malt \& Wolff, 2010). Critically, this semantic diversity is not necessarily mirrored by corresponding conceptual diversity: Where languages differ in their lexical distinctions, conceptual differences are not always observed (e.g., Malt et al., 1999; Munnich, Landau, \& Dosher, 2001; Papafragou, Hulbert, \& Trueswell, 2008). Such findings suggest that, at least at the level of words, language may not be a particularly good window into the mind. In this research, we look beyond individual words to identify other aspects of semantic structure that might prove more tightly connected to the conceptual system. In particular, we propose that prominent conceptual distinctions may be revealed by elements of meaning shared by multiple words. Investigating this hypothesis in the domain of space, we identify clusters of spatial prepositions with similar meanings and assess the extent to which those meanings are spontaneously accessed during the nonlinguistic processing of spatial relations. Our ultimate conclusion will be that language can provide an illuminating window into the mind-if you know where to look.

## Dissociations between words and concepts

A large literature documents the pervasiveness of semantic diversity, with cross-linguistic variation in word meaning observed in such disparate domains as artifacts (Malt et al., 1999), spatial relations (Levinson et al., 2003), and number (Frank et al., 2008), among many others. If language is a window into the mind at the level of words, such diversity should also be observed at the conceptual level. That is, speakers of different languages should perform differently on relevant nonlinguistic tasks, in a manner that aligns with the lexical distinctions of their respective languages.

Although this prediction has been supported by a number of studies investigating the Whorfian hypothesis (see Wolff \& Holmes, 2011), other studies have shown striking asymmetries in performance on linguistic and nonlinguistic tasks. Malt et al. (1999) found that speakers of English, Spanish, and Chinese differed markedly in how they named a set of common household containers (e.g., bottles, jars, etc.), yet showed remarkable agreement when sorting the objects based on overall similarity. Munnich et al. (2001) observed that English, Japanese, and Korean speakers differed in their naming, but not their memory, of spatial locations. Papafragou et al. (2008) found that English and Greek speakers described motion events differently despite showing similar attentional patterns when viewing the events. Together, these findings suggest that the distinctions picked out by words are not invariably salient at the conceptual level, implying some degree of dissociation between words and conceptual representations.

Several factors might account for this word-concept mismatch. Word meanings are shaped, to a much greater degree than conceptual knowledge, by historical forces such as language contact and past speakers' concerns (Malt, Gennari, \& Imai, 2010), and by communicative pressures, such as the need to maximize informativeness and minimize cognitive load (Kemp \& Regier, 2012). As a consequence, the words of a language will tend to reflect the language's history and support efficient communication, but may often fail to capture salient conceptual distinctions - despite the long-standing intuition that they should (cf. Rosch, Mervis, Gray, Johnson, \& Boyes-Braem, 1976).

## The semantic clusters hypothesis

Although the factors outlined above render individual words an unreliable guide to conceptual representations, there may be other ways in which language can provide insight into
the conceptual system. Several recent approaches combine semantic data from multiple languages, motivated by the idea that cross-linguistically frequent semantic distinctions may be linked to prominent, perhaps even universal, conceptual ones (Malt et al., 2011; Regier, Khetarpal, \& Majid, in press). However, a similar idea can be applied to a single language: Elements of meaning that are shared by many words - and hence apply across a wide range of communicative contexts - may be particularly likely to capture key conceptual distinctions. Words that share the same element of meaning can be likened to snapshots of the same underlying concept: No single word will capture the concept on its own, but by examining multiple words with closely related meanings, the concept may emerge (cf. Regier et al., in press). Accordingly, conceptually salient distinctions may be revealed by clusters of related words. We call this proposal the semantic clusters hypothesis.

Testing this hypothesis requires (1) identifying clusters of words within a given domain, and (2) assessing their conceptual salience. The first step may be achieved by obtaining a measure of the similarities among all of the words in a domain. A common method for collecting semantic similarity data is to have people divide words into groups based on their meanings (e.g., Wolff \& Song, 2003). Words with similar meanings will tend to be grouped together often, while words with dissimilar meanings will rarely be grouped together. These co-occurrences may be combined across participants to construct a similarity matrix, which in turn may be analyzed using dimensionality reduction techniques, such as multidimensional scaling (MDS). Any clusters of words, or latent categories, within the semantic similarity space for the domain are likely to be revealed by such techniques.

The second step requires examining the extent to which the latent categories factor into cognitive processes unrelated to language. One way to establish the role of categories in nonlinguistic processing is to show that the category membership of a set of items influences how the items are perceived. Items from different categories are often easier to tell apart than items from the same category, even after controlling for the physical distance between the items - a phenomenon known as categorical perception (CP; Goldstone \& Hendrickson, 2010). In the case of latent categories, CP could be tested by having people discriminate among items from the domain of interest, with the items coming from either different latent categories or the same latent category. CP would be indicated by superior discrimination on between- compared to within-category trials. Such an effect, if found, would indicate that the latent categories are spontaneously accessed in a nonlinguistic context, providing evidence for their conceptual salience.

We adopted the approach outlined above to test the semantic clusters hypothesis in the domain of space, a perennial battleground in research on the language-thought interface (Li \& Gleitman, 2002; Majid et al., 2004). In Experiment 1, participants sorted a large inventory of spatial prepositions into groups, and MDS was used to identify
latent categories. Experiment 2 examined the conceptual salience of these categories, using CP as a diagnostic. Recent evidence suggests that CP is stronger in the left hemisphere than the right (Gilbert et al., 2006), even for unnamed categories (Holmes \& Wolff, 2012) - consistent with specialization of the left hemisphere for categorical processing independent of language (Kosslyn et al., 1989). Thus, even though the items within a latent category might share no common name, we expected CP for such categories to be left-lateralized.

## Experiment 1

The goal of Experiment 1 was to obtain a measure of the semantic structure of the spatial domain, from which clusters of prepositions could be identified.

## Method

Participants Sixty-three Emory University undergraduates, all native English speakers, participated for course credit or payment. One participant was excluded for not following instructions.
Materials An inventory of English spatial prepositions was assembled by adapting a comprehensive list from Landau and Jackendoff (1993). Forty-two prepositions were selected from the original list, omitting archaic (e.g., betwixt, without), intransitive (e.g., apart, downstairs), nonspatial, (e.g., ago, despite) and predominantly metaphorical (e.g., in line with) prepositions, and those requiring a phrasal verb construction (e.g., through, as in "pierce through"). The resulting inventory is shown in Table 1.

Table 1: Spatial prepositions used in Experiment 1.

| about | atop | in | past |
| :--- | :--- | :--- | :--- |
| above | before | in back of | to the left of |
| across | behind | in front of | to the right of |
| after | below | inside | to the side of |
| against* | beneath | near | toward |
| along | beside | off | under |
| alongside | between | on | underneath |
| amid | beyond | on top of | up |
| among | by | opposite | within |
| around | down | outside |  |
| at | far from | over |  |
| *excluded from analyses |  |  |  |

Each of the prepositions was printed in bold at the top of a $4 " \times 6$ " index card. Below each term were two example sentences reflecting prototypical spatial usages of the term.
Procedure The experiment consisted of two phases. In the first phase, participants were presented with the randomly ordered stack of index cards and were asked to write a definition for each preposition based on the two example sentences. The purpose of this task was to encourage participants to think relatively deeply about the meanings of the prepositions. For a subset of participants, the term
against was inadvertently omitted from the stack of cards; as a result, this term was excluded from analyses.

In the second phase, participants were asked to divide the index cards into as many groups as they felt were appropriate. They were told that the prepositions in each group should have "essentially the same meaning." Participants were given as much time as they needed to complete both phases of the experiment.

## Results and discussion

The number of groups of prepositions ranged from 5 to 29 ( $M=14.1, S D=5.8$ ). The raw sorting data were converted into a pairwise similarity matrix, with the similarity between each pair of prepositions taken to be the proportion of participants who grouped them together. For example, if all 62 participants grouped above and below together, the similarity between them would be $62 \div 62=1$; if 31 participants grouped above and below together, the similarity between them would be $31 \div 62=.5$, and so on.

The similarity matrix was submitted as input to a MDS algorithm, ALSCAL (ordinal model), and solutions of increasing dimensionality were generated. Because the largest decline in stress (a measure of the degree of fit between the actual and estimated inter-item distances) occurred between 1 and 2 dimensions, the 2-dimensional solution $($ stress $=.26)$ is shown in Figure 1. ${ }^{1}$

Figure 1: Multidimensional scaling solution of sorting data from Experiment $1 . K$-means clusters are marked on the solution and labeled for descriptive purposes.

To help identify clusters within the solution, the estimated inter-item distances were combined into a new pairwise similarity matrix. This matrix was then submitted as input to a series of $K$-means clustering analyses, using increasing values

[^91]of $K$ (i.e., number of clusters). In these analyses, substantial reduction in within-cluster variance occurred up to $K=4$, with only minimal further reduction thereafter. These results suggest that the MDS similarity space is most optimally partitioned into four clusters. These clusters -labeled abovebelow, front-back, left-right, and in - are marked on the solution in Figure 1. ${ }^{2}$ Notably, three of the clusters contain words that are essentially opposite in meaning. This suggests that the clusters cannot be reduced to individual word meanings, but instead may be viewed as latent categories. ${ }^{3}$ The next experiment investigated the conceptual salience of these categories; that is, the extent to which they play a role in the nonlinguistic processing of spatial relations.

## Experiment 2

In Experiment 2, participants were presented with multiple pictures showing spatial relations from the above-below, left-right, and front-back categories. ${ }^{4}$ Their task was to decide whether the pictures were perceptually identical or one of the pictures (the target) was different from the others (the distractors). On "different" trials, the target was from either the same category as the distractors (within-category; e.g., above vs. below) or a different category (betweencategory; e.g., above vs. left). CP would be revealed by faster or more accurate performance on between- than within-category trials. Note that because the target and distractors had different names on both within- and between-category trials, CP - if observed - would reflect the influence of categorical rather than linguistic representations. Given evidence that CP for both named and unnamed categories is left-lateralized (Holmes \& Wolff, 2012), we expected that latent categories would likewise yield left-lateralized CP. To examine this possibility, the location of the target was varied, with left-lateralized CP indicated by stronger CP effects when the target is presented in the right visual field (RVF; i.e., left hemisphere) than the left visual field (LVF).

[^92]
## Method

Participants Twenty-two Emory University undergraduates, all right-handed native English speakers, participated for course credit or payment. Four participants were excluded, 3 for low accuracy ( $<65 \%$ correct on "different" test trials) and 1 for a mean reaction time (RT) greater than 2.5 standard deviations above the mean for all participants.
Materials The materials were 12 pictures of a bird and an airplane (see Figure 2). Each picture displayed the objects from one of 3 perspectives (front, side, or top view). There were 4 pictures from each perspective, each showing the bird in a different location. The distance from the bird to the airplane, as determined by their closest edges, was the same across locations.

Figure 2: Stimuli used in Experiment 2. (a) front view: above, below, left, and right. (b) side view: above, below, front, and back. (c) top view: left, right, front, and back.

In the discrimination task, each display consisted of a fixation marker surrounded by 4 pictures, all from the same perspective (see Figure 3). In each picture, the center of the airplane subtended $11.5^{\circ}(\mathrm{h}) \times 12.8^{\circ}(\mathrm{v})$ visual angle.

Figure 3: Examples of displays used in Experiment 2.
(a) within-category trial (below target, above distractors).
(b) between-category trial (front target, above distractors).

Design and procedure There were 3 blocks of trials, each consisting of 16 practice trials and 192 test trials. All displays in each block were from a single perspective (front, side, or top). The order of the blocks was counterbalanced.

On half of the test trials in each block, the 4 pictures in the display were identical ("same" trials). This resulted in 4 unique "same" displays in each block, with each display presented 24 times. On the other half, 3 pictures (distractors) were identical and the fourth (target) was different ("different" trials). There were 2 kinds of "different" trials: (a) within-category, in which target and distractors were from the same category (above-below, leftright, or front-back); and (b) between-category, in which target and distractors were from different categories (see Figure 3). Across "different" trials, each picture served as the target at all 4 positions in the display ( $2 \mathrm{LVF}, 2 \mathrm{RVF}$ ), resulting in 48 unique "different" displays per block (16 within-category, 32 between-category), each presented twice. Trials were presented in random order.

On each trial, a fixation marker appeared centrally for 500 ms , followed by one of the displays for 200 ms (to discourage eye movements). Participants indicated whether there was an "odd one out" (i.e., target) by pressing the "S" key for same (i.e., no odd one out) or the "D" key for different, using their left and right index fingers, respectively. The next trial began after participants logged a response. Feedback was provided after practice, but not test, trials.

Following the discrimination task, participants wrote a brief description of the relative locations of the bird and airplane in each of the 12 pictures, presented on index cards. This served as a manipulation check to verify that participants interpreted the pictures as showing the spatial relations they were intended to depict.

Figure 4: Results of Experiment 2.
Error bars are $95 \%$ within-subjects confidence intervals. $\mathrm{LVF}=$ left visual field; $\mathrm{RVF}=$ right visual field.

## Results and discussion

As shown in Figure 4, the categories above-below, leftright, and front-back elicited CP: Participants were faster to discriminate spatial relations from different categories than from the same category. Notably, this effect was found only in the RVF, indicating that CP was left-lateralized, consistent with a left hemisphere specialization for categorical processing (Kosslyn et al., 1989) and previous left-lateralized CP studies (e.g., Holmes \& Wolff, 2012).

On the discrimination task, mean accuracy was $89.1 \%$ ( $S D=7.5$ ), with no difference between "same" and
"different" trials $(p>.1)$. Subsequent analyses focused on the "different" trials, for which CP could be assessed. Trials in which participants responded incorrectly (12.2\%) or RT was greater than 2.5 SD from individual means ( $2.8 \%$ ) were excluded. A 2 (visual field: LVF vs. RVF) $\times 2$ (category relation: within- vs. between-category) repeated-measures analysis of variance (ANOVA) on RT for the remaining trials yielded main effects of visual field, $F(1,17)=8.83, p$ $=.009$, and category relation, $F(1,17)=8.53, p=.01$, and an interaction, $F(1,17)=11.60, p=.003$. Participants responded faster on between- than within-category trials with RVF targets, $t(17)=5.17, p<.0001$, but not LVF targets, $t(17)=.34, p>.7$ (see Figure 4), indicating leftlateralized CP. An analogous ANOVA on the accuracy data yielded no significant effects (all $p \mathrm{~s}>.05$ ), suggesting that there was no speed-accuracy tradeoff.

Figure 5: Results of Experiment 2 by category.
Planned comparisons revealed left-lateralized CP for each of the 3 categories assessed. Within-category trials were divided according to the category membership of target and distractors: above-below (i.e., above target and below distractors, or below target and above distractors), left-right, and front-back. For RVF targets, discrimination was faster on between-category trials than on each of the 3 kinds of within-category trials [above-below: $t(17)=2.17, p=.04$; left-right: $t(17)=2.66, p=.02$; front-back: $t(17)=2.13, p=$ .05 ; see Figure 5]. For LVF targets, none of these differences reached significance ( $p \mathrm{~s}>.2$ ).

The results of the picture description task were as expected. Across the 12 pictures, $87.5 \%$ of the descriptions included prepositions from the intended category (e.g., "the bird is above the plane" or "the plane is below the bird" for above pictures); for 6 of the pictures, there was $100 \%$ agreement. The descriptions of the 4 front-back pictures were the most variable. Six participants consistently described these pictures using horizontal or vertical terms (e.g., "to the right of" for the front picture in Figure 2b), implying that they viewed them as 2-dimensional. Importantly, however, any ambiguity in the stimuli could not itself account for left-lateralized CP, as the existence of multiple interpretations for a given picture would presumably lead to slower responses on both within- and between-category trials (if not more so for the latter, given that individual participants occasionally used the same
preposition to describe pictures from different categories, but never the same category). In addition, none of the 216 descriptions included superordinate terms (e.g., "horizontal" for left-right pictures), suggesting that left-lateralized CP was not driven by linguistic representations.

In sum, the results of Experiment 2 provide evidence for the conceptual salience of the above-below, left-right, and front-back categories identified in Experiment 1. The findings support the semantic clusters hypothesis in showing that clusters of related words align with conceptual categories that are spontaneously accessed during nonlinguistic processing, with consequences for simple perceptual decisions.

## General Discussion

Recent research on the language-thought interface has led to a paradox. Although language has long been viewed as a window into the mind, a number of studies have suggested that word meanings may often be dissociated from conceptual representations. The present research offers a potential resolution to this discrepancy: Language may be a better reflection of the conceptual system at the level of clusters of words than at the level of individual words. According to the semantic clusters hypothesis, clusters of words capture salient conceptual distinctions. Consistent with this hypothesis, groups of spatial prepositions that clustered together in a semantic similarity space in Experiment 1 aligned with conceptual categories that yielded CP in Experiment 2. These findings suggest that language and the conceptual system may share a common underlying structure that is obscured when focusing solely on individual word meanings and their conceptual analogues. In related work, we have shown that clusters of words elicit stronger CP effects than individual words (Holmes, 2012), further supporting our conclusions.

We used CP as a tool for assessing conceptual salience, but our findings also inform the nature of CP itself. In particular, our findings show that CP can occur in the perception of relations, not just in the perception of objects or object properties - the focus of the vast majority of previous CP research (Goldstone \& Hendrickson, 2010). Our findings also lend support to the generality of left-lateralized CP effects, recently contested in the domain of color (e.g., Witzel \& Gegenfurtner, 2011), though they challenge the dominant linguistic interpretation of such effects (cf. Gilbert et al., 2006). Given that left-lateralized CP occurred for categories whose members share no common label, the phenomenon appears to be driven by categories rather than their names (Holmes \& Wolff, 2012), despite the propensity to link left hemisphere processing to language.

Although our findings demonstrate a clear connection between language and the conceptual system, they do not address the origins of this connection, including the possibility that language is the causal agent. The spatial clusters identified here, though shown to be conceptually salient in the minds of English speakers, are not necessarily universal. In principle, the clusters might vary cross-
linguistically, and those differences could lead to differences in nonlinguistic spatial processing. On the one hand, such differences seem unlikely because the elements of meaning associated with the clusters presumably reflect, and are constrained by, structure in the world to a much greater extent than are individual word meanings (see Malt et al., 2010). On the other hand, striking cross-linguistic differences in the meanings of spatial terms have been documented (e.g., Levinson et al., 2003), suggesting the possibility of further differences at deeper levels of semantic structure.

If such differences exist, an investigation of analogous conceptual differences would provide a strong test of the semantic clusters hypothesis. Though agnostic with respect to the universality of semantic structure, the hypothesis would predict that clusters of words within a particular language should be conceptually salient for speakers of that language. Thus, speakers of languages with different sets of clusters should show correspondingly different patterns of CP for those clusters. Notably, this kind of Whorfian effect would be unlike any previously reported, in that it would be driven by categories not explicitly encoded in the semantic system and of which many language users likely have no conscious awareness. Probing the existence of such effects may represent the next frontier in research on linguistic relativity.

## Acknowledgments

We are grateful to Larry Barsalou, Harold Gouzoules, Stella Lourenco, Laura Namy, Marjorie Pak, and Terry Regier for helpful feedback, Ted Guio for graphic design, and Tyler Brown and Lee Kugelmann for help with transcribing and coding descriptions. This research was supported by an APA Dissertation Research Award to KJH.

# Preschoolers' Understanding of Preferences is Modulated by Linguistic Framing 

Taylor F. Holubar (tholubar@stanford.edu)<br>Department of Psychology<br>Stanford University

Ellen M. Markman (markman@stanford.edu)<br>Department of Psychology<br>Stanford University

#### Abstract

Reasoning about others' preferences is an important aspect of understanding the social world. Although there is some evidence that young children reason appropriately about others' discrepant preferences, there are reasons to suspect this ability remains fragile through the preschool years. In particular, we argue that the way preferences are expressed may tap into humans' lifelong tendency toward naïve realism, the belief that my way of seeing the world is the normative, correct one. We present data demonstrating that tolerance for unconventional opinions increases during the preschool years but remains susceptible to influence by linguistic framing.

Keywords: theory of mind; preferences; naïve realism; linguistic framing effects.

## Introduction

Statements of preference are a profoundly strange phenomenon. In principle, preferences are subjective: although finding ice cream delicious may be normative and all but universal, "ice cream is delicious" is not true or false in the way that "ice cream is sugary" is true or "ice cream is hot" is false. Yet statements of this form--describing a subjective valuation as if it were an objective fact--are widespread and remarkably unremarkable. Could talking about preferences as if they were facts influence the way people reason about preferences? We suggest that preferences are a difficult concept to reason about (and particularly susceptible to effects of framing) because they hold a fundamentally different epistemic status from facts. They require acknowledging that one's own (often strongly held) beliefs are not verifiably correct, and that even totally opposite beliefs should be respected as valid. These recognitions require sophisticated perspective taking skills, which preschoolers notoriously lack. However, adults also show similar biases, as the literature on naive realism demonstrates (Robinson, Keltner, Ward, \& Ross, 1995). These observations lead us to ask: how do children reason about preferences that differ from their own? Does the way we talk about preferences impact their reasoning?

It is well documented that preschoolers begin passing classic tests of false-belief understanding around age four (see Wellman, Cross, \& Watson, 2001, for a meta-analysis). A prominent explanation of this shift is that children develop the insight that the mind operates on representations of the world, rather than veridical copies of the world. In other words, for a pre-representational child, mental states are taken as exactly reflecting the state of the world. One
consequence of a non-representational theory of mind could be that a child's evaluative opinions (such as whether she finds ice cream delicious or not) are also taken as direct reflections of objective properties of the world. Such a belief should lead pre-representational children to expect everyone else also to find ice cream delicious, and the subjective, idiosyncratic nature of preferences to be lost.

Some evidence does exist that very young children in fact treat subjective properties like "deliciousness" as features of objects rather than as mental states tied to individuals. Gergely, Egyed, \& Király (2007) report that 14-month-olds expect adults to treat an object in accordance with the total amount of liking or disliking for the object the infant has witnessed, irrespective of whether a particular adult has previously demonstrated liking or disliking for the object. In other words, infants do not reason about an object's likability in terms of a particular person's opinion about that object. Instead, they seem to aggregate information across individuals and associate that totality with the object, not with the individuals who produce the information. This finding is consistent with a relatively impoverished understanding of mental states, whereby children conceptualize beliefs (including those about an item's likability or desirability) as reflecting objective states in the world.

At the same time, the strongest version of this hypothesis is not borne out in the data: at least in some cases, slightly older children respond appropriately to desires different from their own. Children as young as 18 months recognize that adults may desire different foods than they themselves do: when an adult who has previously shown positive affect towards broccoli and negative affect toward goldfish crackers requests more food, 18-month-olds (but not 14-month-olds) respond appropriately to requests for food (Repacholi \& Gopnik, 1997). In some contexts, two-yearolds also show similar understanding of others' desires ( Ma \& $\mathrm{Xu}, 2011$ ). For example, children predict that a character will be happy when she satisfies her desire to play with a given toy, even when the participant has previously said she would choose to play with a different toy over that toy (Wellman \& Woolley, 1991).

Given these discrepant findings, important work remains in charting out how children develop an adult-like understanding of preferences. In this paper, we present two studies in which we specifically probe how preschoolers reason about unconventional preferences--preferences that, while likely not espoused by the child, nonetheless are not
simply false or mistaken in the way that facts can be. We argue that achieving this understanding is an on-going process through the preschool years. Our evidence suggests that preschoolers' understanding of the subjective nature of preferences is fragile and easily disrupted.

## Study 1

## Participants

68 preschoolers from Bing Nursery School at Stanford University participated. Twenty-three 3-to-5-year-old children (12 boys) participated in a marked framing condition. The mean age was 4 years 6 months. Forty-five 3-to-5-year-old children (21 boys) participated in an unmarked framing condition. The mean age was 4 years 5 months.

## Procedure

To evaluate how children understand unconventional preferences, we developed a paradigm in which participants were shown pictures of other children who were said to have answered questions about familiar foods. Questions either concerned factual properties, such as a food's color or texture, or subjective qualities, such as how appealing the food is. All foods used for opinion questions were chosen to be conventionally popular, desirable foods. Characters' responses to opinion questions were either conventional or unconventional (i.e., expressed a positive or negative attitude towards a popular food). Responses to factual questions were either true or false. This permitted us to analyze how children treated conventional and unconventional responses to opinion questions and to compare their treatment of opinion questions with their treatment of factual questions. Each child heard responses to two examples of each of the four statement types (true and false facts, conventional and unconventional opinions) for a total of eight items.

To examine how framing might influence performance, we manipulated how characters responded to opinion questions. In an unmarked framing condition, responses took the form "Ice cream is delicious" or "Ice cream is yucky." In a marked framing condition, responses took the form "I like ice cream" or "I don't like ice cream." We expected children to be more likely to reject an unconventional opinion when it was unmarked than when it was marked as an opinion with "I like."

To assess children's reactions to characters' statements, we directed four questions to participants after each question and statement pair. First, children were asked to explain why the character had made that statement (e.g., "Why did Martin say ice cream is delicious?"). Next, children were asked if the character made a mistake and if the character was "just being silly." (These two questions were designed to cover two of the most frequent categories of explanations that adults gave in pilot work.) Finally, children were shown a picture of another character who was said to hold the opposite belief of the first character (i.e., to hold a negative attitude when the first character held a

| Statement Type | EXAMPLE STATEMENTS |  |
| :---: | :---: | :---: |
|  | Marked <br> Condition | Unmarked <br> Condition |
| True Fact | Milk is white. | Milk is white. |
| False Fact | Milk is green. | Milk is green. |
| Conventional <br> Opinion | I like ice cream. <br> Ice cream is <br> delicious. |  |
| Unconventional <br> Opinion | I don't like ice <br> cream. | Ice cream is <br> yucky. |

Figure 1: Summary of experimental design.
positive attitude or to hold a false belief when the first character expressed a true belief, and vice versa). They were then asked if that contrasting statement "could be right." We thus had three converging yes/no measures of whether children deemed a statement acceptable or mistaken, as well as an open-ended explanation of the characters' beliefs. Although we are primarily interested in children's judgments about opinion statements, including factual questions allowed us a baseline estimate of how often children would label as mistaken statements that adults would also describe as mistakes, against which we could compare children's treatments of opinion statements.

## Results: yes/no questions

For the three yes/no questions, we scored each response as correct or incorrect as follows. True facts should be judged as not a mistake and not silly; when the second character expressed the opposite belief (i.e., a false fact), his response should be judged as not right. False facts should be judged as a mistake and as silly; when the second character expressed the opposite belief (i.e., a true fact), his response should be judged as right. Conventional and unconventional opinions, on the other hand, should be judged the same way as each other: as neither a mistake nor silly. When the second character expressed the opposite opinion (whether conventional or unconventional), their response should be judged as right. To test for possible developmental changes, we divided children into older and younger groups based on the median age for each condition.

As a first analysis, we conducted a logit mixed model using statement type, framing, and age (older or younger) to predict correct responding. We found a significant three-way interaction between statement type, framing, and median age, $\mathrm{b}=-3.4$, S.E. $=1.5, \mathrm{z}=-2.1, \mathrm{p}=.04$. To unpack this threeway interaction, we next analyzed each statement type separately, examining effects of framing and age on children's performance.

True factual statements We first asked how children treated true factual statements (e.g., "Milk is white"). A logit mixed model using framing condition and age group to predict correct responding to questions about true factual statements showed a significant developmental difference $(b=2.4, z=2.4, p=.01)$. The effect of framing was nonsignificant, as expected, since the factual statements were the same across framing conditions. This confirms that children did not differ in their baseline responses to identical statements of true facts across conditions.

To examine performance in a more fine-grained fashion, we created composite scores for each participant by summing the number of correct responses to all yes/no questions for each statement type (e.g., true fact, conventional opinion). The maximum possible score was 6 (three questions per two items for each statement type). In the marked framing condition, both older and younger children appropriately answered questions about true facts at well above chance rates (older: $M=5.5$ out of $6, \mathrm{SD}=.52$, $\mathrm{t}(10)=16.2, \mathrm{p}<.001$; younger: $M=4.3, \mathrm{SD}=1.8, \mathrm{t}(11)=2.5, \mathrm{p}=$. 03). However, as the logit model indicated, older children performed significantly better, $\mathrm{t}(12.9)=2.2, \mathrm{p}=.05$. In the unmarked framing condition, similar patterns emerged, with both older ( $M=5.4, \mathrm{SD}=1.4$ ) and younger children ( $M=4.3$, $\mathrm{SD}=1.8$ ) performing above chance rates, $\mathrm{t}(21)=8.1, \mathrm{p}<.001$ and $\mathrm{t}(22)=3.4, \mathrm{p}=.003$ respectively. As in the marked framing condition, older children somewhat out-performed younger children, $\mathrm{t}(41.1)=2.3, \mathrm{p}=.03$. Thus preschoolers seem to appropriately answer questions about true facts, judging that they are not mistakes at well above chance rates.

False factual statements We then asked how children treated false factual statements (e.g., "Milk is green"). A logit mixed model using framing condition and age group to predict correct responding to these questions showed neither the main effect of age or of framing, nor their interaction, reached significance. The non-significance of the effect of framing was, again, expected, since factual statements were identical across conditions.

On the composite measures, performance was strong for all groups. Questions about false facts were answered appropriately by older children in the marked framing condition at a rate significantly above chance ( $M=5.2$ out of $6, \mathrm{SD}=1.08$ ), $\mathrm{t}(10)=6.7, \mathrm{p}=<.001$. Likewise, younger children also answered appropriately at a rate that exceeded chance $(M=4.8$ out of $6, \mathrm{SD}=1.14), \mathrm{t}(11)=5.32, \mathrm{p}<.001$. Their overall performance was comparable to that seen for the older children, $\mathrm{t}(21.0)=-.93$, n.s.

In the unmarked framing condition, younger children answered an average of 5.2 questions correctly ( $\mathrm{SD}=1.0$ ), which exceeded the number expected by chance, $\mathrm{t}(22)=10.2$, $\mathrm{p}<.001$. Similarly, older children answered an average of 5.3 questions correctly ( $\mathrm{SD}=.98$ ), again more than expected by chance, $\mathrm{t}(21)=10.8, \mathrm{p}<.001$. Older children's performance was not significantly better than younger children's, $\mathrm{t}(43.0)=.18$, n.s. It is not clear why older children would out-perform younger children when questions were asked about true facts but not about false facts. Anecdotally, we have observed that some children are perplexed about the
pragmatics of asking whether a manifestly true fact (like milk being white) is a mistake; it is plausible that younger children answered "yes" to those questions due to some uncertainty about the experimenter's intentions. In any case, these data provide robust evidence that children understand the notion of mistaken facts, leading us to ask how they apply these concepts to opinions.

Conventional opinion statements Preschoolers' treatment of conventional opinions ("I like ice cream" or "Ice cream is delicious") was similar to their treatment of true facts. A logit mixed model using framing condition and age group to predict correct responding to questions about conventional opinion statements showed neither the main effect of age or of framing, nor their interaction, reached significance. When asked about conventional opinions, preschoolers showed a high degree of acceptance without major developmental differences or strong influences of framing. In the marked framing condition, younger children correctly answered these questions at above-chance rates $(\mathrm{M}=4.7, \mathrm{SD}=1.78)$, $\mathrm{t}(11)=3.25, \mathrm{p}=.008$, as did older children $(\mathrm{M}=4.8$ out of 6 , $\mathrm{SD}=1.33), \mathrm{t}(10)=4.54, \mathrm{p}=.001$. The mean number of questions answered correctly did not differ by age group, $\mathrm{t}(20.2)=-.23$, n.s.

In the unmarked framing condition, younger children answered an average of 4.5 questions correctly ( $\mathrm{SD}=1.5$ ), more than expected by chance, $\mathrm{t}(22)=5.0, \mathrm{p}<.001$. Likewise, older children correctly answered an average of 5.0 questions correctly, also more than expected by chance, $\mathrm{t}(21)=6.5, \mathrm{p}<.001$. Performance did not differ by age groups on questions about conventional opinions.

Unconventional opinion statements A different picture emerged when we analyzed preschoolers responses to unconventional opinions ("I don't like ice cream" or "Ice cream is yucky"). The logit mixed model predicting correct responses with framing and age showed a marginal main effect of framing but a significant interaction between framing and age. For younger children, framing had little effect: performance was weak in both framing conditions. In the marked framing condition, younger children correctly answered only 1.6 of the 6 questions about unconventional opinions ( $\mathrm{SD}=2.2$ ), a rate significantly below chance, $\mathrm{t}(11)=-2.2, \mathrm{p}=.05$. In the unmarked framing condition, younger children answered an average of just .70 questions correctly ( $\mathrm{SD}=.93$ ), again well fewer than expected by chance, $\mathrm{t}(22)=-11.0, \mathrm{p}<.001$.

Older children showed a relatively strong understanding of unconventional opinions in the marked framing condition (at least compared to younger children), answering an average of 3.7 correctly ( $\mathrm{SD}=1.5$ ). However, unlike for all other statement types, this success rate did not differ from chance, $\mathrm{t}(10)=1.6$, n.s. Older children's performance was, however, significantly better than younger children's, $\mathrm{t}(19.4)=-2.8, \mathrm{p}=.01$. In the unmarked framing condition, performance dropped dramatically for older children. Older children answered an average of only .59 questions correctly ( $\mathrm{SD}=.80$ ), again fewer than expected by chance, $\mathrm{t}(21)=-14.2, \mathrm{p}<.001$. The difference between conditions was highly significant for older children, $\mathrm{t}(12.9)=6.5, \mathrm{p}<.001$.

Figure 2: Summary of performance by statement type, condition, and age.

Performance in the unmarked framing condition was equally poor for both age groups, $\mathrm{t}(42.5)=.41$, n.s.

Taken together, these data indicate that younger children did not answer our questions about unconventional opinions correctly in either framing condition. Older children did better than younger children in the marked framing condition, although not as well as they had done with questions about facts or conventional opinions. However, framing had a pronounced impact on how older children reasoned about unconventional opinions, reducing their performance to the same level as was seen for younger children.

## Results: open-ended explanations

While the yes/no questions allow us one way of probing children's reasoning about unconventional opinions, there are concerns in the literature that such explicit measures might underestimate children's ability to reason in a sophisticated, adult-like fashion about others' opinions (Banerjee et al., 2007). Exploring children's open-ended explanations for why characters might respond with an unconventional opinion provides a less constrained window into children's spontaneous reactions to unconventional opinions.

It is worth noting that children's "explanations" frequently did not constitute what an adult would call an explanation. Frequently, they were simply comments on or responses to what the character had said. Whatever we call them, though, these comments provide a useful probe. To analyze these data, we coded children's responses as to
whether they indicated agreement or disagreement with the character's statement. Below, we report the mean number of times children disagreed with each statement type. There were two trials featuring each statement type, so the maximum number of disagreements is two. Unlike with the yes/no questions, no main effects of framing or age were found, but for consistency's sake we present means broken down by those variables.

True factual statements Disagreements were rare in response to true factual statements. Younger children in the unmarked framing condition expressed a mean of .25 disagreements, while no disagreements were seen for older children in the unmarked framing condition or in either age group in the marked framing condition.

False factual statements Disagreements were much more frequent in response to false factual statements. In the marked framing condition, younger children disagreed an average of 1.2 times, while older children disagreed an average of 1.1 times. In the unmarked framing condition, younger children disagreed an average of 1.0 times, while older children disagreed an average of 1.2 times Thus across age groups and framing, children expressed disagreement with false facts on more than half of trials. This may not seem terrifically high, but it is worth reiterating that children were asked to explain why the character had made their statement. Disagreements then weren't particularly good answers for the question that had been posed.

Conventional opinions In the marked framing condition, only one younger child ever disagreed, and did so on only one trial. Similarly, in the unmarked framing condition, a total of one disagreement was recorded among younger children and one among older children.

Unconventional opinions. In the marked framing condition, younger children disagreed on an average of .75 trials, while older children disagreed on an average of only . 25 trials. In contrast, in the unmarked framing condition, younger children disagreed on an average of .85 trials, while older children disagreed on an average of .68 trials.

To test whether preschoolers' tendency to disagree differed across statement types, we conducted a logit mixed model using statement type to predict whether the child disagreed on a trial. Contrasts were specified to treat the unconventional opinion as the baseline. Children were significantly less likely to disagree with true factual statements $(b=-3.2, \quad \mathrm{z}=-5.5, \mathrm{p}<.001)$ and conventional opinions ( $\mathrm{b}=-4.1, \mathrm{z}=-5.2, \mathrm{p}<.001$ ) than they were to disagree with unconventional opinions. However, children were more likely to disagree with false factual statements than with unconventional opinions ( $\mathrm{b}=1.5, \mathrm{z}=4.7, \mathrm{p}<.001$ ).

These data present a somewhat different picture from that observed with the yes/no questions. To begin with, age and and framing did not exert significant influences on whether children disagreed with statements. Moreover, although children disagreed with unconventional opinions relatively often, they did not disagree with unconventional opinions as often as they did with false facts. Thus, whereas the yes/no data might lead us to suggest that preschoolers--especially younger ones--robustly fail to understand that opinions differ from facts in that even unconventional opinions are not wrong, our open-ended explanations suggest that preschoolers' understanding is somewhat more nuanced and that they do not entirely conflate facts and opinions.

## Study 2

An important feature of both the framings that we have used above is that they articulate properties of long duration. If ice cream is delicious, it is always delicious, not merely delicious right now. Likewise, if I like ice cream, the suggestion is that I like ice cream in general, not just right now. This permanence (or at least longevity) is very characteristic of facts. In contrast, desires are frequently temporary; they disappear when they have been satisfied. Importantly, even if I like ice cream or agree that ice cream is delicious, I may not always want ice cream, right now. In the literature reviewed above, preferences have always been conceptualized or demonstrated in terms of a situationspecific want. For example, Wellman and Woolley (1991) probe 2-year-olds' understanding of discrepant desires by asking participants which of two equally desirable activities they would want to engage in and saying the character wanted to do the other. This situation of choosing between two attractive options and temporarily prioritizing one is likely to be familiar even to 2 -year-olds, and likely poses weaker demands on children's incipient theory of mind abilities.

One possibility, then, is children's relatively poor understanding of unconventional opinions in study one is that our framings made characters' preferences sound immutable and permanent. If children associate these features with facts but not with desires, children might show themselves to be more tolerant of unconventional opinions if the framing emphasized the transient nature of the unconventional opinion. Below, we present work in progress that tests this possibility by implementing a "want" framing.

## Procedure

The procedure was identical to that of Study 1, except opinion statements were presented using a "want" framing instead of marking them with "I like" or not marking them. Thus, characters who expressed a conventional opinion said, for example, "I want some ice cream" while characters who expressed an unconventional opinion said, for example, "I don't want some ice cream."

## Results

Data collection is on-going. However, in the condition of interest, unconventional opinions, it is clear that this "want" manipulation has not improved performance. The modal number of correct responses is zero; the maximum number of correct responses thus far is three out of six. This pattern is virtually indistinguishable from that seen for the unmarked condition reported above.

We do not wish to over-interpret this preliminary data. Nonetheless, the performance of children in this pilot indicates that using a want framing is no magic bullet. Using language that emphasizes that an unconventional desire might be temporary does not seem to radically improve children's performance.

## General Discussion

Much has been made of quite young children's ability to reason about preferences in several different circumstances. There is no denying that children's appreciation of others' mental lives is far richer than was once thought, but the data we present here underscore that developing a theory of mind is a complex and protracted process. In our samples, even older four-year-olds-who, the literature suggests, would pass traditional tests of false-belief understanding-rejected unconventional opinions as mistaken or silly, at least when those opinions were expressed using factual-sounding language.

Given that toddlers seem able to respond appropriately to desires they do not share, why would our substantially older preschoolers persist in rejecting unconventional preferences? The possibility remains that reasoning about enduring, temporally unbounded likes or dislikes might be more demanding than reasoning about a desire in a specific situation. Our data collected thus far, however, suggests that a very simple change to the framing of characters' desiresusing the stem "I want" instead of "I like"-- is not enough to render preschoolers accepting of unusual wants. It is premature to jump to conclusions, of course. A more explicit
change to the framing to emphasize the temporariness of the desire might have a greater impact.

It may also be more difficult for preschoolers to reason about discrepant preferences when the preferences are highly surprising. In the existing literature, children were asked to reason about comparably attractive options (Wellman \& Woolley, 1991). In these cases, children in fact probably like both alternatives but picked one over the other on that occasion. It might not be difficult to recognize that someone might prefer to go to the park and someone else to the beach on a given occasion. Children also succeed on relatively unfamiliar items ( Ma and $\mathrm{Xu}, 2011$ ), where they may have only a weak opinion of their own.

Moreover, children are highly attuned to statistical information, as work in a broad array of domains demonstrates (Gergely et al., 2007; Kushnir, Xu, \& Wellman, 2010; Ma \& Xu, 2011; Saffran, Aslin, \& Newport, 1996). Liking for ice cream is likely highly overlearned, perhaps so much so that children cannot conceive of someone disliking it. Such a sensitivity to statistical regularities could interact with a non-representational theory of mind, reinforcing the notion that some mental states are veridical copies of the world itself.

Importantly, adults show analogous difficulties with reasoning about preferences and opinions in some circumstances. Ross, Greene, \& House (1977) coined the term "false consensus effect" to describe the robust bias in adults to assume that more people will endorse a belief when the participant also endorses that belief. This is of course a more subtle phenomenon than outright rejecting opinions that do not concord with one's own. Nonetheless, many of the explanations that have been offered to explain the false consensus effect in adults may shed light on children's behavior. For example, adults using anchoring and adjustment heuristics, whereby a person makes an initial prediction about others' behavior based on one's own behavior and then adjusts for others' idiosyncrasies, tend to systematically under-adjust (Epley \& Gilovich, 2006). If children are prone to egocentrism, the failure to adjust sufficiently for differences among people might be especially pronounced.

Likewise, motivational effects have been posited to explain adults' false consensus effects: adults simply want to be in the mainstream, and assuming others agree with them makes them feel good (Marks \& Miller, 1987). The idea of social norms is becoming especially salient in the preschool years (Nucci \& Turiel, 1978), and children may well view liking the right foods as one such norm. Indeed, liking the right foods is an important social signal for adults (e.g., eating caviar or eating french-fries). Not wanting the right foods may thus be a mistake in preschoolers' eyes in a social sense that differs from the way they apply that term to false facts.

These considerations illustrate the range of cognitive factors that underpin reasoning about preferences. Even as children's understanding of mental lives increases through the preschool years, many of the factors that lead to naïve realism in adults render children's understanding of unconventional preferences susceptible to the influence of linguistic framing. The robustness with which children
reject unconventional preferences provides a compelling demonstration of the challenges children face in learning to reason about the social world in an adult-like fashion.

# Eye movement optimization in visual search 

Ryan M. Hope and Wayne D. Gray<br>Cognitive Science Department<br>Rensselaer Polytechnic Institute

#### Abstract

In the present study we investigated whether eye movements in visual search are optimized to reduce time on task. Subjects task was to find a target object in a large field of objects that differed based on shape, color, size and numeric label. The target specification was manipulated, directly influencing the average number of fixations it took subjects to find the target object. Although a microstrategy that allowed for parallel saccade programming and information processing was found to be more efficient in terms of time, a serial microstrategy where saccade programming always follows information processing was found to be the more prevalent microstrategy.

Keywords: visual search, eye movements, microstrategy, optimization, return saccades

## Introduction

Visual search may well be our most ubiquitous cognitive task. Many (dozens? hundreds?) times a day we scan our desk for books or memos, our fridge for eggs or beer, the streets for oncoming traffic, cable television for shows we want to watch, and crowded rooms for faces we recognize. Although our natural scan environments are seldom completely novel, the objects in them and their places in these environments are seldom constant.

How do we do such searches? Most of them have the flavor of being a "one off" on at least one of several dimensions. Even the clutter on top of my dresser varies, if only slightly, from day to day. Do we develop optimal search strategies for each environment? - My fridge? Driving on I-87? Looking for friends to sit next to during Cognitive Science talks in Sage 4101? This strikes us as a likely possibility, meaning that there may be no general high level strategy for scanning my dresser top, the fridge, and I-87. But what about lower level strategies? What about the process of moving our eyes to a location, fixating that location, processing the perceptual and semantic information at that location, and deciding whether that location contains the target of our search, or whether we need to saccade to the next location? Can this strategy be optimized? Can it be optimized for all or many search environments? What would such an optimization strategy optimize?

Although in such a small paper it is obvious that we cannot address most of these issues, we believe we have a good start on addressing the later; namely, what would an optimized fixation and saccade strategy look like - this is the subject of our paper.

## Background

The key characteristic of visual search for an active vision task (Findlay \& Gilchrist, 2003), is one of moving the eyes from one location to another until we find our search target. But what does this really entail and can we bring to bear strategies in this task that cannot be applied to the simpler case of being tachistoscopically presented with a single item and asked whether that is our search target or not?

The case of a serial sequence of single items, each of which demands a "yes" or "no" answer before we are shown the next item, seems to define a procedure in which we perceptually process the visual object, semantically process the results of that perception, and decide whether the current object is a member of the target set defined for us by the experimenter. This strategy or procedure seems well suited for the given task environment and maybe defines the optimal strategy in this environment. Indeed, this procedure could be applied when I am searching my dresser top or searching for the large-red-star in Figure 1. Indeed, vision researchers often describe searches that entail the visual scanning of a busy screen in exactly these terms (e.g., Deubel \& Schneider, 1996; Henderson, 1992). From this point forward we will refer to this strategy as the serial microstrategy.

An alternative strategy differs from the serial microstrategy only in that the programming and subsequent execution of the next eye movement does not wait for the semantic processing and decision processing to complete. Programming of the next eye movement could start as soon as the previous saccade is completed, in parallel with information processing and decision making processes. From this point forward we will refer to this strategy as the parallel microstrategy.

Evidence for the parallel strategy comes from a number of visual search studies (Engel, 1977; Gould, 1973, Hooge \& Erkelens, 1996) where it was reported that subjects often fixated the target, made an eye movement away from the target, and then, on the next fixation, returned to the target (return saccades). Hooge and Erkelens (1996) also reported a number of missed targets. This evidence implies that the fixation durations can be too short to recognize the target. The occurrence of return saccades and missed targets suggest that saccade preparation may start before foveal processing is complete and that complete foveal processing is not necessarily the trigger for the subsequent saccade. For further details of both serial and parallel models of eye movements in visual search see Hornof and Halverson (2003), Hornof and Kieras (1997).

The parallel and serial microstrategies can also be differentiated based on their temporal costs. Since the parallel strategy allows for the concurrent processing of information and saccade preparation, fixation durations could be shorter when the parallel strategy is used than when the serial strategy is used because target identification can continue during the saccade. However, Becker and Jürgens (1979) showed that it is possible for saccades to be aborted during the preparation phase. This could lead to someone using the parallel strategy with apparent fixation durations closer to those observed in the serial strategy. On the other hand, since saccades in the parallel strategy do not necessarily wait for a decision of target presence, the parallel strategy could involve two extra saccades and fixations as a result of return saccades. Therefore in the extreme cases, the parallel strategy has a fixed cost of 2 saccades and 2 fixations whereas the serial strategy has a cost that grows with each fixation. Therefore there exists some threshold, in terms of number of fixations, where the parallel strategy will eventually become more efficient than the serial strategy.

The task used in the present study is a visual search task first used by Williams (1966). In the Williams search task, subjects have to find a target object in a very large field of objects that differ by size, shape, color and a numbered label (e.g., " 11 ", " 25 ", etc). Williams found that when he manipulated which target features were known (e.g., "large blue circle" versus "small yellow" versus "triangle"), a high proportion of fixations were on objects of the specified color and only a moderate proportion of fixations were on objects of the specified size or shape. When two or more characteristics were specified, fixations were generally based on a single characteristic. Additionally, the average number of fixations required to find the target differed based on the target specifications. This aspect of the task makes it perfect for eliciting the use of different microstrategies as the optimal strategy should depend on target specifications.

It seems likely that at least some subjects on at least some trials used a mix of serial and parallel microstrategies. However, the parallel and the serial strategies predict the same pattern of saccades for all but the last two saccades to and from target object. Hence, for this initial report, we make the simplifying assumption that if we find a return saccade, that we can classify the entire trial as having been accomplished using the parallel strategy. Likewise, the absence of return saccades were used to classify trials as having been accomplished using a serial strategy. Based on this classification scheme we had the following hypotheses:

1. Due to the temporal costs of the serial microstrategy with increasing number of fixations, the proportion of trials with return saccades (indicating the use of the parallel microstrategy) should be higher on trials where search is inefficient than it is on trials where search is efficient. Here efficiency corresponds to the number of fixations need to find a target, a function of the target specification or number of cue features.
2. The average fixation duration (all fixations on a given
trial) should be shorter on trials that exhibit return saccades (indicating the use of the parallel microstrategy) than on trials that do not exhibit return saccades.
3. For trials that do not contain return saccades, fixation durations should increase as a function of number of cue features due to increasing processing requirements.
4. Subjects will satisfice by using the microstrategy that results in the most time savings across all trial types.

## Method

## Subjects

Subjects were 15 undergraduate students at Rensselaer Polytechnic Institute ( 10 men, 5 women) who were given course credit for their participation. Subjects were prescreened for their dependence on eyeglasses or contact lenses; only subjects that reported needing neither were allowed to participate in the experiment.

## Apparatus

The experiment was displayed on a 22 " Dell widescreen LCD with a resolution of $1680 \times 1050$ (pixels) and physical dimensions of $473.76 \times 296.1(\mathrm{~mm})$. Eyetracking was performed with a SensoMotoric Instruments RED500 eyetracker running at a sample rate of 500 Hz . On average, subjects were positioned $700 \pm 100 \mathrm{~mm}$ away from the LCD.

## Task

Subjects task on each trial was to find a target in a field of 48 randomly dispersed objects. Each object had a unique combination of shape (4 levels), color (4 levels) and size (3 levels). On each shape was a randomly assigned numeric id which ranged from 01 to 48 . Each trial starts with the search objects masked and a cue at the center of the display. The cue was a text description of the target object. The probe always contained the numeric id and up to three other features (shape, size and color). The particular features shown in the cue, in addition to the numeric id, was systematically manipulated throughout the experiment such that each subject experienced one trial of each object and cue combination. The non-id cue features were ordered randomly with the id always showing last (see Figure 1 for an example of the cue). The 48 objects and 8 cue combinations results in 384 unique trials. Because of the random dispersion of objects on each trial, no subjects experienced identical trials. Subjects were instructed to study the cue until they felt they had memorized it, at which point, they were instructed to press spacebar on the keyboard to reveal the search field and begin searching for the target. The cue remained on screen during the search phase. Once subjects find the target, they end the trial by using the mouse to click on the target. Search time was measured as the time between the spacebar press and the first correct click on the target object. Subjects were given no explicit instruction to emphasize speed, their task was simply to find the target.

Figure 1. An example of a trial search display that contains an end of trial return saccade. In this trial, the cue is "large 18 ". The target is the large yellow oval in the bottom right corner. Eye gaze data is overlaid; red dots correspond to samples that belong to saccades, black dots correspond to samples that belong to fixations. Circles with a 1 degree visual angle radius have been drawn around the center of mass for each fixation. As indicated by the grid formed by the x and y axes, the scanpath for this Ss is: e4, f4, h5, h5, f7, e8, c7, b9, i8, h2, f2, i2. Notice how the last 3 fixations include 2 fixations on the target object separated in time by a fixation on a different object. Neither the grid nor the light gray circles around each object were visible during the trial.

## Stimuli

The four shapes used in the task were star, oval, crescent and cross. The four colors used in the task were red, yellow, green and blue and had hue values (in HSV space) of 0,72 , 144 and 216 respectively. The saturation and value of all four colors was set to 50 and 100 respectively. The search field was a $1050 \times 1050$ (pixel) square centered on the screen and had $65 \%$ gray background color. See Figure 1 for an example of the shapes and colors used in this task. The three object sizes were small ( 48 pixels), medium (119 pixels), and large (191 pixels) and correspond to visual angles of 1.1, 2.7 and 4.4 degrees with a potential error up to $15 \%$ depending on head position.

## Gaze Data Classification

Raw gaze data were classified into events (saccades and fixations) by an algorithm that uses both velocity and acceleration thresholds. The algorithm followed the following general procedure:

1. Convert the $x, y$ screen coordinates from pixels to degrees of visual angle relative to the center of the screen.
2. Compute smoothed first and second order derivatives of the $\mathrm{x}, \mathrm{y}$ visual angle components.
3. Label gaze samples with corresponding velocity and acceleration components that both exceed their respective thresholds as saccades, the rest are labeled as fixations.
4. Identify saccades that last for less than 20 ms , reclassify them as fixations.

Velocity and acceleration (first and second order derivites) were calculated using a Savitzky-Golay filter (as recommended by Nyström and Holmqvist (2010)) for its ability to preserve local minima and maxima. The Savitzky-Golay filter used was a second order filter with a window length of 11 samples which allowed for accurate detection of saccades down to 20 ms in duration (Nyström \& Holmqvist, 2010). The velocity and acceleration thresholds used in the present study were $30^{\circ} / \mathrm{s}$ and $8000^{\circ} / \mathrm{s}^{2}$ respectively and were based on the "cognitive configuration" of the EyeLink software (SR Research Ltd. 2007).

## Results

## Number of Fixations

Our first hypothesis stated that the proportion of return saccades should increase with number of fixations and that number of fixations was directly related to the cue specification (trial type) and number of cues. Therefore, in order to evaluate our first hypothesis we first need to show that trial type has an impact on number of fixations. In order to accomplish this we performed one-way repeated measures analysis of variance. The analysis of variance revealed a significant effect of trial type on proportion of return saccades, $F(7,98)=76.56$, $p<.001, \eta_{g}{ }^{2}=0.73$. The means and standard errors can be seen in Figure 2. The general trend revealed from this analysis is that the number of fixations decreased as the number of cue features increased. We performed a second analysis of variance to test the effect of number of cues on number of fixations. As expected by hypothesis 3 , the greater the number of cues, the fewer fixations, $F(3,42)=96.62, p<.001$, $\eta_{g}{ }^{2}=0.76$. The effect size of number of cue was stronger than the effect of trial type on number of fixations.

## Return Saccades

Return saccades were identified through scanpath analysis. First, the search field was divided into a $9 \times 9$ array which resulted in 81 total cells. The width and height of each cell was approximately 2.6 degrees of visual angle. Second, fixations were recoded as belonging to one of the 81 cells based on their center of mass. After recoding, consecutive fixations occurring in the same cell were combined. This effectively removes any microsaccades and other small amplitude corrective saccades. Finally, for scanpaths of length 3 or greater, the last fixation was compared to the fixation 2 back. In order for a trial to be classified as containing a return saccade two

Figure 2. The average number of fixation for each trial type. Error bars represent standard error. The dashed line represents the threshold where the parallel strategy becomes more efficient than the serial strategy, determined empirically using Equation 5

Figure 3. The average proportion of return saccades for each trial type. Error bars represent standard error.
criterion had to be met. First, the fixation 2 back from the final fixation had to be in the same cell, or any of the surrounding cells, as the last fixation. Second, the fixation 1 back from the last fixation could not be on the center cell where the cue was located (see center of Figure 11). Of the 5939 total trials, 2273 trials contained a return saccade.

In order to test the effect of trial type on the proportion
of return saccades a one-way repeated measures analysis of variance was performed. The analysis of variance revealed a significant effect of trial type on proportion of return saccades, $F(7,98)=12.62, p<.001, \eta_{g}{ }^{2}=0.33$. The means and standard errors can be seen in Figure 3 . The general trend revealed from this analysis is that the proportion of return saccades decreased as the number of cue features increased. In order to confirm this trend we performed a second oneway repeated measures analysis of variance to test the effect of number of cue features on the proportion of return saccades. The analysis of variance revealed a significant effect of number of cue features on proportion of return saccades, $F(3,42)=25.57, p<.001, \eta_{g}{ }^{2}=0.46$. Similar to the analysis of variance involving number of fixations, the effect size of number of cues was stronger than the effect of trial type for proportion of return saccades. In addition, the correlation between proportion of return saccades and number of fixations with respect to trial type, which can be seen by comparing Figure 2 and Figure 3 , is strong; $r=.90, n=8, p=.002$.

## Fixation Durations

In order to test the effect of return saccades and number of cue features on average fixation duration (all fixations within a trial) we performed a $2 \times 4$ (return saccade by number of cue features) repeated measures analysis of variance. The analysis of variance revealed a significant main effect of return saccade, $F(1,14)=27.44, p=.001, \eta_{g}{ }^{2}=0.22$; a significant main effect of number of cues, $F(3,42)=6.68$, $p<.001, \eta_{g}{ }^{2}=0.11$; and a marginally significant interaction effect $F(3,42)=2.62, p=.063, \eta_{g}{ }^{2}=0.02$. The means and standard errors can be seen in Figure 4

Figure 4. The average fixation duration (all fixations within a trial) for each level of number of cue features. Error bars represent standard error.

## Comparison of Search Strategies

The serial strategy search time $T_{\text {serial }}$ can be approximated by the following equation:

$$
\begin{equation*}
T_{\text {serial }}=(N-2) *\left(F_{\text {serial }}+S\right) \tag{1}
\end{equation*}
$$

where N is the average number of fixations on a given trial type, and $S$ is the average saccade duration. Similarly, the parallel strategy search time $T_{\text {parallel }}$ can be approximated by the following formula:

$$
\begin{equation*}
T_{\text {parallel }}=N *\left(F_{\text {parallel }}+S\right) \tag{2}
\end{equation*}
$$

In order to approximate the values for $F_{\text {serial }}$ and $F_{\text {parallel }}$, we first performed mixed effects regression on mean fixation duration with return saccade and number of cues as fixed factors and with subjects as a random factor. The regression yielded the following equation (rounded to the nearest millisecond):

$$
\begin{equation*}
F=213-E * 24+C * 5 \tag{3}
\end{equation*}
$$

where F is fixation duration, E is 1 for return saccade trials ( 0 for non-return saccade trials) and C is the number of cues. The intercept value of 213 ms is consistent with previous research on average fixation durations in visual search (Rayner, 2009, Salthouse \& Ellis, 1980). The 24 ms difference between trials with and with out return saccades (assumed to be associated with the time required to make a decision of target presence) is psychologically plausible (Neisser, 1963; van Diepen, De Graef, \& D'Ydewalle, 1995). In addition, the 5 ms per cue feature seems psychologically plausible. Using Equation 3 we can compute the average fixation duration, $F_{\text {serial }}$ and $F_{\text {parallel }}$, for a given trial type and search strategy by using the average number of fixations, N, as shown in Figure 2 The value of S was set to 45 ms in all computations based on the average of saccade durations in the empirical data.

The time savings (or loss) from using the parallel search strategy can then be computed as follows:

$$
\begin{equation*}
T_{\text {diff }}=T_{\text {serial }}-T_{\text {parallel }} \tag{4}
\end{equation*}
$$

The results of Equation 1 and Equation 2 applied to each of the 8 probe combinations applied to Equation 4 is shown in Figure 5. The parallel search strategy saved more time than the serial search strategy for all trials where color was not an available cue feature. The sum of all $T_{d i f f}$ values was 972.02 ms indicating that overall, the parallel strategy could be more efficient.

This analysis can be taken one step further by setting $F_{\text {serial }}$ equal to $F_{\text {parallel }}$ and solve for N , resulting in Equation 5 , to find the threshold in terms of number of fixations where the parallel strategy becomes more efficient than the serial strategy.

$$
\begin{equation*}
N=\frac{2 * F_{\text {serial }}+2 * S}{F_{\text {serial }}+F_{\text {parallel }}} \tag{5}
\end{equation*}
$$

By using a value of 213 for $F_{\text {serial }}$ and 189 for $F_{\text {parallel }}$ (computed from Equation 3) and a value of 45 for $S$, the threshold turns out to be 21.5 fixations. This threshold is depicted as the dashed horizontal line in Figure 2 Interestingly, for all trials in which color is available as a probe feature, the average number of fixations is less than this threshold. In other words, when color is not available, the parallel search strategy will be more efficient in terms of time.

## Discussion

The goal of this study was to determine if people optimize their eye movements during visual search. In order to accomplish this goal we had subjects perform a difficult visual search task where they had to find a target object in a field of objects that differed in size, shape color and numeric label. We hypothesized that subjects would optimized their eye movements by using the more efficient of two microstrategies: the serial and parallel microstrategies. We used the presence of return saccades as a marker of the parallel microstrategy. Consistent with our first hypothesis, the proportion of trials that contained return saccades were higher on trials that required lots of fixations to find the target as well as on trials where there were few target cues compared to trials that required only a few fixations to find the target or trials that had many target cues. One interpretation of this result is that subjects are indeed sensitive, consciously or unconsciously, to the temporal costs of serial strategy which ensures a target presence decision before the eye is moved to the next location.

Our second hypothesis predicted that fixation durations would be shorter on trials that contained return saccades that on trials that did not contain return saccades. This indeed was the case. We also predicted in our third hypothesis that on trials that did not include a return saccade that fixation durations should increase with respect to the number of known target features. This prediction was mildly supported by the marginally significant interaction we found in our analysis of variance involving return saccades and number of cue features on fixation duration.

Our conservative cost analysis of the serial and parallel microstrategies does show that the parallel microstrategy can more cost effective in terms of time on task. However, return saccades were only observed on $38 \%$ of the trials in our experiment. This could be interpreted as evidence that subjects did not or could not optimize their eye movements. However, we are not positive that is the case. It's possible that return saccades are just not a good enough measure of the parallel search strategy since it is possible for early eye movement programming (that would have cause the eye to move before target analysis) to be aborted in the parallel strategy. This could not only potentially reduce the number of observed return saccades but it could also affect the average fixation durations in trials with and with out return saccades. It is possible that someone could be using the parallel strategy throughout most of a trial but then abort an eye movement that would

Figure 5. The estimated difference ( $T_{d i f f}$ ) in time from using the parallel or serial microstrategy, computed using Equation 4 Positive values favor the parallel strategy, negative values favor the serial strategy.
have resulted in a return saccade. This would result in the lowering of the average fixation duration for trials with out a return saccade due to improper strategy classification. Additionally, a trial that shows a return saccade could still have contained many aborted early saccades inflating the average fixation duration of return saccade trials.

## Conclusion

Our study has provided evidence that eye movements in visual search can be sensitive to millisecond level cost-benefit trade-offs. Whether or not people can actually optimize their eye movements to take advantage of these cost-benefit tradeoffs is still not clear. In addition, the fact that the parallel strategy could under some circumstances appear as if it were actually a serial strategy allows for the possibility that the serial strategy does not even exist. This idea is consistent with the findings of Hornof and Kieras (1997) and Hornof and Halverson (2003). Further research on this topic will need to find better ways to quantify the prevalence of parallel processing in eye movement microstrategies.

# More than a feeling: When emotional reactions don't predict moral judgments 

Zachary Horne (horne2@illinois.edu)<br>Department of Philosophy, 810 S. Wright Street<br>Urbana, IL 61801 USA<br>Derek Powell (derekpowell@ucla.edu)<br>Department of Psychology, 1285 Franz Hall, Los Angeles, CA 90095 USA

#### Abstract

Many moral psychologists have proposed that the difference between people's moral judgments about the Trolley and Footbridge dilemmas can be explained by their differing emotional responses to the dilemmas. In two experiments, we tested this explanation by presenting the dilemmas and measuring participants' reactions using a self-report emotion measure (PANAS-X). As might be expected, participants experienced more intense emotions after reading moral dilemmas when compared to a non-moral dilemma. However, participants' emotional reactions to the Trolley and Footbridge dilemmas did not differ. Our findings call the oft cited emotion explanation into question.

Keywords: moral psychology; emotion; PANAS-X; decision making.

Recently, research on moral dilemmas has crossed disciplines, branching out from ethics into psychology and cognitive neuroscience (e.g., Ciaramelli, Muccioli, Làdavas, \& Di Pellegrino, 2007; Greene, Sommerville, Nystrom, Darley, \& Cohen, 2001; Greene, Nystrom, Engell, Darley, \& Cohen, 2004; Koenigs, Young, Adolphs, Tranel, Cushman, Hauser, \& Damasio, 2007). Within these lines of inquiry, there has been widespread interest in participants' judgments about two famous moral dilemmas: the Trolley dilemma and the Footbridge dilemma. In the Trolley dilemma, participants are told they are at the wheel of a runaway train that will cause the deaths of five workmen if it proceeds on its present course. The only way to avoid the deaths of these workmen is to hit a switch, redirecting the train to a side track where it will kill a single workman instead. This dilemma is often contrasted with another famous moral dilemma, the Footbridge dilemma, which asks participants to consider a situation in which they are on a footbridge, in between a runaway trolley and five workmen who will be killed if nothing is done. Participants are then told that the only way to save the lives of the five workmen is to push a stranger off the bridge and onto the tracks below where his large body will stop the trolley. Surprisingly, in the Trolley dilemma, approximately $80 \%$ of people judge that it is appropriate to take action (hit the switch, killing one person), yet in the Footbridge dilemma, about $80 \%$ judge that is it inappropriate to take action (push the man off the bridge, killing him). Given the apparent similarity of these moral situations, researchers have sought
to understand why people give such drastically different judgments about these cases.

Many researchers have suggested that these two dilemmas can be distinguished by the emotional reactions they elicit. Specifically, the Footbridge dilemma is thought to elicit strong negative emotional reactions, whereas the Trolley dilemma is thought to elicit weak negative emotional reactions. We will refer to this claim as the Emotion Explanation.

The Emotion Explanation has been interpreted as having wide-ranging implications for theories in psychology, cognitive neuroscience, and ethics. For instance, some psychologists have suggested that the Emotion Explanation is revealing of the psychological mechanisms recruited in moral judgment in general (e.g., Greene et al., 2001; Koenigs et al., 2007). Meanwhile, philosophers have employed the Emotion Explanation to diverse ends, using it to advance or undercut normative ethical theories, and to make arguments about the epistemic status of moral intuitions (e.g., Singer, 2005).

There are several reasons to take this explanation seriously. First, there is good evidence that emotions do importantly influence moral judgments (Haidt, 2001). Most directly, cognitive neuroscientists using functional Magnetic Resonance Imaging (fMRI) have reported finding activity in areas of the brain associated with emotional processing while participants made 'deontological' moral judgments, such as judging that it is inappropriate to push the man in the Footbridge dilemma (Greene et al., 2001, 2004). Researchers have also examined the moral judgments of participants with damage to the ventromedial prefrontal cortex (vmPFC), an area of the brain associated with affect. When given a battery of moral dilemmas, these participants gave 'utilitarian' moral judgments in the Footbridge dilemma, whereas healthy control participants tended to give deontological judgments (Koenigs et al., 2007).

Despite this evidence, there are a number of reasons to examine the Emotion Explanation more closely. First, it is not clear how the Emotion Explanation coheres with existing theories about morally relevant emotions, such as guilt. For example, social functionalist theories of emotion suggest that emotions like guilt serve both intrapersonal and interpersonal functions (Keltner, Haidt, \& Shiota, 2006). On this view, guilt is typically elicited as a result of one's perceived transgressions against another, which can damage
relationships (Keltner, 1995). Upon contemplating some action, the experience of guilt might serve an intrapersonal function, deterring the potentially damaging action. Alternatively, if the action is ultimately taken, guilt can serve an interpersonal function, helping to repair whatever damage was done (Baumeister, 1994).

While it is clear that moral dilemmas can differ in the intensity of the emotions they evoke (e.g., dilemmas that ask participants to consider killing their child versus lying), the emotionally salient aspects of both the Trolley and Footbridge dilemmas are held constant. In both scenarios, participants are asked if they should kill a stranger in order to save five other strangers. Causing the death of another person seems likely to place a strain on interpersonal relationships, whatever one's motivation for doing so. Cast in this light, social functionalist theories of emotion seem to predict that people will experience feelings of guilt even as they approve of taking action in the Trolley dilemma.

Second, extant research in moral psychology provides only indirect support for the Emotion Explanation. The most direct support comes from fMRI investigations by Greene and colleagues (2001, 2004). In these studies, researchers presented participants with two large groups of moral dilemmas. One group was composed of the Trolley dilemma and 18 other dilemmas, and the other group was composed of the Footbridge dilemma and 24 other dilemmas. They called the dilemmas they considered Trolley-like 'impersonal', and the dilemmas they considered Footbridgelike 'personal', due to the 'closeness' of the action being performed in the dilemma. They found that the 'impersonal' dilemmas activated areas of the brain associated with deliberative cognition, whereas the 'personal' dilemmas activated areas of the brain associated with emotion. They regarded these results, in part, as evidence for the Emotion Explanation.

However, in order for the data from the studies by Greene and colleagues $(2001,2004)$ to provide compelling evidence for the Emotion Explanation per se, each of their 'impersonal' and 'personal' dilemmas would have to elicit emotions with valence and intensity similar to the Trolley and Footbridge dilemmas, respectively. It is doubtful that such parity was achieved. Dilemmas deemed 'impersonal' frequently did not involve physically harming someone (even though the Trolley dilemma clearly does), whereas those deemed 'personal' almost invariably did. In fact, only 10 of the 19 'impersonal' dilemmas involved harm, whereas 24 of the 25 'personal' dilemmas involved physically harming someone (Moore, Clark, \& Kane, 2008). This difference is a problematic confound because moral situations concerning the bodily harm of another have been shown to elicit stronger negative emotional responses than those not involving any bodily harm (Heekeren, 2005). Misgivings about the representativeness of the dilemmas in these sets are further supported by an item analysis performed by McGuire and colleagues (2009) on Greene and colleagues' data. This analysis demonstrated that only a subset of the moral dilemmas was responsible for the
significantly different patterns of neural activation Greene and colleagues observed, again impugning evidence for the Emotion Explanation.

Given the confound in these materials, and the findings of the item analysis (McGuire, Langdon, Coltheart, \& Mackenzie, 2009), we suspect that people experienced more intense emotions when considering 'personal' dilemmas because the dilemmas much more frequently involved physical harm, not because the Footbridge dilemma itself is more emotionally engaging than the Trolley dilemma. ${ }^{1}$ In other words, Greene and colleagues' (2001) findings do not provide clear evidence for the Emotion Explanation, and thus corroboration of the Emotion Explanation requires a more direct test. These criticisms apply equally to a number of other studies by researchers who have used these same materials and have claimed to have found evidence for the Emotion Explanation (e.g., Ciaramelli et al., 2011; Koenigs et al., 2007). To our knowledge, there is no empirical data taken as evidence for the Emotion Explanation that avoids this criticism.

We sought to test the Emotion Explanation by examining people's emotional responses to the Trolley dilemma and Footbridge dilemma, individually and specifically. We measured participants' emotional responses to moral dilemmas using the PANAS-X, a comprehensive emotional state, trait, and mood self-report measure (Watson, Clark, \& Tellegen, 1988) that has been shown to correlate with neural activation in the amygdala (Irwin, Davidson, Kalin, Sorenson, \& Turski, 1998), as well as in the vmPFC (Zald, Mattson, \& Pardo, 2002). Importantly, use of this self-report measure allowed us to investigate people's emotional responses to individual moral dilemmas, rather than to a battery of different dilemmas. More advanced methodologies such as GSR or fMRI, while in many ways superior to self-report, are ill-suited for investigating responses to individual stimuli.

In line with previous research, we hypothesized that considering the Footbridge dilemma would elicit negative emotions. In contrast to the Emotion Explanation, we predicted that considering the Trolley Dilemma would also elicit increased guilt, as well as other negative emotions. Moreover, because the Trolley and Footbridge dilemmas contain very similar emotionally-relevant content (they both call on participants to imagine killing another person), we expected to find very little difference in people's emotional reactions to these dilemmas. These last two predictions stand in contrast to the way moral psychologists have conceived of the Footbridge and Trolley dilemmas (e.g., Ciarmelli et al., 2007; Greene et al., 2001; Greene et al.,

[^93]2004; Koenigs et al., 2007); hence support for our predictions would cast doubt on the Emotion Explanation.

## Experiment 1

## Method

Participants The participants in Experiment 1 were 442 students enrolled in various undergraduate courses at Arizona State University. Approximately 54\% of the participants were males. The mean age of participants was 20.1 years old.

Materials Four different scenarios were presented to participants in this study, with each participant reading one scenario. Three of these scenarios were moral vignettes, the 'Trolley,' the 'Footbridge,' and the 'Crying Baby' vignette, all taken verbatim from Greene et al. (2001).

One potential concern is that the PANAS-X subscales might not be sensitive enough to detect differences between moral dilemmas of different emotional intensity. To evaluate the sensitivity of our chosen PANAS-X subscales, we presented some participants with a highly emotional dilemma, the Crying Baby dilemma. In this dilemma, participants must consider smothering their own infant child to save the lives of their townspeople.

The Crying Baby dilemma also afforded us the opportunity to explore whether there was a relationship between emotions and moral judgments within an emotionally engaging case. Prior research shows that people tend to be evenly divided over whether or not it is appropriate to take action in the Crying Baby dilemma, permitting meaningful comparisons between those who approve and those who disapprove. The fourth dilemma was a non-moral control dilemma (Coupon) adapted from Greene et al. (2001).

In Experiment 1, we used selected sub-scales from the PANAS-X to measure the extent to which participants experienced several relevant emotions. Participants rated how strongly they felt certain feelings on a 1 to 5 Likert scale, where 1 corresponded to 'Very slightly or not at all' and 5 corresponded to 'Extremely.' Importantly, participants were asked to report on their current emotional state rather than to assess the vignette or to speculate as to how they might feel if placed in the situation they read. These individual ratings were then averaged to obtain a score for each emotion subscale. Data were collected for the Positive Affect, Negative Affect, Hostility, Guilt, Joviality and Self-Assurance sub-scales from the PANASX. The Guilt sub-scale included words like 'Guilty', 'Ashamed', and 'Disgusted With Self', and the Hostility subscale included words like 'Angry', 'Disgusted', and 'Hostile'. The Joviality subscale included words like 'Happy', 'Joyful', and 'Cheerful', and the Self-Assurance subscale included words like 'Proud', 'Strong', and 'Confident'. As the Positive and Negative Affect scales contain many of the same emotion words found in the Guilt, Joviality, Hostility and

Self-Assurance subscales, we do not discuss analyses of the Positive and Negative Affect scales.

Procedure Experiment 1 was administered and data were collected via pen-and-paper questionnaires. The questionnaires consisted of text describing a moral dilemma, followed by an emotion measure (i.e., the PANAS-X). Participants were asked to respond to the emotion measure after considering a statement of the form, 'You are thinking about (action) in order to (outcome).' For example, when considering the Trolley dilemma, participants would read the statement, 'You are thinking about hitting the switch in order to avoid the deaths of the five workmen.' The text indicating the outcome was italicized for all conditions. On the opposite side of the questionnaire participants were asked to make a judgment of appropriateness. In making their judgments of appropriateness, participants were asked, 'Is it appropriate for you to (action) in order to (outcome).' They were instructed to circle 'yes' or 'no.' Participants were also asked to describe the emotions they experienced while reading the vignettes, and were given several lines to write in their response. These descriptions were used to identify problematic responses or inconsistencies between participants' reported emotions on the PANAS-X. Finally, participants were asked to provide demographic information.

Experiment 1 was conducted during various lecture classes at Arizona State University. The questionnaires were passed out at the beginning of the class, and students were given approximately 10 minutes to complete them. Instructions were given both verbally and in writing. Participants were instructed not to talk to each other while completing the survey, and were observed for compliance.

## Results

Of the 442 participants originally involved in the experiment, 12 gave written descriptions of their emotions that were primarily non sequitur or conflicted with the emotion ratings they had given on the PANAS-X. These 12 participants were removed from further analyses. Only participants who had complete data sets for all the emotion subscales were included in the final analysis. This resulted in 86 participants responding to the control vignette, 147 to the Crying Baby, 71 to the Footbridge, and 77 to the

| $92 \%$ | $91 \%$ | $25 \%$ | $46 \%$ |

Figure 1: Mean emotion ratings on each PANAS-X sub-scale for the four dilemmas in Experiment 1.

Trolley. Additional participants were included in the Crying Baby in order to achieve adequate statistical power for comparisons to be made within that condition. Mean subscale ratings for each vignette are shown in Figure 1.

Participants' judgments are summarized in table 1. Their responses accord with those obtained by previous investigations of these scenarios.

PANAS-X scores were examined with four ANOVA tests with vignette type as a between-subjects variable. Significance was obtained on the $\operatorname{Guilt}(F(3,377)=62.57$, MSE $=1.334, p<.001)$, Hostility $(F(3,377)=65.66$, MSE $=.953, p<.001)$, Joviality $(F(3,377)=21.19$, MSE $=.453$, $p<.001)$ and Self-Assurance $(F(3,377)=2.74, \mathrm{MSE}=$ $.737, p=.04)$ subscales.

For each of these ANOVA tests, planned comparisons examined differences between the three moral vignettes and the control vignette in the emotion ratings on the Guilt, Hostility and Joviality subscales. The moral vignettes elicited significantly more Guilt $(t(377)=8.69, p<.001)$ and Hostility $(t(377)=7.90, p<.001$, and significantly less Joviality $(t(377)=-6.83, p<.001)$ than the control vignette. Though significance was obtained on the respective ANOVA analyses, no significant difference was found between the moral vignettes and control vignette for SelfAssurance ratings $(t(377)=-.475, p=.635)$, suggesting that the Self-Assurance subscale was not relevant to moral judgments. No further analyses were conducted for SelfAssurance ratings.

As predicted, participants' ratings of Guilt, Hostility and Joviality were compared between the Trolley and Footbridge vignettes with three separate t-tests. These tests found no significant differences between the two groups for Guilt $(t(146)=-.09, p=.93)$, Hostility $(t(148)=-.33, p=$ $.74)$ or Joviality $(t(148)=1.24, p=.22)$. This finding is consistent with our prediction that such highly similar moral

Table 2: Summary of Logistic Regression Models Predicting Moral Judgments in the Crying Baby Dilemma in Experiment 1.

|  | Model 1 |  |  |  | Model 2 |  |  |  |  |
| ---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\beta$ | SE | $e^{\beta}$ | $p$ | $\beta$ | SE | $e^{\beta}$ | $p$ |  |
| Hostility | -.21 | .23 | .81 | .36 | -.22 | .24 | .81 | .37 |  |
| Guilt | -.06 | .19 | .94 | .76 | -.02 | .20 | .98 | .91 |  |
| Joviality | .21 | .40 | 1.24 | .59 | .41 | .41 | 1.20 | .66 |  |
| Gender |  |  |  |  | 1.19 | .35 | 3.27 | .001 |  |
| $\chi^{2}$ |  | 4.08 |  |  | 15.81 |  |  |  |  |
| df | 3 |  |  | 4 |  |  |  |  |  |
| $p$ |  | .253 |  |  | .003 |  |  |  |  |

scenarios were unlikely to elicit meaningfully different emotional reactions.

Participants who read the Trolley vignette reported greater levels of Guilt $(t(377)=4.66, p<.001)$ and Hostility $(t(377)=4.22, p<.001)$, and lower levels of Joviality $(t(377)=-5.39, p<.001)$ than those who read the control vignette. Further planned comparisons tested whether the Crying Baby vignette was more emotionally salient than the Footbridge and Trolley vignettes. The Crying Baby vignette elicited more Guilt $(t(377)=9.11, p<.001)$ and Hostility $(t(377)=10.23, p<.001)$, and less Joviality $(t(377)=-2.79, p<.001)$ than the Footbridge and Trolley vignettes. These differences indicate that the PANAS-X is sufficiently sensitive as an emotion measure to detect differences between moral dilemmas of different emotional intensity.

Finally, we used logistic regression analyses to assess the relationship between emotions and moral judgments in the Crying Baby dilemma. We evaluated this relationship using two different regression models. The resulting equations are summarized in Table 2. The first model uses the Guilt, Hostility, and Joviality subscale scores as predictors of people's moral judgments. No significant relationship was found between participants' emotion ratings and their moral judgments for the Crying Baby problem $\left(\chi^{2}(3)=4.082\right.$, $p=$ .25). The second model adds gender to the three regressors from the original model. This model significantly predicted moral judgments $\left(\chi^{2}(4)=15.813, p<.01\right)$. Within this model, the gender coefficient was statistically significant ( $\beta$ $=1.185, e^{\beta}=3.271, p<.01$ ), indicating that women were less likely to judge it appropriate to smother the child. Importantly, this relationship between gender and moral judgments was significant over and above the emotion ratings.

## Experiment 2

As the results of Experiment 1 stand in stark contrast to the Emotion Explanation, we sought to replicate the findings of Experiment 1 in a different population.

## Method

The participants in Experiment 2 were 221 workers recruited using Amazon Mechanical Turk (mTurk). Approximately $53 \%$ of the participants were males. The mean age of participants was approximately 31 years old.

Materials The materials and measurements used in Experiment 2 were identical to those of Experiment 1, with two exceptions. The results of Experiment 1 indicated that participants' emotion ratings on the Self-Assurance subscale in moral conditions did not differ from participants in the control condition. Consequently, in Experiment 2, we only used the Guilt, Joviality and Hostility subscales to measure participants emotional responses. In addition, rather than asking participants to give moral judgments as a binary 'yes/no' response, we asked them to rate the moral rightness or wrongness of the proposed act on a 1-6 Likert scale. The end points of the Likert scale were labeled 'Completely Inappropriate' and 'Completely Appropriate.' This change was made in order to increase our statistical power for detecting any potential relationship between emotions and moral judgments in the Crying Baby dilemma.

Collection Experiment 2 was administered and data was collected through the mTurk work-distribution website. Eligible workers were redirected to Qualtrics, where they completed the study. Afterwards, workers were directed back to mTurk, where they were compensated with $\$ .20$.

Procedure The survey presented to participants in Experiment 2 was nearly identical to the survey in Experiment 1, save for being computerized rather than pen and paper based. It consisted of text describing a moral dilemma, followed by an emotion measure (PANAS-X). After rating their emotions, participants made a moral judgment about the dilemma presented to them.

## Results

Experiment 2 replicated the findings from Experiment 1. In Experiment 2, 61 participants read the Coupon vignette, 51 read the Crying Baby, 57 read the Footbridge, and 52 read the Trolley. On average, participants judged it appropriate to use the coupon (mean $=5.51$ ) and to switch the track in the Trolley dilemma (mean $=4.69$ ). Participants were divided over whether to smother the baby (tending to disapprove somewhat, mean $=2.88$ ), and in general disapproved of pushing the man $($ mean $=2.32)$.

An ANOVA revealed significant differences between the moral and control vignettes in terms of the emotions they elicited, with significance obtaining for the Guilt $(F(3,217)$ $=31.86, \mathrm{MSE}=1.389, p<.001)$, Hostility $(F(3,217)=$ 52.57, MSE $=.929, p<.001)$, and Joviality $(F(3,217)=$ 15.339, MSE $=.824, p<.001$ ) subscales. Planned comparisons again revealed the sensitivity of the PANAS-X for measuring the different emotions elicited by different moral cases. The Crying Baby vignette elicited more Guilt

Table 3: Summary of Linear Regression Model Predicting Moral Judgments in the Crying Baby Dilemma in Experiment 2.

|  | $b$ | SE | t | $p$ |
| ---: | :---: | :---: | :---: | :---: |
| Guilt | -.020 | .345 | -.059 | .954 |
| Hostility | .298 | .392 | .758 | .452 |
| Joviality | .175 | .336 | -.521 | .605 |
| Intercept | 2.216 | 1.038 |  |  |
| F |  | .764 |  |  |
| df |  | 47 |  |  |
| $p$ |  | .52 |  |  |
| $\mathrm{R}^{2}$ |  | .047 |  |  |

$(t(217)=4.08, p<.001)$ and Hostility $(t(217)=5.72, p<$ .001) than did the Footbridge and Trolley vignettes. The same contrast for the joviality subscale approached significance $(t(217)=1.81, p=.07)$.

As was observed in Experiment 1, participants who read the Trolley vignette reported greater levels of Guilt ( $t(111)$ $=6.05, p<.001)$ and Hostility $(t(111)=7.01, p<.001)$, and lower levels of Joviality $(t(111)=-3.67, p<.001)$ than those who read the non-moral control vignette. To provide a second test of the Emotion Explanation, participants' ratings of Guilt, Hostility and Joviality were compared between the Trolley and Footbridge vignettes with three separate $t$-tests. These tests again found no significant differences between the two groups for Guilt $(t(107)=-1.42, p=.16)$, Hostility $(t(107)=-.34, p=.74)$ or Joviality $(t(107)=1.27, p=.21)$.

The use of Likert scale ratings of moral judgments in Experiment 2 enabled us to assess the relationship between emotions and moral judgments in the Crying Baby dilemma using a simpler linear regression model. The model used the three PANAS-X sub-scale scores as predictors of people's moral judgments. The resulting equation is summarized in Table 3. Replicating our findings in Experiment 1, no significant relationship was found between participants' emotion ratings and their moral judgments for the Crying Baby dilemma $(F(3,45)=.90, p=.45)$. This model accounted for less than 5 percent of the variance in participants' Crying Baby judgments, indicating an extremely weak (and non-significant) relationship between emotions and moral judgments about the case.

## Discussion

We hypothesized that the Trolley dilemma would be more emotionally engaging than many moral psychologists have claimed. Additionally, we suspected that because of the high degree of similarity between the Trolley and Footbridge dilemmas, any differences between the emotions elicited by the two dilemmas would not be sufficient to explain the large difference in participants' judgments about the dilemmas. The results of Experiments 1 and 2 confirm these two predictions. We found that participants reported significantly more guilt and hostility in response to the Trolley dilemma than to the control dilemma, and
significantly less joviality. Additionally, we found no difference in emotion ratings from participants who responded to the Footbridge dilemma and those who responded to the Trolley dilemma, despite the rather large sample size of our experiment.

To our knowledge, this is the first use of the PANAS-X to compare the emotions elicited by different moral dilemmas. Additionally, one of our primary hypotheses was that there would be no differences between the emotions elicited by the Footbridge and Trolley judgments. This made it important to confirm that the PANAS-X is sufficiently sensitive to detect emotional changes, not just between moral dilemmas and a non-moral dilemma, but also between different moral dilemmas. We found that participants who responded to the Crying Baby dilemma reported significantly stronger negative emotions and weaker positive emotions than did participants who responded to the Trolley and Footbridge dilemmas, demonstrating the sensitivity of the PANAS-X.

The Emotion Explanation, as stated, concerns the Trolley and Footbridge dilemmas specifically. However, this explanation has been employed to a number of different ends, not all of which necessarily hinge on facts about these specific dilemmas. In this way, some proponents of the Emotion Explanation might argue for a more general claim, viz., in general, deontological moral judgments recruit gut, emotional processes. In an emotionally salient case like the Crying Baby dilemma, proponents of this more general Emotion Explanation ought to predict a relationship between emotions moral judgments, such that the stronger the negative emotional reaction a participant experiences, the more likely they are to give a deontological judgment. Across two experiments, we observed no such relationship between emotions and moral judgments in the Crying Baby dilemma.

In sum, our findings indicate that the Trolley, Footbridge and Crying Baby dilemmas fail to conform to the more general Emotion Explanation. It is a question for future research whether these dilemmas are simply exceptions to the rule, or whether the more general Emotion Explanation should be rejected. Our findings cast doubt on the Emotion Explanation and may call for revision of the psychological, ethical, and epistemological theories in which it has been employed.

# Young children's developing sensitivity to discourse continuity as a cue to reference 

Alexandra C. Horowitz<br>ahorowitestanford.edu<br>Department of Psychology<br>Stanford University

Michael C. Frank<br>mcfrank@stanford.edu<br>Department of Psychology<br>Stanford University

#### Abstract

Children can learn new words in pedagogical contexts, but they may also infer reference using a variety of other information sources. Here we investigate children's sensitivity to the placement of novel labels within discourse structure as a possible mechanism for word learning. In Experiment 1, children ages 2-6 years participated in word learning trials featuring two novel items and one novel label. In critical trials, the labels were embedded between two sentences about the same item, whereas in a control condition, the label was introduced after two sentences about the item. Children of all ages were more likely to attribute the label to the toy whose descriptions bracketed the embedded label, and response strength increased with age. Children across all ages responded at chance in the control condition. In Experiment 2, adults showed the same patterns of responses as children in both critical and control conditions. Together, these results suggest that discourse continuity is a reliable cue to reference for both children and adults.

Keywords: word learning; discourse; social cues; language development.

## Introduction

Children use a variety of strategies for learning new words. In overtly pedagogical situations, children can use cues such as pointing, joint attention, and labeling to establish a direct mapping between an object and name. However, many situations do not feature ostensive labeling events. In these cases, children must rely on other strategies to infer the referent of a novel word. One source of information may come from discourse structure (the order of utterances and how they relate to each other). Recognizing how speakers relate topic information may help children resolve reference that would otherwise be ambiguous in the absence of the broader context.

For example, a child may not have an idea of what chinchilla means from an utterance such as, "I love chinchillas!", but she may apply her knowledge of discourse structure to infer its meaning when the same utterance is related to topical information, such as "I got a new pet. I love chinchillas! They're so soft." Children are exposed to information about discourse structure whenever they hear speech, and their accumulation of experience may help them to update and refine their expectations about topic relationships. This developing expertise may allow children to infer meaning that is locally ambiguous, yet resolvable in the context of broader discourse.

Little work has explored whether children use discourse structure to scaffold reference disambiguation. Our aim is to address this question by investigating children's and adults' recognition of communicative structure when dissociated from other social and ostensive cues. Understanding the contribution of discourse knowledge in children's reference disambiguation may help identify opportunities for children to infer meaning from topic coherence.

A large body of research has been devoted to children's ability to map names to inferred referents through disambiguation of a single new item and label. In the presence of a known item and an unknown item, children map a novel label to the novel item rather than the already-named item (Markman \& Wachtel, 1988; Merriman, Bowman, \& MacWhinney, 1989; Mervis \& Bertrand, 1994; Clark, 1990). Though the mechanisms at play are debated, this finding establishes that children can make inferences about a speaker's likely intended meaning in constrained contexts. While employing their repertoire of word-object mappings may allow children to disambiguate some novel referents, there may be other situations in which multiple items are unknown.

Children can also use social-pragmatic cues to infer novel word reference. By age 2, children map novel labels to novel objects that the speaker attends to rather than what they themselves may be attending to (Baldwin, 1991), and even after a time delay (Baldwin, 1993). Young children apply new terms to the target but not non-target items of a speaker's search (Tomasello \& Barton, 1994), show evidence of considering not only their own novelty perspective, but also what is novel to a speaker in a discourse context (Akhtar, Carpenter, \& Tomasello, 1996), and can recognize that speaker naming events may convey social-pragmatic implications about information that is expected to be shared (Diesendruck \& Shemer, 2006).

Despite this body of evidence on general pragmatic cues, few studies have investigated children's sensitivity to discourse structure. Nevertheless, some work suggests that discourse continuity may provide important opportunities for learning. Frank, Fernald, and Tenenbaum (2013) examined a video corpus of caregivers interacting with their 6-18 monthold children. In these natural settings, they found discourse continuity (that utterances in close succession are likely to relate to the same topic) was as reliably linked to reference as were social cues such as pointing and gaze (Frank, Tenenbaum, \& Fernald, 2013). Although this result suggests that discourse continuity may be an available cue to disambiguate reference in the presence of competitors, their work did not provide evidence that learners actually make use of this information. Therefore, our present studies provide the first test of whether discourse position can be used to determine reference in word learning.

We discuss two experiments indicating that both children and adults can use discourse position to resolve reference ambiguity. Additionally, our control condition shows that children and adults rely on the informativeness of discourse structure rather than simpler heuristics such as temporal proxim-

Figure 1: Schematic order of events for "A" trials across conditions. In the During condition, the experimenter makes eye contact without other gaze cues and introduces the naming event between two descriptions of a single toy. In the After control, events are identical except that the experimenter introduces the naming event after two descriptions of a toy.
ity. Our findings suggest that language users are able to apply their knowledge about how utterances relate within a discourse to make inferences about speakers' intended referents. Overall, this work suggests that children are not constrained to social and contextual cues from individual utterances, but can evaluate how information may relate across broader discourses.

## Experiment 1

We designed a novel task to investigate children's recognition of discourse structure as a cue to reference. In a large sample of 2- 6 year-olds, we introduced children to two novel toys accompanied by only one novel label, and we manipulated where in discourse the name was introduced. We were interested in which toy children selected as the referent of the label. The experimenter made eye contact with the child but gave no gaze or gesture cues to the referent of the label during the naming event, so the only cue to reference was the location of the naming event within the broader discourse. In the critical During condition, children were introduced to a novel label within descriptions about either the first ("A") or second ("B") toy (see Figure 1). Because the label was embedded within descriptions of the same toy in critical trials, we were interested in whether children would infer topic continuity and link the label to that toy.

An alternative explanation for why children might choose the toy whose descriptions bracketed the naming events is that children are making a temporal association between the label and the toy descriptions rather than considering discourse structure per se. That is, children may be selecting the toy that is described closest to the naming event, which would always correspond with the toy surrounding the introduction of the label in During trials. Therefore, we also ran a control condition to dissociate temporal proximity from discourse coherence. In the control After condition, the naming event was introduced after descriptions of either Toy A or Toy B rather than between descriptions of that toy. Thus the naming event could occur next to descriptions of both toys in After $A$ trials, or next to only Toy B in After B trials. Sample scripts for each trial type are listed in Table 1.

Our design allows us to make the following predictions: If children recognize discourse continuity as a cue to reference, they should infer that new information contained within a single topic is likely to also refer to that topic. Therefore, children should select Toy A in During A trials and Toy B in During $B$ trials, but not have a clear strategy in After trials. If children rely on temporal association rather than topic coherence, they should select a referent according to what comes closest to the naming event, i.e. Toy A in During $A$ and Toy B in During $B$ trials, as well as Toy B in After $B$ trials because
it is the only description proximal to the naming event. These predictions are outlined in Table 2.

Table 1: Sample scripts for each condition (During or After) and trial type (Toy A or Toy B). The green sentences are descriptions of Toy A, and the blue sentences are descriptions of Toy B.

| During A | After A |

| After B | either | B |

## Methods

Participants One hundred sixty-six children were recruited from the San Jose Children's Discovery Museum to complete a planned sample of 128 children. Children were given a sticker and certificate as compensation their participation. Parents were asked to fill out a short demographic form about their children's language background, and only children who were reported to hear English at least $75 \%$ of the time were included in the study. Twelve children were excluded due to insufficient English exposure, 12 children whose language information was not reported were excluded, and 14 children were excluded for not completing all four trials of the study.

Children were recruited in four age groups: 2-year-olds ( $\mathrm{n}=32,18$ girls, mean age 2 years 6 months), 3 -year-olds years ( $\mathrm{n}=32$, 10 girls, mean age 3 years 6 months), 4-yearolds ( $n=32$, 14 girls, mean age 4 years 6 months), and 5-yearolds ( $n=32,18$ girls, mean age 5 years 4 months).
Stimuli Four pairs of unusual items (e.g. a faucet aerator and a spaghetti measure) served as the novel toys. An additional item was used for training.

Procedures Participants were seated across from the experimenter in a quiet room at the museum. Children participated
in a training trial featuring ostensive labeling of a single toy ("This toy is called a blicket. Can you point to the blicket?") before seeing four discourse disambiguation trials. For the discourse disambiguation trials, the experimenter placed two toys on the table and described each in turn (see Figure 1). The toy pair remained in view of the child throughout the duration of the trial. All children heard the same scripts used to describe the toys; the only difference was the discourse location where the label was introduced. In a between-subjects manipulation, half the participants in each age group ( $\mathrm{n}=16$ per age) participated in four During trials; the other half participated in four After control trials. Order and toy pairs were counterbalanced across participants. At the end of each trial, the experimenter prompted the child to identify the named item by pointing. If children did not respond immediately, they were prompted again to make their best guess. The sessions were videotaped and coded offline. The entire task took about 5 minutes to complete.

Sample scripts for each condition and trial type are shown in Table 1. In During trials, the experimenter introduced the naming event between two sentences about the same toy (e.g. "You can push this button. Hey [child's name]! Have you seen a toma before? Tomas are so neat! What cool handles."). For two trials the label introduction was embedded during descriptions of the first toy (Toy A) and for two trial it was introduced during descriptions of the second toy (Toy B). When describing the toys, the experimenter directed her gaze to the toy and demonstrated a feature of the toy. There was a brief pause between each sentence. For the naming event, she disengaged from the toy and maintained a neutral position while drawing the children's attention using their names and establishing eye contact. The experimenter did not give any gaze cues or other indicators to the referent of the novel name. Thus, the naming event in itself carried no information to guide disambiguation; the only cue available was its location within discourse. In During trials, the naming event was always embedded between descriptions of a single toy. The After trials were identical except that the naming event appeared after the two descriptions about a toy (e.g. "You can push this button. What cool handles. Hey [child's name]! Have you seen a toma before? Tomas are so neat!").

## Results and Discussion

Figure 2 illustrates the proportion of children selecting the second toy (Toy B) as the referent of the label across conditions (During and After) and trial types (whether the label was introduced with Toy A or Toy B). The figure also includes adult performance across conditions and trial types from Experiment 2.

Children showed increased sensitivity to discourse coherence over development. Overall, children in the During condition were more likely to select Toy B when the label was embedded during descriptions about Toy B , and were less likely to select Toy B (thus more likely to select Toy A) when the naming event was bracketed by descriptions about Toy A. This pattern became more pronounced as children got older.

Figure 2: Combined data from Experiments 1 and 2. Mean proportion of selection of the second toy across condition (During or After) and trial type (label given with first toy: A, or second toy: B). Chance performance is at 0.5 , error bars represent $95 \%$ confidence intervals.

This finding suggests that children's sensitivity to discourse coherence as a cue to disambiguate reference increases across ages 2-6 years.

In After trials, children were at chance in selecting either toy for both After $A$ and After $B$ trials for all age groups. This result shows that children did not develop a consistent strategy to disambiguate reference when cues to topic coherence from discourse structure were not available.

To test the reliability of these patterns, we ran a generalized linear mixed model predicting toy selection as an interaction between condition (During or After), trial type (trial location A or B), and age with random effects of participant. There was a significant three-way interaction between condition, trial type, and age ( $\beta=0.89, p=0.03$ ), indicating that, with increasing age, participants were more likely to select Toy A in A trials and Toy B in B trials only for the During condition. No other factors were significant.

We also ran a series of paired $t$-tests to examine response differences between trial types (naming event with Toy A or Toy B) within condition (During or After) for each age group $(2-3 \mathrm{~s}, 3-4 \mathrm{~s}, 4-5 \mathrm{~s}$, and $5-6 \mathrm{~s}$ ) (Table 3). Significant differences in reference selection were found across trial types in the During condition for children ages 3-6 years; at these ages, children were more likely to select Toy A in During A trials and Toy B in During $B$ trials. By age 3, children were able to consider the broader discourse structure to help disambiguate the target referent.

In the naming events, children shared eye contact with the experimenter and were introduced to a novel word, but there were no indicators of the referent of the label other than its location within the broader discourse. Children's systematic responding to selecting the toy whose descriptions bracketed the naming event thus suggests that they can recognize and
refer to discourse coherence to infer reference in the absence of other social cues.

Could participants have assumed that the novel labels referred to both toys at once? The uniqueness of the toys makes this situation unlikely. Toys were distinct artifacts with different colors, shapes, and functions, and items in a pair were presented at opposite ends of the table, giving no visual signal that the toys were grouped. Additionally, if participants believed that both toys in a pair were examples of a novel category, we would have observed responding at chance across both During and After conditions. Thus we do not believe that a superordinate interpretation of the novel terms would explain the pattern of data we observed.

Finally, children did not appear to use temporal proximity to disambiguate reference in After trials. We found no significant differences between reference selections across After A and After $B$ trials for any age group, suggesting that children did not have consistent strategies for disambiguating the intended meaning of a novel term when topic coherence information is not available. While the After trials lacked definitive cues to establish reference, we were unsure whether adult users might have strategies for interpreting these trials.

## Experiment 2

In Experiment 2, we extended our design to adult participants. We wanted to confirm adults' sensitivity to discourse continuity as a cue to word learning in During trials, and assess strategies for referent disambiguation in After trials to compare with our developmental results.

## Methods

Participants Twenty-five adult participants were recruited from the San Jose Children's Discovery Museum, and were

Table 3: Results from paired t-tests examining response differences across trial types (naming location with Toy A or Toy B) within condition (During or After) for each age group (2$3 \mathrm{~s}, 3-4 \mathrm{~s}, 4-5 \mathrm{~s}$, and $5-6 \mathrm{~s}$ ). Children ages 3-6 years show significant differences in their response selections between During $A$ and During $B$ trials. No other significant differences across trial types are found.

|  | During condition |  |  | After condition |  |  |
| :---: | ---: | ---: | ---: | ---: | ---: | ---: |
| Age | $t$-value | df | $p$-value | $t$-value | df | $p$-value |
| $2-3$ | -1.23 | 15 | 0.24 | -1.58 | 15 | 0.14 |
| $3-4$ | -2.52 | 15 | $\mathbf{0 . 0 2}$ | -1.23 | 15 | 0.24 |
| $4-5$ | -5.48 | 15 | $<\mathbf{0 . 0 1}$ | -1.95 | 15 | 0.07 |
| $5-6$ | -8.22 | 15 | $<\mathbf{0 . 0 1}$ | -1.58 | 15 | 0.14 |

offered a sticker and certificate for their participation. They were informed that the task was designed for children. Only participants who reported using English at least $75 \%$ of the time were included in the study. One participant was excluded for reporting English use under this threshold.

Stimuli and procedure The stimuli and procedure were identical to Experiment 1, with the exception that adults did not undergo a training trial to practice pointing. Otherwise, adults were randomly assigned to either the During or After condition, and trial order and toy pairs were counterbalanced across participants.

## Results and Discussion

Results were coded for whether participants selected the second toy (Toy B) as the referent of the novel label (see Figure 2). Participants almost never selected Toy B in During A trials, but were near ceiling at selecting Toy B for During $B$ trials. Responses to each trial type were significantly different from chance in exact binomial tests ( $p<0.01$ for both trial types), and significantly different from each other ( $\beta=-2.06, p=0.01$ ) in a generalized linear mixed model predicting toy selection by condition (During or After) and trial type (trial location A or B) with random effects of participant. These results illustrate that adults were sensitive to naming events within discourse structure as informative cues to referent disambiguation; like the results in Experiment 1, adults demonstrate referent selections that correspond with discourse coherence, selecting the toy whose descriptions bracketed the naming event.

For After trials, adult participants were at chance in selecting Toy B in both After A and After B trials ( $p>0.3$ in exact binomial test for each). Performance was not significantly different between After $A$ and After $B$ trials ( $\beta=0.85$, $p=0.15$ ). These findings indicate that adults did not exhibit a strategy for disambiguating reference in After trials; they were at chance in determining a referent when the naming event followed the descriptions of either toy. This pattern of results also parallels the developmental results. Adults, like children, did not show systematic response patterns when discourse information was not available.

Together, these results suggest that language users are sensitive to how information relates within discourse structure. Adults and children systematically disambiguated reference when they could infer topic coherence in During trials. In contrast, we found that listeners did not develop consistent response strategies for information that is isolated from social and discourse context in After trials. Neither children nor adults followed heuristics such as resolving reference by temporal association.

## General Discussion

We investigated whether adults and children could use position in discourse as a cue to resolve reference. In our experiments, adults made use of discourse position effectively and children showed increasing sensitivity to discourse position across childhood. All groups except the youngest in our study successfully used discourse position to infer the mapping of a label. Taken together, our findings suggest that language users learn to make inferences about reference not only from pragmatic or social cues, but also from information about the general discourse in which a novel label is embedded.

Our experimental design ruled out two alternative explanations. The first is that children were simply selecting the referent most proximal to the naming event. In the During condition, this temporal proximity account would make the same predictions as a discourse-based account. Our After condition allowed us to rule out this possibility. While temporal proximity remains ambiguous in After $A$ trials, it is unambiguous in After B trials because Toy B is the only toy described proximate to the naming event. However, children at all ages responded around chance for both After $A$ and After B trials with no difference between naming location, suggesting that children did not use temporal proximity alone to make their judgments.

Our After condition rules out a second possible interpretation as well: that children's mappings are driven purely by novelty. By age 2, children state novel rather than given information in their productions (Baker \& Greenfield, 1988) and apply similar expectations to other speakers by mapping new labels to items novel to the speaker's perspective (Akhtar et al., 1996). Children's behavior in the During condition is consistent with a novelty account: they chose the toy that was most recently attended to by the experimenter (the one newest to the discourse). But on this account, children should assign Toy B as the referent in After A trials, because the naming event directly precedes the introduction of this toy. Instead, responses from the After A condition were at chance between the two toys, suggesting that novelty alone also did not account for our findings.

Children can learn from ostensive naming events when they are available, but many situations they encounter are not overtly pedagogical, and the ability to extract information that is embedded in discourse may help children deduce the meanings of words in these cases. As our initial chinchilla example illustrated, discourse position is a powerful informa-
tion source for understanding language and for learning new words. Children who can infer how new information relates to the current topic may be able to accumulate knowledge more accurately and more efficiently. Because of its accessibility to young children in our study (and the possibility that even younger children might use discourse position in a simpler task), the use of discourse structure to help disambiguate reference might be one of the array of learning mechanisms that helps explain children's rapid vocabulary growth. Using topic coherence to make inferences about novel terms and information may allow children to access learning opportunities that would otherwise be unavailable.

# Anxiety Can Influence Analogy-Making Both Positively and Negatively Depending on the Complexity of the Mapping Task

#### Abstract

In attempt to resolve the controversial issue of the influence of the anxiety state on analogy-making this paper presents a replication of the original Tohill and Holyoak study extending it with a new factor - the complexity of the mapping. It turns out that the anxiety influence interacts with the complexity of the mapping task. This has certain implications for the models of analogy and for the further study of the role anxiety plays in analogy-making.

Keywords: analogy; emotion, state anxiety, complexity.

## How Anxiety Changes Analogical Mapping

The chronologically first studies that focus on analogies under anxiety, suggest that analogical performance drops significantly when the state anxiety is heightened. Leon and Revelle (1985) manipulated anxiety via time pressure. They found that people are more accurate under low timepressure, but unfortunately, as Tohill and Holyoak (2000) have argued, these results could also be interpreted as a speed/accuracy trade-off. The negative correlation between anxiety and accuracy reported for the low time-pressure group is also inconclusive with respect to the possible causal link between anxiety and analogies.

Tohill and Holyoak (2000), however, also found decline in identification of the relational mappings under an induced state anxiety in a well-controlled study (Exp2). Prior to the analogy-making session, they manipulated the state anxiety via a serial subtraction task with negative feedback. The procedure turned out to differentiate successfully the anxiety of the two groups, measured with the State-Trait Anxiety Inventory (STAI) (Spielberger, Gorsuch, \& Lushene, 1970). Analogy performance was measured by a cross-mapping visual task. Participants saw two pictures on the screen for 15 seconds, then one object in the first picture was pointed at and they were instructed to indicate either which object from the second picture "goes with" the pointed one (Exp1), or to indicate the object from the second picture that "relationally matches" the pointed one (Exp2). The task is difficult because the target object has always two plausible matches - one at the level of object similarity (i.e., the same
or an extremely similar object present in the second picture) and another at the level of relational similarity (i.e., a superficially distinct object that plays an analogous role in the second picture). Less relational responses (Exp1) and less accuracy of identifying the relational match (Exp2) were found for participants from the high state-anxiety group. The decline in relational reasoning was explained by the Processing Efficiency Theory of Eysenck and Calvo (1992). According to that theory and its successor - the Attentional Control Theory (Eysenck, Deraksan, Santos \& Calvo, 2007), attention of highly anxious individuals is distracted by the anxiety related thoughts. Thus, instead of focusing on the main task, anxious individuals ruminate about the threatening situation, the stimuli or the potential failure. Hence, as Holyoak (2012) has pointed out, anxiety seems to place individuals in a dual task situation that definitely reduces the available working memory resources and in turn, changes analogical mapping from relational (based on common relations) to superficial mode (based on common features). Besides, it was argued that both the capability to integrate multiple relations and to inhibit distracting information during analogy-making depend crucially on the available resources (Cho, Holyoak, \& Cannon, 2007; Krawczyk, Morrison, Viskontas, Holyoak, Chow, Mendez, Miller, \& Knowlton, 2008; Sweis, Bharani, \& Morrison, 2012; Viskontas, Morrison, Holyoak, Hummel, \& Knowlton, 2004). To sum up, it seems reasonable to consider that state anxiety reduces the capability of an individual to integrate the relevant relations and to inhibit the irrelevant ones, which are directly connected to analogical mapping.

However, analogy-making involves not only choosing among various potential relational matches, but is a much more complicated process that integrates perception and encoding of the existing relations in the environment (among the many possible relations some are relevant for the analogy, others are not), building hypotheses about possible pairs of corresponding relations, and choosing among these hypotheses which are forming the most consistent mapping.

Anxiety could have an influence on all these processes, including the perception of relations. However, it was shown that threatening stimuli prompt participants to search faster for both threatening and non-threatening stimuli (Becker, 2009). Likewise, Phelps, Ling, and Carrasco (2006) reported that contrast sensitivity increases after a presentation of a fearful face. In addition, Pacheco-Unguetti, Acosta, Callejas, and Lupianez (2010) reported neuroimaging data suggesting that state and trait anxiety modulate differentially the work of the three attentional networks presumed by Posner and Petersen (1990) and Posner, Rueda, and Kanske (2007). State anxiety was associated with overfunctioning of the alerting and the orienting attentional networks, while trait anxiety with insufficiency of the executive control network. In other words, state anxiety reinforces bottom-up processing (i.e., perception and selection of relevant information), and traitanxiety hampers the top-down control (i.e., voluntary action control and conflict resolution). That is why Hristova and Kokinov (2011) studied the influence of anxiety on the perception of relations. They reported that people in heightened state anxiety are superior in encoding of relations between superficially dissimilar geometric figures: they were both faster and significantly more accurate than participants in the control group in recognizing identical relations between two sets of figures. Therefore, it was argued that the superior encoding of relations under heightened state anxiety may improve, instead of impeding analogical mapping. Indeed, some research supports this hypothesis.

Richert, Whitehouse, and Stewart (2005) showed that religious rituals, performed in high anxiety states, lead to a higher percentage of generated reflections (including ones, based on analogies) and that percentage increased significantly over a one-month time period. They argued that rarely performed religious rituals, accompanied by high physiological arousal become the focus of conscious rumination and in that way advantage the drawing of more and deeper analogies between the current anxious situation and the individual personal memory. This leads to a better memory for a given ritual and binds the religious ideas to personal experience. The reported results, however, were inconclusive, since arousal was manipulated through the ritual itself (high arousal and low arousal rituals) and analogies were only part of the interpretations that were measured.

Later, Feldman, Hristova, and Kokinov (2010) demonstrated that participants in high state anxiety were more prone to relational matches between superficially dissimilar stimuli instead of superficial matches between structurally dissimilar stimuli in a match-to-sample task. Participants were shown a sample set that consists of three geometric figures and were asked to indicate which of the two target sets of figures is more similar to the sample one. High state anxiety participants were significantly more likely to indicate the relational target instead of the superficially similar one, for a comparable amount of time
(i.e. the difference between RTs in the anxiety and the control group was insignificant). Thus, surprisingly, it was demonstrated that induced state anxiety can support analogies in a situation quite similar to the one used in the first experiment of Tohill and Holyoak (2000). Both experiments require a choice between superficially similar and relationally similar options. The authors (Feldman et al., 2010) discussed the controversy between the data and suggested that it can be potentially explained by the difference in the experimental procedures that possibly eliminated the benefits of the superior encoding (if any) for the anxiety group in the Tohill and Holyoak's case: maybe the 15 sec stimulus presentation used in the Tohill and Holyoak's study (Tohill \& Holyoak, 2000), but not in theirs ${ }^{1}$, had restricted the effect of the superior encoding of relations that was discussed above.

Alternatively, however, as Feldman et al. (2010) discussed, the same empirical inconsistency may be due to the difference in either the intensity of the induced state anxiety or the difficulty of the analogical tasks used in either or both studies. That particular explanation corresponds to the well-known Yerkes-Dodson Law (Yerkes \& Dodson, 1908) that postulates a nonlinear inverted U-shaped relationship between stimulus strength and the rapidity of habit formation for tasks varying in discrimination difficulties. Taking into account the fact that later, it was largely assumed that the same U-shaped relationship is also valid when describing the relation between (emotional) arousal and performance (Broadhurst, 1957), and that arousal is largely recognized as the physiological component of any emotional state, including anxiety, it is reasonable to assume that the studies of Tohill and Holyoak (2000) and Feldman et al. (2010) could have been run with anxiety states that differ in intensity. Unfortunately, the two studies differ in both the procedure used for anxiety induction $^{2}$ and the manipulation-check instrument ${ }^{3}$, so it was not possible to reject that explanation at that point. Moreover, those studies used different stimuli ${ }^{4}$ and tasks ${ }^{5}$. Hence, if one of the tasks was more difficult than the other,

[^94]the respective optimal levels of arousal will also differ, since the more difficult the task is, the lower the respective level of optimal arousal is.

Thus the goal of the present study is to replicate Experiment 2 of Tohill and Holyoak (2000), while explicitly varying the complexity of the task. And we expect interaction between the anxiety state (low and high anxiety) and the complexity of the analogy task. The complexity here is operationalized by the number of potential hypotheses that could participate in the competition for the best match. This is manipulated in the task by the number of alternatives offered among which the answer is to be chosen.

## Experiment: Many vs. Small Number of Alternatives

This experiment varies within-subject the number of the suggested alternatives for the answer. This seems an easiest way to manipulate the complexity of the task without changing the stimuli themselves: choosing between two alternatives is easier than choosing between four.

## Method

## Design

We used a $2 x 2$ mixed factorial design with two levels of state anxiety (anxiety and control) and two options for complexity of the task (choosing between 2 answers vs. choosing between 4 answers). The level of state anxiety was varied between-subject by serial subtraction task, described thoroughly in the procedure section below. The complexity of the task was operationalized as the number of possible alternatives for the answer and it was varied within-subject. Half of the trials for each participant required a choice of answer between 2 alternatives, the other half between 4 alternatives. The dependent variables of this study were the accuracy, defined as correct identification of the relational match, and the response time.

Between-subject counterbalancing: Stimuli were betweensubject counterbalanced with the number of alternatives (i.e. 2 or 4 alternatives for answer). In addition, the letters of the available alternatives for answer (i.e. A, B, C or D) were also balanced across stimuli and participants.

## Stimuli

The stimuli were 14 analogical picture-pairs with crossmapping (i.e., they allow both an attribute mapping of a key object and a relational one). Nine of those pairs were redrawn from the original stimuli used in the study of Tohill and Holyoak (2000) ${ }^{6}$. Taken as a whole, the pictures look

[^95]quite different from their originals, but they consist of the same relations and preserve the cross-mapping structure of their originals. We add 5 new picture-pairs that also have a cross-mapping structure. So, overall we used 14 black and white picture-pairs in our study. For all of them, the key object in the top picture (i.e. the circled one) corresponds to two objects in the bottom picture in the same picture-pair: in picture-pair 1 in Figure 1 the fisherman in the picture corresponds to both the fisherman and the seagull in the bottom picture. The former correspondence is based on shared physical characteristics and that is why, it can be considered as a result from an attribute mapping, while the latter is based on shared relations (i.e. they both catch the fish) and hence it can be considered to be based on a relational mapping. Similarly, the circled girl in the top picture of pair 2 (Figure 1), maps both the girl and the teddy-bear in the bottom picture. The former mapping is an attribution one (i.e. the two girls possess similar physical characteristics), the latter is an relational one (i.e. they both receive an injection).

Figure 1: Examples of picture-pairs that contain crossmapping. Picture-pair1 is a redrawing of one of the original drawings used in the Tohill and Holyoak study (2000).
Picture-pair2 is an example of one of the new stimuli with cross-mapping created purposely for the current study. Picture-pair3 is the training picture-pair, used to explain the meaning of relational correspondence.

## Procedure

Participants were tested individually in a soundproof cubicle. They were randomly assigned to the control or anxiety condition. All of them were informed that they would take part in a study on representation of numbers and they might be asked either to count backward or forward from a given number. They were told that the specific direction for each of them will be chosen randomly. However, since the counting procedure should be accomplished twice they were notified that we would asked them to take part in two short unrelated investigations inbetween: the first one, connected to relational reasoning and the second one, connected to an on-going standardization of a questionnaire for a Bulgarian population.

Participants in the anxiety condition were asked to count aloud backward beginning at 1000, 970 or 950 in increment of 13 . The starting point for each participant was randomly
assigned. Two experimenters took part in the experiment: one of them corrected the mistakes, while the other one measured the time and urged participants to count faster and faster, since the predetermined time of 45 seconds was about to expire. When the counting task was finished, one of the experimenters left the cubicle. Participants in the control condition were asked to count forward aloud beginning at 1 for 45 sec . They were instructed to count at a pace that relaxes them.

Both groups started the analogy-making task immediately after the counting. The procedure for stimuli presentation and the instruction given to the participants were analogous to those used by Tohill and Holyoak in Experiment 2 of their study (2000). Participants were told that they would be shoun picture-pairs one by one on the screen. Some of the objects in the top picture would be numbered and some of the objects in the bottom picture would be lettered. The two pictures will stay on the screen for 15 seconds before one of the numbered objects in the top picture will be circled in red. Their task is to indicate by pressing the respective button on the BBOX, which of the lettered objects from the bottom picture corresponds to the circled one from the top picture. They were trained to focus on the relations between objects with the robot example used by Tohill and Holyoak (2000) (Figure 1). Frist, the participants were asked to think and say, whether robot "A", "B" or "C" from the bottom picture is related analogously to the robot 1 from the top picture. Independent of the answer all participants received the same explanation: "Robot " 1 " corresponds to robot "A" because they took part in similar relations, i.e. they both are using weapons".

Then participants were instructed that some trials would require a choice between two alternatives, others between four alternatives. Finally, they were asked to indicate their answer as accurately and as fast as possible. If participants confirmed that they have understood the task and they have no questions concerning the experiment they move on to the target trails.

After the analogy-making task the participants filled out the Bulgarian adapted version of Spielberger's STAI (Щетински, Паспаланов, 1989). Then they count again forward or backward, depending on the condition and were not urged so frantically this time to count faster. In fact, the last counting was exclusively made to restore participant's mood after anxiety manipulation. Anxious participants were told that they have counted backward exceptionally well during their second turn. In addition, although we did not revealed the real hypothesis of the experiment, we told them that the counting task sometimes leads people to feel a little bit disturbed or tense, so if they feel in that way it may well be because of the task.

The whole experiment lasts between 15 and 20 minutes. The timing of events during the whole experiment is presented in Figure 3.

The experiment was double-blind: the experimenters knew that they should induce anxiety via the serial subtraction task and that we are looking for some differences in performance due to that anxiety. However
they didn't know what kind of differences were expected between conditions.

Figure 3: Stimulus displays and the timing of events.

## Participants

90 ( 44 female and 46 male) volunteers took part in this experiment. All of them were students at New Bulgarian University from different university specialties. The mean age was 23.5 years ranging from 19 to 39 years. The control group consisted of 44 participants, the anxious group - of 46. The groups were balanced on gender.

## Results and Discussion

The anxiety manipulation was successful; the mean state anxiety scores of STAI significantly differed between groups: the mean state anxiety for the anxious group was 40.59 ( $\mathrm{SD}=10.701$ ) and for the control group was 36.05 ( $\mathrm{SD}=9.977$ ). That difference in state anxiety turned to be significant tested with ANOVA: F $(1,89)=4.327$, $\mathrm{p}=0.040$. The mean trait anxiety scores, however, did not differed significantly between groups: $\mathrm{F}(1,89)=0.293, \mathrm{p}=0.590$ (means of 41.57 ( $\mathrm{SD}=10.100$ ) for the control condition and of 42.70 ( $\mathrm{SD}=9.661$ ) for the anxious condition). Hence, any difference between the groups should be due to that change in state anxiety, instead of some individual differences in trait anxiety. The difference in the state anxiety scores, however, is only 4.54 , while the same difference in the Tohill and Holyoak Experiment 2 was $9.2^{7}$. Therefore, any direct comparisons between the two experiments seem not well-grounded.

The mean percentage of relational responses for all conditions is presented in Table 1.
A Repeated Measures ANOVA with one within-subject variable (complexity of the task: task with 2 options and task with 4 options) and one between-subject variable (the level of state anxiety: anxiety and control) was carried out on the accuracy data. The main effect of state anxiety on accuracy was not significant $\left(F(1,88)=0.001, p=0.970, \eta_{p^{2}}\right.$ $=0.000$ ) but the main effect of complexity on accuracy was significant $\left(F(1,88)=8.996, p=0.004, \eta_{p^{2}}=0.093\right)$ such that

[^96]accuracy was higher when two alternatives were considered (86\%), compared to four (78\%).

Table 1: Mean percentage of relational mapping per condition.

| Condition | \%relational mappings |
| :--- | :---: |
| Control_2 alternatives | $89 \%$ |
| Control_4 alternatives | $75 \%$ |
| Anxiety_2 alternatives | $83 \%$ |
| Anxiety_4 alternatives | $81 \%$ |

There was a significant interaction between complexity and anxiety, $\mathrm{F}(1,88)=5.724, \mathrm{p}=0.019, \eta_{\mathrm{p}^{2}}=0.019$. The impact of complexity on accuracy was only significant for the control condition (Figure 4).
Interestingly, the $2 x 2$ Repeated Measures ANOVA on response time revealed a main effect of complexity ( F $(1,88)=6.606, p=0.012, \eta_{p^{2}}=0.070$ : response times were less for 2 alternatives than for 4 alternatives condition, means of 4255.093 msec and 4692.856 msec , respectively) but not of anxiety $\left(F(1,88)=0.027, p=0.871, \eta p^{2}=0.000\right)$. Besides, the interaction between complexity and anxiety was not significant: $F(1,88)=0.274, p=0.602, \eta_{p^{2}}=0.003$. Thus, the accuracy data are not explainable in terms of performance time, they are rather due to real differences in processing.

Figure 4: Mean number of relational mappings per condition.

To sum up, the obtained difference in accuracy but not in response time data only for the control group speaks in favor of processing that compensate the complexity of the task in high state anxiety. An increase in the number of alternatives slows the answers down significantly for both the control and anxiety groups. The accuracy, however, differs. If 4 alternatives require a higher level of inhibition to come up with a relational mapping as the results in the control condition seem to suggest, then the logical result would be that anxiety would diminish the accuracy for more complex tasks. Moreover, as Holyoak (2012) has pointed out, if anxiety reduces the available cognitive resources, crucial for the inhibition of irrelevant information, then it
would hamper analogical mapping even more than in the control condition. That seems not to be the case in our data: participants in the anxiety condition do not differ in terms of accuracy when searching for a relational match among 2 or 4 alternatives.

However, the fact that state anxiety fosters encoding of objects as well as relations (Hristova \& Kokinov, 2011) may suggest a plausible explanation of the obtained results. When the relational match is chosen between 2 and 4 alternatives, it is not only that the mapping becomes harder with the number of the available alternatives, the number of required relations that should be considered also increases. Hence, the state anxiety group would have an appreciable encoding superiority over the control group in the case of four alternatives: they will encode the necessary relations faster and may use the time for resolving the harder mapping. In other words, the superior encoding of the anxiety group may compensate for the difficulties in the subsequent mapping, associated with the more complex task. Of course, it is possible, actually quite probable, that the improvement of relational encoding and the suggested impoverished inhibition due to the state anxiety, depend on the level of anxiety. On one hand that may explain the inconsistency between the reported results and Tohill and Holyoak's data (2000, Experiment 2): the difference between the anxiety levels in the control and anxiety groups in their experiment was almost twice the difference in the current study. That might indicate quite different outcomes with regard to the Yerkes-Dodson Law (1908).

The experiment described here, however, points to an interesting interplay between the subprocesses of analogy making under anxiety.

## Conclusion

The data from this experiment suggest that anxiety influences differentially the encoding of relations and the inhibition of alternative hypotheses, which are crucial for the final analogical mapping. Complexity does change relational mapping under low but not under high state anxiety.

In a recent paper Vendetti, Knowlton, and Holyoak (2012) varied the semantic distance between analogical domains and showed that anxiety does not decrease the number of correct relational responses, but increases the number of false alarms in verbal $\mathrm{A}: \mathrm{B}:: \mathrm{C}: \mathrm{D}$ analogies. This was interpreted as switching to a non-analogy strategy which looks for the superficial overlap of the domains, rather than their structure. That explanation, however, does not seem applicable to our data, since the superficial overlap between the two structures represented in the two pictures of each stimulus pair are identical, but differ only in the number of relations that should be considered in the case of 2 and 4 alternatives.

Finally, the current conflict between the data in the field can be explained both via differences in the complexity of the tasks and in the obtained level of state anxiety, which in turn highlights the importance of experiments that
manipulate anxiety on at least three levels (in order to capture a particular nonlinear relationship between anxiety and performance on analogy tasks), while controlling for the complexity of the given task.

## Acknowledgments

We express our gratitude to Art Markman and Keith Holyoak, who gave us the opportunity to work with the original stimuli used in the studies, respectively of Markman and Gentner (1993) and Tohill and Holyoak (2000). We also thank the artist Kristian Sarbinov who redrew all the pictures and drew the new ones under our guidance. This study, would be impossible without the work of our experimenters Dilyana Nikolova and Pavlina Petrakieva, who did their best to apply the anxiety induction procedure without knowing its purport.

Finally, we would like to thank the anonymous reviewers for their helpful comments and suggestions.

This work has been supported by the European Office for Aerospace Research and Development under grant FA8655-10-1-3061.

# A Neural Model of Human Image Categorization 

Eric Hunsberger (ehunsberger@uwaterloo.ca)<br>Peter Blouw (pblouw@uwaterloo.ca)<br>James Bergstra (jbergstra@uwaterloo.ca)<br>Chris Eliasmith (celiasmith@uwaterloo.ca)<br>Centre for Theoretical Neuroscience<br>University of Waterloo, Waterloo, ON, Canada N2L 3G1

#### Abstract

Although studies of categorization have been a staple of psychological research for decades, there continues to be substantial disagreement about how unique classes of objects are represented in the brain. We present a neural architecture for categorizing visual stimuli based on the Neural Engineering Framework and the manipulation of semantic pointers. The model accounts for how the visual system computes semantic representations from raw images, and how those representations are then manipulated to produce category judgments. All computations of the model are carried out in simulated spiking neurons. We demonstrate that the model matches human performance on two seminal behavioural studies of image-based concept acquisition: Posner and Keele (1968) and Regehr and Brooks (1993).

Keywords: category representation; image categorization; neural engineering framework; vector symbolic architecture

## Introduction

Although studies of categorization have been a staple of psychological research for decades, there continues to be substantial disagreement about how the mind represents information about unique classes of objects. Theories involving prototypes, exemplars, and explanatory schemas have all been shown to account for only a subset of known categorization phenomena, and progress toward a unified theory of category representation has been limited (for reviews, see Murphy, 2002; Machery, 2009; Smith \& Medin, 1981). Historically, the difficulty in modelling category representation has been to balance generality and accuracy.

On one hand, many of the models developed from these theories have a fairly narrow scope of application. Consider, for instance, similarity-based accounts of concept reference; these models produce impressive results at matching human behaviour in tasks that involve feature comparisons (see Smith \& Medin, 1981), but they do not generalize well to other tasks that require the use of deeper category knowledge or explanatory inferences (see Murphy, 2002).

On the other hand, approaches with greater scope tend to pay a price in terms of predictive accuracy or viability. For example, Barsalou's (1999) theory of perceptual symbol systems is a more or less unified account of category representation, but it lacks a corresponding computational model (Dennett \& Viger, 1999). Rogers and McClelland's (2004) account of semantic cognition provides a powerful model that performs well across a range of categorization tasks, but employs both an idealized neural architecture and an idealized set of inputs (i.e. it is an abstract connectionist network that
does not use raw percepts as input). Many researchers now recognize that object perception and conceptual cognition are not distinct (Palmeri \& Gauthier, 2004), making it important that models integrate both perception and cognition.

In this paper, we argue that advances in our understanding of the visual system and new principles for the design of neural architectures can be used to overcome many of the difficulties in providing a viable, neurally grounded, computational model of image categorization. We use the techniques of the Neural Engineering Framework (NEF) (Eliasmith \& Anderson, 2003) to develop a model of category representation that connects retinal activity to high level cognitive judgments using a class of vector-symbolic representations called semantic pointers (Eliasmith et al., 2012). The model receives natural images as input, produces category judgments as output, and carries out intermediate processing in simulated neurons. The proposed model replicates human performance on two independent studies of human judgment in prototype-based and exemplar-based image categorization, with no changes to the model. Semantic pointer architectures have been shown to support several important cognitive capacities (e.g. Stewart \& Eliasmith, 2011; Eliasmith et al., 2012). Our study extends this line of research, showing that semantic pointers computed by a plausible visual system model can be used to replicate human category judgments.

## Model Description

We developed a model of human image categorization that consists of a feed-forward visual perception model (similar to Hinton \& Salakhutdinov, 2006) driving a vector-symbolic associative memory (see Gayler, 2003; Plate, 2003). The model was first constructed using a rate approximation of the spiking leaky integrate-and-fire (LIF) neuron model for the visual system and explicit vector computations for the associative memory. The model was then implemented fully in spiking neurons using the principles of the NEF.

The visual system component of the model is a sequence of feed-forward neural populations that compresses high dimensional input images into comparatively low dimensional vectors, which we refer to as semantic pointers. The first population, analogous to the retina and lateral geniculate nucleus (LGN), is a rasterized image, as would be captured by a conventional digital camera. Like the retina, a camera adapts to global lighting conditions and provides an image with standard intensity levels. Our (small) LGN population corre-
sponds to a square $30 \times 30$ image region that is best compared to a small portion from the centre of the visual field. The second population, analogous to visual area V1, comprises 2500 neurons with local connectivity: each neuron responds to a randomly chosen $9 \times 9$ patch in LGN. Neurons in the third (V2), fourth (V4), and fifth (inferotemporal (IT) cortex) populations (with size 900,400 , and 225 respectively) are connected to all neurons in the previous population. The activation pattern in the fifth population (with latency similar to visual area IT) is the semantic pointer representing the image stimulus. Representations generated in this manner are stored in an associative memory as category exemplars (during training), and used to probe the associative memory to yield a category judgment during testing (see Figure 2).

## Adaptation to Natural Images

A large fraction of neuron cells in visual area V1 are well modelled as luminance edge detectors (Hubel \& Wiesel, 1968; DiCarlo, Zoccolan, \& Rust, 2012). There is mounting evidence that visual system neurons behave as they do because they continuously adapt to statistical patterns in visual stimuli (Olshausen \& Field, 1996; Hyvärinen, 2009). Computer vision systems inspired by principles of adaptation to unlabelled visual images are among the best-performing computer vision systems, and reproduce several phenomena discovered by electrode recordings (Lee, Ekanadham, \& Ng, 2008; Le et al., 2012). One strategy for adaptation to unlabelled images is the autoencoder (Ackley, Hinton, \& Sejnowski, 1985; Rumelhart, Hinton, \& Williams, 1985), which was first applied to images by Cottrell, Munro, and Zipser (1987).

The connection weights of our visual system model were trained as a deep autoencoder, with an additional $\ell_{1}$ penalty on the hidden node activation rates to model the energy cost of spiking and encourage sparser activation patterns. The objective function for one layer is given by

$$
\begin{equation*}
O=\frac{1}{K} \sum_{i, k}\left(x_{i}^{(k)}-y_{i}^{(k)}\right)^{2}+\lambda \sum_{j}\left|q_{j}-\rho\right| \tag{1}
\end{equation*}
$$

where $x_{i}^{(k)}$ is the value of visual node $i$ for example $k, y_{i}^{(k)}$ is the autoencoder's reconstruction of node $i$ example $k, q_{j}$ is a running average of the activation of hidden node $j$, and $\lambda$ and $\rho$ control the importance of sparsity and the desired sparsity level, respectively. Uniquely, our autoencoder used an LIF response function as the feature activation function.

The autoencoder was trained on random $30 \times 30$ natural image patches chosen from the first 10 images of the van Hateren Natural Image Database (van Hateren \& van der Schaaf, 1998). with each patch normalized to zero mean and unit variance. We trained only on un-whitened images, which contain the full spectrum of spatial frequencies. We found that whitening was not required to extract Gabor-like filters from the statistics of the natural images (Figure 1), and was in fact undesirable since it removed some low-frequency features important for classification.

Figure 1: Filters from the first layer of the visual system, after autoencoder training on natural images. Like neurons in area V1, our model neurons detect luminance edges at a variety of frequencies and orientations.

Like Hinton and Salakhutdinov (2006), each layer of the autoencoder was pretrained individually; however, layers were pretrained as autoencoders, not restricted Boltzmann machines, allowing us to use an LIF response function for the neuron nonlinearity. The layers were then combined into a deep autoencoder and trained together using backpropagation.

## Semantic Pointers: Memory and Retrieval

We refer to the vectors processed by the model as semantic pointers because they function as compressed symbol-like representations that encode the statistically relevant aspects of the information they represent (Eliasmith, in press). In the non-visual component of the architecture, semantic pointers representing the compressed images are bound with category labels using the mathematical operation of circular convolution (see e.g. Plate, 2003). Subsequently, the bound representations are added to the memory via superposition. This process is captured formally by Equation 2:

$$
\begin{equation*}
M=\sum_{i=1}^{N}\left(P_{i} * L_{i}\right) \tag{2}
\end{equation*}
$$

where $P_{i}$ is a semantic pointer produced by the visual system from the $i^{\text {th }}$ raw image, $L_{i}$ is a vector representing the category label associated with the image, $M$ is the memory pointer, and $*$ is the circular convolution operator.

Once the memory is built up with a number of learned category exemplars, it can be used to produce categorization judgments in response to novel input images via the use of an inverse of the convolution operation. This inverse operation probes the memory for the category label that is most likely to fit the input image on the basis of prior learning. As a whole, the categorization process conforms to the following mathematical description:

$$
\begin{equation*}
c=\operatorname{argmax}_{c}\left[\left(P^{-1} * M\right) \cdot L_{c}\right] \tag{3}
\end{equation*}
$$

where $c$ refers to the resulting category judgment, $P^{-1}$ refers to the pseudoinverse of the semantic pointer corresponding to the test image, $L_{c}$ refers to the label pointer of category $c$, and $a \cdot b$ refers to the dot product of $a$ and $b$. For the rate model, these operations were implemented directly in vectors; for the spiking model, the operations were implemented in spiking LIF neurons using the NEF.

Figure 2: The schematic of our visual categorization model has three components. Left: The visual system comprises four populations of leaky integrate-and-fire neurons corresponding to the LGN, visual areas V1, V2, V4, and IT, which we take to represent a semantic pointer. The connections between these populations are adapted to natural scene statistics by unsupervised learning. Upper Right: The memory of our model is encoded as a single semantic pointer, which is the sum of several labelled training patterns (three are shown here). Labels have been bound to their corresponding image representations through the mathematical operation of circular convolution. Lower Right: At test time, our model labels visual stimuli by deconvolving the activity patterns of IT with the memory vector, and matching the result against several possible label decisions.

In short, the model builds category representations by storing compressed and labelled percepts, and produces categorization judgments by evaluating the similarity between an input percept and the exemplars stored in memory. However, since all labelled percepts are compressed into the same vector, there is significant interaction between stored percepts; this can be likened to creating a prototype based on the percepts. The model categorization system thus falls part way in between pure exemplar-based categorization and pure prototype-based categorization; it has elements of both.

## Experiment 1: Prototype-based Categorization

To account for the sort of phenomena that have traditionally motivated prototype theories of category representation, we tested the model on a task from Posner \& Keele's (1968) classic study of pattern classification. We chose to model Experiment 3 of the study, which was designed to test whether human subjects are learning about class prototypes when they only ever see distorted examples. In the study, subjects are trained to classify classify random dot patterns into three mutually exclusive categories. Each pattern consists of nine dots dispersed over a $30 \times 30$ grid, with each dot occupying one cell in the grid. The patterns used for training are generated from three prototypes; each training pattern is created by choosing a prototype pattern, and moving each dot according to a random distortion rule (see Figure 3.) Thirty (30) subjects were trained by corrective feedback to classify twelve 'high distortion' patterns (four from each category). After training, the subjects were asked to classify twenty-four pat-
terns without feedback: patterns from the training phase (2 per prototype, 6 total), the prototype patterns (3), prototype patterns with a smaller degree of distortion (6), new highly distorted prototype patterns (6), and entirely random new patterns (3). Subjects were tested on these patterns on two consecutive days, in terms of both accuracy and reaction time.

The protocol for evaluating our categorization model was nearly identical. We presented the model with the twelve training images, and it stored the semantic pointers associated with the labels and the images into the model's memory (see Figure 2). Then we presented our model with each of the twenty-four testing patterns. Figure 4 compares the accuracy of our model to the classification accuracy of the human subjects. Since our model lacks motor output, we did not evaluate it on reaction time. Figure 4 shows the results of our model; in sum, the model performs much like the human subjects.

## Experiment 2: Exemplar-based Categorization

To account for effects more commonly aligned with exemplar theories of category representation, we tested the model on a task from Regehr \& Brook's (1993) study of the comparative influence of analytic and non-analytic processes on categorization behaviour. The study involves a number of experiments in which subjects are asked to classify simple drawings of imaginary animals into one of two categories. The animals all possess an analytic structure that varies along five binary dimensions (e.g. a round vs. angular body), but the exact perceptual manifestation of a particular dimension value (i.e.

Figure 3: Sample stimuli for Experiment 1, modelling a classic study by Posner \& Keele (1968). The dot patterns are created by distorting three randomly drawn prototype images (left) with low (centre) and high (right) levels of noise. Subjects are trained to classify a set of twelve high-distortion patterns and tested without feedback on the same prototypes at different distortion levels.
feature) can vary across animals. For example, two animals might have round bodies, and thus be analytically equivalent to some extent, but the actual roundness of their respective bodies might be quite distinct (see Figure 5). This allows for the construction of stimuli sets that possess drawings that are analytically equivalent but perceptually dissimilar, along with drawings that are analytically distinct but perceptually similar. By training subjects through corrective feedback to classify these images into categories defined by an analytic rule, Regehr \& Brooks were able to test hypotheses regarding the relative importance of perceptual similarity and analytic structure during categorization.

In the experiment 1C of Regehr \& Brooks' study, 32 subjects are placed into one of two conditions and then trained to classify a set of eight images into two categories. For subjects in the first condition, the perceptual manifestations of a given dimension are constant across the images (See Figure 5, left). For subjects in the second condition, the perceptual manifestations of a given dimension vary across images (See Figure 5 , right). Every subject was trained to learn one of four labelling rules based on analytic structure. The rules had the form: An image is a 'builder' if it has at least two of X, Y, and spots, otherwise it is a 'digger'. The criteria X and Y referred to things like "long neck", "angular body", "short legs" and so on (see Regehr \& Brooks, 1993, for details). Training occurs through corrective feedback and is considered complete after five runs through the image set.

During the transfer phase of the experiment, subjects are asked to classify a set of sixteen images, eight of which are from the training set and eight of which are qualitatively similar, but new. The new images have been designed to pair up with a specific training image, and only differ on the dimension of "spots on body." Half of the new images belong in the same category as their twin from the training set, while the other new images have a different category from their twin. The idea motivating this experimental design is that if sub-

Figure 4: Comparison of human and model performance for Experiment 1. The model is able to account for human results when presented with the schema, low distortion (5), and high distortion (7) patterns. Occasional random errors by human subjects may explain the discrepancy on training examples. Error bars indicate $95 \%$ confidence intervals. Human data from Posner \& Keele (1968).
jects attend primarily to the analytic structure of the images during testing, then they should make relatively few errors on the new bad transfer items (because both analytic structure and perceptual similarity favour the correct judgment). Alternatively, if subjects attend primarily to similarity to past exemplars, then they should make relatively more errors on the bad transfer items (because perceptual similarity and analytic structure favour opposing judgments). The study is designed to test the effect of appearance on subjects' use of structural vs. perceptual mental representations.

We model experiment 1C of Regehr \& Brooks' study with the same model that we used in Experiment 1. We presented our model with the same eight training images used in the original experiment (though downsampled to fit in a $30 \times 30$ patch), drawn either in the composite style or in the individuated style. The semantic pointers created by the visual system, together with semantic pointers for the corresponding image labels, were stored into the model's memory, as described by Equation 2 shown in Figure 2. We tested the representations of our visual system by classifying the goodtransfer and bad-transfer test images, as well as the original training images. The accuracy of our model in each case is presented in Figure 6. Our model provides a good match to human performance, and replicates the effect that perceptually individuated stimuli foster substantially different error profiles than perceptually un-individuated stimuli.

Individuated Parts

Figure 5: Sample stimuli for Experiment 2, modelling experiment 1C of Regehr and Brooks (1993). (Left) Images are composed of interchangeable (composite) feature manifestations. (Right) Images expressing the same attributes are drawn in a more coherent (individuated) style. Regehr \& Brooks (1993) drew a distinction between good transfer and bad transfer test stimuli. A test stimulus is a good transfer case when the addition or removal of spots matches a training case with the same label, and a bad transfer case if adding or removing spots matches a training case with the opposite label. (Adapted from Regehr \& Brooks (1993) Figure 2A).

Figure 6: Comparison of human and model performance for Experiment 2. Our model accounts for the key difference in human performance on the good transfer (GT) versus bad transfer (BT) pairs for the individuated stimuli. Error bars indicate $95 \%$ confidence intervals. Human data from Regehr \& Brooks (1993).

## Discussion

Posner \& Keele's (1968) study is considered to be seminal in the development of prototype theory, and the result that subjects categorize the training patterns and prototype patterns equally well is taken to indicate that the subjects are abstracting information about the prototypes during the training phase. Our model's replication of this performance provides good evidence that our approach is capable accounting for the sort of prototype effects that the study uncovered. Interestingly, the spiking version of the model performs slightly worse than humans on the prototypes, indicating that it might be performing a more exemplar-based classification. However, we hypothesize that adding more neurons to the associative memory will attenuate this effect.

Regehr \& Brooks' (1993) study is more easily located in the tradition of exemplar theories of category representation. The fact that the model replicates the effects of interference from exemplar memories on more analytic categorization approaches suggests that it is well-equipped to deal exemplarbased phenomena. Moreover, the architecture of the model almost trivially assures that this is true-the contents of the associative memory essentially are exemplars produced from visual experience. It is thus reasonable to expect that phenomena found in studies using different kinds exemplars will be reproducible with the model.

Overall, the results of the simulations indicate that our model is able to account for an important set of phenomena closely associated with exemplar and prototype theories of category representation. The fact that the simulation employs a neural architecture for all stages of processing, and that it begins with raw image input, provides an important contribution to the current literature.

However, the model has several limitations as it stands. Nevertheless, we believe it is reasonable to expect that the architecture is capable of capturing an even wider range of phenomena. We identify two requirements of scaling that an architecture utilizing semantic pointers can likely achieve.

For one, it is possible to incorporate a more realistic account of category learning into the model. In the actual experiments, subjects learn the relevant categories through corrective feedback, and the feedback process continues either for a set number of trials, or until the subjects can accurately classify all of the items without error. By comparison, our model learns by memorizing a set of training images labelled with the correct category. In the model, the label/image relationships are forgotten when the model is shown another set of stimuli. However, the recent development of methods for introducing biologically plausible learning rules into the neural framework we employ indicates that this simplification could be removed in the future. Other cognitive models that make use of semantic pointers have already incorporated a form of reinforcement learning using such rules (e.g. Eliasmith et al., 2012).

Second, we believe it is possible to account for a broader range of categorization phenomena. The architectural prin-
ciples used in our model have also been used to construct what is currently the world's largest functional brain model, able to account for tasks involving serial-order recall, syntactic induction, and the manipulation of numerical concepts (Eliasmith et al., 2012). The fact that other large-scale cognitive models make use of the same representations and processes as this model provide good reason to think that a similar scale of functionality can achieved with models specifically focused on category representation. These two extensions will be the focus of future work.

## Conclusion

This paper has presented a neural architecture for categorizing visual stimuli using a semantic pointer architecture. Our model replicates human behaviour on two important studies of visual categorization: Posner \& Keele's (1968) and Regehr \& Brooks’ (1993). Modelling efforts have traditionally had to face the dilemma of choosing between plausibility and scope. The end-to-end neural model described here takes a suggestive first step in addressing this dilemma. Overall, this promise of scalability adds further theoretical significance to the empirical results we describe. The combination of a hierarchical visual model and a neurally implemented vector-symbolic architecture yields a new, effective approach to building models of category representation that are scalable, biologically plausible, and comprehensive, in that they capture the stages of processing from perception to judgment.

# How to improve on Quinian bootstrapping - a response to nativist objections 

Zoltan Jakab (zoltan.jakab@barczi.elte.hu)<br>Institute for Psychology of Special Needs, Loránd Eötvös University, Ecseri út 3 1097 Budapest, Hungary

#### Abstract

Quinian bootstrapping is Susan Carey's solution to Fodor's paradox of concept learning. Carey claims that contrary to Fodor's view, not all learning amounts to hypothesis testing, and that there are ways in which even primitive concepts can be learned. Recently Georges Rey has argued that Carey's attempt to refute radical concept nativism is unsuccessful. First it cannot explain how the expressive power of mental representational systems could increase due to learning. Second, both Fodorian circularity charges and Goodmanian problems of indeterminacy apply to Carey's examples of Quinian bootstrapping. I argue that Carey's examples of bootstrapping can be amended to escape Fodorian and Goodmanian objections. I suggest some ways to improve on our models of concept learning to this end. I also argue that skill learning is the way for mental representational systems to increase their own expressive power, that is, to enrich their conceptual repertoire beyond what compositionality alone affords.

Keywords: Quinian bootstrapping; nativism; concept learning; expressive power

## Introduction: Fodor's paradox

Jerry Fodor's famous argument for concept innateness has taken different forms. According to its early version (Fodor, 1975, 1981), all learning is hypothesis testing, and to formulate a hypothesis one needs to possess all the concepts that the hypothesis involves. Therefore, in the course of learning one can seek for evidence supporting or undermining a hypothesis, but formulating hypotheses will never result in the acquisition of new concepts. In order to work, this argument needs an immediate qualification. Some concepts are structured, whereas others are not; they are primitive. At any rate, this distinction holds on Fodor's own representational theory of mind which endorses compositionality. Complex concepts arise as combinations of primitives (or simpler complexes). For example, WHITE RAVEN ${ }^{1}$ is a complex concept which has two constituents: WHITE and RAVEN; the two constituents are related by a conjunction. Now if one wishes to test the hypothesis that White ravens are quite rare, and it is conceded that forming WHITE RAVEN out of WHITE and RAVEN counts as learning a new concept, then evidently hypothesis formation makes room for concept learning. For more complex cases the idea that compositionality affords concept learning does

[^97]often sound intuitively plausible. ${ }^{2}$ Hence Fodor's early view on concept acquisition, according to which primitive concepts cannot be learned, and so they must be innate. In Fodor $(1990,1998)$ this idea is supplemented by argument that most of our concepts are primitive, giving rise to radical concept nativism.

More recently, Fodor (2008) has found this conclusion much too weak, and formulated a stronger version according to which the obstacle to concept learning is not that most concepts are primitive, but rather that compositionality cannot increase the expressive power of cognitive systems. Very roughly, expressive power is the range of concepts and hypotheses (theories, conceptions) that a given representational system could formulate, or express, given its primitive symbols (concepts) and rules of combination. As we currently understand cognition, any case of learning seems to be underlain by some mental process that exploits compositionality: forming complex mental representations out of simpler ones governed by rules, plus adjusting certain parameters of the primitives. ${ }^{3}$ If this is how cognition operates, then all that learning can achieve is the manifestation of what's born with us: we actually come to express what we are innately capable of expressing. In formal logic, building new complexes out of primitives (symbols and rules of combination) does not count as increase in expressive power - only adding certain new primitives ${ }^{4}$ does. The same restriction seems to apply in the realm of mental representation, if indeed compositionality is the only game in town for cognitive theorizing.

In sum, since no cognitive mechanism that we can currently think of transcends compositionality, and compositionality cannot increase expressive power beyond one's innate endowment, no cognitive mechanism can increase the expressive power of mental representational

[^98]systems. Now if genuine concept learning requires increase in expressive power, then no cognitive mechanism that we can currently think of amounts to genuine concept learning - only triggering of some sort. Thus the challenge is: supply a theory of cognition which can somehow pass beyond the limits of ordinary compositional systems, and is a candidate for expressive power increase. This seems like a challenge that is next to impossible to meet. This is how I understand Fodor's claim (2008) that it is true and a priori that the whole idea of concept learning is per se confused.

In the rest of this paper I first look at Susan Carey's (2009) response to Fodor's challenge. Then I briefly present Georges Rey's (2012) critique of Carey's views. Finally, I suggest some ways to address Rey's and Fodor's critique and reinstate concept learning roughly along the lines Carey proposed.

## Quinian bootstrapping

Susan Carey (2009) makes the following claims about concept acquisition. First, some of our concepts are innate and modular in origin, whereas the majority of our concepts are constructed out of the innate resources and originate from the explicit knowledge systems (roughly, domain general central systems). Second, the newly constructed concepts have more expressive power than the innate system. Third, Carey suggests a mechanism of acquisition for the second set of concepts that is allegedly more powerful than ordinary compositionality based on formal logic. This mechanism is called Quinian bootstrapping (hereafter QBS), and a number of examples of it are supplied throughout Carey's book. The general scheme of QBS is that in trying to understand some new ideas (e.g., fractional numbers, or density as mass per volume), children first form an ordered set of empty placeholders ("mental symbols") which are then gradually filled up with relevant content as a result of analogical reasoning. Empirical evidence for transition from an initial to a more powerful set of concepts involves within-child consistency of performance over a wide range of relevant tasks, and observations that the acquisition of the new set of concepts is difficult. That is, initially children try to assimilate the new terms to their earlier concepts - for instance, they take numerals to be quantifiers of some sort.

Carey's answer to Fodor's argument in particular is that QBS constitutes concept learning, because it does not consist in construction from antecedently available concepts using the machinery of compositional semantics alone. The newly bootstrapped concepts are definitional primitives in Carey's view, therefore they cannot arise from logical construction. Carey takes this line of argument to undermine Fodor's claims that (i) all learning mechanisms reduce to hypothesis formation and testing, and that (ii) the relevant hypotheses must be formed in terms of available concepts via compositional semantics. In addition to the details she herself provides, Carey endorses other proposals that primitive concepts can be learned (Margolis, 1999; Margolis \& Laurence, 2002).

## Nativist objections redrawn

Rey (2012) argues that even though Carey supplies valuable data on how children in fact acquire concepts, she fails to meet Fodor's nativist challenge. This is so because she conflates certain semantic issues, namely how expressive power might increase, with epistemological ones, that is, cognitive accounts of mental representation and its development. In logic, expressive power increases only if new primitives (e.g., operators, predicates) are added to a logical system - primitives which cannot be expressed by combinations of the antecedently available ones. The development of mental representation, on the other hand, includes episodes in which new complexes are formed out of certain innately available primitives. So how could QBS increase the expressive power of mental representational systems?

In addressing this issue, Rey points out an interesting parallel between Quinian bootstrapping and Ramsey sentences. Ramsey sentences are logical formulas that serve to define certain new theoretical terms by specifying their relations to already given old terms. A Ramsey sentence is a huge formula that is a conjunction of all the claims made by some theory. This conjunction involves all the relevant concepts: old ones, and new ones which are to be theoretically defined by the entire formula. The Ramsey sentence contains a unique existential quantification of each of the new terms. For example, on certain varieties of functionalism about the mind, types of mental states are characterized by the relations that they exhibit to other states (mental states, stimuli, and behaviors). Here the old terms are those of stimuli and behaviors; the new ones are those of mental states. For instance, the mental state of hunger is elicited by certain bodily conditions, it tends to evoke thoughts about food and food-seeking, and food-seeking behavior (unless some higher-order motivational states like the desire to lose weight cancel that behavioral effect out). Ramsey sentences could also be formed about theories in other domains of science.

According to Rey, this way of introducing new terms is reminiscent of Quinian bootstrapping. As we have seen, QBS consists in introducing some new set of empty placeholder symbols together with the relations in which they stand to one another, then gradually filling up the placeholders with content. The analogy between Ramsey formalism and QBS may not be perfect, as only the former assumes that the meaning of the newly introduced theoretical terms is exhausted by their relations to other terms. Rey then suggests that even if Ramsey sentences cannot capture the format of mental representation, they can at least capture its content. Mental representation probably does not have the format of Ramsey sentences, but some Ramsey sentences might have content equivalent to conceptual representations in the mind.

Ramsey-sentences can even capture the general type of content-enrichment that arises from locking to new environmental kinds. Simply adding a rigidifying operator (Kaplan, 1978) to the logical devices utilized by Ramsey
sentences would capture the reference-fixing aspect of cognitive architecture. Kaplan's dthat operator has the following interpretation: dthat $\mathrm{F}:=$ the unique thing that is F in the actual world, but not in all possible worlds, where F is some non-rigid role concept. For example, 'watery stuff' picks out $\mathrm{H}_{2} \mathrm{O}$ in the actual world (but not in all possible worlds). 'dthat watery stuff' designates $\mathrm{H}_{2} \mathrm{O}$ - the actual filler of the watery-stuff role - in every possible world. This is also the semantic function of Fodorian conceptual primitives like WATER: according to Fodor, the concept WATER refers to the very natural kind that happens to fill the watery stuff role on Earth in our world. Therefore these dthat expressions can be equivalent in content (if not equivalent in format) to referring conceptual primitives. The question now is, may dthat expressions as reference fixers increase the expressive power of a representational system into which they are introduced? Rey notes that this is a purely logico-semantic issue which is crucial for resolving the nativism debate, still empirical evidence concerning concept acquisition appears irrelevant to it.

Rey still acknowledges that some form of QBS, or the introduction of new referring primitives, might increase the host system's expressive power. However, currently we cannot see how this could happen, because Carey's solution cannot adequately handle Fodorian problems of circularity and Goodmanian worries of indeterminacy. ${ }^{5}$ Rey's argument for this claim is based on one of Carey's key examples, the acquisition of NATURAL NUMBER. On Carey's account, the crucial step of induction in this process is when the child notices that the numerals name successive sets each of which has one more member than the previous one (Carey, 2009; Rey, 2012). This noticing, however, could not happen without tokening the concept ONE MORE THAN, aka SUCCESSOR, which is the very essence of the concept NATURAL NUMBER. Without tokening SUCCESSOR the child could generalize in a number of other ways when seeing the sets in question, never arriving at the proper meanings of the numerals. Thus Carey's bestelaborated example of Quinian bootstrapping is still subject to both Fodorian and Goodmanian worries.

Rey also supplies some examples to argue that known cases of analogical reasoning (a crucial process in QBS) are subject to the same objections. He says in his footnote 13: "Or consider the bewildering analogy often provided in introductions to General Relativity, in terms of a rubber sheet, whose shape is of course ordinarily deformed by rolling onto it a heavy metal ball. 'The curvature of fourdimensional space-time is just the same,' we're told, 'except that there's no rubber sheet, no gravity and the deformation

[^99]occurs in four dimensions'! Analogies may help in causing the manifestation of a concept, but it's hard to see how they'd be sufficient for the bringing out the possession of one." Thus it seems that nothing short of innately possessing concepts can result in their manifestation. We still cannot see a non-circular account of concept construction that can also handle the inherent indeterminacy in induction.

## Getting out of the circle

In this section I propose a slightly amended, non-circular account of bootstrapping SUCCESSOR, trying to save Carey's original account. I shall also point out some ways to handle Goodmanian worries associated with the same concept. Then I suggest one example of analogical reasoning in order to provide an existence proof that analogies play a role in concept learning, and not just triggering. Following these examples, I shall argue that some forms of procedural learning, namely the acquisition of certain skills is necessary for learning new referring concepts, and this kind of learning is essential for increasing expressive power in human minds. Finally, I briefly discuss Fodor's new nativist argument outlined in the Introduction.

## Bootstrapping SUCCESSOR

Step 1. Imagine that a child is playing with toy horses and riders; she has a bunch of both, and she is trying to mount exactly one rider on the back of each horse. Two general outcomes are possible: (i) each horse has a rider, and each rider is sitting on a horse (ii) there remain horseless riders, or riderless horses. Suppose that when (i) happens it makes the child happy giving her a feeling like "it's all nice and complete". So (i) is a Good Case. On the other hand, (ii) leaves the child with a mild frustration, as the pairing activity cannot be finished - this is a Bad Case. Thus a Good Case is one where the pairing activity can be completed, and there remain no unpaired objects in either set.

Step 2. Suppose that the child, on carefully observing a Good Case, notices two possible groupings. One is that all members in each group (e.g., horses, riders) look alike; the other is that two different objects (a horse and a rider) constitute a pair. Looking alike is judged on the basis of perceptual similarity; but the immediate question is, does the child need to be born with PAIR, in order to proceed with the second recognition? The answer is no: let us make a little detour to see how PAIR might be bootstrapped.

Here we take for granted something like Margolis and Laurence's account of primitive concept acquisition (Margolis, 1999; Laurence \& Margolis, 2002). The first step in bootstrapping PAIR is to take two generic kind-concept frames, and fill into them the two perceptual prototypes (horses and riders, in our case). I take it that such generic concept frames have two placeholders: one for perceptual information (I call this placeholder the P-slot), the other for abstract information, represented by other concepts (A-slot). For any particular concept, these slots may have a varying amount of information in them, from minimal to very rich.

Suppose that in the horses and riders case, the A-slot of both concepts initially contains only the core cognition concept OBJECT. What distinguishes the two concepts is the perceptual information in their P-slots. In order to represent a particular pair of objects, the two concepts need to be linked by means of association. In the present case this is based on the fact that the two were manipulated together (one in the child's left hand, the other in the right, etc.). To obtain the generic concept PAIR from context-dependent representations of particular object pairs, we need abstraction which in our case takes the form of feature elimination. While forming representations of different pairs of objects on different occasions, the child notices that there are varying as well as constant features in these representations. That there are two concept frames (i.e., two objects connected in experience) is the constant part; P-slot contents, and the experiences that set up the associative connections may vary. Thus PAIR will be the abstract schema TWO CONNECTED OBJECTS (i.e., two generic kind concept frames linked by association).

We can now return to SUCCESSOR. In Step 3 the child notices that the Good Cases consist of pairs only, whereas the Bad Cases contain leftover single entities for which pairing cannot be finished. Once again a move of feature elimination is needed: for being a Good Case, the quantity of pairs does not matter. Quantity of pairs may be represented by the analog magnitude system, so there is no threat of circularity: we do not need NATURAL NUMBER to account for GOOD CASE, for instance.

Step 4. Suppose that the child does further experiments with some Good Cases, trying to find out how to turn a Good Case into a bad one. She discovers that adding pairless objects of one of the two kinds will do. She then notes the minimum effort to spoil a Good Case: adding exactly one object (horse or rider, as in our example). The concept ONE is available from set-based quantification, so we have still not closed Fodor's circle. ${ }^{6}$ To summarize, the recipe for obtaining SUCCESSOR is this: take a Good Case, spoil it with the minimum effort. Disassemble the pairs; form two groups of the two kinds of objects. Now the kind group that was added an extra item a moment ago is the successor of the other (redo the pairing if you forget which one is which). At the end, MINIMALLY SPOILED GOOD CASE will serve as SUCCESSOR.

Let us now turn to Goodmanian worries. The question is, what cognitive factor is shepherding mental construction in this particular direction, given that there are so many other possible ways to assemble structures from representational primitives? Perhaps the directing forces are the innate concepts PAIR and SUCCESSOR, lurking in the background? That need not be the case. Children's and

[^100]adults' constructions do in fact proceed in many different directions, forming a lot of representational complexes. There is a lot of search going on in the vast logical space of compositional representation, but many of the constructs are soon dropped as useless - either as a result of social influence, or in an effort to understand what is going on in the environment. Some constructs, however get promoted.

For an example, imagine that Daddy and little Victor are playing a board game. At some point, little Victor wants to know who has more game pieces on the board. As a matter of fact, Daddy has six blue ones, whereas little Victor has eight red ones. Little Victor stubbornly thinks that the proper way to count is $1,2,3,4,2,2,2,2$, (repeating 2 ad infinitum). He notices that Daddy's set of pieces maps onto 2, and so do his ones, therefore he tentatively concludes that both of them have the same number of pieces. But he also has the impression that the blue and red pieces are different in number. He manages to prove this by pairing them up, producing a Bad Case. Meanwhile, Daddy is vehemently arguing that he is doing his counting in the wrong way, and offers a different system. Now unless little Victor is no smarter than the present prime minister of Hungary, he will quickly realize that something has gone wrong with his system of counting. So he switches to the one proposed by Daddy, and resolves the inconsistency. Very similar stories could be told about learning to play chess, and a number of other cases; note that this solution is quite close to Goodman's original one, namely entrenchment (Goodman \& Putnam, 1983).

## Analogical reasoning

I declare up front that at present $I$ do not have a bootstrapping story for CURVATURE OF FOURDIMENSIONAL SPACE. I can only show, using a much simpler example, that analogical reasoning may indeed be an important means of actually learning, and not just triggering, a new concept. Here is my story. The carburetor was invented by two Hungarians, Donát Bánki, and János Csonka. According to an anecdote, a key step in the process happened when Csonka was walking by a florist in a busy boulevard of Budapest. The lady was using her spray bottle to water her flowers. Csonka saw the event, and immediately realized that that was the way to manage fuel introduction into the cylinders of internal combustion engines (instead of evaporating gasoline by engine heat, as was done in some early motors). This is a fairly simple, yet powerful analogy: the recipe is, replace water by gasoline, and flowers by steel cylinders, and you pretty much got the carburetor. So we can meaningfully claim that feeding the engine with gas is like using a spray bottle - only there is no spray bottle.

This solution, however, does not generalize to the concept of four-dimensional space. An important difference between the carburetor and the 4D-space cases is that all by itself the image of a steel ball rolling on a rubber sheet may not give a physics student the crucial insight into the target concept; this image may simply be an initial intuition pump, or even
just a funny attention-grabber. I presume that a convincing account of how to learn FOUR-DIMENSIONAL SPACE will be much more complex than that of learning CARBURETOR; still we seem to have an existence proof that analogies may contribute to genuine learning.

For another example, why suppose that LIGHT BULB must be innate, given that learners can construct this concept somewhat similarly to how Edison constructed the light bulb itself? It is a matter of accumulating experience to realize that white hot metals may serve as light sources especially if they don't melt, don't burn, and don't set your house on fire. Satisfying these constraints was the result of a long cultural development, and an obvious example of skill acquisition. The crown was put on by the inventor, but he was far from being the only one to contribute. And while the relevant skills are possessed only by some expert workers, the basic principle can be understood by virtually anyone.

## Reference and ramsification

Recall Fodor's new argument for nativism, according to which (P1) compositionality cannot increase expressive power, and (P2) expressive power increase is the hallmark of concept learning, therefore (C) from the principle of compositionality no account of concept learning can be derived. What supports this argument - in particular, what supports (P1)? Fodor and Rey suggest the following analogy. Just like in formal logic, where compositionality cannot increase expressive power, in mental representation systems (MRS) combination cannot increase expressive power either. To this analogy the immediate reply is, minds are not exactly like systems of formal logic - not even on Fodor's own view. Next, however, Rey contends that no matter how the format of MRS differs from formal logic, contentwise it can be captured by logical formalism. Now the argument becomes, IF the content of MRS can be captured by logical formalism, AND compositionality in logical formalism cannot increase expressive power, THEN the kind of compositionality that obtains in MRS cannot increase expressive power either, never mind the differences in format. This is a giant leap. It needs support, which Rey provides by (i) reiterating the circularity objection and Goodmanian worries, trying to show that they undermine Carey's examples of QBS, and (ii) arguing that not even newly acquired primitive concepts can increase the expressive power of MRS. We have seen that via (i), the general argument leads us back to particular learning accounts: if learning theories can take care of circularity and Goodmanian indeterminacy objections, that will undermine Fodor's and Rey's nativist arguments. In defending (ii), Rey makes two points. First, conceptual role is essential for concept possession; a primitive concept that causally covaries with some environmental kind, but is causally or inferentially detached from other concepts does not increase the expressive power of its host MRS. Second, consider Twin-Earth thought experiments: any denizen of Earth or Twin Earth has the power to represent either XYZ or $\mathrm{H}_{2} \mathrm{O}$, even before one of these substances appears in their
environment. In this sense, there is no increase in their mind's expressive power at all.

Here is my response to this argument. Referring is an ability; it is not a logical construct. If you have the ability to refer to Fs, then some mental symbol of yours carries information about Fness. Information carried about Fness is a semantic issue, whereas the mechanism or ability that secures the locking and thereby endows the symbol with content belongs to metasemantics. As such, it is not captured by logical formalism. The distinction between skills or procedural knowledge on the one hand, and factual knowledge on the other, is a familiar idea in philosophy. Putnam (1981) argued that logical formalism can never unambiguously determine its own interpretation. However, the referential grounding of symbols in human minds reduces interpretational indeterminacy. It has also been argued that procedural knowledge does not reduce to factual knowledge captured by logical formalism or statements in natural language (Carroll, 1895; Winch, 1990; see also Lewis, 1990).

Keeping semantics and metasemantics separate is quite important. Metasemantic factors are the sources of mental (representational) content, thus candidates for a source of increasing expressive power. Semantics alone cannot account for the origin of mental content. Metasemantics does that, and a metasemantic account of how mental content arises may well involve psychological mechanisms - for example, skill leaning.

Some examples of perceptuo-motor skills that I have in mind are the following.
(1) The cultural development of artifacts. The example of light bulbs above is a case in point: the creation of new artificial kinds comes with the invention of new conceptual primitives.
(2) Deference. Learn to communicate with experts, ask for information. Is this ring made of gold or brass? Is that animal an insect or a crustacean? By gaining relevant information, you can ground new concepts.
(3) Actions. Learn or invent new types of action, and call them dances, martial arts, singing, etc.
(4) Theoretical concepts. This is admittedly the most difficult case, since on current views in philosophy of science theoretical concepts are not introduced by skill learning in the first place. Rather, they are formulated on the basis of earlier theories, and scientists' creativity. For example, scientists first inferred that electrons must exist (an exercise of already possessed inference skills), then they developed methods to detect them (detection of electrons was a newly constructed skill routinely applied later), and not the other way around. I agree that a lot more needs to be said about theoretical concepts to make a skill-based account of concept learning more plausible. One way to address this problem is to develop further the ideas of concept construction supplied above, and applying them to the acquisition of theoretical concepts. The kind of constructivism that I have proposed so far is Piagetian in
spirit, but a possible way to develop it further is to consider certain neoconstructivist approaches (e.g., Johnson, 2009).

In his paper, Rey distinguishes between functioning psychological expressive power, and semantic expressive power; he argues that learning can increase the former, but not the latter. Here is how this distinction is to be understood. Rey thinks that learning and innateness are not incompatible. Hypothesis testing and experience may select from innately specified concepts and hypotheses, similarly Chomsky's principles and parameters view of the acquisition of grammar. Experience may tell us which of the innately available concepts of ours are useful in understanding our environment at many different levels of description, ranging from social to microphysical.

I am defending a view stronger than this one: as I have argued, there exist ways in which even the semantic expressive power of human minds may increase. I agree with Carey that many of our concepts arise in ontogenesis as a result of bootstrapping from experience and a smaller set of innate concepts. Therefore they are not innate in the sense Rey thinks they are. New logical constructions out of antecedently given concepts do not increase expressive power, but new logical constructions which also contain new referring primitives inexpressible in antecedent vocabulary do so, at least according to the standards of formal logic. Moreover, as I have argued, skill learning paves the way to learning new referring primitives.

Let me add one more note on the skill-based account presented here. Fodor would say that even if you learn the skill to refer to Fs, this does not entail that you learn the concept F - you may simply trigger an innate concept by learning a skill.

What motivates this distinction between learning the relevant skill whereas only triggering the concept? In Fodor's view, what keeps this distinction compelling is that no particular skill is necessary for possessing the concept F. The criterion of concept possession is locking a mental symbol to its extension, and locking is multiply realizable (Fodor, 1998). Here is my reply. The idea that referring is an ability can easily accommodate multiple realizability: there are many different skills that can ground a given concept. My concept ELM is a deferential one at present, but I could become an expert at recognizing trees in the future. One needs to learn some of a range of relevant skills in order to come to possess a particular referring concept.

Finally, note that Fodor's new, expressive-power-based argument for nativism is not nearly an a priori one. As we have seen, this argument takes us straight back to particular theories of concept learning when we check the support for its premises. I think the really serious problems of concept learning remain Fodor's circularity objection, Goodmanian indeterminacy, and Fodor's other question of how concept learning can be anything other than hypothesis formation. Solving these problems takes a lot of work: we need to devise detailed accounts of the acquisition of particular concepts, or types of concepts. But that is just what Susan Carey started doing in her book.

## Acknowledgments

An earlier version of this paper was presented at the Budapest Workshop in Philosophy of Mind and Cognitive Science at Central European University, May 14, 2012, as a commentary on Georges Rey's talk. I wish to thank the organizers Katalin Balog and Barry Loewer for the invitation, and Georges Rey for critical discussion. I am also grateful for the valuable commentaries by the four anonymous reviewers of this submission.

#### Abstract

Can our gestures help us think, and, if so, how? Previous work suggests that they can. Here, students, alone in a room, studied descriptions of environments for later tests of knowledge. The majority of participants spontaneously gestured while reading the descriptions, and most of those also gestured while answering true-false questions. They did not gesture proportionately more time for environments with many landmarks than for environments with few. Their gestures laid out the environments, primarily using points to places and lines for paths. Descriptions and questions accompanied by gestures were remembered more accurately. Participants rarely looked at their hands. Gestures seem to promote learning by establishing embodied representations of the environments.

Keywords: Gesture; embodiment; spatial representation; spatial memory; route/survey perspectives; navigation.

## Introduction

Gestures serve many ends and have many forms. People gesture in communications to others, but also for themselves, that is, they gesture to think (Goldin-Meadow, 2003; McNeill, 1992). Gestures for thinking help thinking in different ways. They help people find words (Krauss \& Hadar, 2001). They offload memory (Cook, Yip, \& GoldinMeadow, 2012; Goldin-Meadow, Nusbaum, Kelly, \& Wagner, 2001). They help people perform mental rotation (Chu \& Kita, 2008; Wexler, Kosslyn, \& Berthoz, 1998; Wohlschlager \& Wohlschlager 1998). They help people count (Carlson, Avraamides, Cary, \& Strasberg, 2007).

Gestures are actions in space, and as such, can readily represent spatial structures and spatial actions. In fact, gestures help people solve spatial problems (Kessell \& Tversky, 2006; Schwartz \& Black, 1996). Interestingly, in solving spatial problems, gestures can serve much like diagrams. When given paper and pencil during problem solving, one group diagrammed the same spatial problems that another group gestured to solve (Kessell \& Tversky, 2006). Diagrams also offload memory, but they serve cognition in many other ways. Creating a good diagram entails extracting the crucial information and structuring it to represent a problem to be solved or information to be
comprehended and learned felicitously, yielding an integrated external model of the information that can be inspected and mentally manipulated (e. g., Tversky, 2011). Gestures are crude, and as such almost necessarily abstract. They can also create integrated external models. In explaining complex environments or scientific systems, people produced a coordinated and integrated series of gestures that modeled the spaces of environment (Emmorey, Tversky, and Taylor, 2000), family trees (Enfield, 2003), and scientific processes (Kang, Tversky, and Black, 2013) to be learned.

People gesture to explain spatial environments to others, creating external models with their hands. Will they do so for themselves, as aids to comprehension and memory? Here, we investigate whether people, alone in a room studying descriptions of complex environments will gesture for themselves. If so, what is the nature of their gestures? And does gesturing help them learn and remember the environments?

Gesturing could help learning and memory indirectly by off-loading memory to another modality. Gestures have been shown to be effective in off-loading memory during explanations (Goldin-Meadow, et al, 2001). But gestures could also help learning and memory in direct ways, by constructing an external model of the environment to be learned. Half the environments participants studied had 4 landmarks and half had 8 landmarks; the latter should put greater stress on working memory (e. g., Jonides, Lewis, Nee, Lustig, Berman, and Moore, 2008). If the primary role of gestures is to offload working memory, participants should gesture more when studying descriptions with more landmarks. If the primary role of gestures is to construct a model of the environment, much like a diagram, then there is little reason to expect more gesturing for the environments with more landmarks. Gestures can reflect mental representations (e. g., Alibali, Bassok, Olseth, Syc, and Goldin-Meadow, 1999). Description perspective was manipulated because route and survey descriptions yield different mental representations early (but not late) in learning (Lee and Tversky, 2005).

## Method

Participants. 48 ( 28 female, 20 male), primarily graduate students from Columbia University, were paid to participate in the study. Participants were native English speakers or have graduated from an English speaking high school.
Descriptions. The environments had 4 or 8 landmarks. There were three outdoor environments, Etna City, Chinatown, and the Financial district, and three indoor environments, a spa, an electronics show, and a grocery store. There were 8 landmarks and 4 landmarks versions of each of these.

There were also versions of each environment from route $(\mathrm{R})$ or survey (S) perspectives. A route perspective takes an imaginary traveler, you, through an environment describing the turns and landmarks with respect to "you" in terms of your left, right, front, and back. A survey perspective takes an overview of an environment and describes landmarks with respect to each other in terms of north-south-east-west. The route descriptions always began with cardinal directions so that participants could answer questions from a survey perspective. The descriptions and the environments were based on earlier work (Taylor \& Tversky, 1992).

The average length of the 8R descriptions was 141 words, of the 8 S descriptions, 127 words, of the 4 R descriptions, 69 words, and of the 4 S descriptions, 72 words. Table 1 shows an example of a description of an outdoor environment with 4 landmarks from a survey perspective, and of an indoor environment with 8 landmarks from a route perspective.

## Table 1: Examples of descriptions

## Example 1: 4S outdoor environment

Etna is a charming town nestled in an attractive valley, entered on River Highway. River Highway runs eastwest at the southern edge of the town of Etna. Toward the eastern border, River Highway intersects with Mountain Rd, which runs north of it. At the northwest corner of the intersection is a gas station. North of the gas station, Mountain Road will intersect with Maple Ave, which runs west.

## Example 2: 8R indoor environment

Rock Creek Center is a showcase for new electronic devices. Enter Rock Creek Center from the east side of the building near the southeast corner. As you enter, you see, on the left wall, a Bulletin Board. Past the Bulletin Board, on your right is the Video Camera room and on your left is the Office stretching to the corner of the building. Past the office you are forced to turn right and you will find the Cafeteria on your left stretching to the corner of the building. After the Cafeteria, you are forced to turn right and you will find a large room with Mobile Phones on your left. On your right you will see the Televisions room. At the end of the hallway, turn right and you will find the Laptop Center on your left. Past the Laptop Center, you will return to the entrance on your left.

Design. Each participant read four descriptions, one with 4 landmarks and one with 8 landmarks from each perspective. The specific environment for each condition was chosen from the set of three outdoor environments and three indoor environments. All variables, size, perspective, environment, order were counter-balanced and appeared equally often across participants.
True-false Questions. Verbatim and inference statements were designed for each description, 10 for the 8 landmark environments and 6 for the 4 landmark environments. For the 8 landmark environments, there were 2 statements taken verbatim from the text with the same perspective, 2 statements taken verbatim from the text with the other perspective, and 6 inference statements, 3 route, and 3 survey. For the 4 landmark environments, there were a total of 6 statements: 1 verbatim from the route perspective, 1 verbatim from the survey perspective, 2 inference from a route perspective, and 2 inference from a survey perspective. Inference statements could be verified from information provided in the descriptions. Half of the statements were true and the other half was false. The statements were presented in a random order for each participant. Table 2 shows examples of true/false statements for Etna.

Table 2: Examples of true/false statements

|  | Verbatim | Inference |
| :---: | :--- | :--- |
| Route | Going east on River <br> Highway, at the <br> intersection with <br> Mountain Rd, you will <br> find a gas station on <br> your left. | From Mountain Rd, <br> turn right on River <br> Highway and you <br> will have the Gas <br> Station on your <br> right. |
| Survey | North of the gas <br> station, Mountain <br> Road will intersect <br> with Maple Ave, <br> which runs east. | South of Maple Ave <br> to the west of <br> Mountain Rd is the <br> Gas Station. |

Procedure. Participants first signed a consent form, assenting to participating in the experiment and to being videotaped. They were additionally asked for permission to show their videos in presentations of the research. They then completed a paper version of the Mental Rotation Task (Vandenberg \& Kuse, 1978), a common test of spatial ability.

Participants were seated in front of a Mac OS X 10.7, as shown in Figure 1. Video records of the computer screen and front views of participants were captured with Silverback© software, and participants' side views with a videocam. The experimenter explained the procedure to each participant: "In this study you will be asked to read 4 text descriptions of environments. After reading each description, your memory for the information in the text will be tested. You will start with a practice text description. Throughout the study, you will not have access to a
keyboard and will send commands to the computer with your voice." The participants responded verbally, saying "next", "yes", or "no" when appropriate, to advance from screen to screen. Their responses were analyzed by the Mac speech recognition program and used to advance screens and record responses. This left participants' hands free to gesture, on or off the table.

Participants first had a practice trial. The first screen explained the task: "You will be asked to read the description of an environment as practice. Once you are done reading the description say aloud "Next". After the description you will be asked to judge the truth of some statements about the environment. You may take as much as time you need." Then participants read a description of an amusement park. The complete description was on the screen. Participants were free to read the practice and experimental descriptions as long as they liked. Immediately after reading the description, participants were presented with 4 true/false questions, one on each screen. They said "yes" for true and "no" for false. After the practice trial, the experimenter answered any questions the participant had, and then left the room.

Participants then proceeded through the experiment, reading each of the four descriptions and answering the corresponding true/false questions after each.

Figure 1: Experimental Setup. Participant gesturing while studying description.

## Results

Coding. Two trained coders, coded 10 of 48 videos for gesturing while studying, Kappa $=0.76(\mathrm{p}<0.001)$, for length of time spent gesturing while studying, $\mathrm{t}(39)=0.244$, $\mathrm{p}=0.809$, for looking at their hands while gesturing while studying, Kappa $=0.56(p<0.001)$, for studying time, $\mathrm{t}(39)=1.402, \mathrm{p}=0.169$, for gesturing while verifying statements, Kappa $=0.90(p<0.001)$, for looking at their hands while gesturing in verifying statements, Kappa $=0.44$ ( $\mathrm{p}<0.001$ ), and for length of time to verify statements, $t(359)=0.120, p=0.90$. Any movement of hands or fingers, excluding beat gestures, was coded as gesturing. Any glance at hands while gesturing was coded as looking. The coded duration of the gesture included active movements and periods when individuals left their hands still on the table or in mid-air in a certain position and form. Times were coded from the Silverback© videos of the screen and by using ELAN software. In cases of disagreement coders consulted
a third coder. One coder coded the remaining videos, discussing uncertain cases with the second coder. Qualitative coding of the gestures is ongoing, but it is clear that gestures indicating places, primarily points, and indicating connections between places, drawing lines or placing the edge of a hand, predominate. Most gestures were performed on the table, but some were in the air (see Figures 1 and 2).
Gesture at study. Seventy-three percent of participants (35 out of 48) gestured at least once for at least one description during study. Twelve participants ( $25 \%$ ) gestured for all four descriptions, 7 gestured for three, 10 gestured for two, and 6 for only one. Notably, number of landmarks in the environments ( 4 vs. 8) did not influence whether participants gestured at study, $\chi^{2}(1, \mathrm{~N}=48)=1.132, \mathrm{p}=$ 0.289 . Similarly, neither perspective (route vs. survey), $\chi^{2}(1, \mathrm{~N}=48)=.023, \mathrm{p}=0.879$, order $\left(1^{\text {st }}, 2^{\text {nd }}, 3^{\text {rd }}\right.$, or $\left.4^{\text {th }}\right)$, $\chi^{2}(3, \mathrm{~N}=48)=1.687, \mathrm{p}=0.171$, or MRT score, $\mathrm{F}(1,185)=$ $0.089, \mathrm{p}=0.765$, influenced gesturing at study.

For each participant, the percentage of time gesturing while studying was computed. Neither spatial ability F(1, $45)=0.357, \mathrm{p}=0.553$ ) nor gender $(\mathrm{F}(1,45)=0.505, \mathrm{p}=$ $0.481)$ affected the percent of time gesturing
Gesture at test. Sixty-five percent of participants (31 out of 48) gestured at least once when verifying the true/false statements. Table 3 shows number of statements for which participants gestured both when studying and answering, only when studying, only when answering, or not at all, out of the total of 1526 statements (excluding 10 cases in which participants' answers were missing).

Figure 2. Participant gesturing while answering question.
Table 3: Number of questions and gesture behavior

| Gesturing | Frequency | Percentage |
| :--- | :---: | :---: |
| Both at study and when <br> verifying | 547 | $35.8 \%$ |
| Only at study | 220 | $14.4 \%$ |
| Only when verifying | 21 | $1.4 \%$ |
| None | 738 | $48.4 \%$ |

As evident from Table 3, participants were far more likely to gesture to verify statements for the descriptions they gestured at study. Only $1.4 \%$ of the questions received
gestures at verification that had not received gestures at study.

Moreover, for $85 \%$ of the descriptions accompanied by gesture, at least one question was also accompanied by gesture. Participants, who did not gesture at all while studying the descriptions did not gesture when answering questions. Specifically, $27 \%$ of participants ( 13 out of 48) did not gesture either at study or at verification.

Overall, neither the environment's perspective (survey vs. route), $\chi^{2}(1, \mathrm{~N}=48)=.743, \mathrm{p}=0.389$, nor question perspective, $\chi^{2}(1, \mathrm{~N}=48)=.264, \mathrm{p}=0.608$, nor number of landmarks ( 4 vs. 8 ), $\chi^{2}(1, \mathrm{~N}=48)=.028, \mathrm{p}=0.868$, nor type of statement (verbatim vs. inference), $\chi^{2}(1, \mathrm{~N}=48)=.439$, $\mathrm{p}=0.508$, nor MRT scores, $\mathrm{F}(1,1520)=0.899, \mathrm{p}=0.343$ influenced whether participants gestured at verification.

In short, most participants gestured while studying and verifying and most who gestured at verification had also gestured at study. Neither spatial ability nor length nor perspective of the descriptions or questions affected whether participants gestured.
Accuracy. As evident in Figure 3, when participants had gestured at study, they were more likely to be accurate at testing ( $\mathrm{M}=0.821, \mathrm{SD}=0.29$ ) than when they had not gestured at study $(\mathrm{M}=0.743, \mathrm{SD}=0.30), \mathrm{F}(1,1517)=$ $8.249, \mathrm{p}=0.004<0.01$. Not surprisingly, accuracy was higher for the 4 landmark environments ( $M=0.810$, $\mathrm{SD}=$ 0.24 ) than for the 8 landmark environments ( $\mathrm{M}=0.760, \mathrm{SD}=$ $0.28), \mathrm{F}(1,1517)=6.561, \mathrm{p}=0.011<0.05$. Accuracy improved with spatial ability, $F(1,1517)=10.210, p=0.001$ $<0.01$ but the correlation between accuracy and spatial ability was low and not significant. Accuracy varied with kind of statement, $F(1,1517)=7.182, \mathrm{p}<0.001$. Replicating Taylor and Tversky (1992), post-hoc analyses showed that verbatim statements ( $\mathrm{M}=0.838, \mathrm{SD}=0.21$ ) were more accurate than inference statements ( $M=0.720, \mathrm{SD}=0.31$ ), $\mathrm{t}(1513)=3.809, \mathrm{p}<0.01$, and that for inference statements, there was no advantage for statements in the perspective of reading (same perspective ( $\mathrm{M}=0.727, \mathrm{SD}=0.30$ ); other perspective $(M=0.718, S D=0.31), t(1513)=0.311, p=$ 0.756 ), indicating that memory representations were perspective-free.

Figure 3. Accuracy by gesturing at study. Error bars represent standard error

The effects of gesturing at verification were analyzed separately. Participants were more likely to be accurate verifying statements when they gestured ( $M=0.814, S D=$ 0.23 ), than when they $\operatorname{did}$ not ( $\mathrm{M}=0.757, \mathrm{SD}=0.29$ ), $\mathrm{F}(1$, $1515)=5.325, \mathrm{p}=0.038<0.05$. As before, accuracy increased with spatial ability, $F(1,1515)=10.191, p=0.001$ $<0.01$, and was affected by statement category in the same ways as the previous analysis, $\mathrm{F}(1,1515)=17.084, \mathrm{p}<$ 0.001 .

Figure 4: Accuracy by gesturing at verification.
To examine the effects of gesture at study and gesture at response, participants were divided into 4 groups: gesture at both, gesture only at study, gesture only at response, no gesture. Gesture behavior had an effect on accuracy, $\mathrm{F}(3$, 1494) $=3.593, \mathrm{p}=0.013<0.05$. Post-hoc analyses showed that participants were more accurate at testing when they had gestured both at study and verification ( $\mathrm{M}=0.780, \mathrm{SD}=$ 0.27 ), than when they did not gesture at all $(\mathrm{M}=0.705, \mathrm{SD}=$ 0.32 ), $\mathrm{t}(1494)=2.491, \mathrm{p}=0.013<0.05$. Similarly, they were more accurate when they only gestured at study ( $\mathrm{M}=0.816$, $\mathrm{SD}=0.23$ ), than when they did not gesture at all, $\mathrm{t}(1494)=$ 2.655, $p=0.008<0.01$. However, there was not a significant improvement for gesture only at response ( $M=0.811$, $\mathrm{SD}=0.25$ ) than for no gesture, $\mathrm{t}(1494)=0.333, \mathrm{p}=0.739$; this could be due to the severely limited number of cases in which participants only gestured at response (See Table 3).
To make sure that the advantage of gesturing was not because the better learners gestured, comparisons were done within participants who gestured when studying two or three descriptions, but not all descriptions. For those who gestured sometimes, accuracy was higher when they gestured at study ( $\mathrm{M}=0.762, \mathrm{SD}=0.29$ ) than when they did not $(\mathrm{M}=0.677, \mathrm{SD}=0.35), \mathrm{F}(1,513)=3.938, \mathrm{p}=0.048<$ 0.05 . Similarly, they were more accurate verifying statements when they gestured ( $\mathrm{M}=.764, \mathrm{SD}=0.29$ ) than when they did not gesture ( $\mathrm{M}=0.628, \mathrm{SD}=0.35$ ), $\mathrm{F}(1$, $513)=3.910, p=0.049<0.05$. So, gesturing itself helps - it is not just that those who tend to gesture also remember better.
Studying Times. As expected, participants took longer to study the longer descriptions with 8 landmarks ( $\mathrm{M}=$ $112.14 \mathrm{sec}, \mathrm{SD}=28.43$ ) than the shorter ones with 4 landmarks ( $\mathrm{M}=56.57 \mathrm{sec}, \mathrm{SD}=28.43$ ), $\mathrm{F}(1,187)=94.104$, p
$<0.001$. Gesturing did not influence study time, $\mathrm{F}(1,187)=$ $1.212, p=0.272$. Similarly, neither spatial ability, $F(1,187)=$ $2.198, p=0.140$, nor text perspective, $F(1,187)=0.101, p=$ 0.752 , affected study times.

Verification Times. Figure 5 shows that gesture behavior influenced verification time, $\mathrm{F}(3,1441)=3.431, \mathrm{p}=0.016<$ 0.05 . Post-hoc Bonferroni comparisons showed that participants were faster to verify statements when they had only gestured at study $(M=8.95 \mathrm{sec}, \mathrm{SD}=2.61)$ than when they had not gestured at all ( $\mathrm{M}=10.35 \mathrm{sec}, \mathrm{SD}=4.16$ ), $\mathrm{p}<$ 0.001 . By contrast, answering took longer when participants only gestured at verification $(M=15.65 \mathrm{sec}, \mathrm{SD}=6.19)$ than when they only gestured at study, $\mathrm{p}=0.004<0.01$. There was no difference on verification time when participants gestured both at study and at verification ( $\mathrm{M}=11.47 \mathrm{sec}$, $\mathrm{SD}=3.88$ ), compared to when they did not gesture at all. Spatial ability, perspective, and size of environment did not effect verification times. Thus gesture at study decreased verification time while gesture at responding increased verification time, and in cases when they gestured both at study and at verification, the two effects cancelled each other.

Figure 5: Verification time by gesture behavior
Did participants look at their hands while gesturing? For the most part, participants did not look at their hands while gesturing; they looked at their hands for $35.8 \%$ of the texts during reading but they were typically brief glances. Out of the 35 participants who gestured at least once when reading texts, 15 never looked at their hands. At verification, participants looked at their hands for less than $10 \%$ of the statements they gestured while verifying. Out of the 31 participants who gestured for at least one of the statements, 16 never looked at their hands.

## Discussion

Participants, alone in a room, read descriptions of a variety of complex environments that they were to learn for later questions. While they were studying, most of them gestured at least once, and the majority gestured for most of the descriptions, in the absence of any communication. The
descriptions accompanied by gestures were remembered better than those that were not, and the questions that were accompanied by gestures were answered more accurately than those that were not. The advantage of gesturing on memory cannot be explained as the better participants both gestured and remembered better. Even within those participants who frequently gestured, gesturing at study and at responding improved memory. Gestures modeled the structures of the environments, pointing to places and outlining paths between places. Except on rare occasions, participants did not look at their hands as they gestured, suggesting that it is the actions per se that serve comprehension and learning, rather than the visual accompaniments. Overall, spontaneous gesturing at learning and spontaneous gesturing at memory retrieval promoted learning. Gestures appeared to improve learning by establishing embodied representations of the structures of the environments and appear to improve memory by redintegrating the queried parts of the environments.

In addition to providing embodied representations of the environments, gestures might also have served to offload memory, as in previous research (e. g., Cook, et al., 2012; Goldin-Meadow, et al., 2001), just as diagrams offload memory. However, the proportion of study time gesturing did not increase as memory load increased from light to heavy. Thus, the role of gesture in lightening memory load appears to be less important for comprehending and learning complex environments than other features of gestures, notably, creating embodied representations.

Gestures are actions, and thereby provide an additional code beyond the verbal code participants read. Multiple codes in multiple modalities are known to promote memory (e. g., Paivio, 1986). Motor codes in particular augment memory (e. g. Engelkamp \& Zimmer, 1994; Hommel, Musseler, Aschersleben, \& Prinz, 2001) but the cases that have been studied have primarily been cases where the memory was for the action per se. In the present case, the actions served memory not for the actions but rather for what the actions represented.

Actions, like diagrams and words, can represent, that is, they can stand for something other than themselves. Certainly for the case of words but also for the case of diagrams, representation seems to be their primary function. Not so for actions. Actions can represent, but they are primarily used for the ordinary (and extraordinary) tasks of life, manipulating objects and navigating environments. Gestures are a special class of actions that serve to represent rather than to act on or in the world. Similar to diagrams, gestures can represent more directly than purely symbolic words; they bear some resemblance to what they represent (e. g., Tversky, 2011).

Like diagrams, gestures can use space to represent ideas that are spatial or metaphorically spatial (e. g., Enfield, 2003; Emmorey, et al., 2000; Tversky, 2011; Tversky, Heiser, Lee, \& Daniel, 2009). Like diagrams, gestures are spatial and visual. However, it seems that the spatial and action components of representational gestures serve
comprehension and memory rather than the visual. Participants rarely looked at their hands. Researchers in art, sketching, and design refer to drawing as gesture. Blindfolded architects gesture copiously as they design, and they cannot see either their gestures or their designs. Nevertheless, their designs equal those they create without blindfolds (Bilda and Gero, 2006). Together, these findings suggest that some of the benefits of gesturing to those who gesture may be the embodiment of thought into action.

# Relational labels can improve relational retrieval 

Anja Jamrozik (a.jamrozik@u.northwestern.edu)<br>Dedre Gentner (gentner@northwestern.edu)<br>Department of Psychology, Northwestern University<br>2029 Sheridan Road, Evanston, IL 60208 USA

#### Abstract

Retrieval that is based on common relational structure, such as an underlying principle or pattern, is useful but typically rare. Based on evidence that comparison-derived schema abstraction can improve relational retrieval, we asked whether the use of relational labels can also promote abstraction and improve relational retrieval. Using a cued-recall paradigm, we varied the presence of relational labels at encoding and test. As compared to a no-label baseline condition, relational retrieval improved when relational labels were given at encoding and at test and also when relational labels were given only at encoding. The findings demonstrate that one way to improve relational retrieval is through the use of labels that name relational structure.

Keywords: relational retrieval; relational language; inert knowledge

## Introduction

When encountering a new example or problem, we sometimes retrieve examples from memory that share relational structure with the current example. This can be very useful as it allows us to transfer existing knowledge to the new example. For instance, if a social psychology student learns about the classic findings that a person's attitude can become resistant against very persuasive arguments after the person has argued against weak versions of such arguments (e.g., McGuire, 1961; McGuire \& Papageorgis, 1961), then this might remind the student of how someone can become immune to a disease after being exposed to a weakened form of that disease. Based on this connection, they may be able to draw some conclusions about the new situation, such as why the attitude becomes resistant to change, or why the initial arguments against the attitude have to be weak.

As useful as it can be, relational retrieval-retrieval based only on common relational structure-is typically rare (e.g., Gentner, Rattermann, \& Forbus, 1993; Gick \& Holyoak, 1980, 1983; Holyoak \& Koh, 1987; Ross, 1987, 1989). Instead, memory retrieval is likely to be based either on overall similarity or on surface commonalities, such as matching entities (e.g., Brooks, Norman, \& Allen, 1991; Gentner et al., 1993; Holyoak \& Koh, 1987; Ross, 1987, 1989). This is an instance of the inert knowledge problem (Whitehead, 1929) - that people are often unable to retrieve knowledge and apply it to new situations even when that information has been stored in memory (e.g., Barnett \& Ceci, 2002; Bransford, 1979).

Even though relational retrieval is typically rare, it is more likely for experts in a domain. For example, when solving challenging science problems, experts often retrieve problems that share common relational structure (e.g., Clement, 1988). Likewise, the likelihood of relational retrieval is better for students with greater mathematical expertise than for novices (Novick, 1988), and mathematical expertise can predict the likelihood of transferring a solution strategy to analogous math problems (Novick \& Holyoak, 1991).

What contributes to experts' improvement in relational retrieval? Two factors that might be involved are having experienced many opportunities to compare examples and acquiring a technical vocabulary. There is abundant evidence that comparison of examples can improve the likelihood of relational retrieval. When learners compare two instances of the same relational structure, the process of alignment renders their common structure more salient. This process of schema abstraction increases the likelihood of retaining this common relational structure and transferring it to other instances (e.g., Gentner Loewenstein, Thompson, \& Forbus, 2009; Gentner \& Markman, 1997; Gick \& Holyoak, 1983; Markman \& Gentner, 1993; Reeves \& Weisberg, 1994; Ross \& Kennedy, 1990).

In the current research, we focus on the second factor and ask how acquiring a vocabulary may impact relational retrieval ${ }^{1}$. As someone develops expertise in a domain, they may acquire terms that name common relations or relational patterns in that domain. We ask whether the use of such relational language can improve relational retrieval.

## Relational Language

In the current research, we ask whether an abstraction process like the one that operates during comparison also applies when relational language is used. Specifically, we ask whether using known relational terms like reciprocity or inoculation to label examples promotes the abstraction of their relational structure and leads to improved relational retrieval. The idea is that using a relational term to label a situation can promote the abstraction of relational structure

[^101]and change the construal of the situation by shifting the focus to its relational structure (e.g., Gentner, 2003, 2010; Genter, Angorro, \& Klibanoff, 2011; Gentner \& Loewenstein, 2002). This may result in improved relational retrieval in response to another example that shares the same relational structure.

Applying relational labels shares some similarities with comparison of examples, in that both involve the extraction and retention of relational structure. The difference is that in the case of relational labels, the alignment is between a labeled example and the relational structure conveyed by the label (which has already been abstracted). For instance, if the label inoculation is applied to a situation in which someone becomes immune to the stronger form of smallpox after being exposed to a milder form of smallpox, this invites a construal of the situation with a heightened focus on the common relational structure, such as 'exposure to a weakened form of something protects against the stronger form'. If so, then this might increase transfer to a further, more distant example of the relational structure. For instance, if someone encodes the example from medicine labeled inoculation and later receives an example about attitude change labeled inoculation, then both of the examples should be construed with a focus on the relational structure that each shares with inoculation. These similar relational construals should then improve the likelihood of relational retrieval of one example given the other.

The logic of the current experiment is to vary the presence of relational labels and to test the likelihood of subsequent relational retrieval. In the experiment, participants read a series of stories at encoding either with or without relational labels. Later, they were given test stories that shared relational structure with the encoding stories and asked to write out of the encoding stories they were reminded of. In one condition, the same relational labels were used at encoding and at test. The prediction is that this will lead to heightened relational retrieval, because the labels will invite the same construal across examples. Of course, if the same label is used at encoding and at test, then this leaves open the possibility that the label may also be acting as a common surface feature between examples that share relational structure.

We will also test a more interesting possibility: that labels may improve relational retrieval even if they are only present at encoding. If a relational label is applied to the initial example, then this can result in a construal in which there is a greater focus on the invited relational structure. Later, if the relational structure of the test example is apparent (or even partially apparent), then it should be more likely to match the initial (stored) example than it would have been had the initial example not been labeled. For instance, if the initial medical example is labeled inoculation, then this may increase its likelihood of being retrieved given a new passage involving the analogous phenomenon in attitude change.

Finally, it is possible that relational labels present at test only may likewise improve relational retrieval. There is some evidence that deriving a relational abstraction from comparison can improve relational retrieval of past examples that share the same relational structure (Gentner et al., 2009). If, as we have suggested, labels also promote abstraction of relational structure in much the same way as comparison, then they may also improve relational retrieval when they are given at test.

In the current experiment, we tested whether relational labels can improve relational retrieval in one of the ways described above. We varied the presence of labels at encoding and at test. As outlined above, the pattern of results can inform us about the underlying processes through which relational labels might be having their effect.

## Logic of the Experiment

We used a cued recall paradigm similar to that used in previous studies of relational retrieval (e.g., Gentner et al, 1993). Participants studied one set of stories during an encoding phase. After a delay, in the test phase they received a new set of stories. For each story, their task was to write down any stories that they were reminded of from the encoding phase.

Each story in the test phase described the same relational pattern (e.g., positive feedback, reciprocity) as one story in the encoding phase and came from the same domain (e.g., medicine, political science) as another story in the encoding phase. Thus for each test story there were two likely retrieval candidates, one sharing the same relational pattern as the test story (the relational match), and one coming from the same domain as the test story (the domain match).

We expected that domain matches would be quite likely to be retrieved because stories from the same domain often involve both surface commonalities and associative connections. As reviewed earlier, retrieval is likely to be based on surface commonalities (e.g., Gentner et al., 1993; Holyoak \& Koh, 1987; Ross, 1987) and there is also evidence that the degree of association between examples affects retrieval (e.g., Howard \& Kahana, 2002; Pollio, Richards, \& Lucan, 1969; Wolfe, 2005). Assuming that domain retrieval would be dominant and relational retrieval relatively rare at baseline, we could assess improvement in relational retrieval when relational labels were added.

We varied whether participants received relational labels during the encoding and test phases in a $2 \times 2$ betweensubjects design (no relational labels at encoding or at test; relational labels at encoding only, relational labels at test only, or relational labels at both encoding and at test). The condition in which no relational labels were given during either the encoding or test phases provides a baseline of performance against which we could measure gains in relational retrieval. We tested whether (a) the use of relational labels can improve the likelihood of relational retrieval, and (b) whether this benefit occurs only when the
same relational labels are used both at encoding and at test, or whether there is also a benefit for the use of relational labels only during encoding or only during test.

The relational labels we used were schema noun labels that named the relational patterns described by the stories (e.g., positive feedback, reciprocity, inoculation). Schema nouns are a subtype of relational nouns, which name categories whose members share relational structure (e.g., Gentner \& Kurtz, 2005; Goldwater, Markman, \& Stilwell, 2011; Markman \& Stilwell, 2001). Since schema nouns name entire relational structures, they seemed particularly well-suited for promoting abstraction and a relational construal of the stories.

The most obvious prediction is that giving relational labels at encoding and at test should improve relational retrieval. This effect would be consistent with the interpretation that the label invited a similar relational construal for the two examples. Unfortunately, this result by itself is subject to another interpretation. Perhaps relational labels also act as a common surface feature between examples that share relational structure. If labels invite relational construal and/or act as a common feature, there should only be a benefit of relational labels on retrieval if labels are present at both encoding and test.

The two conditions of most interest are whether participants' relational retrieval improves when relational labels are given only during the encoding phase or during the test phase. If relational labels promote a construal in which there is a greater focus on the invited relational structure, then this may enable it to be retrieved more easily if the same relational structure (or a part of this relational structure) is encountered in future situations. If this is the case, then providing relational labels at encoding should also improve retrieval. It is possible that providing relational labels at test might also improve relational retrieval. If relational labels help people abstract the named relational structure and retrieve prior examples that share the same structure, then receiving labels during the test phase may also lead to improvement in relational retrieval. In sum, the two single labeling conditions allow us to examine the effects of selective abstraction on relational retrieval. The pattern of results will inform us about how relational labels might be having their effect.

## Method

## Participants

Participants $(N=60$, 39 female, mean age $=22.48)$ were recruited from the Northwestern University community and were paid or received course credit for their participation in the experiment. All participants were native English speakers.

Participants were assigned to one of the four conditions as follows: 15 participants received no relational labels at encoding or at test, 15 participants received labels only at
encoding, 16 participants received labels only at test, and 14 participants received labels at encoding and at test. An additional four participants were tested but excluded from further analyses, either for failing to follow the test instructions (one participant), or for failing to respond to at least half of the test items (three participants).

## Materials and Design

The materials consisted of two sets (A and B) of fourteen stories each that served as the encoding and test story sets (with A/B assignment counterbalanced). Each of these two story sets was made up of ten key stories and four filler stories. The ten key stories described relational patterns. The relational patterns were chosen to be applicable in different domains. For example, as described earlier, the relational pattern inoculation can appear in domain of medicine and also in the domain of psychology. Half of the key stories described causal systems (e.g., a positive feedback system), and the other half described other relational schemas (e.g., reciprocity). Some of the causal systems stories were adapted from an earlier study by Rottman, Gentner, and Goldwater (2012).

Within each of the two story sets (i.e., the encoding and test sets), each of the test stories was set in a different domain (e.g., mechanical engineering, political science, psychology). Across the two story sets, each test story matched one encoding story in terms of its relational structure, and matched a different encoding story in terms of its domain. For example, in one set, the story describing reciprocity was set in the domain of political science. In the other set, the story describing reciprocity was set in the domain of psychology, and the story set in the domain of political science described a different relational pattern.

As a check on our manipulation of domain-relatedness, we used Latent Semantic Analysis (LSA) to measure the degree of relatedness between the stories (Landauer \& Dumais, 1997). For each of the ten test stories in story set A, we calculated the LSA relatedness scores (Landauer \& Kintsch, 1998) to the story in set B that came from the same domain and to the story from set B that described the same relational pattern. Stories that came from the same domain had higher relatedness scores $(M=0.35, S D=0.20)$ than did stories that shared relational structure $(M=0.14, S D=$ $0.07), t(9)=3.38, p=.008, d=1.40$. This confirmed that, as intended, stories that came from the same domain were more semantically related than stories that described the same relational pattern.

Each of the two story sets also contained four filler stories. Across the two story sets, the filler stories were matched both in their relational pattern and in their domain setting.

The presence or absence of relational labels during the encoding and test phases was varied in a 2 (label present vs. absent at encoding) x 2 (label present vs. absent at test) between-subjects design.

## Procedure

There were two phases: an encoding phase and a test phase. Before the encoding phase, participants were informed that the experiment was composed of two parts. They were told that they would read a number of stories and that they would use the information they read about during the second part of experiment.

In the encoding phase, participants read one set of stories, either story set A or B. The order of the stories was randomized. If participants were in either of two labeling conditions (labels at encoding, labels at encoding and test), an additional sentence was added to the end of each story that described the relational pattern (e.g., "This is an example of reciprocity"). Participants were allowed as much time as they needed to read the stories.

After the encoding phase, participants completed a 15 minute filler task and then began the test phase of the experiment. In the test phase, participants received the set of stories that they did not receive during the encoding phase. For each story, they were asked to write down any of the original stories of which they were reminded. They were told that they could write down multiple original stories if they were reminded of them by one test story. Likewise, they could write down an original story multiple times if they were reminded of it by multiple test stories.

The test stories were presented one at a time on the screen, with a large text box below each story for participants to write down their responses. Participants were allowed as much time as needed to make their responses. As in the encoding phase, in the two labeling conditions (labels at test, labels at encoding and test), each of the stories ended with a sentence describing the relational pattern.

For each participant, we calculated two measures: the number of relational matches retrieved and the number of domain matches retrieved. A trained research assistant, who was blind to condition, coded the responses as relational matches, domain matches, or other responses. Other responses included extraneous retrievals that were neither domain matches or relational matches, and responses that were ambiguous or that did not provide enough information to be classified.

## Results

As predicted, relational labels led to more relational retrievals and fewer domain retrievals overall. Label condition had an effect on the number of relational matches, $F(3,56)=15.51 p<.001, \eta^{2}=0.454$, and domain matches, $F(3,56)=3.51, p=.021, \eta^{2}=0.158$, retrieved. As expected, Tukey HSD tests ${ }^{2}$ revealed that participants who received labels at encoding and at test retrieved more relational matches $(M=6.86, S D=2.45)$ than participants who received no labels $(M=1.87, S D=1.60), p<.001, d=$

[^102]2.52, participants who received labels at encoding ( $M=$ 4.13, $S D=2.23$ ), $p=.005, d=1.21$, and participants who received labels at test $(M=2.81, S D=2.04), p<.001, d$ $=1.87$ (see Figure 1). More interestingly, participants who received labels only at encoding also retrieved more relational matches than participants who received no labels, $p=.023, d=1.21$.

Domain matches showed a somewhat complementary pattern. Participants who received no labels retrieved more domain matches $(M=3.60, S D=1.96)$ than participants who received labels in both the encoding and test phases ( $M$ $=1.43, S D=1.55), p=.015, d=1.27$. There were no other differences between conditions in the number of domain matches retrieved. There were no differences between conditions in the total number of items (domain, relational, and other) retrieved, $F(3,56)=1.76, p=.166, \eta^{2}=0.086$.

Figure 1: The average number of relational matches retrieved by condition.

## Discussion

As predicted, we found that relational labels are able to improve relational retrieval. Relational retrieval improved over the baseline level when participants received relational labels at encoding and at test. More interestingly, relational retrieval also improved significantly when participants received relational labels only at encoding. There was evidence that relational labels can also promote a relational focus: participants who received relational labels at encoding and at test retrieved fewer domain matches than did participants who did not receive labels.

Earlier, we suggested that the use of known relational labels might improve relational retrieval by promoting a consistent relational construal of examples that share the same label. Further, we proposed that if an example is construed with a focus on the relational structure invited by the label, then this construal might be more likely to be
retrieved in response to another example that shares the same relational structure. Finally, we suggested that if a label promotes abstraction of relational structure, that this might improve the likelihood of retrieving prior examples that share this relational structure. We found evidence for the first and the second predictions, but not for the third.

The likelihood of relational retrieval was greatest when relational labels were present at both encoding and test, consistent with our hypothesis that labels promote a consistent relational construal (though, as noted earlier, it could also have resulted simply through labels acting as a common feature). Turning to the second prediction, we found that relational labels at encoding improved relational retrieval. This suggests that the labels promoted abstraction and storage of the named relational structure so that it could be retrieved more easily when a test example shared the same relational structure.

We did not find an effect of labels at test. One reason for this asymmetry between encoding and test may be that relational labels at encoding could have primed people to adopt a relational focus that carried over into the test.

At the start of the paper, we raised the question of why relational retrieval becomes more likely with domain expertise. Our findings suggest that one factor may be learning a technical vocabulary to name relational patterns in the domain.

The present findings have implications for learning and education. In order to promote relational retrieval and transfer, it could be useful to provide learners with labels for important relational structures. Our findings suggest that relational labels may highlight relational structure and make it more likely that it will be accessed again in the future. Additionally, the finding that relational retrieval is best when the same labels are used at encoding and retrieval suggests that labels for relational structures should be consistent. This fits with Forbus et al.'s (1995) claim that uniform relational encoding promotes relational retrieval.

Our findings are compatible with prior work demonstrating that other kinds of relational language can improve relational retrieval and transfer. For example, Clement, Mawby, and Giles (1994) found that using the same or synonymous verbs to describe relational structure in analogous situations improved the likelihood of relational retrieval. This suggests that using relational terms that invite a similar construal of situations, even if the labels are not identical, can increase the likelihood of noticing their similarity. Another finding related to this work is that receiving relational terms when learning about a new domain can improve the likelihood of relational transfer (Son, Doumas, \& Goldstone, 2010). In Son et al.'s (2010) studies, participants completed a tutorial about a domain they did not know about (Signal Detection Theory) and later solved transfer problems that involved the same principles. Half of the participants received relational terms (e.g., target, distracter, false alarm) in the tutorial. Since the
domain was new to participants, these particular uses of the terms were novel to them. The studies manipulated whether the semantics of the relational terms matched the tutorial scenario and whether the tutorial and transfer scenarios were easily alignable. The use of relational terms improved transfer performance the most dramatically when the semantics of the relational terms matched the tutorial and when the tutorial and transfer situations were easily alignable. These findings are consistent with the framework we presented earlier. If a relational term already had some initial stored meaning, then if it were applied in a new context (the tutorial scenario), this should lead to an alignment that resulted in the abstraction of their common relational structure. If participants then received the easily alignable transfer scenario and attended to its identical relational structure, then they should be able to retrieve the past case that shared this relational structure and transfer solution strategies from it to the transfer scenario.

In sum, the current research suggests that one way to improve relational retrieval is through the use of relational labels. This raises a number of interesting questions about how relational labels bring about this improvement. In this research, we investigated the effects of known relational labels. What effects would unknown or partially understood labels have? What would be the most effective way to introduce new vocabulary to improve relational retrieval and transfer? Would the benefits of relational labels on retrieval remain with greater delays? This line of research promises to shed light on the way in which symbolic learning and analogical processes combine in the acquisition of expertise.

## Acknowledgments

This research was supported by ONR Grant N00014-08-10040. We thank Laura Willig for her help in coding the data and members of the Cognition and Language Lab for their helpful suggestions.

# Verb bias and structural priming in non-linguistic grammar acquisition task 

Marius Janciauskas (m.janciauskas@liv.ac.uk)<br>Franklin Chang (franklin.chang@liverpool.ac.uk)<br>University of Liverpool, School of Psychology, Bedford Street South, Liverpool, L69 7ZA UK

#### Abstract

Domain-general statistical learning (SL) is thought to support language phenomena like verb bias and structural priming. We explored this idea by inducing these phenomena within a non-linguistic serial reaction time (SRT) task where participants learned an English-like artificial language using SL. In a series of two experiments we found error rates to be sensitive to verbs' structural preferences and abstract structural priming. The similarities between the behaviour in this task and previous linguistic research suggests that this method may be useful for studying the nature of SL in language learning and processing.

Keywords: statistical learning; verb bias; structural priming.
An important question in the study of language is the degree to which language acquisition depends on language-specific mechanisms or general-purpose statistical learning (SL) mechanisms (e.g., Kidd, 2012). Research has found that SL takes place in real and artificial language learning tasks (Fine \& Jaeger, 2013; Qi, 2012; Saffran, 2003, Wells, Christiansen, Race, Acheson, \& MacDonald, 2009). However, the use of language or auditory stimuli could cause language-specific systems to become activated in these tasks (Gervain, Nespor, Mazuka, Horie, \& Mehler, 2008). Non-linguistic artificial grammar learning (AGL) or serial reaction time (SRT) tasks provide a paradigm for studying grammar learning that is independent of linguistic knowledge. But the grammars used in the existing studies (e.g. Hunt \& Aslin, 2010) are quite different from real language and it is hard to link findings in these studies to human syntactic phenomena. Thus, it is still not known if domain-general SL can account for the acquisition and processing of human syntactic knowledge.

The present study set out to develop a method to study SL processes within a non-linguistic task designed to approximate the contexts in which certain linguistic phenomena occur. We developed an SRT task where participants had to implicitly learn statistical regularities in symbol sequences generated from an English-like grammar in a symbol-matching task. If participants learn this language as they process it (linguistic adaptation; Chang, Janciauskas, \& Fitz, 2012), then their accuracy and reaction times should reveal how linguistic phenomena arise out of general-purpose SL.

We applied our paradigm to explain two language phenomena: verb bias and structural priming. Verb bias is the tendency for individual verbs to prefer particular structures. For example, if a verb occurs more often in the double object (DO) structure as in "the man gave the woman the dress" rather than the prepositional dative (PD) structure "the man gave the dress to the woman", the verb is
said to have double object dative bias. This phenomenon is thought to occur as a result of learning distributional relationships between verbs and structures (Juliano \& Tanenhaus, 1994). In this example, the DO bias arises from stronger probabilistic association of the verb 'give' with the DO structure. A verb's occurrence in its preferred structure (verb-structure match hereafter) is known to influence structural choices and reduce processing time at the choice point where alternating structures diverge (Ferreira, 1996; Garnsey, Pearlmutter, Myers, \& Lotocky, 1997; Stallings, MacDonald, \& O'Seaghdha, 1998).

Another phenomenon of interest is structural priming, which is the tendency for participants to repeat previously produced sentence structures (Bock, 1986). For example, if participants heard the DO sentence like "the boy threw the dog the ball" and are then given a picture which can be described using a DO (e.g. "the man gave the woman the dress") or a PD (e.g. "the man gave the dress to the woman") structure sentence, they were more likely to use the same DO structure. Structural priming has been found to persist over time, suggesting that it is supported by learning (Bock \& Griffin, 2000). Chang, Dell and Bock (2006) used a connectionist model to show that priming could be explained as SL over abstract structural representations. Like verb bias, structural priming influences structural choices in sentence production and comprehension times at the post-verbal position (Corley \& Scheepers, 2002; Weber \& Indefrey, 2009).

In sum, verb bias and structural priming are thought to depend on SL processes involving linguistic units. If these processes are not specific to language then it should be possible to find verb bias- and structural priming-like effects in a non-linguistic SRT task. The present studies are a step towards such a paradigm.

## Study 1: Dative Alternation SRT Task

The first study used a variant of Hunt and Aslin's (2001) SRT study. In the centre of a computer screen participants saw sequences of letters appearing one at a time, which required them to find that letter on a circle of 21 letters surrounding the centre by moving a mouse cursor over it. The sequences were structured based on a grammar that included English dative alternation-like structures. For example, the symbol string "H J Z C M" approximated a PD sentence without articles like "man gave dress to woman". The corresponding DO symbol string was "H J M Z" ("man gave woman dress"). Verb bias was created by varying the frequency of the symbols (verbs hereafter) appearing in the verb's position with particular structures. For example, J and B occurred more often with PD structure, while D and

N occurred more often with DO structures. Structural priming was tested by manipulating the structures of adjacent strings (prime and target) so that half of them had matching structures (e.g. DO-DO) and half of them had mismatching structures (e.g. DO-PD). The input was created in sections of 24 items consisting of eight prime-target pairs separated by structurally unrelated fillers ( 120 items total). Twelve of the 16 PD and DO strings in each section contained a verb which matched its preferred structure and four strings contained a verb that mismatched it. These sections created temporal points at which the behaviours associated with learning structural constraints could be assessed.

Like in language studies, verb bias and structural priming effects were measured at the first 'post-verbal' symbol (e.g. after ' $G$ '), hypothesizing that verb-structure match and structural match between adjacent strings would reduce error rate and the reaction times taken to process that element. If these effects are the result of learning, we predicted that verb bias and structural match between adjacent strings would show a growing influence over the different sections of the study.

## Method

## Participants and materials

An opportunity sample of 79 participants was recruited from the University of Liverpool student population. The visual display consisted of letter symbols forming a circle (Fig. 1) and a space in the centre where stimulus strings were presented one symbol at a time. The language from which the strings were created consisted of 17 letters randomly allocated to 7 categories that resembled syntactic categories found in English language (Table 1). The categories were combined following English grammar rules to create grammatical letter strings (Table 2).

To test structural priming, presentation of the strings was structured so that PD and DO occurred in all combinations in pairs (prime and target) followed by one filler sentence of either intransitive (IN) or transitive (TR) structure. To create 'verb bias', the DVERBP (PD bias) and DVERBD (DO bias) categories occurred in PD and DO structures respectively $75 \%$ of the time.

The letter strings were generated by randomly selecting symbols from the appropriate categories with no overlap in symbols between adjacent strings with the priority given to the lower frequency members to ensure equal distribution. A total of 120 letter strings were used in the experiment. The development of verb bias and structural priming effects was tested every 24 items, which created 5 temporally different sections containing 8 instances of prime-target pairs.

After the letter-matching task people were given a grammaticality judgment test. Twenty-four randomly generated whole grammatical strings were presented side-by-side with another string that was identical to the target string but with two members belonging to the different
categories swapped to create ungrammatical transitions (e.g. MBHF and MHBF).

Figure 1: Visual display for Experiment 1 (left) and Experiment 2 (right, production trial)

Table 1: Category type, names, and symbols in Exp 1.

| Category Type | Category | Symbols |
| :--- | :--- | :--- |
| Animate Noun | ANOUN | X,M,Y,H |
| Inanimate Noun | INOUN | F,Z,Q,P |
| Intransitive Verb | IVERB | W,L |
| Transitive Verb | TVERB | S,G |
| Dative verb with PD bias | DVERBP | J, B |
| Dative verb with DO bias | DVERBD | D,N |
| Preposition | PREP | C |

Table 2: Rules used to create letter strings.

| Type | Category | Letter string <br> (English-equivalent) |
| :---: | :--- | :--- |
| IN | ANOUN IVERB | X W (Boys sleep) |
| TR | ANOUN TVERB | Y G Z (Girls like |
|  | INOUN | books) |
| DO | ANOUN | M B H F (Woman |
|  | DVERBD/DVERBP | showed boys car) |
|  | ANOUN INOUN |  |
| PD | ANOUN | H J Z C M (Man gave |
|  | DVERBD/DVERBP | dress to woman) |
|  | INOUN PREP ANOUN |  |

## Procedure

Participants were tested in a quiet room, with up to six people on individual computers per session. They were not told that the letter strings followed certain rules. They processed the strings by matching the letters appearing in the centre to those on the circle using a mouse on a letter-by-letter basis. Each response reset the position of the mouse cursor to the centre and triggered the next symbol. Letter strings were separated by a blank screen. After 120 items participants received a grammaticality judgment task (described above). Participants were told that the strings they saw earlier followed certain rules and that their task was to decide which of the two strings was grammatical. The experiment took approximately 20 minutes to complete.

## Data collection and analysis

Error rates and reaction times in milliseconds were recorded for the time taken to move the mouse cursor to the correct symbol on the circle. Verb bias and priming were tested after the DVERBD/DVERBP symbol ( $3^{\text {rd }}$ position). For the reaction time data, only correct items were used and responses were log-transformed. Reponses that were two standard deviations above or below the mean were removed.

## Results

The grammaticality judgment task was assessed using a one-sample $t$-test against chance ( $50 \%$, two-tailed). Participants successfully recognized $56 \%$ of grammatical strings $(t(76)=4.4 ; p<.001)$ showing that they had learned some structural aspects of the language.

The task produced a total of 36,340 responses with an error rate of $5.7 \%$. To assess the influence of verb bias on error rate, accuracy data (correct or incorrect response) were submitted to a binomial mixed model with verb-structure match (match vs. mismatch, effect coded) crossed with section (centered) as predictor variables. Participants were included as a random factor with maximal random structure (Barr, Levy, Scheepers, \& Tily, 2013). We found a significant two-way interaction ( $b=-0.22, S E=0.11, z=2.09$, $p=.04$ ), showing that verb-structure match reduced the likelihood of making an error and that this knowledge grew as the participant learned the language (Figure 2).

Figure 2: Mean proportions of errors (top) and reaction times (bottom) in each section when verb and structure matched (solid line) or mismatched (dashed line).

Similar mixed model assumptions were used for the reaction time analysis unless specifically mentioned. Reaction times were submitted to a mixed model. We found faster reaction times as the experiment progressed, showing a general learning effect ( $b=-0.03, S E=0.005, X^{2}=26.13$, $p<.001$ ). Verb-structure match increased processing times (Fig. 2; $\quad b=0.05, \quad S E=0.01, \quad X^{2}=19.02, \quad p<.001$ ). This
suggested speed-accuracy tradeoff but the exact nature of this effect remains to be established. No two-way interaction was observed.

For the structural priming error analysis, a binomial mixed model was used with structural prime-target match (match vs. mismatch, effect coded) crossed with section (centered) as predictor variables. Since verb bias was varied in these items, verb was included as an additional random factor and maximal models were fitted. We found no significant main effects or interactions. For reaction times, a main effect of section was observed ( $b=-0.03, S E=0.005$, $X^{2}=7.67, p=.006$ ) indicating that reaction times decreased as the experiment progressed, showing a general learning effect. In sum, participants implicitly acquired knowledge of symbol strings such that they were better than chance at judging their grammaticality. We found a growing verb bias effect in the error rates but no structural priming effects were observed, suggesting that people may not have learnt to distinguish the required structures well enough.

## Study 2: Semantic and Task Constraints

We postulated that the lack of a priming effect was due in part to the difficulty in distinguishing the PD/DO structures. In natural language, non-linguistic animacy provides a cue that enhances the distinctiveness of these structures (e.g. gave the dress/woman). In addition, the random position of the letters on the circle made anticipation more difficult. Therefore, we conducted a second experiment where symbols were grouped together (Figure 1b). To add animacy cues, we replaced the animate noun letters with the stick figures and the inanimate noun symbols with object-like symbols.

Since abstract priming is not always found in reaction times in comprehension (Tooley \& Traxler, 2010), we added a production-like string generation task (production hereafter), where participants occasionally saw the whole string in the centre and were required to produce it from memory by selecting the appropriate symbols in the circle (Figure 1b). Studies of human sentence production often use sentence recall to test verb bias or priming (e.g., Potter \& Lombardi, 1998).

Like before, we predicted that verb-structure match and structural prime-target match would influence processing times and error rates in both comprehension and production tasks. If these effects are learned over the study, they would increase over section.

## Participants and materials

39 participants were recruited from the pool of university students participating for course credits. The task was identical to Experiment 1 with the following changes. To aid category learning, letters belonging to the same category were grouped together on the circle (Figure 1b). ANOUN and INOUN letters were replaced with symbols providing semantic cues to those categories. To implement the production task, participants were shown the whole string, which disappeared once the mouse was moved. They were
then required to produce the string from memory by selecting the appropriate symbols as quickly as possible. Twenty-four production trials were added by replacing four comprehension trials (target strings) in each section. An additional section of 24 items was added for a total of 144 items.

## Results

Participants' grammatical knowledge at the end of the experiment was assessed using a one-sample $t$-test comparison against chance ( $50 \%$, two-tailed). They successfully recognized $64 \% \quad(t(41)=6.63, p<.001)$ of grammatical strings showing that they learned the language as in other artificial language learning studies.

Figure 3: Mean proportions of errors and reaction times in each section in production and comprehension tasks when verb and structure matched (solid line) or mismatched (dashed line).

The task produced a total of 22,464 responses, $5.5 \%$ of which were incorrect. Error data and reaction times were analyzed as in Experiment 1 with the addition of task type (production or comprehension, effect coded) fully crossed with the other variables. We found that error rates went down over section ( $b=-0.2, S E=0.06, z=-3.15, p=.002$ ) showing general learning effect. Participants made more errors in production than in comprehension ( $b=1.47$, $S E=0.23, z=6.34, p<.001$ ), but also improved more in production over sections $(b=-0.26, S E=0.12, z=-2.22$, $p=.03$ ). Finally we found that error rates were higher when verb and structure matched $(b=0.71, S E=0.21, z=3.36$, $p<.001$ ), which contradicts our prediction. However, this is due to the fact that the majority of errors belonged to the
target category ( $67 \%$ ), indicating that in most cases people anticipated the correct category but chose the wrong symbol. This was likely to be due to the grouping and visual similarity of the symbols.

The reaction time analysis revealed a general learning effect in which participants reacted faster across trials ( $b=-0.03, S E=0.003, X^{2}=122.38, p<.001$ ). Participants were also faster in production than in comprehension ( $b=-0.32$, $\left.S E=0.902, X^{2}=83.04, p<.001\right)$ due to task differences. Verbstructure match produced a significant main effect where reaction times decreased when verb matched its structure ( $b=-0.07, S E=0.01, X^{2}=21.42, p<0.001$ ). The mismatch with error rate resulted from speed-accuracy tradeoff where faster reaction times in verb-structure match condition resulted in more errors ( $b=0.001, S E=0.0004, z=2.95, p=.003$ ).

Figure 4: Mean proportions of errors in each section in production and comprehension tasks when prime structure was the same (solid line) or different (dashed line).

To examine structural priming, error rates and reaction times were submitted to similar mixed models as in Experiment 1 with the addition of task type fully crossed with other variables. A general learning effect was indicated by decreasing error rates over sections ( $b=-0.18, S E=0.07$, $z=-2.68, p=.007$ ). Participants produced more errors in production than in comprehension ( $b=1.14, S E=0.23$, $z=5.23, p<.001$ ), reflecting task demands. Finally, there was a three-way interaction between structural match, section and task type ( $b=-0.98, S E=0.24, z=-4.0, p<.001$ ), indicating that the reduction in error rates due to prime structure was greater in production relative to comprehension as section increased (Figure 4).

The reaction time analysis found a general improvement over section ( $b=-0.04, S E=0.004, X^{2}=84.13, p<.001$ ) and
faster responding in production $(b=-0.32, S E=0.02$, $X^{2}=11.12, p<.001$ ), reflecting a general learning effect and the nature of the task respectively. No priming effect was found in reaction times.

In sum, the production task and semantic grouping gave rise to structural priming in participants' errors. The fact that this priming is only evident at the end of the study suggests that participants had to learn structures before generalizing across the different strings (structural priming as language learning, Chang, Dell, \& Bock, 2006). Verb bias seemed to be present early in the experiment suggesting that grouping of the letters on the circle made verb bias acquisition relatively easy and did not allow capturing the growth of the effects over time.

## Discussion

This is the first study to provide evidence that verb bias and structural priming in a non-linguistic artificial language task arise from learning distributional constraints. Verb bias was found in Experiment 1, where participants were less likely to make errors when the structure matched the verb's preference. Structural priming was found in Experiment 2, where participants were less likely to make an error in producing a target sentence from memory if the previous sentence was of the same structure. Importantly, the prime and target shared no common symbols, so this effect cannot be due simply to the recall of particular symbol combinations. Both verb bias and priming effects increased over the experiment as participants learned the language, showing that these effects resulted from learning some language-related knowledge and not from some methodspecific features. This supports the prediction that such linguistic effects would also manifest in non-linguistic tasks, pointing to the commonalities in the underlying SL mechanisms (Chang, Janciauskas, \& Fitz, 2012).

One may note, however, that reaction times and errors showed conflicting results for verb bias, where in Experiment 1, verb-structure match created fewer errors, but slower reaction times, while the opposite pattern was observed in Experiment 2. The main difference between the two studies was the semantic similarity and grouping of the stimuli (verb bias did not interact with task type in Exp. 2). In Experiment 2, the semantic grouping meant that anticipation of the category that resulted from verb's bias (left for ANOUNs, right for INOUNs) resulted in faster reaction times, but also triggered more errors, particularly for the same category members. However, the exact cause for the patterns observed in Experiment 1 remains to be established but it is likely to be due to the differences in the way the letters were distributed on the screen in the two experiments. Interestingly, speech errors in natural language also exhibit speed-accuracy tradeoffs with speech rate (MacKay, 1982) and within-category effects (Dell, 1986) warranting further investigation of these effects in such nonlinguistic tasks.

Although our task is an artificial grammar-learning task, there are intriguing similarities with dissociations in human
verb bias and priming tasks. Errors in this study are related to structural choice in production tasks, because an "error" at the choice point can become a grammatical utterance depending on how the participant completes the sentence. Reaction time is related to graded measures like sentence initiation time or comprehension reading time. Effects of verb preferences on structural choice are well documented (Ferreira, 1996; Stallings et al., 1998), but the results for reaction times are mixed, with some studies finding facilitation (Garnsey et. al, 1997) and other studies finding no effect (e.g. Kjelgaard \& Speer, 1999). Likewise, structural priming results are robust in production (Pickering \& Ferreira, 2008), but abstract priming across verbs is less robust in comprehension studies (Arai, Van Gompel, \& Scheepers, 2007; Branigan, Pickering, \& McLean, 2005). Since the computational properties of the linguistic and non-linguistic mechanisms show these similarities, the differences observed in the way people express their knowledge in the comprehension-like task and the production-like task suggests that it may be beneficial to study these mechanisms within such an SRT paradigm, where both tasks are closely matched and the input tightly controlled.

To conclude, linguistic theories have long claimed that language involves specialized linguistic systems (Chomsky, 1965). These systems help to explain why verbs govern the structures that they appear in and how children acquire abstract syntactic representations from experience with word sequences. For these reasons, it should be difficult to use a domain-general visual-motor task to model the acquisition of a new language and find behaviours that mirror linguistic phenomena like verb bias and abstract structural priming. The fact that we observed these effects is particularly intriguing considering the short time taken to learn our language (our study took 20 minutes compared to 360 minutes in Hunt and Aslin, 2001). These difficulties were overcome in part due to the integrated learningprocessing approach taken here. The approach that is often used in SL studies involves separating testing from learning in order to test novel combinations that provide a strong test of abstract grammatical knowledge. Instead, we used linguistic adaptation of the existing representation in response to the input as evidence for abstraction and learning (e.g., structural priming). Since these items can be tested multiple times, it is possible to factor out individual variation and see changes as learning unfolds. The addition of semantic cues made it easier for participants to exhibit structural knowledge and allowed linguistic adaptation to take place at a higher level with these categories as lower level elements. Since our goal was to look at how representations change over time, rather than how they emerge from scratch, building semantics into the task is justified as children have an animacy distinction before they fully acquire structures like the dative (Gropen et al., 1989). Finally, an addition of a production task showed that the effects of learning manifest differently depending on the task that draws upon the acquired knowledge. In sum,
although there are still methodological issues to address, our results so far suggest that this task could be a way to examine the processes that take place in language production and comprehension.

# Not so innocent: Reasoning about costs, competence, and culpability in very early childhood 

Julian Jara-Ettinger (jjara@mit.edu)<br>Joshua B. Tenenbaum (jbt@mit.edu)<br>Laura E. Schulz (lschulz@mit.edu)<br>Department of Brain and Cognitive Sciences, MIT<br>Cambridge, MA 02139 USA

#### Abstract

Social evaluations depend on our ability to interpret other people's behavior. In adults, these evaluations are influenced by our perception of the competence and motivation of the agent: helping when it is difficult to help is praiseworthy; not helping when it is easy to help is reprehensible. Here we look at young children's capacity to make competence attributions and its relation to their social evaluations. We find that as early as 18-months, infants can use the time and effort associated with achieving a goal-directed action to distinguish agents, and that infants prefer more competent agents. When asked to choose between two agents who act as moral bystanders and refuse to engage in a helpful action, we find a sustained preference for the more competent agent until the age of three, when the preference is reversed. We argue that the ability to calculate the cost and benefits of goal-directed action originates in early childhood and plays a fundamental role in moral reasoning.

Keywords: Action Understanding; Morality; Social Cognition; Theory of Mind.

## Introduction

The past decade has seen a revolution in our understanding of psychosocial reasoning in early childhood. Recent findings suggest that infants infer the false beliefs of others (Onishi \& Baillargeon, 2005; Southgate, Senju, \& Csibra, 2007; Kovács, Téglás, \& Endress, 2010), distinguish helpers, hinderers, and moral bystanders (Kuhlmeier, Wynn, \& Bloom, 2003; Hamlin, Wynn, \& Bloom, 2007); draw different inferences about actions directed towards member of in-groups and out-groups (Baillargeon et al., in press); predict actions based on social dominance (Thomsen, Frankenhuis, Ingold-Smith, \& Carey, 2011), judge third party agents transitively, based on how they interact with moral transgressors (Hamlin, Wynn, Bloom, \& Mahajan, 2011; Sloane, Baillargeon, \& Premack, 2012); and consider agents' knowledge about a target agent's preferences in making moral judgments (Hamlin, Ullman, Tenenbaum, Goodman, \& Baker, 2013). The discovery of infants' sophisticated social intelligence is among the most exciting recent developments in the field of cognitive science. However, to date relatively little is understood about the types of computations that underlie these social judgments.

## Rational Planning, Social Evaluations, and a Naïve Utility Calculus

Here we propose a new approach to thinking about social reasoning in infancy, drawing on the insight that the ability to reason about goal-directed action is at the core of our cognition about agents. (See Carey, 2009; Gergely \& Csibra,

2003 for review). Consistent with a large body of prior work, we assume that inferences about agents' goal-directed actions are governed by a principle of rational expectation: the idea that agents act efficiently to achieve their goals (e.g., Scott \& Baillargeon, 2013; Gergely \& Csibra, 2003). Computational work on the principle of rational expectation as probabilistic inference over rational planning has been used to successfully model adults' reasoning about agents' goals (Baker, Saxe, \& Tenenbaum, 2009, 2011; Ullman et al., 2010; Jara-Ettinger, Baker, \& Tenenbaum, 2012).

The principle of rational expectation is predicated on the understanding that agents act in ways that will minimize costs and maximize rewards. We propose that the ability to compute the costs and benefits of actions forms the heart of a naïve utility calculus that supports inference at the earliest stages of children's theories of agency. (See Jara-Ettinger, Gweon, Tenenbaum, \& Schulz in prep, for a detailed version of this argument and experimental studies in childhood). Here we provide an informal description of this approach and test one of its qualitative predictions: that an analysis of the cost functions associated with agent actions is central to the moral judgments even of very young children.

Intuitively, adult social evaluations are influenced by our perception of how much an action will cost the agent who performs it. Imagine for instance, that your neighbor, Sally, watches a child struggle to reach a package on the top shelf of a grocery store. Sally stands by and does nothing at all. Although there is no intrinsic relationship between height and moral worth, you may well judge Sally less harshly if she is $4^{\prime} 11^{\prime \prime}$ than if she is an NCAA Division 1 basketball player.

What analysis underlies this inference? We suggest that in evaluating and predicting agents' actions, observers automatically compute the cost of actions. The perceived cost of an action (controlling for constraints imposed by the environment) reflects inferences about the agents' level of competence; the perceived benefits of the action to the agent reflect inferences about the agents' level of motivation. Motivation and competence jointly affect the probability of the agents' actions so the two attributions trade-off with each other. If we know that an agent is highly motivated and she fails to act, we may infer that she is incompetent; conversely, if we know the agent is highly competent and she fails to act, we may infer that she is unmotivated. Morally, lack of competence to help is an exonerating factor; lack of motivation is not.

More generally social evaluations depend heavily on the agent's motivation (Cushman, 2008; Knobe, 2005; Young, Cushman, Hauser, \& Saxe, 2007). This may not be known and must then be inferred. If the agent performs a morally worthy action, then the higher our estimate of the cost of the action, the higher our estimate of the agents' motivation to act morally. Similarly, if the agent fails to act, then the lower our estimate of the cost of action, the lower our estimate of the agent's motivation. Ambiguity arises when the agent acts but the cost of action is very low, or the agent fails to act but the cost of action is very high; in such cases, we may be unsure of the agent's level of motivation. In our example, if Sally is $4^{\prime} 11^{\prime \prime}$, there is a high cost to reaching the shelf. This renders her failure to act ambiguous. Did she not want to help or was it simply too hard for her to do so? By contrast, if Sally is an NCAA basketball player, we can infer that the cost of reaching a shelf is low; thus we are more confident that her failure to act derives from a morally suspect lack of motivation.

We propose that these kinds of considerations are part of a general calculation of a cost function that, even early in development, is used to reason about goal-directed behavior and interpret agents' actions. However, to date no empirical work has looked at how differences in the cost function of agent actions affect children's evaluative and moral judgments. Similarly, no previous computational work has looked at how learners might compute the cost function of agent actions; work on goal inference has implicitly assumed that the cost function of actions is known (e.g., Baker et al., 2009; Ullman et al., 2010).

Here we test the prediction that very young children can estimate the cost functions associated with agents' actions and that this analysis affects children's moral judgments. In Experiment 1, we test the basic premise that children can use the perceived cost of actions to estimate agents' competence. We predict that at baseline children will prefer more (versus less) competent agents. In Experiment 2, we look at whether children can use differences in the cost of actions to infer differences in agents' motivations. We predict that when agents are moral bystanders, children may overcome their baseline preference for competent agents and be more likely to consider the merits of incompetent (but potentially more wellintended) agents.

## Experiment 1: Early Competence Attribution

In Experiment 1 we look at whether toddlers can use the time and effort associated with achieving a goal-directed action to estimate the cost of the action to the agents. We also look at whether toddlers have an early preference for competent agents.

## Participants

Twenty-four toddlers (mean age (SD): 21.19 months (97 days), range 16.8-28 months, 16 males) were tested at an ur-
(a) Experiment 1

Figure 1: Procedure for Experiments 1 and 2. Both experiments begin by introducing two puppets and a toy. One puppet (the Competent agent) was able to make the toy play music on the first attempt; the other puppet (the Incompetent agent) succeeded only after many attempts. In Experiment 1 (blue arrow), children were then asked to choose one of the puppets to play with. In Experiment 2 (green arrows), after the child saw both puppets activate the toy, the parent turned around and asked each puppet for help with the toy. Both puppets refused. As in Experiment 1, children were then asked to choose one of the puppets to play with.
ban children's museum ${ }^{1}$. Five children were excluded from analysis: four by decision of a blind coder and one for parental interference (See Results). All subjects were tested at an urban children's museum.

## Stimuli

Participants were shown two puppets and a yellow cylindrical toy with a black button at the top. The toy played music when the button was pressed.

## Procedure

Participants were tested in a quiet room at the museum. The child's parent was seated on a chair facing away from the testing table and the parent was asked to hold the toddler over his or her shoulder. Thus the child could see the stimuli but the parent could not.

Once the parent and toddler were positioned the experimenter presented the yellow toy to the child and introduced the two puppets. See Figure 1. He said, "Here are my two friends! They are going to show you how the toy works." Both puppets were continuously present throughout the experiment and each puppet approached the toy (order counterbalanced between participants) one at a time. The puppet said, "It's my turn!" and then pressed the button. When the toy activated, the toy played a song for approximately $10 \mathrm{sec}-$

[^103]

Figure 2: Results from Experiment 1: Number of children choosing each agent. $* *=p<.001$ by binomial test.
onds and then the puppet released the button. During this time, both puppets moved rythmically to the sound of the song. After releasing the button, each puppet said "Yay!" to celebrate the success.

The puppets differed in how many attempts it took them to activate the toy. The competent agent was always able to make the toy play music on the first attempt. The incompetent puppet tried several times to activate the toy (flattening his hand over the button but not depressing it fully). After the third or fourth failed attempt, the incompetent puppet backed away to look at the button, and then tried again. The incompetent puppet made a few more failed attempts and then successfully activated the toy. (The number of total attempts ranged from 6-8 trials across participants, allowing some flexibility in maintaining the child's attention to the task.) After the show, the parent was asked to turn around and to place their child at a marker on the middle of the edge of a lower table. The experimenter placed both puppets on opposite sides of the table equidistant from the child and asked the child which one she wanted to play with.

## Results and Discussion

All videotapes were coded by a coder blind to condition. Four children were excluded from analysis due to the coders' judgment that the puppets were not placed equidistant from the child. One additional child was excluded from analysis due to parental interference. The coder recorded the toddlers' first contact with a puppet following the prompt. If the child did not make a choice within a 30 -second window following the prompt, the experiment was ended. Three children did not make a choice. Of the 16 children who did make a choice, 15
preferred the competent agent ( $p<0.001$ by binomial test). See Figure 2.

In our design, the incompetent agent both made more attempts to activate the toy and took longer to activate the toy. Additionally, after some initial failures, the incompetent puppet studied the toy before trying again. Thus there were redundant cues to the agent's incompetence and we do not know whether toddlers' preferences were driven by the overall effort to achieve the goal, the time to achieve the goal (and thus perhaps the relative novelty of the puppet who achieved the goal more quickly), or a more abstract judgment about these factors as indices of competence per se. Future research might look at the range of factors that affect toddlers' inferences about the cost of agent actions. However, the result of Experiment 1 give strong evidence that by 18 months, children distinguish agents from differential cues to competence and prefer agents who appear to incur fewer costs to achieve a goal.

## Experiment 2: Competence and Social Evaluations

In Experiment 2, we look at how children's judgment of agent competence affects their social evaluation. Because pilot work suggested that the task in Experiment 2 was more demanding than the one in Experiment 1, we tested slightly older children: two and three-year-olds.

## Participants

Seventeen two-year-olds (mean age (SD): 30.8 months (83 days), range 26.6-34.9 months, 9 males); one was dropped from analysis for failure to make a choice. Thirty three-yearolds (mean age (SD): 42 months (104 days), range 36-50.09 months, 17 males) were recruited in the test condition; 7 were dropped from analysis, 4 by decision of a blind coder and 3 for failures to make a choice. An additional 9 three-year-olds (mean age (SD): 35.4 months (131.67 days), range 29.1-42.03 months, 4 males) were recruited for a control condition, 1 was dropped from analysis due to failure to make a choice. All subjects were tested at an urban children's museum ${ }^{2}$.

## Stimuli

The stimuli used in Experiment 2 were identical to stimuli used in Experiment 1.

## Procedure

The protocol in Experiment 1 was identical to the protocol in Experiment 2 with the following exceptions (See Figure 1). Because the children were older, they were given a choice of sitting in a small chair or standing in front of the testing table, behind the parent's chair. Additionally, before the experiment began, the parents were given a script to read telling them that when prompted to do so, they should turn around and pick up

[^104]Experiment 2: Children's preferences as a function of age

Figure 3: Children's choice of puppet in the test condition of Experiment 2 as a function of their age. The logistic regression with $95 \%$ confidence interval is shown on top. At early ages we find a preference for the competent agent, which disappears in older subjects.
the toy from the table. The experimenter would then place one puppet at a time in front of them. Parents in the test condition were instructed to ask each puppet: "Can you help me make the toy go?" Parents in the control condition were instructed to ask each puppet "Do you have a toy like this at home?"

Otherwise, the first part of the protocol proceeded as in Experiment 1. After both the competent and incompetent puppets successfully made the toy play music, but before the child was asked to make a choice, both puppets were removed and the toy was placed in the middle of the table. At this point the parent was asked to turn around. The parent picked up the toy and the experimenter returned a puppet to the middle of the table (order of puppets counterbalanced). Only one puppet was visible at a time. After the parent asked the puppet the target question, the puppet looked at the toy, then at the parent and said "No!" The puppet then turned around and hid under the table. This was repeated with the next puppet. To ensure that the child understood, in the test condition the experimenter said, "No one seems to want to help!" In the control condition he said, "No one seems to have this toy!" The questions and answers were then repeated with each puppet a second time.

After each puppet had said "no" twice, the experimenter took the toy from the parent and asked the child to stand on a marker in the center of a table edge. As in Experiment 1, the experimenter then set each puppet on opposite sides of the table, equidistant from the child and asked the child which puppet she would rather play with.

## Results and Discussion

Results were coded from videotape by a coder blind to conditions, as in Experiment 1. Children were excluded from analysis if, in the coder's judgment, the puppets were not placed equidistant from the child or if children did not make a choice within the 30 -second window, resulting in 162 -year-olds and 23 3-year-olds in the test condition and 83 -year-olds in the control condition (See Participants).

In the test condition, a logistic regression showed an effect

Figure 4: Number of subjects choosing to play with the competent (red) and incompetent agent (blue) in each age and condition of Experiment 2. $*=p<.05$.
of age on children's preferences: older children were more likely than younger children to choose the incompetent puppet ( $p<0.02$ ). See Figure 3 .

We followed-up with planned comparisons of the two and three-year-olds separately. See Figure 4. The two-year-olds showed a robust preference for the competent puppet. Of the 16 two-year-olds who made a choice, 12 chose the competent puppet ( $p<.05$ by binomial test). By contrast, the three-year-olds in the test condition chose between the puppets at chance; 13 of the 26 three-year-olds chose the competent puppet ( $p=n s$ by binomial test).

These results are consistent with the possibility that three-year-olds can use differences in agents' competence to attribute differences in agents' motivation, and can overcome their baseline preference for competent agents if agents fail to act helpfully. Arguably however, the three-year-olds chose at chance because they simply forgot which puppet was more competent (perhaps because the three-year-olds were more engaged than the two-year-olds by the puppets' refusals).

To see whether three-year-olds retained the competence information we looked at three-year-olds' performance in the control conditions. Failure to recall the more competent puppet seems unlikely to explain the results; preliminary results from the control condition suggest that the three-year-olds have no difficulty remembering which puppet was more competent when moral culpability is not at issue: 6 of the 8 three-year-olds showed a preference for the more competent puppet.

These results suggest that by the age of three, children can override a preference for competent agents if those agents act as moral bystanders. Given that it is morally objectionable to refrain from helping when a helpful action is relatively low cost, three-year-olds seem to be able to look more favorably on agents who have the excuse of incompetence to exonerate them.

The current findings are consistent with previous work sug-
gesting that both toddlers (Tomasello et al., 2005) and chimpanzees (Call, Hare, Carpenter, \& Tomasello, 2004) differentiate between agents who are unwilling to act helpfully from those who are unable to act helpfully. Here we also find that children distinguish competence to help from motivation to help. Critically however, participants in the earlier studies could assess the agents' motivation directly, from overt behavioral cues: serious, if failed, attempts to help indicated a motivated agent; "teasing" indicated an unmotivated one. Additionally, the "unable" agent in the earlier studies was genuinely unable: every attempt the agent made failed.

By contrast, in the current study, both agents were unwilling to help (both puppet said "no" and turned away from the parent) and neither agent was unable to help (both puppets were in fact able to activate the toy). Children could only evaluate the agents on the basis of graded differences in the agents' competence; however, this is precisely the kind of ability children should have if, as we have proposed, social reasoning in early childhood is informed by a naïve utility calculus, supporting computations of the costs and benefits of actions.

## General Discussion

Consistent with the idea that a naïve utility calculus is integral to children's understanding of agents, we found that inferences about the relative cost of agents' actions affect children's social evaluations from very early in development. Toddlers seem to be sensitive to cues associated with the relative competence of agents and prefer agents who achieve goals quickly and easily to agents who achieve the same goals at apparently higher costs. By the age of three, children seem to be able to use differences in agent competence as grounds for evaluating agents differently, even when the agents act identically in refusing to act at all.

As noted, we provided redundant cues to the competence and incompetence of these agents, including the time it took for each agent to make the toy play music, and the number of times each puppet pressed the button. We do not know to what extent toddlers' preferences were driven by each individual cue, or if their choice was guided by a more abstract representation of competence. Future research can shed light on the full range of cues we use to infer an agent's competence both in the physical domain and the epistemological domain, where some form of competence preference has also been found (Koenig, Clément, \& Harris, 2004; Pasquini, Corriveau, Koenig, Harris, et al., 2007).

There are several hypotheses consistent with the developmental change we observed between the age of two and three. One possibility is that toddlers distinguish competent and incompetent agents, but they do not infer that relative competence implies an obligation to act helpfully, or that relative incompetence exonerates an agent from such actions. A related possibility is that toddlers might make categorical distinctions between classes of behavior (e.g., "helping", "not helping", and "hindering") but make no distinctions within each cate-
gory; because both puppets in our paradigm refused to help, toddlers might find them equally blameworthy. A final intriguing possibility is that both two and three-year-olds can integrate judgments of agents' competence with moral judgments, but the children find themselves in a moral dilemma (and resolve the dilemma differently at different ages): they believe the incompetent agent is less culpable; however, they also believe it is a good idea to affiliate with competent agents. Future work is necessary to disambiguate these possibilities.

Additionally, because the children were given a forced choice between two agents, we do not know whether the one and two-year-olds' choices were based on a preference for the competent agent, an aversion to the incompetent one, or both. Similarly, we do not know whether the three-year-olds' choices reflect a relatively greater preference for the less competent (and therefore morally exonerated) agent, a relative devaluing of the more competent (and therefore morally culpable) agent, or both. Further research might disambiguate the specific attributions underlying children's preferences.

What this study does show is that human beings are sensitive to the cost of actions very early in development and form an early preference for competent agents. As children progress through early childhood, they become increasingly able to use inferences about an agent's competence to draw inferences about the agent's moral status. At an age when children themselves are still largely both incompetent and innocent, their ability to understand how the one characteristic might bear upon the other suggests remarkably sophisticated inferential abilities and highlights the importance of building a new theoretical synthesis for understanding the development social reasoning.

## Acknowledgments

We thank the Boston Children's Museum and the families who volunteered to participate. Thanks to Salvador Esparza, Eric Garr, and Aviana Polsky for help with data collection. We thank Rachel Magid for help with coding the data. Special thanks to Hyowon Gweon and Kim Scott for helpful comments and discussions. This research was funded by the National Science Foundation and the Simons Center for the Social Brain.

# Developmental See-Saws: Ordered visual input in the first two years of life 

Swapnaa Jayaraman, Caitlin M. Fausey, \& Linda B. Smith<br>(\{swapnaa, cfausey, smith4\} @indiana.edu)<br>Department of Psychological and Brain Sciences, Indiana University<br>1101 East Tenth Street, Bloomington, IN 47405 USA

#### Abstract

The first two years of life are characterized by considerable change in all domains - perception, cognition, action, and social interactions. Here, we consider the statistical structure of visual input during these two years. Infants spanning the ages from 1 to 24 months wore body-mounted video cameras for 6 hours at home as they engaged in their daily activities. Our data strongly suggest that the statistical structure of the learning environment is dynamic and ordered. The available visual statistics are not stationary, but rather they are gated by young children's developmental level. We find a rolling wave of "See-Saw" patterns over developmental time in two classes of important social stimuli: First faces, then hands; and within hands, first other-then-self-then-touching-then-holding. These ordered environments may help learning systems "start small," find the optimal path to the optimal solution, and determine the architecture of the system that does the learning.

Keywords: natural statistics; first-person camera; faces; hands

## Introduction

Growing evidence across many domains indicates that human learners, including infants, are highly sensitive to the statistical regularities in the learning environment (Saffran, Aslin \& Newport, 1996) and that in many domains the regularities in the learning environment contain sufficient information to yield deep conceptual representations (Chater, Tenenbaum \& Yuille, 2006) of the kind that appear responsible for syntax (Griffiths, Steyvers \& Tenenbaum, 2007), semantics (Griffiths, et al., 2007), categories (Madole \& Oakes, 1999), and human visual object recognition (Logothetis \& Sheinberg, 1996; Quinn, Eimas \& Tarr, 2001). As methods for understanding structure in large data sets advance, it seems likely that we will discover rich insights in even broader domains about how the statistical structure of learning environments shapes human learning and knowledge. The research presented in this paper makes two contributions to this endeavor: by extending the study of the statistical structure of the learning environment to social stimuli - faces and hands; and by showing that the statistical structure of the learning environment is not stationary. Rumelhart and McClelland's (1986) model of the learning of the past tense was once famously criticized (Pinker \& Prince, 1988) as a cheat because the network was presented with learning examples in an ordered way rather than as batch statistics. However, the statistics of the learning environment can change substantially with development itself. The present findings provide one clear and dramatic example of this reality. We return to the more
general issue of what constitutes a developmentally appropriate conceptualization of statistical learning in the General Discussion.

## Faces and Hands as Important Social Stimuli

The first two years of life are characterized by considerable change in all domains - perception, cognition, action, and social interactions. Findings in all of these domains indicate the important role of other people, in scaffolding and supporting developmental process (Tomasello, 1988). Research into the social behaviors of mature partners that support infant learning have centered on two body regions face and hands. Research into the adult actions that infants attend to as guides to learning and understanding the world also focus on two body regions - faces and hands. And, indeed, a very large literature suggests that infants are highly sensitive to what are very small movements in these body regions - a shift in eye gaze (Butterworth \& Jarrett, 1991), a mouth opening (Moll \& Tomasello, 2012), a point (Leung \& Rheingold,1981), and a grasp (Woodward, 1998). It seems likely that faces and hands are everywhere in early infant experience. From the statistical learning perspective, this would mean that face and hand experiences present a very large data set for mining the structure and meaning of social gestures.

However, contemporary research is also consistent with the idea that this statistical learning might be modulated by internal (and innate, Meltzoff \& Moore, 1977; Slater, 1999) biases that privilege faces early in development. Research on infant face perception begins from the perspective that faces are a special class of stimuli. A large set of findings using diverse tasks indicate that very young infants are differentially sensitive to face-like visual stimuli relative to other stimulus categories (Goren, Sarty \& Wu, 1975; Johnson, et al., 1991) and can discriminate familiar faces from unfamiliar ones (Field et al, 1984) shortly after birth. Moreover, the earliest social interactions consist of face-toface play (Stern, 1971) and these have been characterized as "proto-conversations" that teach critical components of turn-taking and seem a likely context for learning about the facial cues that modulate social interactions and infant learning. Other evidence suggests that this early sensitivity to faces plays a critical role in tuning face perception processes: By 6 months infants recognize faces that are similar to those that have dominated their visual experiences (same race) better than faces that are dissimilar (different
race) (Kelly et al., 2007). Early visual deprivation appears to disrupt indices of face expertise such as configural processing of faces (Maurer, Le Grand \& Mondloch, 2002), and identification of faces with altered orientations and expressions (Geldart et al, 2002).

Systematic attention to hand actions as social indicators as pointers to objects to which infants should attend -- has been shown in 4 month olds (Rohlfing, Longo \& Bertenthal, 2012) but as far as we know this is the youngest demonstration of an understanding of a hand action. Most of the evidence indicating infant attention to and understanding of the meaning of hand actions - both in the context of language learning (Bates et al, 1989) and in the context of understanding the causal structure of events (Baldwin, 1991; Woodward, 1998) - focuses on older infants. For example, 10 and 12 months olds have been shown to use hand actions to predict causal sequences (Sommerville \& Woodward, 2005), 11 month olds have been shown to use the structure of a hand action to predict where an event will occur (Canon \& Woodward, 2012), in a large number of experiments 9 to 14 month olds have been shown to use points and other hand gestures to determine the intended referent of a heard word (Rader \& Zukow-Goldring, 2012), and 18 month olds may even understand hand gestures that mimic actions as pointers to objects and events more readily than words (Namy \& Waxman, 1998), as may 2-4 year olds (Hahn \& Gershkoff-Stowe, 2010). Several recent studies on 12 to 18 month old infants' attention in naturalistic contexts indicate that these older infants differentially - and perhaps systematically - look to the hand actions of mature partners when engaged in joint play with the parent (de Barbaro, Chiba \& Deák, 2011; Franchak, et al., 2010; Yoshida \& Smith, 2008), a result that suggests that these older infants know that hand actions contain important social information.

These findings indicate that infants may know about faces as sources of social information before they know about hands and suggest the following hypothesis: Although faces and hands are equally ubiquitous in the learning environments of infants, learning about these two classes of social cues is gated by infants’ early differential sensitivity to faces.

## Ordered input

Traditional approaches to statistical learning have concentrated on non-incremental learning tasks, tasks in which the entire training set is fixed at the start of learning and then is either presented in its entirety or randomly sampled. From this perspective, if learning needs to be constrained in some way or directed to some portion of the input, it must be accomplished by internal constraints on the learning system (Markman \& Hutchinson, 1984; Pinker, 1989), such as an innate sensitivity or interest in faces. But infants do not encounter the world as a single set of fixed statistics; they encounter it one learning instance at a time.

Because of this, they may encounter and experience selected regularities in just one small region of the total batchstatistics learning environment (Smith \& Gasser, 2005). Given the dramatic changes in the skills of human infants over the first two years of life, this seems highly likely. Given the ordered nature of these changes - first rolling over, then reaching, then sitting stably, then crawling, and then walking -- these selected statistics will also be ordered. West and King (1987) proposed the concept of ontogenetic niche: the idea that developmental level orders experiences in ways that constrains and canalizes developmental process. For example, in humans (and most mammal and some bird species) the young require constant caretaking and this constant caretaking limits as well as structures the input, and thus the regularities that can be learned one at a time. Humans' changing sensory motor abilities seem likely to constrain and expand visual experiences in different ways at different times. Human infants spend their first 6 months where others place them - on the floor, in infant seats, in a crib, in arms - and see what is in those places and what their mature caretakers care to show them. By 12 months, infants are much more masters of their own visual environments placing themselves in different locations and actively selecting what they will show themselves (Adolph et al., 2012).

These considerations raise an alternative hypothesis about faces and hands: Although faces and hands are equally ubiquitous in human environments, they are not equally ubiquitous in the visual environments of infants of different ages; instead, experiences of faces and hands are ordered, with dense experiences of faces characterizing the early ontogenetic niche and dense experiences of hands characterizing the later ontogenetic niche.

## Rationale for the present approach

The findings reported here are part of a larger program of research examining the statistical structure of natural visual environments as it relates to social cues and language learning. We build on the approach of a growing number of researchers using ego-centric cameras (Fathi, Hodgkins \& Rehg, 2012; Kanade, 2009) to capture first person visual environments. Studies of infants’ first person perspectives (mostly small laboratory studies, Aslin, 2009; Franchak et al., 2011; Smith, Yu, \& Pereira, 2011) have shown that these first person environments are characterized by properties of early visual experience that are not evident from third-person observer perspectives (Yoshida \& Smith, 2008) and have also documented the impact of infant body movements on infant visual experience (Kretch et al., 2012). Intriguingly, all the head-camera studies conducted with toddlers to date have noted that faces are rarely in the head camera images whereas hands - the child's and social partner's - are often in view (Franchak et al, 2011; Frank, 2012; Smith et al, 2011; Yoshida \& Smith, 2008). These studies, however, did not broadly sample the natural or
representative experiences of participants. The present study was designed to do just this. Infants spanning the ages from 1 to 24 months wore body-mounted video cameras for 6 hours at home as they engaged in their daily activities. The first questions we asked of these data, the results we report here, are these: How prevalent are faces and hands in the visual environment? Do the frequencies of faces and hands change systematically with development?

## Method: Capturing early visual environments

## Participants

23 infants and toddlers provided up to 6 hours of video each. This visual corpus consists of four subsets grouped by age. All videos within an age range are treated as a set.

Table 1: Infant and toddler visual corpus

| Age (months) | n | Hours of video | Frames coded |
| :---: | :---: | :---: | :---: |
| $1-3$ | 7 | 19.26 | 13,865 |
| $7-9$ | 5 | 21.88 | 15,754 |
| 18 | 6 | 22.64 | 16,303 |
| 24 | 5 | 14.59 | 10,505 |
| Total | 23 | 78.37 | 56,427 |

## Materials and Procedure

A small, lightweight camera was used to record the visual environments of infants and toddlers (Looxcie 2, Looxcie, Inc.). The diagonal FOV is 62 degrees with a 2 ":infinity depth of focus. The camera was secured to a wearable hat or harness. Parents were given a camera, hat and/or harness, and instructions about camera operations. Parents recorded up to 6 hours of video when their child was awake.

## Video pre-processing

Recorded videos were screened for private content and blank screens (e.g., camera was left turned on while not on child). Remaining videos were converted to images sampled at one frame for every five seconds of video. This first-of-akind corpus has approximately 78 hours of video and 56,000 frames of the natural visual environments of infants and toddlers in the first two years of life.

## Video coding: A reliable crowd-sourced approach

Frames were presented to coders on Amazon's Mechanical Turk (mturk.com) and analyses consider only those frames for which at least $75 \%$ of coders agreed (across all coding passes, $93.7 \%$ reliable judgments). Coding proceeded in six separate passes through the data. For each pass, coders viewed an instructions page with example images.

## Faces and Hands

The first broad passes coded for the presence of Faces and Hands. The infant (1-3, 7-9 months) and toddler (18, 24 months) data were coded with slightly different protocols. For infants, each coder saw up to eight frames and answered several questions about each frame. The two relevant questions were: (1) Do you see a human face or face part? and (2) Do you see other body parts or skin? If yes, which do you see? (a) bare hands/fingers, (b) bare feet/toes, (c) other body parts (neck, shoulder, knee, etc.), (d) body parts covered in clothes, (e) two or more of the above. In these analyses, only responses that indicated the presence of bare hands were further analyzed. Four unique coders judged each frame. For toddlers, each coder saw up to 100 frames and answered the same yes-or-no question for all frames. In separate passes, coders answered either (1) Do you see a human face in this picture? or (2) Do you see a human hand in this picture? Five unique coders judged each frame.

## Free, touching and holding hands

The next coding passes focused specifically on hands. First, we identified whether hands in the visual input belonged to the child or to someone else. Then, we identified whether the child's own hand was free, touching something, or holding a small object. In four distinct passes, coders answered one of these questions: Does any hand you see belong to the child wearing the camera?, Is the child's own hand touching something?, Is the child's own hand holding onto something?, Is the child's own hand holding something that can be carried?

## Results: Ordered visual input

## Body parts in the visual environment

How prevalent are faces and hands in the visual environments of infants and toddlers? The relative frequency of these two key body parts depends on the developmental stage of the child (Figure 1). The visual environments of the infants had more faces than hands (1-3 months: . 29 Faces, .01 Hands; 7-9 months: . 15 Faces, .06 Hands). For toddlers, hands were more prevalent than faces (18 months: . 11 Faces, .28 Hands; 24 months: 07 Faces, .32 Hands); $\chi^{2}(3, N=17962)=6936.84, p<.001$.

Faces and hands appear to trade-off, suggesting ordered visual input: Faces first, then hands. The developmental trend is not just increased variability of body parts in the visual input: The total proportion of faces and hands together is more stable across the first two years of life (.30, $.21, .34, .34$, for each age range respectively). The key finding is a "See-Saw" pattern: What is first available to infants (here, Faces; "See") fades to developmental history ("Saw") as infants creates new tasks for themselves with advancing motor, language and social skills.

Figure 1: Faces and hands in early visual environments

## Hands in the visual environment

What kinds of hands are potentially in view for infants and toddlers? The answer to this question changes over the first two years of life. Here, we focus on three kinds of developmentally relevant input: hand identity, contact between hands and the world, and holding small objects. For each, we find patterns of ordered visual input: What is visually available early is replaced by something else later.

Hands Identity: Other-to-Own Whose hands are available in the visual input to infants and toddlers? Over the first two years of life, the child's own hands are increasingly available (Figure 2a). Early, the kinds of hands in the visual environment are overwhelmingly other people's hands, but by toddlerhood the child's own hands are nearly half the available hand visual input (1-3 months: . 05 Own; 7-9 months: . 35 Own; 18 months: . 44 Own; 24 months: . 46 Own), $\chi 2(3, \mathrm{~N}=9096)=152.64, \mathrm{p}<.001$. The pattern is: First someone else's hands, then your own hands.

Hands Contact: Free-to-Touch When your visual environment includes your own hand, what else is potentially in view? Over the first two years of life, infants increasingly make manual contact with the world (Figure 2b). Early, hands are free -- flailing and reaching. The visual environment of 1-3 month-old infants does not include their own hands contacting the world. But, by 24 months, over two-thirds of the views of their own hands also include something they touch (1-3 months: 0 Touching; 7-9 months: . 68 Touching; 18 months: . 68 Touching; 24 months: . 77 Touching), $\chi^{2}(3, \mathrm{~N}=3936)=61.76, p<.001$. The pattern is: First hands free, then hands touching the world.

Hands on Objects: Touch-to-Hold How often do early visual environments include one's own hand holding an

Figure 2: Ordered visual input of Hands
object? Over the first two years of life, an increasing proportion of visual instances of touching the world are instances of holding objects (Figure 2c). Before 18 months, the visual environment includes few instances of hands together with objects (7-9 months: . 19 of all touching instances). Toddlers' visual input, however, includes many of these instances (18 months: .54; 24 months: .61). That is, infants and toddlers find themselves in very different visual circumstances with respect to hands-on-objects, $\chi^{2}(2, \mathrm{~N}=$ $2814)=141.61, p<.001$. The pattern is: First hands touching, then hands holding.

## General Discussion

Our corpus of visual environments is unprecedented in scope: We are capturing visual regularities throughout the first two years of human life. Importantly, we capture environments throughout these two years, rather than zooming in to focus on one unique time, or zooming out to collapse across many different times. Everyday acting and thinking happens within nested timescales and complete theories of how environmental regularities matter for human cognition demand evidence from each scale: from realtime measures of in-the-moment attention through summaries of long-term experience. Our project provides critical insight into a scale currently missing from theories of statistical learning: developmental time.

Our data strongly suggest that input is dynamic and ordered. Visual regularities in developmental time may be a rolling wave of "See-Saw" patterns. Here, we see this across two classes of important social stimuli - faces, then hands. We also see this within hands, going from Other-to-Self-to-Touching-to-Holding. If our investigation into early visual statistics had zoomed into 3-month-old infants, we would have missed important regularities about hands; if we had zoomed out to batch statistics over the first two years of life,
we would have concluded that the environments of infants and toddlers include roughly one-third body parts. Instead, we find a key pattern in environmental regularities: Developmental statistics are dynamic and ordered.

The available visual statistics are gated by young children's developmental level. A 3-month-old infant who is placed and carried finds herself in different visual environments than a walking, talking 24-month-old. Like other species, our data suggest that humans experience distinct ontogenetic niches as they progress toward adultlike motor, social, and language abilities. These visual niches may do a lot of important filtering for young learners: rather than sophisticated internal attentional control, "starting small" in structured input may be accomplished by other developmental constraints. Of course, the fact that developmental changes in many skills constrain the visual environment does not rule out the possibility of additional attentional gating. It may, however, reduce the challenges that attentional gating must resolve.

Does this temporal ordering of statistical regularities matter? It could be that outcomes at 2 years are best predicted by the total set of regularities and not by the order of those visual environments. Alternatively, some paths through the search space may be optimal, and mother-nature may optimize social learning by guiding the learner along optimal paths. More radically, the order of these experiences may not just enhance the optimal solution, but may determine the class of outcomes. Developmental process consists not just in the sampling of information but also in the change in the very internal structure of the learner. Considerable evidence from a psycho-biological perspective shows that the ordering and timing of sensory information play a critical role in brain development (Held \& Hein, 1963; Lord, 2012; Turkewitz \& Kenny, 2004). Reordering the usual sensory experiences within a developmental individual changes the architecture of the brain, not just what is known but what is knowable (Knudsen, 2006). A related idea, from cognitive theorists is the "starting small" hypothesis: limits that arise from the immaturity of the neural system constrain the input and, rather than holding back development, play a role in fostering development (Dominguez \& Jacobs, 2003; Elman, 1993; Fox, Levitt \& Nelson, 2010; Newport, 1990; Westermann, 2000). Between birth and 2 years, human infants travel through a set of highly distinct developmental environments determined first by their early immaturity and then by their growing emotional, motor, and cognitive competence. These ordered environments may help learning systems "start small," find the optimal path to the optimal solution, and determine the architecture of the system that does the learning.

#### Abstract

Syntactic constructions roughly correspond to sentence meanings. Previous research has shown that Chinese children can associate an SVO construction with a causative event at age 2, but do not always map an SV construction to a noncausative event even after reaching 5 years of age. The latter results may be attributed to the fact that Chinese allows argument-dropping (Jiang \& Haryu, 2010). This paper investigated Chinese adults' syntax-semantics knowledge and found that even adults do not always map an intransitive construction to a non-causative event, although they are likely to use an intransitive construction to describe a non-causative event. The results suggest that although Chinese adults understand that causative and non-causative events should typically be described using transitive and intransitive constructions, respectively, the use of this knowledge in inferring novel verb meanings seems to be regulated by the actual usage of SV sentences in Chinese.

Keywords: argument structure; Mandarin Chinese; adults; verb meanings; intransitive; transitive.

## Introduction

It is said that for children, learning verbs is difficult (e.g., Gentner, 1978, 1982; Imai et al., 2008). This is due to the fact that when a novel verb is introduced for a particular scene, there are an infinite number of possibilities concerning which aspect of the scene the verb refers to. For example, if we hear the novel verb "gorping" while watching a scene in which a girl is walking with a dog, the verb "gorping" may refer to "walking," "taking a dog for a walk," or "moving from one place to another." Even for adults, it is difficult to infer the meaning of a given verb if it is presented without any syntactic information (Gillette, Gleitman, Gleitman, \& Lederer, 1999). When they are told in what syntactic construction the verb appears, however, adults find it much easier to infer its meaning. Thus, the syntactic constructions in which verbs appear provide us with a very important cue to verb meanings, since the types of verb meanings roughly correspond to the syntactic structures in which those verbs appear (Gleitman, 1990). For example, a verb that appears in an intransitive construction with a single argument (e.g., "The boy goes") is likely to describe a non-causative event, while a verb that appears in a transitive construction with two arguments (e.g., "The girl pushed the boy") typically refers to a causative event.

Developmental psycholinguists have investigated whether and when children are able to use syntactic constructions to infer verb meanings. In recent studies, a forced-choice pointing task has been used to investigate this problem. In this task, children are typically presented with two videos side-by-side, one showing a causative event and the other a non-causative event, and asked to select a scene that matches a presented sentence involving a novel verb. Two types of test sentences are used: In one type, the novel verb is presented in a transitive construction, and in the other type, the novel verb is embedded in an intransitive construction. For example, while watching two events, a causative one in which a duck is pushing a bunny into a squat position and a non-causative one in which a duck and a bunny are moving one of their arms in a circle, children hear the novel verb "blick" in a transitive sentence such as "The duck is blicking the bunny," or in an intransitive construction with a conjoined noun such as "The duck and the bunny are blicking." The children are then asked to point to the event that matches the presented sentence. Thus, these studies have focused on whether children would select a causative event for a transitive sentence, and a noncausative event for an intransitive one.

These previous studies have found that English-learning 2-year-olds associate a transitive construction with a causative event. However, children of the same age do not always map an intransitive construction to a non-causative event (Arunachalam \& Waxman, 2010; Noble, Rowland, \& Pine, 2011). They become able to map an intransitive construction to a non-causative event by 3 years of age (Noble et al., 2011). Research that examined Chineselearning children using the same method also found that Chinese 2-year-olds were able to map a transitive construction to a causative event. However, Chinese children did not always associate an intransitive construction with a non-causative event even after reaching 5 years of age (Jiang \& Haryu, 2010). That is, in both English and Chinese, children seem to have some difficulty in acquiring knowledge of intransitive constructions, and their acquisition of intransitive constructions is later than that of transitive constructions.

The fact that it takes longer for children to become able to use intransitive constructions to infer verb meanings may be partly attributed to the fact that there are some verbs that have a general meaning and can be used in an intransitive construction but can refer to a causative event, not only in

English but also in Chinese. For example, the verb "play" can be used in an intransitive construction to refer to a causative event in which a girl makes a boy perform an action, by saying "The girl and the boy are playing." Thus, the existence of such intransitive verbs may contribute to the fact that both English- and Chinese-learning children need more time to acquire knowledge of intransitive constructions, compared to the time they take to acquire knowledge of transitive constructions.

Furthermore, a certain characteristic of Chinese might make it even more difficult for Chinese-speaking children to learn the correspondence between an intransitive construction and a non-causative event. Unlike English, Chinese allows pervasive ellipsis of noun arguments. Either or both the subject and the object can be dropped from the sentence. Therefore, in Chinese, an SV sentence could be either an intransitive sentence or a transitive sentence with the object omitted. As a result, SV sentences Chineselearning children hear in their daily life do not always refer to a non-causative event. This may also contribute to the difficulty that Chinese children have in learning the correspondence between an intransitive construction and a non-causative event. Given this characteristic of the Chinese language, it may also be the case that Chinese adults do not associate an intransitive construction with a non-causative event.

In the present research, two experiments were carried out to investigate whether Chinese-speaking adults associate a sentence with a single argument with a non-causative event in the same way that they associate a sentence with two arguments with a causative event. In Experiment 1, by presenting Chinese adults with two videos, one showing a non-causative event and the other a causative event, we examined whether they would map an SV sentence to a noncausative event, and an SVO sentence to a causative event, respectively. In Experiment 2, we presented Chinese adults with a video showing either a causative or a non-causative event, and asked them to select an appropriate sentence to describe the scene out of two types of test sentences, an SV sentence and an SVO sentence.

## Experiment 1

In Experiment 1, we investigated Chinese adults' syntaxsemantics knowledge using a forced-choice pointing task, which has been used in recent studies on children. In the current experiment, participants were presented with a novel verb placed in a transitive construction or in an intransitive construction with a conjoined noun ("the woman and the man") as the subject while they watched two events, one causative and the other non-causative. The participants were then asked to point to the event that matched the presented sentence. If, as argued by Jiang \& Haryu (2010), the pervasive ellipsis of noun arguments in Chinese makes it difficult not only for Chinese-learning children but also for Chinese-speaking adults to map an SV sentence to a noncausative event, then the adults would not map an
intransitive construction to a non-causative event, even when they assign a transitive construction to a causative event.

## Method

Participants The participants were 40 undergraduate students ( 20 males and 20 females, mean age 21 years, range 20 to 24 years). The participants were randomly assigned to two conditions: the intransitive condition and the transitive condition. In each condition, there were the same number of males and females. All the participants were native speakers of Mandarin Chinese.

Materials Six sets of videos were used (see Table 1 for details). They were the same videos that were used in the experiment with Chinese children in the previous research conducted by Jiang and Haryu (2010). Each set consisted of two videos, one showing a non-causative event and the other showing a causative one. In the non-causative event, a young woman and a young man performed the same repetitive action separately, side by side. In half of the causative videos, the young woman made the young man perform an action, while in the other half the man made the woman perform an action (see Figure 1 for an example).

As novel verbs, six monosyllabic nonsense words, the same ones in Jiang \& Haryu (2010), "xia3," "kao2," "pa3," "de4," "mu1," and "tie2," were used. Ten college students who were native speakers of Mandarin Chinese agreed that these words are senseless in that language. However, in the present experiment, these novel words were all low-pass filtered so that the sounds did not cause the participants to remember similar-sounding verbs that already exist in Chinese. The auditory stimuli were created by embedding these low-pass filtered words in the verb position of SV or SVO sentences, which were recorded clearly by a female adult native speaker of Mandarin Chinese.

Procedure Participants were tested individually using a forced-choice pointing task. The video stimuli were presented on a note PC using PowerPoint. All videos lasted about 10 seconds. In each test trial, a sentence was presented twice using Windows Media Player while the participant was watching two videos side-by-side, one showing a causative event and the other a non-causative event. The participant was then asked to point to the matching video. Participants in the intransitive condition heard a novel verb in an intransitive construction, such as "A1yi2 he2 shu1shu zai4 X (The woman and the man are Xing)," while those in the transitive condition were presented with a novel verb embedded in a transitive construction, such as "A1yi2 zai4 X shu1shu (The woman is X -ing the man)." Each participant received six test trials.

## Results and discussion

The selection of a causative event was scored as a causative response. The mean proportions of causative responses were calculated for each condition (see Figure 2).

Table 1: Stimulus materials used in Experiment 1

| Set | Non-causative events | Causative events | Novel <br> verb |
| :---: | :--- | :--- | :--- |
| 1 | A woman and a man sway side by side. | A woman tugs at a man's hand. | xia3 |
| 2 | A man and a woman move up and down <br> by bending their knees. | A man shakes a woman by the shoulders. | kao2 |
| 3 | A man and a woman twist their torsos <br> from left to right. | A man makes a woman bend down by <br> pressing on her shoulders. | pa3 |
| 4 | A woman and a man bow repeatedly. | A woman pats a man on his shoulder. | de4 |
| 5 | A woman and a man swing both of their <br> arms up and down together. | A woman turns a man's body in a circle. | mu1 |
| 6 | A man and a woman stamp their feet. | A man holds a woman's hand and waves <br> it. | tie2 |

Figure 1: A sample set of video events used in Experiment 1 (Set 1)

Figure 2: Mean proportions of causative responses in Experiment 1

The participants in the transitive condition selected causative events .88 of the time, which was significantly above chance level $(t(19)=10.48, p<.001, d=2.34)$. However, the participants in the intransitive condition
selected causative events .48 of the time, which was not different from chance $(t(19)=.64, p=.53, d=.14)$. That is, participants in the transitive condition matched a transitive sentence with two arguments to a causative event, while those in the intransitive condition did not always select a non-causative event for an intransitive sentence. Furthermore, an unpaired $t$-test revealed a significant difference between the two conditions, $t(38)=7.64, p$ $<.001, d=2.42$, indicating that participants in the transitive condition chose causative events much more frequently than those in the intransitive condition. The above results suggest that while Chinese adults assign a transitive construction to a causative event, they do not always map an intransitive construction to a non-causative event.

To summarize, when shown a non-causative and a causative event and asked to select which of the two events the given sentence described, Chinese adults were likely to select a causative event in response to a transitive construction, while they did not show a clear tendency to choose a non-causative event over a causative event in response to an SV construction. Their behavior was consistent with that of the young Chinese-speaking children in Jiang \& Haryu (2010).

## Experiment 2

The results of Experiment 1 suggest that Chinese adults think an SVO construction describes a causative event while at the same time they think that an SV construction can be used to describe not only a non-causative event but also a causative event. This belief seems to be consistent with the usage of SV sentences in Chinese. However, does this mean that there is no typical scene that should be described by using an SV construction? In Experiment 2, we investigated this problem by presenting the participants with a noncausative or a causative event and asking them to choose which of two given sentences, i.e., an SV sentence and an SVO sentence both containing the same novel verb, matched the event.

## Method

Participants Twenty undergraduate students, who were not tested in Experiment 1, took part in this experiment. The participants consisted of 8 males and 12 females (mean age 20 years, range 18 to 21 years), who were all native speakers of Mandarin Chinese.

Materials and procedure The visual materials were the same videos (six non-causative and six causative) as used in Experiment 1. In addition to the six nonsense words ("xia3," "kao2," "pa3," "de4," "mu1," and "tie2") used in Experiment 1, another six ones ("pei3," "ne1," "mai1," "diu4," "ka2," and "hua3") were also used as novel verbs. These 12 words were all confirmed as nonsense in Mandarin Chinese by 10 college students whose native language was Mandarin Chinese. Unlike Experiment 1, these words were not low-pass filtered, because participants in this experiment were asked to select one out of two sentences involving the same novel word, and thus the sounds of the novel words would not affect their performance.

While a video was shown, two sentences (i.e., an SV sentence and an SVO sentence, both involving the same novel verb) were presented. The participants were asked to select which sentence better matched the video. For example, when presented with a causative event in which a woman was tugging at a man's hand, the participants heard the intransitive sentence "A1yi2 he2 shu1shu zai4 Xia3 (The woman and the man are Xia3-ing)" together with the transitive sentence "A1yi2 zai4 Xia3 shu1shu (The woman is Xia3-ing the man)" and were asked to choose the one that matched the event. This procedure was repeated for 12 videos. That is, each participant received six causative trials and six non-causative trials.

## Results and discussion

We counted the number of responses in which the participants chose an intransitive sentence in response to a non-causative event, and a transitive sentence in response to a causative event, respectively. The mean scores each for the non-causative and the causative events were 5.7 ( $\mathrm{SD}=$ 0.57 ) and $5.7(\mathrm{SD}=0.57)$ out of 6 , respectively. Two $t$-tests were conducted to see whether these scores were
significantly above chance. The analyses revealed that participants were more likely to choose intransitive sentences to describe a non-causative event than expected by chance, $t(19)=21.14, p<.001, d=9.11$, and that they described a causative event by using transitive sentences more frequently than chance, $t(19)=21.14, p<.001, d=$ 9.11.

These results suggest that Chinese adults prefer SV sentences to SVO sentences when describing non-causative events, and use SVO sentences more often when referring to causative events.

## General Discussion

The present research examined Chinese-speaking adults' understanding of argument structure through two experiments that tested whether Chinese adults associate an SV and an SVO construction with a non-causative and a causative event, respectively. In Experiment 1, we found that when shown two events (a non-causative and a causative one) and asked to choose which one matched the presented sentence, Chinese adults were willing to map an SVO sentence to a causative event, while at the same time they did not always associate a given SV sentence with a non-causative event, which was also the case with Chinese young children (see Jiang \& Haryu, 2010). In contrast, when given two sentences (an intransitive and a transitive one) and asked to select which matched the given event in Experiment 2, Chinese adults were likely to assign a transitive sentence and an intransitive sentence to a causative event and a non-causative event, respectively.

The results of Experiment 1, together with those of Jiang and Haryu (2010), indicate that Chinese speakers, whether young children or adults, do not assume that SV sentences refer to non-causative events. At the same time, they think that SVO sentences describe causative events. This attitude in Chinese speakers is in contrast with what was found in English speakers who match SV constructions to noncausative events as well as matching SVO constructions to causative events (Arunachalam \& Waxman, 2010; Noble et al., 2011). This difference between Chinese- and Englishspeakers appears to come from the fact that English does not allow argument-dropping whereas Chinese allows pervasive ellipsis of noun arguments. Due to this particular property of Chinese, SV sentences could be either an intransitive construction or a transitive construction with the object dropped. Therefore, it is not appropriate for Chinese speakers to assume that a given SV sentence always refers to a non-causative event. In this respect, the behavior of Chinese speakers that do not automatically associate an SV sentence with a non-causative event seems to be in accordance to the actual usage of SV constructions in the language, indicating the possibility that the knowledge of argument structure is learned from the language input.

However, at the same time, as shown in Experiment 2, when Chinese adults are asked which of two constructions, an SV or an SVO construction, should be used to describe a
causative and a non-causative event, respectively, they answer that an SV construction rather than an SVO construction should be used to describe a non-causative event. In addition, they prefer to use an SVO construction rather than an SV construction to describe a causative event. This belief appears inconsistent not only with the Chinese input they have received, but also with the fact that Chinese speakers do not always map SV constructions to noncausative events.

Two possibilities may be considered as the origin of such asymmetrical behavior in Chinese speakers. The first possibility is that the knowledge of argument structure may be universal and innate, but one of the characteristics of Chinese (the fact that it allows the pervasive ellipsis of noun arguments) may guide people to regulate the use of this knowledge in inferring the meaning of a given sentence. Lidz, Gleitman, \& Gleitman (2003) argued for the view that the knowledge of argument structure is universal, based on their findings: Children learning Kannada make use of the number of noun arguments rather than morphological inflections as a cue to determine whether the given sentence refers to a causative or a non-causative event, although in Kannada not number of arguments but morphological inflections are definitive cues to the causativity of described events.

The other possibility is that owing to the pragmatic demands of communication, people independently of the properties of their native language prefer to use an SVO construction to describe a causative event and an SV construction to describe a non-causative event. When an SV construction such as "The woman and the man are playing" is used to describe a causative event in which the woman is making the man perform a certain action, what action the woman is in fact making the man perform is not known. In order to precisely convey what is happening, the different roles played by different agents should be described separately, using SVO constructions. On the other hand, using SV constructions may convey that all the agents play the same role in the event. Such pragmatic needs may guide people to prefer to use SVO constructions to describe causative events, and SV constructions for non-causative events, even though SV constructions do not always correspond to causative events in the Chinese input.

In sum, the present research has shown that although Chinese adults prefer to use SVO and SV constructions to describe causative and non-causative events, respectively, they do not always use this knowledge of syntax-semantics correspondences in deciding whether a given sentence refers to a causative or a non-causative event. The latter result suggests that the particular property of Chinese that allows argument-dropping might guide Chinese speakers not to automatically map an SV sentence to a non-causative event. However, despite this property of the Chinese language, why do Chinese speakers prefer to use SV and SVO constructions to describe non-causative and causative events, respectively? Is this because the knowledge of syntaxsemantics correspondences is universal, as suggested by

Lidz et al. (2003)? Or does it relate to the pragmatic demands of communication? Further research is required to investigate this question.

# Efficient codes for multi-modal pose regression 

Leif Johnson Joseph Cooper Dana Ballard<br>Department of Computer Science, The University of Texas at Austin, USA<br>\{leif, jcooper, dana\}@cs.utexas.edu

#### Abstract

Redundancy reduction, or sparsity, appears to be an important information-theoretic principle for encoding natural sensory data. While sparse codes have been the subject of much recent research, they have primarily been evaluated using readily available datasets of natural images and sounds. In comparison, relatively little work has investigated the use of sparse codes for representing information about human movements and poses. This paper proposes a basic architecture for evaluating the impact of sparsity when coding human poses, and tests the performance of several coding methods within this framework for the task of mapping from a kinematic (joint angle) modality to a dynamic (joint torque) one. We show that sparse codes are indeed useful for effective mappings between modalities and examine in detail the sources of error for each stage in the model.

## Overview

Recent work from machine learning (Ranzato, Boureau, \& LeCun, 20077; Lee, Battle, Kaina, \& Ng, [2007) and neuroscience (Olshausen \& Field, [996; Smith \& Lewicki, [2006) has emphasized the role that sparsity, or redundancy reduction (Barlow, 1961), appears to play when coding sensory data. Sparse codes are well suited to represent natural sensory data because the space of all possible inputs (e.g., all possible $1000 \times 1000$ images) is not uniformly covered by the samples (e.g., photos or retinal inputs) that we tend to encounter in the natural world. In fact, many types of natural data are theorized to lie along a low-dimensional manifold embedded in the larger space (Olshausen \& Field, [2004). Sparse codes are effective for representing data along such lowdimensional manifolds because the basis vectors in the code can be used efficiently (i.e., using just a few nonzero coefficients) to indicate, for a particular data point, its location along the manifold rather than its coordinates in the higher-dimensional space.

Many of the results in this area of research have focused on codes for sensory information like images and sounds. Concurrently, research in control theory has suggested that human movements might also lie along a relatively low-dimensional manifold embedded in the space of all possible movements (Scholz \& Schöner, [1999; Latash, Scholz, \& Schöner, [002). Sparse codes might be useful, then, for representing information about movement and pose in humans. To our knowledge, however, such codes have not been evaluated extensively on natural movement or pose data.

This paper proposes a basic architecture for testing the effectiveness of a broad class of coding techniques when mapping from kinematic (joint angle) to dynamic
(torque) data in human poses. While computationally straightforward, the model allows us to compare and evaluate several possible approaches to this coding and regression task. We show that, for the class of techniques captured by our model, sparsity is indeed useful for representing and manipulating pose data. In fact, even though the absolute decoding error associated with sparse codes can be larger than the corresponding absolute error for dense codes, the information captured by each coefficient in a sparse code is larger than for dense codes. In addition, sparse codes appear to facilitate the task of mapping or regressing from one information modality to another, making these codes particularly interesting from the perspective of a whole organism, which must integrate information from many different sources of information to make effective survival decisions.

## Problem setting

The human body is marvelously complex, with over 630 muscles and, by some estimates, more than 240 degrees of freedom (Winter, [200); Zatsiorsky \& Prilutsky, [2012). Despite this complexity, humans are skilled at controlling their bodies to make movements that accomplish a wide variety of tasks in the world. Humans also seem to be skilled at transforming information about movement between different modalities. For example, a person can normally mimic the posture of another person without much conscious effort, even though this task requires some sort of conversion from the visual configuration of the conspecific's body (possibly expressed in world or visual coordinates) to the kinematic configuration of their own. Along these lines, it is conceivable that the tasks of computing potential movements, evaluating proposed movements, and selecting and executing a particular movement all require separate ways of looking at the movements.

Studying human movements is difficult: the parameters describing movements are high-dimensional and time-varying, and, in addition, most of the quantities that are relevant for describing the control of movement are invisible to an outside observer. Although we do not have a practical way to observe the control signals or even accurately measure all of the joint torques or angles during a complex, multijoint human movement, we can use technologies like motion capture (Figure 『) to measure the external aspects of movement with high accuracy. Given motion capture data, Cooper and Ballard (2012) proposed a technique to compute the angles

Figure 1: Information processing architecture for multimodal coding and regression. Information from a frame of one modality of pose data, such as angles (orange), is to be mapped onto information from another modality, such as torques (blue). This mapping is accomplished by coding a frame of angle data, augmented with its derivative $\Delta$, using parameters $\mathbf{P}$; likewise, torques augmented with derivatives $\Delta$ are encoded using parameters $\mathbf{Q}$. Finally, a parametric regression $\mathbf{R}$ is computed between the codes (yellow and green).
and forces that would have been required for a simplified model of the human skeleton to effect the same movements. These computed angles and forces, while still a coarse proxy for some of the information that might be used by the central nervous system, constitute the data for this paper.

Theoretically, one could transform information from one modality into another by amassing a large quantity of corresponding data from these two modalities and computing regression coefficients directly. However, this is inefficient for at least two reasons. First, computing a regression between two datasets becomes increasingly problematic as the dimensionality of the data increases; this difficulty is compounded when there is noise in the data. Second, if the manifold hypothesis is accurate, then each modality of the raw data will have statistical redundancies that would need to be captured by the regression process. Rather than working in the space of raw measurements, then, we hypothesize that manipulating or combining movement information is more efficient in a space defined by codes that somehow represent the raw signals (Srivastava \& Salakhutdinov, [ШII2). The question addressed by this paper is, which types of codes are most efficient for processing information about movement?

## Pose coding and regression

We assume that we have a set of data that represents kinematic and dynamic views of human motion, modeled using an articulated body with $n$ degrees of freedom, and measured over a consecutive sequence of $m$ discrete time
steps. Formally, we represent a sequence of raw joint angles as a matrix $\mathbf{B} \in \mathbb{R}^{n \times m}$, where each column $\mathbf{b}^{(t)}$ represents a single frame of angle data. Similarly, we represent a sequence of raw joint torques as a matrix $\mathbf{U} \in \mathbb{R}^{n \times m}$ whose columns $\mathbf{u}^{(t)}$ each contain a frame of torque data. We define these matrices as complementary views of a single motion trajectory, so that for any frame $t$, the joint angles $\mathbf{b}^{(t)}$ correspond to the torques $\mathbf{u}^{(t)}$.

As mentioned above, movement is complex to model because it is high-dimensional ( $n$ is often large) and varies over time ( $m$ is often large). Rather than attempt to tackle both of these challenges at once, we simplify the modeling task here by considering the task of mapping between these two modalities for single poses (frames). Such a simplification makes the modeling task obviously difficult, since a single frame of kinematic pose data, for instance, does not indicate the direction in which the joint angles will be changing in subsequent frames. To address this issue, we make use of a common technique from speech recognition (Picone, [1993) and augment each of the raw data frames in our system with its first derivative. This provides information about the rates at which the angles and torques are changing, which could be useful when trying to compute torques on the basis of angles. The augmented data matrices $\mathbf{A}, \mathbf{V} \in \mathbb{R}^{2 n \times m}$ are then defined as

$$
\mathbf{A}=\left[\begin{array}{c}
\mathbf{B} \\
\Delta \mathbf{B}
\end{array}\right] \quad \text { and } \quad \mathbf{V}=\left[\begin{array}{c}
\mathbf{U} \\
\Delta \mathbf{U}
\end{array}\right],
$$

where $\Delta \mathbf{X}^{(t)}=\left(\mathbf{x}^{(t+1)}-\mathbf{x}^{(t-1)}\right) / 2$ represents a secant approximation to the derivative at each frame.

Having created a set of kinematic and matched dynamic data describing sequences of human poses, we propose an information processing architecture for computing regressions from angles to torques. In this framework (see Figure [) , a single frame of $n$ input angles, augmented with its derivative, is encoded first into $k$ angle-code coefficients using a coding model characterized by parameters $\mathbf{P} \in \mathbb{R}^{k \times 2 n}$. Then a regression model characterized by parameters $\mathbf{R} \in \mathbb{R}^{k \times k}$ transforms the $k$ angle-code coefficients into a $k$ torque-code coefficients. Finally, this torque encoding is converted back into a frame of $n$ torques, augmented with its first derivative, by inverting the torque coding model characterized by parameters $\mathbf{Q} \in \mathbb{R}^{2 n \times k}$. If the manifold hypothesis holds for human pose data, then code parameters $\mathbf{P}$ and $\mathbf{Q}$ can be learned independently, because these parameters will describe the structure of the manifold for each modality of pose data; codes for each manifold should then be useful for a wide variety of other information processing tasks (Vincent, Larochelle, Lajoie, Bengio, \& Manzagol, (20II). Regression parameters $\mathbf{R}$ can then be learned using the encoded data from each modality.

Given our parametric framework for coding and regression, the coding approaches considered here all as-
sume a finite "codebook" $\mathbf{D} \in \mathbb{R}^{2 n \times k}$ whose columns $\mathbf{d}_{i}$ each represent a "basis vector" that is used in some way to encode data. This paper does not focus specifically on learning the codebook, though it does mention a few approaches to codebook learning below.

Separating the model into coding and regression stages brings three advantages to the problem at hand. First, it allows us to manipulate the number of parameters in the model in a controlled way. The multistage model contains $k^{2}+4 k n$ parameters, while direct regression requires $4 n^{2}$ parameters. When $k<2 n$, the multistage model has fewer parameters than direct regression, but when $k$ exceeds the dimensionality of the data, the multistage model has more parameters. Models with more parameters tend to be more accurate, but they might overfit the data and capture more noise than desired. Second, separate modules for coding in each modality, and regression between codes, allows for in-depth analysis of the performance of each module: codes for one modality that provide for low decoding error could also be ones that do not permit easy regression, for example. Finally, defining distinct coding modules permit an analysis of the degree to which coding, in isolation, provides an efficient representation of the data.

## Coding algorithms

Mathematically, this paper treats coding as a general term for transforming a vector of raw data $\mathbf{x} \in \mathbb{R}^{2 n}$ into another vector of coefficients $\mathbf{z} \in \mathbb{R}^{k}$, such that $\mathbf{z}$ contains sufficient information to recover $\mathbf{x}$ with some tolerated level of error. More formally, coding is often defined in terms of minimizing a cost function

$$
\|g(\mathbf{D}, \mathbf{z})-\mathbf{x}\|_{2}^{2}+\lambda R(\mathbf{z})
$$

where $g(\mathbf{D}, \mathbf{z})$ refers to a decoding operation that converts coefficients $\mathbf{z}$ into an estimate of the raw data $\hat{\mathbf{x}}$, and $R$ is a regularizer that can be chosen to prevent overfitting, promote sparsity in the code, etc. For this paper, we evaluate several approaches to coding, each described briefly below.

PCA Principal component analysis (PCA) is widely used as a data preprocessing technique, but here we use PCA to refer to an encoding that simply computes the inner product of a data point $\mathbf{x}$ with each of the codebook vectors $\mathbf{d}_{i}$ : that is, $\mathbf{z}=\mathbf{D}^{T} \mathbf{x}$.

The PCA codebook consists of the eigenvectors of the covariance matrix of the data, sorted in decreasing order of magnitude of the corresponding eigenvalue. By retaining only the first $k$ eigenvectors in the codebook, PCA retains the maximally varying components of the data first, and progressively refines the error by retaining smaller components.

Used in this way, PCA implicitly models the underlying data as a multivariate normal distribution. Because the codebook for PCA is composed of eigenvec-
tors (which are orthogonal to each other), there can be at most as many codebook vectors as dimensions in the input data.

K-means K-means (MacQueen et al., 1967) can be seen as an extremely sparse coding technique that represents a data point $\mathbf{x}$ using only the closest basis vector in the codebook: for this approach, $\mathbf{z}=\left[\xi_{1} \ldots \xi_{k}\right]^{T}$ such that

$$
\xi_{i}= \begin{cases}1 & \text { if }\left\|\mathbf{x}-\mathbf{d}_{i}\right\|_{2}<\left\|\mathbf{x}-\mathbf{d}_{j}\right\|_{2} \text { for } j \neq i \\ 0 & \text { otherwise }\end{cases}
$$

The codebook corresponding to this coding approach is learned from the data by setting the $\mathbf{d}_{i}$ to random elements from the training data, and then iteratively adjusting the columns of $\mathbf{D}$ so that the sum of the Euclidean distances from each data point to its closest codebook vector is minimized.

Sparse coding Sparse coding (Tibshirani, 1996), also called lasso regression, computes the coefficients $\mathbf{z}$ for data point $\mathbf{x}$ by minimizing a least-squares cost function with a regularization penalty on the magnitude of the code coefficients:

$$
\mathbf{z}=\underset{\zeta}{\arg \min }\|\mathbf{D} \zeta-\mathbf{x}\|_{2}^{2}+\lambda\|\zeta\|_{1}
$$

$\lambda$ is a parameter that controls the tradeoff between accurate representation and sparsity; following results from the literature, we set $\lambda \propto 1 / \sqrt{n}$.

Coates and Ng (2011) reported that sparse coding worked well across many types of codebooks for their tasks (image classification). For this coding algorithm, then, we tested several different codebooks: random, sampled, and learned. The random codebook consisted of IID vectors drawn from the standard normal distribution, normalized to unit length. The sampled codebook contained samples drawn uniformly from the training data, also normalized to unit length. The learned codebook used a fast, online algorithm developed by Mairal, Bach, Ponce, and Sapiro ( 20019 ) to tune the codebook to the data. Briefly, the general algorithm is a variation of coordinate descent, where sparse encoding computations are alternated with codebook updates. The codebook learning process attempts to minimize the lasso cost function above, both with respect to the codes $\mathbf{z}$ and also with respect to the codebook $\mathbf{D}$.

## Regression

Once codes have been computed for the source and target datasets, the next task is to compute a regression matrix $\mathbf{R}$ that will convert coefficients from one modality into coefficients from another. We used ridge regression (Hoerl \& Kennard, 1970$)$ to compute the best parameters for inferring coefficients across coded modalities. We can express the regression task between codes $\mathbf{z}_{\alpha}$ and $\mathbf{z}_{\beta}$

Figure 2: The motion capture environment consists of a full-body motion capture suit (black, with red LEDs), and a treadmill centered in the motion capture space.
as optimizing the cost function

$$
\left\|\mathbf{R} \mathbf{z}_{\alpha}-\mathbf{z}_{\beta}\right\|_{2}^{2}+\lambda\|\mathbf{R}\|_{F}^{2}
$$

where $\lambda$ captures the degree to which the modeler is willing to tolerate large values in $\mathbf{R}$ when explaining the observed data. Essentially, ridge regression is the same as linear regression, but it adds a penalty on large values of the coefficients that are used to describe the data. In our experiments, the value of $\lambda$ was set empirically by cross-validation on the training set.

## Experiments

To measure and collect human movement data, we used a 16-camera Phasespace ${ }^{\text {m }}$ motion capture system in conjunction with a standard treadmill (Figure [7]). Human subjects in the motion tracking area wore a full-body suit equipped with active-pulse LED motion tracking markers and were recorded as they walked and ran on the treadmill at a variety of speeds.

For the results reported here, we recorded the positions of $L=48$ markers from one subject as he walked at speeds ranging from 0.22 to $2.68 \mathrm{~m} / \mathrm{s}$. The recording lasted twenty minutes. The Phasespace system produces frames of motion capture data at a rate of 120 Hz , so this recording resulted in more than 120,000 frames of raw motion-capture data. These frames were processed using the articulated forward model proposed by Cooper and Ballard (2012), resulting in three sequences of measurements for the observed motion: the sequence of interpolated marker positions $\mathbf{X}=\left[\mathbf{x}^{(1)} \ldots \mathbf{x}^{(N)}\right]$

[^105]representing the positions of the segments of the articulated model over time; the sequence of observed angles $\mathbf{A}=\left[\mathbf{a}^{(1)} \ldots \mathbf{a}^{(N)}\right]$ for each of the 54 degrees of freedom in the model; and the corresponding torques $\mathbf{V}=\left[\mathbf{v}^{(1)} \ldots \mathbf{v}^{(N)}\right]$ that were necessary to cause those angles to move through the observed dynamic trajectory of the model.

## Preprocessing

For this paper, we were concerned with mapping angles to torques, so we discarded the marker data $\mathbf{X}$. To obtain datasets for training and testing the coding and regression models, we needed to perform some preprocessing to obtain matched sets of frames that would permit a fair comparison.

First, the sequences obtained from the model were smoothed by convolving each channel in each modality with a 5 -sample ( 42 millisecond) rectangular window over time. After smoothing, each channel of the data was normalized by subtracting out the mean value and dividing by the standard deviation. These steps ensured that the data did not contain residual noise due to marker dropouts, and also that the data values were all approximately the same scale.

Each frame of data was then augmented with an approximation of its first derivative by calculating the secant approximation of these quantities using the neighboring two frames. ${ }^{\text {[] }}$

Next, the smoothed, normalized, derivativeaugmented frames were segmented into three distinct regions, each containing 24000 frames ( 200 seconds) of data: the first (segment A) consisted of slow walks, the second (segment B) consisted of fast walks, and the third (segment C ) consisted of running movements. To evaluate the coding and regression models, each segment was further partitioned into disjoint training, validation, and test sets such that $10 \%$ of frames from each segment were used for validation, $10 \%$ were used only for testing, and the remainder were available for training.

## Coding efficiency

We first analyzed the performance of the different coding techniques discussed above when reconstructing the raw torque data using the torque codes. Formally, after training the dictionaries as needed, we computed $\mathbf{z}$ for each frame of augmented torque data $\mathbf{v}$ in the test set, and then computed the decoding operation to obtain an estimate $\hat{\mathbf{v}}$. The decoding error $e_{\mathbf{v}}$ was then defined as the RMS value of the residual:

$$
e_{\mathbf{v}}=\sqrt{\frac{1}{n}\|\hat{\mathbf{v}}-\mathbf{v}\|_{2}^{2}}
$$

[^106]

Figure 3: Mean RMS decoding error for joint torques, measured with respect to the size of the codebook. Larger codebooks result in codes that capture more of the variance in the data, even when the codebook is created using IID standard normal samples. A log scale has been used on both axes to reveal trends more clearly.

Figure 3 shows the mean RMSE for each coding approach, measured with various sizes of codebooks, and applied solely to the torque data. (Results for the angle data were similar.) Unsurprisingly, larger codebooks were able to capture more of the variance in the data than smaller codebooks, regardless of the coding method. Perhaps more interesting, however, was the finding shown in Figure 74: when measured by the number of nonzero coefficients used in the code, sparse codes produced more accurate reconstructions than dense codes. This was somewhat vacuously true of K-means, since it only uses 1 coefficient for each $\mathbf{z}$; in comparison, however, this was not true for sparse coding combined with the random codebook.

## Predicting torques from angles

In addition to comparing the effectiveness of different coding schemes for torque data, we also used our framework to compare the encoding methods in a larger context, namely predicting torque values on the basis of angle values. This task could be seen as a coarse approximation for a control task: given a target kinematic pose, what might be the torques that would be associated with that pose?

Because the analysis framework proposed in this paper breaks down this task into three separate stagesencoding, regression, and decoding-we can analyze the regression component of the task separately from the other components. In general, RMS error for the regression task alone (Figure ${ }^{\text {a }}$ ) followed the same pattern as errors for the encoding and decoding components: larger codebooks tended to yield lower errors. However, sparsity played a critical role in this task, since K-means yielded the lowest regression errors, while PCA yielded

Figure 4: Mean RMS decoding error for joint torques, measured per nonzero coefficient in the encoding. Sparse codes like lasso regression were more effective, per coefficient, than dense codes like PCA, but only when the codebook was tuned to the dataset.

Figure 5: RMS regression error, measured with respect to encoded torque values.
relatively large errors.
Finally, we compared the overall torque regression error for all components of the model together, as measured by comparing the outputs from our processing model with the true torques measured during the experiment (Figure []). As a baseline, we computed a direct regression from angle to torque data: this resulted in an RMS error of 0.65 on the test set. PCA performed at baseline for complete codebooks, which is unsurprising since PCA simply rescales the data. However, some of the sparse coding approaches did outperform PCA by a large margin (up to $30 \%$ reduction in error). In particular, using lasso coding combined with a large, learned dictionary produced lower RMS errors than any of the other approaches examined here.

Figure 6: Mean RMS reconstruction error, measured with respect to true torque values for each frame. Note that the RMS reconstruction error for direct regression between true angles and true torques is 0.652 , which is approximately at the asymptote shown for PCA.

## Discussion

This paper presented an efficient coding and regression model for human pose information, and used this model to examine the performance of several coding algorithms on human pose information. The model allowed us to examine separately the errors in coding information about poses and in regressing from one modality to another. We learned that even though some approaches produce extremely low coding and decoding errors, and other approaches were conducive to learning regressions between codes, in order to perform well on the task of predicting information across information modalities, a coding approach must have extremely low error on both tasks.

In several ways this paper is just a first look at this sort of modeling on human pose information. In particular, we limited our examination of human pose information to snapshots of single moments in time. Movement, however, is fundamentally dynamic, so we plan to expand the techniques presented here to temporal sequences of poses, by learning codes for entire movements.

#### Abstract

We present a task-based model of human gaze allocation in a driving environment. When engaged in natural tasks, gaze is predominantly directed towards task relevant objects. In particular in a multi-task scenario such as driving, human drivers must access multiple perceptual cues that can be used for effective control. Our model uses visual task modules that require multiple independent sources of information for control, analogous to human foveation on different task-relevant objects. Building on the framework described by Sprague and Ballard (2003), we use a modular structure to feed information to a set of PID controllers that drive a simulated car and introduce a barrier model for gaze selection. The softmax barrier model uses performance thresholds to represent task importance across modules and allows noise to be added to any module to represent task uncertainty. Results from the model compare favorably with human gaze data gathered from subjects driving in a virtual environment.

Keywords: Visual attention; eye movements.

## Introduction

Humans routinely interact with complex, noisy, dynamic environments to accomplish tasks in the world. For example, while driving a car, a person navigates to a desired destination (e.g., grocery store) while paying attention to different types of objects in the environment (pedestrians, vehicles, etc.) and obeying traffic laws (speed limit, stop signs, etc.). Humans are able to balance competing task demands while simultaneously gathering information from the world through a foveated visual system, which must be actively moved to different targets to obtain high-resolution imagery.

During the deployment of attention, in particular overt eye movements towards an object, humans are sensitive to bottom-up salience (color, motion, etc.) as well as top-down task priority and the rewards associated with a task (Knudsen, 2007; Wolfe, Butcher, Lee, \& Hyle, 2003). In particular when engaged in "natural" tasks, eye movements are largely directed towards task relevant objects (Hayhoe \& Ballard, 2005; Land \& Hayhoe, 2001). Typically in natural environments, there are multiple task relevant objects spread over space and time that require active visual strategies to properly gather information. While human vision research has often focused on models of visual saliency, i.e., a stimulus based controller of attention (Bruce \& Tsotsos, 2009; Itti \& Koch, 2001; Zhang, Tong, Marks, Shan, \& Cottrell, 2008),
such models are inappropriate to address task-based behavior because they do not incorporate information about the state of the agent whose vision is being modeled. An alternative approach is to consider vision as part of a control process where information from the senses is used to guide motor behavior (Butko \& Movellan, 2010; Nunez-Varela, Ravindran, \& Wyatt, 2012; Senders, 1980; Sprague \& Ballard, 2003; Sullivan, Johnson, Ballard, \& Hayhoe, 2011). Both stimulus and taskbased approaches have led to a variety of formulations concerning how eye movements should be selected, e.g., using energy models, information theoretic measures, or measures of reward and uncertainty. In the present work, we focus on how selection of eye movement targets may be controlled in part by task related uncertainty and reward.

We present a model of visual processing and control that simultaneously takes into account the reward and uncertainty in multiple tasks associated with a dynamic, noisy driving environment. The model successfully accounts for variations in gaze deployment seen in humans driving in a virtual reality driving environment. Additionally, we discuss future research allowed by inversion of the soft barrier model. Inversion allows human data to be mapped into parameters in the model space so that it can be understood and compared quantitatively within the model framework.

## Model

The model proposed in this paper follows the modular architecture of Sprague and Ballard (2003) by factoring complex behaviors like driving into a set of simple control modules that each focus on a well-defined task-for example, a module to follow the road and another to avoid oncoming cars. Intuitively, a module is an abstract black-box controller that can be used alone to guide an agent through a single task. More interestingly, modules can be used together dynamically to engage in multiple ongoing behaviors. While the human visual system is highly parallel, processing and attentional focus are largely biased towards the fovea, meaning humans typically get information in a serial fashion by foveating different objects over time. In our model, multiple task modules run concurrently; however, to incorporate the foveation constraint, only one module at a time actively gains new percep-
tual information.
At a high level, modules are responsible for gathering and updating information about specific aspects of the state of the world, and for using that information to generate control signals for the agent. A central component of the model is that it requires a usable control policy even in the absence of updating its state information. Human short term memory decays with time, so to simulate this we allow the state information upon which the actions are computed to be corrupted by noise. We incorporate these into our model using simple scalar values for each module. Formally, we define a module as a tuple $M=\left(S, \mathcal{A}, \pi, \mathbf{s}^{*}, \rho, \varepsilon\right)$, where:

- $\mathcal{S}=\left\{s_{1}, \ldots, s_{n}\right\}$ is a set of the $n$ state variables that are relevant to the module,
- $\mathcal{A}=\left\{a_{1}, \ldots, a_{k}\right\}$ is a set of the $k$ action variables that are relevant to the module,
- $\pi: \mathbb{R}^{n} \rightarrow \mathbb{R}^{k}$ is a control policy that maps state values onto actions,
- $\mathbf{s}^{*} \in \mathbb{R}^{n}$ is a vector of target state values,
- $\rho$ is a scalar uncertainty threshold value for the module, and
- $\varepsilon$ is a scalar noise value for the module.

The first three elements of $M$ are common to typical Markov decision process (MDP) scenarios. The state space, spanned by elements of $\mathcal{S}$, represents all possible combinations of world state that are relevant for the task. The action space, spanned by elements of $\mathcal{A}$, describes all possible actions that the agent can take. The control policy maps states to actions; an optimal policy maps states to the best action for each state. The fourth element of the tuple, $\mathbf{s}^{*}$, is a vector of target values for each state variable. These target values are used in place of the more traditional formulation of scalar reward; this is discussed in further detail below. Finally, each module incorporates explicit values for both task priority $1 / \rho$ and task uncertainty $\varepsilon$, which are also explained below.

A learning agent is equipped with $N$ individual modules $M^{(1)}, \ldots, M^{(N)}$ that each specialize in one task and can be used in conjunction to control behavior in the world. To simplify the control problem, in our model all modules share a common set of action variables. In the driving environment described in this paper, there are two action variables: one represents changes in the vehicle's speed and another represents changes in the vehicle's heading.

## State estimates

Each module depends on a set of world-state variables that are relevant to the module's specific task. When driving, relevant state variables for a car-following task, for example, could include the agent-centric distance and angle to the leader car, the speed and heading relative to the leader car, etc. Relevant state variables for a target-speed task might be as simple as monitoring the absolute speed of the agent.

Figure 1: Evolution of state variable and uncertainty information for two single-variable modules. On the left, the solid blue lines represent the observed values of the state variable $A$ over time, while the shaded blue regions represent the region in which the true value of the state variable is likely to occur. On the right, the observed values and uncertainty regions are shown in green for a different state variable, $B$. Vertical dashes in each plot indicate times where the state estimates are updated with a new observation of the true value; these updates also reduce the magnitudes of the uncertainties in each estimate towards zero. The $\varepsilon$ parameter in this scenario is greater for the module tracking variable $A$ than for the module tracking variable $B$.

In MDP scenarios, agents are assumed to have constant access to accurate state variable information. Humans, on the other hand, have a foveated visual system that often requires active serial collection of updated state information. We assume that this serial process requires that when one visual task is accessing new information all other tasks must rely on noisy memory estimates.

To incorporate this state uncertainty into the model, each module $M^{(i)}$ maintains an explicit estimate of the current value of each of its state variables, $\hat{\mathbf{s}}^{(i)}(t)$. (We will henceforth omit the module superscript except to resolve ambiguities.) This estimate could be designed to incorporate many sorts of prior information about the evolution of the world, but the model in its current state simply treats state estimates as samples drawn IID from a spherical normal distribution

$$
\hat{\mathbf{s}}(t) \sim \mathcal{N}\left(\mu(t), \sigma^{2}(t) I\right)
$$

where $\mu(t)=\left[\mu_{1}(t) \ldots \mu_{n}(t)\right]^{T}$ is a vector of the most recently observed state values, and $\sigma(t)$ is the standard deviation for the state variable estimates in the module. Figure 1 shows the state updates over time for a simple, hypothetical system containing two modules, each tracking one state variable.
Uncertainty propagation Uncertainty propagates over time within each module by maintaining a small set of $J$ "uncertainty particles" $\mathcal{E}=\left\{\beta_{1}(t), \ldots, \beta_{J}(t)\right\}$. Each particle represents one potential path of deviation that the true state value might have taken from the last-observed state value. At every time step in the simulation, all uncertainty particles are displaced randomly by a step drawn from $\mathcal{N}(0, \varepsilon)$, thus defining a random walk for each particle. The root-mean-square value of the uncertainty particles is then used to define the standard
deviation

$$
\sigma(t)=\sqrt{\frac{1}{J} \sum_{j=1}^{J} \beta_{j}^{2}(t)}
$$

of state estimates for this module. Periodically, a module will be updated with accurate state information from the world (described below); when this happens, the magnitude of each uncertainty particle for the module is reduced according to $\beta_{j}(t+1)=(1-\alpha) \beta_{j}(t)$. After an informal parameter search, we set $\alpha=0.7$ for all modules; with $\alpha=1$, the model tends to produce many short updates because uncertainty is instantly reduced to 0 , but with $\alpha<1$ the uncertainty increase due to noise competes with the uncertainty reduction from the updated state information. Figure 2 shows the uncertainties over time for the hypothetical two-module system shown in Figure 1.

The state estimation approach described here can be seen as a sort of particle filter (e.g., Arulampalam et al., 2002), using an uninformed proposal distribution and equal weights for all particles. Interestingly, the behavior of the simulation was largely unaffected by the choice of $J$; for our simulation, we used $J=10$.

## Control policy

Each module relies on a policy to determine which action to take when the world is in a particular state. There are multiple ways an MDP may be solved for a control policy, e.g. in reinforcement learning a $Q$-table can be learned, which explicitly represents the expected future reward for each possible state and action combination; the policy is then given by a simple maximum over available actions for each state.

For a task like driving, however, continuous variables are the most natural representation of state (distance to another car, current speed, etc.) and action (change in speed, change in steering) variables. Although MDP algorithms can converge on policies for tasks in continuous spaces, for many real-world tasks the resulting policies can be more easily modeled using a simple parametric function. In addition, many algorithms for solving MDPs require significant training time to arrive at these regularly-shaped policies. The model described here instead uses a continuous proportional-integral-derivative (PID) control strategy.
PID controllers A PID controller $C(e)$ is a feedback control functional that maps state errors $e(t)$ onto control signals $u(t)$. Formally,

$$
C(e)=K_{P} e(t)+K_{I} \int_{0}^{t} e(v) d v+K_{D} \dot{e}(t)
$$

where $K_{P}, K_{I}$, and $K_{D}$ are parameters that affect the convergence speed and stability of the PID controller output when encountering a step change in error. In our model, these parameters are tuned manually for each module in isolation (O’Dwyer, 2006) to produce qualitatively appropriate driving behavior.

Each module in the model uses one PID controller for each state variable. Given estimates $\hat{\mathbf{s}}(t)$ of the current values of each variable and a vector of target state values $\mathbf{s}^{*}$, the control policy becomes

$$
\pi(\hat{\mathbf{s}}(t))=U\left[C_{1}\left(\hat{s}_{1}(t)-s_{1}^{*}\right) \ldots C_{n}\left(\hat{s}_{n}(t)-s_{n}^{*}\right)\right]^{T}
$$

where $U$ is a $k \times n$ mixing matrix that combines control policy recommendations from each PID controller into a final control output for each action variable. Note that, in this model, the control policy $\pi$ does not have access to the true state values $\mathbf{s}(t)$, but rather to the module's estimates of those state values $\widehat{\mathbf{s}}(t)$.

The composition of $U$ is determined by the needs of the modeling task. For the driving task, for example, each module generally has one state variable corresponding to a desired distance, and another corresponding to a desired heading. For this case, $U$ is set to the $2 \times 2$ identity matrix, since the PID controller that is monitoring a distance variable provides a natural control signal for vehicle speed, and the PID controller that monitors an angle variable provides a control signal for the vehicle heading. The exception to this is the module focusing on maintaining a target speed; this module only monitors current speed in the world, so it always provides a zero-output control value for the change-of-heading action variable.

## Priority

Modules can be prioritized by increasing their importance relative to one another, to allow modular agents to perform one task (for example, following a leader car) in preference to another (like achieving a target speed). In a traditional MDP scenario, this is modeled by controlling the ratio of reward values between two subsets of world states. In the present model, module priority is manipulated through the $\rho$ parameter: as $\rho$ increases, the module's relative priority decreases.

This relative priority value is incorporated into the model as a soft bound on the diffusion of uncertainty for each module. The specifics of this integration of uncertainty and priority are described in more detail next, as part of the perceptual arbitration process.

## Simulation

In simulation, an agent is placed in a two-dimensional virtual driving world. The world contains a single road with multiple lanes. Several non-agent cars are placed on the lanes at random locations, and one of the non-agent cars is designated as the leader car.

The basic simulation loop updates the state of the world at a fixed frequency $f_{s}$ (set to 60 Hz to match experimental conditions from (Sullivan, Johnson, Rothkopf, Ballard, \& Hayhoe, 2012)) according to an elementary physics simulation. At each time step, each car in the world moves ahead proportionally to its speed, in a direction given by its heading. For the non-agent cars, the simulator constrains these speed and heading values so that the cars always follow the lanes in the world.

Figure 2: Example random walks for uncertainty particles in the two modules shown in Figure 1. The individual particles are shown as small dots in each plot; their RMS uncertainty value $\sigma(t)$ is shown with a solid blue (left) and green (right) line. Vertical dotted lines indicate time steps when each module received an update; these updates reduce the magnitudes of the uncertainty particles towards 0 . The uncertainty threshold $\rho$ for each module is indicated by the shaded gray region in the center of the plot; in this example, the module tracking state variable $B$ (right) has higher priority (lower uncertainty threshold $\rho$ ) than the module tracking variable $A$. However, because the module on the left has a higher noise parameter $\varepsilon$, it receives more updates than the module on the right in the same duration of time.

After moving all vehicles in the world, the simulation additionally requests a control update from the learning agent, which changes the heading and speed of the agent before the next frame begins. Every time the simulator requests a control update for the learning agent, the modules are also updated by displacing their uncertainty particles according to each module's noise parameter $\varepsilon$.

## Perceptual Arbitration

If the simulation only performed the steps above, the agent's performance would become increasingly erratic over time, because the uncertainty particles would drift further away from zero. The resulting erroneous state value estimates would produce poor PID controller outputs, and the resulting actions chosen by the agent would further compound the uncertainty in the state estimates. In a human driver, this behavior would be analogous to taking one look at the world when getting into the car, and then driving with a blindfold thereafter.

Clearly this is not what humans tend to do when driving. Instead, people continually and regularly reposition their gaze toward objects in the environment as the driving task progresses. The final step in our model is to incorpate a scheduler to arbitrate between task modules, such that updated sensory information is delivered to the PID controllers dependent on task uncertainty and priority. Like Sprague and Ballard (2003), we hypothesize that this repositioning serves to reduce uncertainty about the state of relevant variables in the world-distance to a leader car, current speed, etc. To capture this behavior, the simulator periodically selects a module for receiving updated state information through a perceptual arbitration mechanism. This selection process happens at a constant frequency $f_{p}$ (set to 3 Hz for the results reported here
to approximate the frequency of human gaze behavior).
The perceptual arbitration process incorporates priority and uncertainty in the following way. We first define, for each module $M^{(i)}$, a weighted uncertainty at time $t$ that incorporates both the RMS uncertainty and the scalar priority of the module:

$$
\zeta^{(i)}(t)=\sigma^{(i)}(t)-\rho^{(i)}
$$

We also define a global variable $\phi(t)$ to represent the index of the module that gets updated at time $t$. Then the soft barrier model defines the probability that module $M^{(i)}$ is selected for update at time $t$ as a Boltzmann distribution over each of the priority-weighted module uncertainties:

$$
p\left(\phi(t)=i \mid \zeta^{(1)}(t), \ldots, \zeta^{(N)}(t)\right)=\frac{\exp \left(\zeta^{(i)}(t)\right)}{\sum_{j=1}^{N} \exp \left(\zeta^{(j)}(t)\right)}
$$

Intuitively, if the uncertainty in $M^{(i)}$ is currently above the threshold for that module-that is, if $\sigma^{(i)}(t)>\rho^{(i)}$-then $M^{(i)}$ is much more likely to be selected for update than another module, especially if none of the other modules have uncertainties exceeding their thresholds. However, the softmax selection process allows for nondeterminism: even if $\zeta^{(i)}(t)>\zeta^{(j)}(t)$ for $j \neq i$, there is some nonzero probability that $i$ will not be selected for update at time $t$. Finally, because module updates are always selected at frequency $f_{p}$ by sampling from the above distribution at the appropriate time, a module might be selected for update even if none of the agent's task modules have exceeded their uncertainty boundary (i.e., if $\zeta^{(i)}<0$ for all $i$ ).

Although inspired by diffusion models of decision making, this model contrasts somewhat with traditional models. Many diffusion models with "hard" bounds were developed for forced-choice, two-alternative tasks (e.g., Carpenter \& Williams, 1995); our model, in comparison, is designed to incorporate a wider variety of tasks. The "soft" barrier, driven at a fixed frequency, can incorporate more than two choices into the model simultaneously, while accounting for biologically realistic delays in planning and executing saccades.

As described above, and illustrated in Figures 1 and 2, when a module is selected for update, it is provided with the true state of each world state variable in $S^{(i)}$, and each of its uncertainty particles $\beta_{j}$ is reduced towards zero for every simulation frame until another module is selected for update.

## Simulation results

We implemented the model described above ${ }^{1}$ and ran several simulations to assess its qualitative behavior. Our simulated driving environment was identical in layout to the virtual environment used by Sullivan et al. (2012), so that we could directly compare our results to human performance. Our implementation consisted of three modules: a "speed" module

[^107]$M^{(s)}$ that attempted to drive at a particular target speed; a "follow" module $M^{(f)}$ that attempted to follow a lead car, and a "lane" module $M^{(l)}$ that attempted to steer so as to follow the nearest lane on the road. All cars in the simulation drove in a simulated 2-dimensional world, described above. Each time gaze was allocated to a new module, we recorded the module that received the gaze, as well as several behavioral measurements (e.g., distance to leader car, current speed, etc.) to verify that the agent was driving appropriately.

## Categorizing looks

The gaze selection process in our model is Markovian, meaning that each selected module is independent of the previously-selected modules; more formally, $p(\phi(t) \mid \phi(t-$ $n), \cdot)=p(\phi(t) \mid \cdot)$ for all $n>0$. Thus, it is possible that multiple consecutive module updates are directed at the same module, or $\phi(t)=\phi(t-n)$. Similar refixation behavior exists in human gaze during complex tasks; presumably observers use the visual information across multiple fixations for a continuous control signal for a single task. To make analysis simpler and more consistent between simulation and human results, we grouped multiple consecutive updates for a given module into a single "look." For instance, in the example shown in Figures 1 and 2, updates are provided first to module A, then B, then A twice, then B twice. In this example, each module receives two "looks," with the second look for each module being twice as long as the first.

## Comparison with human results

Sullivan et al. (2012) instructed subjects driving in a virtual environment to follow a leader car and maintain a certain speed, but the priority of which of the two tasks was most important was varied so that one was high and the other was low. Additionally, subjects drove in some conditions where noise was added to the speed of the car, with the intent of disrupting the maintenance of a constant speed. These manipulations resulted in four conditions where either following a leader or maintaining a constant speed was most important, and velocity noise was either present or absent. They found that task priority increased fixation behavior on task-related objects. Additionally, an interaction between priority and uncertainty was found, whereby uncertainty alone did not guarantee increased fixation behavior. Instead, only if a task related object had sufficiently high priority did the addition of uncertainty further increase fixation behavior. Look duration histograms for this experiment are replicated in the top row of Figure 3.

We ran a set of simulations with our model attempting to replicate this behavior using parameters set to mimic the orginal human driver conditions. We used a simple grid search to locate these parameters. Because all of the parameters taken together can present a scaling ambiguity (e.g., if all $\varepsilon^{(i)}$ and $\rho^{(i)}$ are multiplied by 2 , then the same qualitative behavior will result) we fixed $\rho^{(f)}=1$ and explored only settings for the other parameters.

Once we identified the parameter settings corresponding to the experimental conditions, we evaluated our model by running it in each of these conditions 10 times, with each simulation run for approximately 4000 steps. The sequence of module updates for each simulation run was stored and labeled as looks as described above, then normalized to form a probability distribution. These results were compared the distributions of look durations from the human data. The model was able to capture several important aspects of the human data, including a sensitivity to both noise and priority, but also a gating effect whereby noise in low-priority tasks had a smaller effect than noise in high-priority tasks. Our results, shown under the human data in Figure 3, are qualitatively similar to the human performance in a virtual driving environment.

In addition to our scheduling model, a baseline fixation scheduler was run in the simulation. This scheduler incorporated only the priority of each task in selecting modules for update, but uncertainty was not incorporated. The results from this baseline scheduler are shown in the bottom row of Figure 3. The probability distributions from our scheduler and the baseline compared against the human data via the Kullback-Leibler (KL) divergence. Over all the conditions, our model had an average KL divergence of 2.20, versus 4.43 for the baseline scheduler (lower numbers are better).

## Discussion

This paper described a modular, "soft" barrier approach for modeling eye movements in human drivers. The model includes explicit measurements of an agent's estimates of external world state, and uses a random walk to model the uncertainty in these estimates over time. Uncertainty, modulated by the priority of a task, is then used to arbitrate gaze allocations among competing modules. Our priority-plusuncertainty model provides a better fit of a set of human driving data than a priority-only baseline fixation scheduling model. We are currently working on comparing this model to predictions from a standard salience model (Itti \& Koch, 2001), a central bias model (Tatler \& Vincent, 2009) and the original scheduling model that inspired our work (Sprague \& Ballard, 2003). In addition, the softmax approach to selecting modules for update permits a clean inversion of the model; that is, given human eye fixation behavior, the model can be inverted to provide the most likely set of parameter settings to explain those data. We plan to develop this inversion more fully so as to replace the grid search described in this paper. Once the inversion process is in place, we can use this model to recover the task priorities and uncertainty levels that human drivers appear to be experiencing in these conditions.

Figure 3: Distribution of look durations for human subjects (a-d; from Sullivan et al., 2012), model predictions (e-h), and baseline predictions (i-1). In all plots, look duration (in seconds) is shown along the abscissa, with the proportion of looks indicated on the ordinate. Looks to the speedometer are plotted with green squares; looks to the leader car are plotted with blue circles. ( $a, b$ ) In conditions where driving at a target speed was emphasized, human looks at the speedometer were approximately matched in duration to looks at the leader car. (c, d) In conditions where following a leader car was emphasized, human looks at the speedometer were brief. Noise added to the car's speed (b, d) affected human looks in the speed task more than looks in the following task. Similar results hold for our model (e-h), but not for a baseline model that incorporates task priority but ignores the effects of uncertainty (i-l).

# Meaning Overrides Frequency in Idiomatic and Compositional Multiword Chunks 

Hajnal Jolsvai (jolsvai@cornell.edu)<br>Stewart M. McCauley (smm424@cornell.edu)<br>Morten H. Christiansen (christiansen@cornell.edu)<br>Department of Psychology, Cornell University, Ithaca, NY 14853 USA

#### Abstract

In line with usage-based accounts, recent psycholinguistic studies have confirmed that frequency of occurrence impacts processing latencies for multiword strings (e.g., Arnon \& Snider, 2010). However, these studies have not been concerned with the meaning of the multiword chunks in question, which is central to accounts of formulaic language rooted in cognitive linguistics (e.g., Wray, 2002). Here, we address this issue by comparing processing latencies for three types of multiword chunks: idiomatic expressions, meaningful compositional phrases, and less meaningful fragments. All three chunk types were matched for wholeand sub-string frequency. Our results show that frequency facilitates processing for all three chunk types, but to a lesser extent than their "meaningfulness" (as assessed in a separate norming study), indicating that the meanings of multiword expressions may have implications for models of language processing which extend beyond those of frequency of occurrence.

Keywords: idiomatic phrases; chunks; distributional statistics; Construction Grammar (CG); usage-based approach; cognitive linguistics

## Introduction

It has been recognized through a large number of corpus studies that everyday language involves a wide array of fixed co-occurring multiword sequences (such as let it go), or formulaic sequences (e.g., Sinclair, 1991). Usage-based theories suggest that strings of words can become fixed linguistic patterns through simple repetition of use (e.g., strong tea or powerful computer, as opposed to powerful tea or strong computer; Bybee, 2006; Bybee \& Hopper, 2001; Tomasello, 2003). Indeed, recent psycholinguistic work has shown that the processing of a multiword sequence is affected by the frequency of the sequence as a whole (e.g., Arnon \& Snider, 2010; Tremblay, Derwing, Libben, \& Westbury, 2011).

But how much insight does frequency alone give us into formulaic language processing? Is it possible that some multiword chunks become conventionalized because they convey a highly specific meaning, in much the same way as do individual words (e.g., let it be)? In addition to their frequency of use, the "meaningfulness" of multiword chunks may be another factor affecting stored linguistic units, in line with what would be expected from a cognitivegrammar perspective (e.g., Fillmore, Kay, \& O’Connor, 1988; Langacker, 1987).

Idioms are perhaps the most canonical form of formulaic language, involving a particular string of words which is linked to a specific meaning that does not follow compositionally from the meanings of the constituent words (e.g., spill the beans). Importantly, it has traditionally been assumed that idiomatic phrases are represented and retrieved from memory as single units and thus processed faster than compositional phrases (e.g., Swinney \& Cutler, 1979). Whereas idioms are often treated as special cases, Construction Grammar approaches suggest that both idiomatic and high-frequency compositional multiword expressions are stored as conventionalized form-meaning pairs (Goldberg, 2003).

Supporting the lexicalized idioms assumption (e.g., Swinney \& Cutler, 1979), an eye-tracking study by Underwood, Schmidt and Galpin (2004) found fewer and shorter fixations for the last words of idiomatic expressions (e.g., met the deadline by the skin of his teeth) as compared to the same words in non-idiomatic contexts (e.g., the dentist looked at his teeth). In a self-paced reading study, Conklin and Schmidt (2008) found that idiomatic expressions (e.g., hit the nail on the head) were read faster when compared to similar phrases (e.g., hit his head on the nail). Moreover, a recent eye-tracking study demonstrated a processing advantage for idiomatic expressions (e.g., at the end of the day) over similar phrases (e.g., at the end of the war) (Siyanova-Chanturia, Conklin, Schmitt, 2011). However, a shortcoming of these studies, which reveal faster processing for formulaic expressions, is that wholeand sub-string frequencies were not controlled for in a systematic way.

Nevertheless, recent experimental evidence has shown that language users are sensitive to the frequency of compositional multiword phrases. Typically, in these studies, pairs of high- and low-frequency phrases are compared, using corpus data to control for substring frequencies. Bannard and Matthews (2008) found that 3 - and 4 -years-olds repeat more frequent variants of compositional four-word phrases (such as a drink of milk) more easily than similar but less frequent four-word strings (such as a drink of tea). Similarly, high-frequency compositional multiword phrases are processed faster by adults than comparable sequences of lesser frequency (e.g., Arnon \& Snider, 2010; Tremblay \& Baayen, 2010).

In addition to findings of frequency effects for compositional multiword phrases, recent studies have investigated whether similar frequency effects can be
revealed for multiword sequences crossing syntactic boundaries. For instance, higher $n$-gram frequency chunks crossing syntactic boundaries (such as in the middle of the) are read faster compared to less frequent non-constituents (e.g., in the front of the) when embedded in a sentence (Tremblay, Derwing, Libben, \& Westbury, 2011). Similarly, Arnon and Cohen-Priva (in press) found no effect of constituency when comparing production latencies for highand low-frequency constituent and non-constituent pairs. The presence of frequency effects for not only phrases, but for sentence fragments as well, suggests that constituency may be a less important factor for theoretical accounts seeking to incorporate multiword chunks as linguistic units in their own right. Alternatively, it is possible that meaning may also need to be considered in order to reveal constituency effects for multiword sequences.

Although these findings make it clear that more frequent multiword phrases are processed faster, there is work to suggest that other factors may need to be taken in to consideration. For instance, Siyanova-Chanturia, Conklin and van Heuven (2011) found that readers are also sensitive to the fixedness of multiword chunks, above and beyond their frequency of occurrence. In this eye-tracking study, more frequent formulaic binominal phrases (such as bride and groom) were more easily read by participants as compared to their less preferred reversed forms, which nevertheless shared the same syntactic and semantic attributes (groom and bride). More importantly, even lower frequency formulaic chunks with fixed configurations (like sweet and sour), were read faster than higher frequency reversed phrases (such as west and east).

The above-mentioned studies are limited in that the "meaningfulness" of multiword chunks is not taken into account. Language users may also be sensitive to the relative meaningfulness of a multiword sequence as a whole, in line with predictions made by cognitive linguists (e.g., Langacker, 1987; Wray, 2002).

In the current study, we attempt to fill a gap left by previous psycholinguistic studies concerned with the processing of multiword sequences, which have tended to focus primarily on distributional properties, such as frequency of occurrence. We investigate the processing of multiword chunks that vary in the degree to which people find them meaningful as a whole unit, while controlling for frequency. Specifically, our goal is to determine whether the relative meaningfulness of multiword chunks may impact their processing over and above the well-known effects of frequency. Moreover, we aim to test the idea that highly meaningful chunks show processing advantages independently of their compositional status, in accordance with Construction Grammar approaches that treat both idiomatic and compositional sequences as pairings between form and meaning (e.g., Goldberg, 2003).

We address these issues by examining readers' processing of three different types of 3-word sequences; idiomatic expressions, highly meaningful compositional phrases. and less meaningful fragments which cross syntactic boundaries.

All three types of trigrams were selected from the same corpora and matched for phrase (trigram) and substring (bigram, unigram) frequencies. Both idiomatic expressions and compositional phrases were rated as being equally meaningful in an initial norming study. Furthermore, participants in this norming study rated sentence fragments as being significantly less meaningful than their frequencymatched idiomatic and meaningful compositional phrases. A different set of participants found the three types of tokens to be equally plausible as part of an English sentence in a separate norming study (thus, our items differed only in their meaningfulness, and not plausibility as possible sequences of words in English sentences). Instead of comparing pairs of high and low $n$-gram frequency sequences differing by only one word (don't have to worry vs. don't have to wait), as in previous studies, we investigated sequences which varied in the whole-string frequency ( $\log _{2}$ transformed) with which they appeared in a large corpus, along a continuum ranging from 1.0 to 10.4.

We predicted that idiomatic expressions and compositional phrases would be processed faster than less meaningful fragments because they vary in the extent to which people find them meaningful as units. We also predicted that when controlled for phrase and substring frequencies, idiomatic expressions would not be processed faster than compositional meaningful sequences. This prediction is at odds with the traditional view that contrasts faster access to stored idiomatic expressions with slower processing of computed compositional phrases (e.g., Swinney and Cutler, 1979). However, our prediction is in line with a Construction Grammar perspective (e.g., Goldberg, 2003).

## Methods

Three different types of trigrams were extracted from the American National Corpus (ANC; Reppen, Ide, \& Suderman, 2005) and the Fisher corpus (Cieri, Graff, Kimball, Miller, \& Walker, 2004, 2005). The two corpora were combined into a single corpus containing a total of 39 million words of American English. The Fisher corpus comprises spoken language (telephone conversations), while the ANC consists of spoken as well as written texts. From this combined corpus, we selected all 3-word idiomatic expressions using the following collections: McGraw-Hill's Essential American Idioms Dictionary (Spears, 2008); Handbook of Commonly Used American Idioms (Makai, Boatner, Gates 1991); and the IdiomQuest (http://www.idiomquest.com) and American Idioms (http://www.americanidioms.net) online idiom dictionaries. Eighty-two 3-word idiomatic expressions from these collections appeared in the combined corpus. For each idiomatic expression (e.g., over the hill) we selected frequency-matched compositional phrases (e.g., had a dream) and frequency-matched fragments (e.g., by the postal). $\log _{2}$ transformation was applied to all raw phrase and substring frequencies prior to the selection process (described below). Table 1 presents examples of the three
groups of items alongside their frequencies in the corpus. Each token belongs to a "triad" of whole- and sub-string frequency-matched items, with one from each of the three conditions (idiomatic expression, compositional phrase and fragment).

Table 1: Example triads of idiomatic expressions, compositional phrases, and fragments with their $\log _{2}$ transformed phrase frequencies

| Idiomatic <br> Expressions |  | Compositional <br> Phrases |  | Fragments |
| :--- | :--- | :--- | :--- | :--- | :--- |

Both the compositional phrases and the fragments were frequency-matched to a corresponding idiomatic expression such that trigram frequency, first bigram, second bigram, first unigram, second unigram, and third unigram frequencies were within $\pm 10 \%$ of the corresponding idiomatic phrase's frequencies, respectively. Table 2 shows the results of the individual ANOVA tests of the phrase and substring frequencies across idiomatic expressions, compositional phrases, and fragments.

Table 2: Individual ANOVA tests showing no differences between the averages of the six frequency measures across the three experimental conditions

|  | Df | F-score | p-value |
| :--- | :---: | ---: | ---: |
| Phrase | 2 | 0.0338 | 0.9668 |
| $1^{\text {st }}$ bigram | 2 | 0.092 | 0.9121 |
| $2^{\text {nd }}$ bigram | 2 | 0.0259 | 0.9745 |
| $1^{\text {st }}$ unigram | 2 | 0.8341 | 0.4368 |
| $2^{\text {nd }}$ unigram | 2 | 0.6037 | 0.5485 |
| $3^{\text {rd }}$ unigram | 2 | 0.05 | 0.9513 |

To ensure that the items differed only in the extent to which they would be judged as meaningful (i.e., that the fragments were less meaningful than the idiomatic expressions and compositional phrases, which in turn should not differ from one another) as opposed to plausibility of occurrence, we conducted two norming studies. In the first norming study, participants judged the plausibility of each trigram. In the second norming study, a different set of
participants rated the tokens according to how meaningful they were as units.

## Norming Study 1: Plausibility

The purpose of the first norming study was to collect judgments regarding the plausibility of the idiomatic expressions, compositional phrases, and fragments. This was necessary to ensure that stimuli from each condition were equally plausible as strings in American English, despite any differences in the extent to which items from each condition conveyed coherent meanings as units.

Participants Thirty-three native speakers of American English from the Cornell undergraduate population participated in the study for extra credit (mean age = 19.69; $\mathrm{SD}=1.74$ ). Data from 2 participants were omitted because their overall performance fell below $80 \%$ in a random memory recall task (see below).

Materials The materials consisted of 3-word sequences of 82 idiomatic phrases, 236 compositional phrases, and 218 fragments. The 3 -word sequences were presented to participants on a computer screen (one 3 -word sequence at a time). As a control, 90 impossible 3-word combinations were also included. The impossible tokens were created by scrambling matching compositional phrases and fragment tokens that were not introduced in the experimental material.

Procedure Participants' task was to rate each trigram according to how plausible the sequence of words was as part of an English sentence. Participants rated each token on a 1-7 scale by pressing a key. To ensure that participants read each sequence, a random memory recall test was included. In $10 \%$ of the trials for each condition (idiomatic expression, compositional phrase, and fragment), participants were asked to type an English sentence that included the 3-word sequence they had just seen.

Results Table 3 shows the mean scores for each condition in the plausibility norming study. As the trigrams were rated as equally plausible, we submitted them to a second norming study evaluating their meaningfulness.

Table 3: Mean ratings and standard deviations of plausibility (Norming Study 1) scores for idiomatic expressions, compositional phrases, and fragments.

|  | Mean | SD |
| :--- | ---: | ---: |
| Idiomatic Expressions | 6.84 | 0.32 |
| Compositional Phrases | 6.91 | 0.22 |
| Fragments | 6.87 | 0.22 |

## Norming Study 2: Meaningfulness

The purpose of the second norming study was to collect judgments regarding the meaningfulness of the idiomatic expressions, compositional phrases, and fragments as units.

Participants A different set of 33 native speakers of American English from the Cornell undergraduate population (mean age $=19.84$; $\mathrm{SD}=1.15$ ) participated in the study for extra credit. Data from two subjects were removed because their overall performance on the random memory recall test (see below) was less than $80 \%$.

Materials The materials consisted of the same 3-word sequences used in the first norming study (82 idiomatic phrases, 236 compositional phrases, and 218 fragments). The 3-word sequences as a whole were presented to participants one-by-one on a computer screen.

Procedure Participants' task was to rate each trigram according to how meaningful they found each sequence as a unit. Participants rated each token on a scale of 1-7 by pressing a key. To ensure that participants read each sequence, a memory recall test was included. In $10 \%$ of the trials for each condition (idiomatic expression, compositional phrase, and fragment), participants were asked to type an English sentence that included the last 3word sequence they had seen.

Results Table 4 shows the mean scores for each condition in the meaningfulness norming study.

Table 4: Mean ratings and standard deviations of meaningfulness (Norming Study 2) scores for idiomatic expressions, compositional phrases, and fragments.

|  | Mean | SD |
| :--- | ---: | ---: |
| Idiomatic Expressions | 5.90 | 1.02 |
| Compositional Phrases | 5.89 | 0.86 |
| Fragments | 1.98 | 0.48 |

In order to arrive at the final set of experimental items, we submitted the following to a selection algorithm (more details below): the arcsine-transformed proportion of subjects rating each item 6 or 7 ( 1 or 2 for fragments) in Norming Study 2, the arcsine transformed proportion of subjects rating each item as a 6 or 7 in Norming Study 1, and the whole- and sub-string frequencies of each item. The algorithm selected the set of 40 triads (each comprising an idiomatic expression, a compositional phrase, and a fragment) which differed least according to plausibility norming scores as well as phrase and substring frequencies across the three trigram types, while also differing maximally in Norming 2 scores between fragments and the other two conditions.

## Reaction Time Study

Our prediction was that the overall meaningfulness of a sequence would facilitate processing over and above mere frequency of use, independently whether the sequence was an idiomatic phrase. Thus, we predicted that processing latencies for idiomatic phrases and compositional meaningful phrases would not differ from one another. However, both idiomatic phrases and compositional phrases should show processing advantages over fragments.

Participants An additional 40 native speakers of American English from the Cornell undergraduate population were recruited, none of which participated in either of the two norming studies (mean age $=20.5 ; \mathrm{SD}=1.58$ ).

Materials A final set of frequency-matched tokens from the trigrams rated in the two norming studies was selected for the reaction time study (using a selection algorithm which sought to minimize differences along the frequency dimensions as well as the norming scores between the conditions). This set consisted of 40 triads, each comprising an idiomatic phrase, a compositional phrase and a fragment. The resulting set of 40 idiomatic expressions, 40 compositional phrases and 40 fragments did not differ significantly along the 6 frequency dimensions (trigram, first bigram, second bigram, first unigram, second unigram, third unigram) or according to the percentage of subjects rating items as 6 or 7 in the first plausibility norming study. Additionally, the items were constrained such that the idiomatic and compositional phrases did not differ in terms of their meaningfulness ratings from second norming study, whereas the fragments were chosen to have the lowest meaningfulness scores possible. All comparisons: p $>0.4$.

The $\log _{2}$ phrase frequencies of the final set of 40 triads introduced in the behavioral study ranged between 1 and 10.4. Besides the 40 experimental triads, 120 impossible sequences (such as hear I isn't) were used as fillers.

Procedure We based our reaction time study on Arnon and Snider's (2010) phrasal decision task (which in turn is based on the classic lexical decision task). Participants were presented with the three-word sequences (120 experimental and 120 impossible filler tokens) separately, in random order, on a computer screen, and asked to judge (by quickly hitting one of two keys) whether they formed possible word combinations in the context of English sentences.

Data Analysis Data points corresponding to reaction times of less than 200 ms were removed, along with extreme outliers (defined as those reaction times exceeding the upper quartile by more than three times the inter-quartile range), resulting in a $1.5 \%$ data loss. The data were then submitted to a linear mixed-effects (LME) analysis, with Item and Subject as random effects, and the scores from the second norming study (hereafter referred to as the Meaningfulness Scores), Trigram Type (using Idiomatic Expressions as the base case), Frequency (whole-string), substring frequencies
(including frequency predictors for First Bigram, Second Bigram, First Unigram, Second Unigram, and Third Unigram), Length in Characters, and the Trigram Type x Frequency interaction term as fixed effects. Because the Meaningfulness scores had a fixed range of 1 to 7 , they were converted to proportions ( $\mathrm{n} / 7$ ), which were then logittransformed prior to entry in the model (cf. Armitage \& Berry, 1984). As the reaction times were not normally distributed, they were log-transformed prior to the analysis.

The LME resulted in no significant interaction between Frequency and Trigram Type and was therefore simplified to involve Item and Subject as random effects, and Meaningfulness scores, Trigram Type (using Idiomatic Expressions as the base case), Length in Characters, Frequency (whole-string), and the substring frequency predictors as fixed effects. There did not appear to be substantial multicollinearity between the fixed effects: The condition number for the matrix of predictors (cf. Belsley, Kuh, \& Welsch, 1980) was only 6.6.

The final model was compared to a version without the fixed effects ( $\chi^{2}=140.63, \mathrm{p}<0.0001$ ) as well as a version of the model without the variables of interest (Meaningfulness Score, Frequency, Trigram Type; $\chi^{2}=111.07, \mathrm{p}<0.0001$ ), indicating that the full model captured more of the variance in both cases.

## Results

As predicted, participants showed sensitivity to the meaningfulness of the trigrams. Decision times were faster for more meaningful tokens, as revealed by a highly significant main effect of Meaningfulness Score ( $\beta=-0.037$, $\mathrm{p}<0.0001$ ). Also in line with our predictions, reaction times were affected by trigram type: It took longer for participants to decide whether fragments were possible strings in English ( $\beta=0.089, \mathrm{p}<0.05$ ). However, decision times for compositional meaningful phrases were no slower than for idiomatic expressions ( $\beta=0.003, \mathrm{p}>0.3$ ). Table 5 presents the mean RTs and standard deviations for each condition.

Table 5: Mean RTs and standard deviations for idiomatic expressions, compositional phrases, and fragments.

|  | Mean | SD |
| :--- | ---: | ---: |
| Idiomatic Expressions | 766.4 | 247.9 |
| Compositional Phrases | 789.4 | 260.3 |
| Fragments | 949.9 | 343.7 |

Frequency (whole-string) also reached significance ( $\beta=-0.014, \mathrm{p}<0.05$ ) indicating that subjects responded faster to trigrams with greater whole-string frequency. Importantly, the effect of Frequency was less than that of Meaningfulness Score.

Of the fixed effects included to control for substring frequency and character length, only Length in Characters ( $\beta=0.08, \mathrm{p}<0.05$ ) and Third Unigram $(\beta=0.014$, $\mathrm{p}<0.05$ ) reached significance.

## General Discussion

In this study, we compared the processing latencies for triads consisting of idiomatic expressions, compositional phrases and less meaningful fragments. In each triad, both the meaningful compositional phrases and the fragments were frequency-matched to the idiomatic phrases. The aim of the study was to investigate (i) whether the relative meaningfulness of multiword chunks affects processing latencies in addition to their frequency, and (ii) whether idiomatic and meaningful compositional phrases are processed similarly, once frequency is adequately controlled for.

Our results indicate that participants were sensitive to the meaningfulness of the chunks. The meaningfulness of a given trigram-as indicated by the second norming studysuccessfully predicted reaction times in the final experiment. Participants' decision times for more meaningful trigrams were faster than for less meaningful ones. Furthermore, our findings show that the whole-string frequency of the tokens predicted the processing latencies, but to a lesser extent than the meaningfulness of the different chunks. These results thus suggest that in addition to frequency of occurrence, as emphasized by usage-based theories, the relative meaningfulness of multiword chunks should also be considered in accounts of language processing.

Our findings also showed that processing latencies for idiomatic phrases did not differ from frequency-matched compositional meaningful phrases, while processing latencies for less meaningful fragments were significantly greater. This suggests that meaningful compositional sequences may be represented and processed similarly to idiomatic phrases, despite their compositional nature. This is at odds with traditional distinctions between stored idioms and compositional phrases (Swinney \& Cutler, 1979). However, these results are in line with Construction Grammar approaches, suggesting that there are no fundamental differences between the representation and processing of idiomatic constructions and compositional phrases; they are both instances of conventionalized formmeaning mappings (Goldberg, 2003).

Additionally, higher meaningfulness scores were associated with reduced processing latencies. These results, when viewed alongside the weaker frequency effect, provide a step forward for studies of formulaic language, suggesting that that the meaningfulness of multiword chunks may be as important to their processing as their distributional properties.

It is possible that the processing latencies for compositional phrases in the current study were affected by their status as constituents, whereas fragments crossed syntactic boundaries. There exists only one study that has investigated whether constituency affects multi-word sequence processing while controlling for frequency. In a recent production study, Arnon and Cohen-Priva (in press) found that constituency did not affect processing. In their study, similar frequency effects were found when
comparing high- and low-frequency variants of constituents (a lot of work vs. a lot of years) as well as non-constituents crossing syntactic boundaries (as far as $I$ vs. as far as you). Similar frequency effects for both phrases and fragments suggest that constituency may be a less important feature of multiword chunk processing. On the other hand, it is possible that the lack of a constituency effect in the Arnon and Cohen-Priva study stems from not taking chunk meanings into account. Further studies are needed to examine the exact nature of the relationship between constituency and chunk meaningfulness.

To conclude, our results provide new insights into the representation and processing of formulaic expressions; they suggest that multiword compositional phrases that people find highly meaningful are likely to be processed similarly to idiomatic phrases, as a linguistic unit in its own right. Our findings are thus relevant for usage-based approaches to language, indicating that meaning provides an additional dimension that such approaches must take into account, in line with a number of expectations derived from cognitive linguistics (e.g., Langacker, 1987).

## Acknowledgments

We would like to thank Jaclyn Jeffrey-Wilensky and Julia Krasnow for their assistance with the reaction time study. Thanks also go to Jaclyn Jeffrey-Wilensky and László Kálmán for their help during material selection. Finally, we are grateful to Haim Bar for his valuable comments on our statistical analyses.

#### Abstract

Many studies have examined the distinction between featureand relation-based categories (Gentner, 2005; Genter \& Kurtz, 2005; Jung \& Hummel, 2009; Tomlinson \& Love, 2011). Those findings suggest that featural and relationl categories have fundamentally different learning algorithms, where relational categories rely on explicit representations and thus require working memory and attention, as opposed to featural categories which may be learned more implicitly. In this study, we investigated further the distinction between feature-and relation-based category learning using a dual task methodology. Our results revealed an interaction: featural category learning was more impaired by a visuospatial dual task than by a verbal dual task, whereas relational category learning was more impaired by the verbal dual task. Our results suggest that in contrast to featural category learning, which may involve mainly non-verbal mechanisms, relational category learning appears to place greater demands on more explicit and attention-demanding verbal or verbally-related learning mechanisms.

Key words: featural category learning; relational category learning; dual task; verbal dual task; visuospatial dual task; category learning algorithms

The ability to categorize plays a central role in human mental life. We use categories to makes sense of the world. They allow us to generalize knowledge form one situation to another, to decide which objects in the world are fundamentally the same, and to infer the unseen properties of novel category members. Research on categorization has mainly focused on feature-based categories-that is, categories defined by their exemplars' features, as when "bugs" in one category tend to have a particular kind of head, body and tail and "bugs" in the opposite category tend to have a different kind of head, body and tail (e.g., Taylor and Ross, 2009)—and comparatively little on relationbased categories-i.e., categories by the relations between exemplars' parts, or by relations between category exemplars and other objects in the world (for reviews, see Gentner, 2005; Goldwater, Markman, \& Stilwell, 2011; Jung \& Hummel, 2009; Kittur, Hummel \& Holyoak, 2004).

The distinction between featural and relational categories matters because features and relations are very different things-so different that we can have little or no
confidence that anything learned about category learning using feature-based categories will generalize at all to the case of relational categories. For example, the kinds of learning algorithms that work well with feature-based categories (i.e., various kinds of statistical learning) are completely incapable of learning relational categories (Doumas, Hummel \& Sandhofer, 2008; Hummel \& Holyoak, 2003; Jung \& Hummel, 2009; Kittur et al., 2004, 2006).

One of the clearest examples of this difference comes in the form of peoples' ability to learn probabilistic (aka family resemblance) category structures. It has been known since the 1970s that people have no difficulty learning categories with probabilistic structures, in which any given feature is likely to belong to a given category (e.g., "bugs" in category A are likely to have one kind of head whereas "bugs" in category B are likely to have another), but no feature is deterministically associated with any given category (e.g., sometimes, bugs from category B will have heads typical of bugs from category A and vice-versa; see Murphy, 2002, for a review). However, as noted by Kittur et al. (2004), such prototype effects have always been observed with feature-based categories. With categories defined by the relations between their exemplars' features, such prototype effects have proven difficult or impossible to observe (Jung \& Hummel, 2009, 2011; Kittur et al., 2004, 2006).

These differences between peoples' ability to learn featural and relational categories are consistent with the claim that fundamentally different learning algorithms may be at work in the two cases. For example, whereas associative learning may work in the case of featural categories, relational category learning may require a more sophisticated algorithm based, for example, on structured intersection discovery, in which learners compare examples to one another, retaining what the examples have in common and discarding or discounting the details on which they differ (Gick \& Holyoak, 1983; Hummel \& Holyoak, 2003; Jung \& Hummel, 2009, 2011; Kittur et al, 2004, 2006).

A fundamental assumption underlying this intersection discovery hypothesis is that people's mental representations of relational categories are explicitly relational (see Hummel \& Holyoak, 2003; Jung \& Hummel, 2009, 2011). That is, we assume that people notice and explicitly represent the relations between objects (and object parts) and use these relations as the basis for making their categorization responses. This assumption also leads to another critical contrast with feature-based approaches to mental representation and categorization. In contrast to featurebased representations, which come to us effortlessly, relational representations require attention and working memory (see, e.g., Hummel \& Holyoak, 1997, 2003; Logan, 1994; Maybery et al., 1986).

In this study, we examined what kinds of working memory might be involved in feature- or relation-based category learning. In particular, our interest was in how featural and relational category learning tasks respond to verbal and visuospatial dual tasks. If featural and relational category learning are based on different learning algorithms, then they might be differentially sensitive to different kinds of dual tasks.

Other researchers have also argued for multiple systems of category learning (Ashby et al., 1998). Miles and Minda (2011) showed that verbal dual tasks, which impose an executive functioning load, impaired rule-defined category learning, whereas a visual dual task impaired non-rule-defined learning regardless of executive functioning demand. Their findings provided evidence that verbal working memory and executive functioning are engaged in the rule-defined system, and visual processing is more engaged in the non-rule-defined system.

Our experiment will test the prediction that relational category learning will be more subject to verbal dual-task interference than feature-based category learning. By contrast, feature-based learning will be more subject to visuospatial dual-task interference than relational learning.

We used deterministic category structures; i.e., there was always one relation or feature that was deterministically predictive of category membership. The reason for using deterministic categories is that the categories must be learnable, even in the relational case, so that we can observe the effects of our manipulation on trials to criterion (i.e., how long it takes subjects to learn the categories).

We orthogonally crossed relational vs. feature-based categories with verbal dual task vs. visual dual task vs. no dual task. In the verbal dual task conditions, subjects had to perform a task known to interfere with relational processing (memorizing digits) while they simultaneously performed the category learning task. In the visual dual task condition, subjects had to memorize the locations of filled squares in 3 X 3 grids while simultaneously learning the categorization. In the no dual task condition, subjects simply performed the category learning task by itself.

## Method

Participants. A total of 75 subjects participated in the study for course credit. Each participant was randomly assigned to one of the six conditions.

Materials. Each exemplar consisted of a grey ellipse and a grey rectangle. Each exemplar had both relational properties (e.g., ellipse bigger than rectangle) and featural properties (e.g., ellipse of size 4). Each subject was tasked with deciding whether the objects they saw belonged to one of two featural or one of two relational categories.

Each exemplar was defined by three category-relevant properties: size (absolute in the featural condition or relative in the relational condition), darkness (absolute or relative) and orientation (absolute or relative). In the featural condition, the orientation of the ellipse was deterministically associated with category membership (i.e., horizontal orientation for category A, vertical for category L), whereas in the relational category condition, the relative orientation of the ellipse and rectangle (i.e., either same or different) was deterministically associated with category membership (with same for category A and different for category L). The other properties were probabilistically associated with category membership.

Figure 1. Three relevant properties in the featural condition: category A (above) and L (below)

For the featural category condition, the prototypes of the categories were defined as $[1,1,1]$ for category A and [ $0,0,0$ ] for $L$, where $[1,1,1]$ represents an rectangle size 3 [out of 9] for category A, 7 for category L, the color 3 [out of 9] for category A, 7 for category L, and horizontal orientation for category A, vertical for category L (Figure 1). Similarly, for the relational category condition, the prototypes were defined as $[1,1,1]$ for category $A$ and
[ $0,0,0$ ] for L , where [1,1,1] represents an ellipse larger, darker, and same orientation and $[0,0,0]$ represents a rectangle larger, darker, and different orientation (Figure 2). Exemplars of each category were made by switching the value of one dimension in the prototype (e.g., relational category A exemplar [1,0,1] would have the ellipse larger, lighter, and same orientation as the rectangle). Four copies of each exemplar type were presented on each block, two paired with a "Yes" responses on the dual task and two with a "No" responses, resulting in 32 trials per category per block.

Figure 2. Three relevant properties in the relational condition: category A (above) and L (below)

Design. The experiment used a 3 (dual task: none vs. verbal vs. visuospatial) X 2 (relevant property: features vs. relations) between-subjects design.

Procedure. Participants were assigned randomly to one of the six groups. For the dual task conditions, on each trial, a memory task was provided first and followed by a categorization task and by a recall task. For the control conditions, only the categorization task was provided (Figure 3). Both categorization and dual task responses were followed by accuracy feedback.

Participants in the verbal dual-task condition were first given a verbal working memory task, in which 5 random digits were displayed for two seconds with spaces between them (so that they appeared to be individual numbers rather than digits of a single number). Participants were asked to memorize the digits while they performed the categorization task. In the categorization task, an exemplar consisting of a rectangle and an ellipse was shown. Participants were instructed to press the A key if the stimulus belonged to category A and the L key if it belonged to L. Each exemplar
remained on the screen until the participant responded. Responses were followed by accuracy feedback. Participants then saw one random digit and were asked to decide whether it was in the set they saw previously.

Figure 3. Experimental design by each condition
In the visuospatial dual-task condition, a 3 by 3 grid was displayed in the middle of a screen for two seconds with two randomly-chosen cells filled. Participants were asked to memorize the locations of the filled cells until they completed the categorization task. In the recall task, one filled cell was displayed in the grid and participants were asked whether the cell had been filled in the original display. The experiment consisted of 30 blocks ( 960 trials) and continued until the participant responded correctly on at least twenty nine of thirty two trials ( $90.6 \%$ correct) for two consecutive blocks or until all 30 blocks had transpired, whichever came first.

## Results

Dual task accuracy. We discarded the data from participants whose accuracy was below $70 \%$ correct on the dual task ( 2 subjects in the verbal/featural condition). Mean accuracy on the verbal dual task was $M=.94(S D=.03)$ for the featural category learning condition, and $M=0.91$ ( $S D=$ 0.06 ) for the relational learning condition. Mean accuracy on the visual dual task was $M=0.91(S D=0.06)$ for the featural condition, and $M=0.89$ ( $S D=0.04$ ) for the relational condition. There was no reliable difference between the verbal and visuospatial tasks $[t(51)=1.61, p$ $=$.114], suggesting that these tasks occupied cognitive resources to roughly the same extent.

## Category learning task accuracy: trials to criterion.

 Since our primary interest is the rate at which participants learn the categories as a function of the dual tasks, we reportour data first in terms of trials to criterion. These analyses are conservative in the sense that participants who never learned to criterion were treated as though they reached criterion on the last block. Figure 4 shows the mean trials to criterion by condition. A 3 (dual task) $\times 2$ (category learning task) between-subjects ANOVA revealed a main effect of dual task $[F(2,69)=5.058, M S E=579014.858, p<0.01]$. Since our main interest is in how different dual tasks affect the different kinds of category learning, one-way ANOVAs were conducted for the featural and relational learning conditions. The results revealed reliable differences between dual tasks in the featural category learning condition $[F(2,35)=4.981, M S E=617725.846, p<0.05]$. Planned comparisons in the featural category learning showed that there was a reliable difference between the verbal ( $M=386$, $S D=387)$ and visuospatial dual task $(M=697, S D=411)$ [ $t(35)=-2.288, p<0.05]$. There was also a reliable difference between the visuospatial and the control condition ( $M=262, S D=191$ ) $[t(35)=3.014, p<0.01]$. The difference between the verbal and the control condition was not reliable [ $t(35)=0.877, p<0.386$ ]. The ANOVA results from the relational condition revealed reliable differences between the dual tasks $[F(2,34)=7.641, M S E=$ 799483.887, $p<0.01]$. Planned comparisons revealed that there was a reliable difference between the verbal ( $M=739$, $S D=352$ ) and visuospatial dual task $(M=330, S D=362)$ $[t(34)=3.221, p<0.01]$. There was also a reliable difference between the verbal and control conditions ( $M=$ 276, $S D=222$ ) $[t(34)=3.014, p<0.01]$. The difference between the visuospatial and control conditions was not reliable [ $t(34)=0.404, p<0.689$ ]. No other main effects were statistically reliable. Most interestingly, there was a reliable interaction between dual task and category learning, indicating that relational category learning was disrupted more by the verbal dual task, whereas featural category learning was disrupted more by the visuospatial dual task $[F(2,69)=2.475, M S E=855659.946, p<0.01]$.

Response times. Since the category learning accuracy results yielded a reliable interaction between the dual and category learning tasks, we also analyzed these tasks in terms of participants' mean response times on individual trials in order to gain insight about the strategies participants in each condition may have adopted. A 3 (dual task) $\times 2$ (category learning task) between-subjects ANOVA revealed a main effect of dual task $[F(2,69)=3.202, M S E=0.961$, $p<0.05]$. One-way ANOVAs were also conducted in each category learning condition. The main effect of dual task was not reliable $[F(2,35)=2.137, M S E=0.612, p=0.133]$ in the featual learning condition. But since the accuracy data showed that participants in visuospatial feature-learning required many more trials than to reach to the criterion than participants in verbal featural learning, we expected a reliable difference between two conditions in a planned comparison analysis. Our prediction was confirmed. There was a reliable difference between the verbal ( $M=0.99$, $S D$ $=0.31$ ) and visuospatial dual task ( $M=1.41, S D=0.78$ )
$[t(35)=-2.037, p<0.05]$, indicating that response times in visuospatial feature-learning condition were longer than those in verbal feature-learning. No other differences were statistically reliable. There were no reliable differences in the relational learning condition. Also, ANOVA showed a reliable main effect of category learning $[F(1,69)=3.883$, $M S E=1.166, p=0.053$ ], indicating that feature learning ( $M=1.17, S D=0.55$ ) was marginally faster than relational learning ( $M=1.42, S D=0.56$ ) (Figure 5).

Figure 5. Response times by dual condition

## Discussion

To the extent that relational concepts are qualitatively similar to feature-based concepts, our understanding of concepts can be expected to generalize from the (extensively investigated) case of feature-based categories to the (largely neglected) case of relational categories. However, there is reason to believe they are not, casting doubt on our ability to generalize our conclusions from studies using feature-based categories to the case of relational concepts.

Most notably, people have no difficulty learning feature-based categories in which no single feature remains invariant across all members of a category (see Murphy, 2002). By contrast, Kittur and colleagues showed that relational categories are extremely difficult to learn when there is no such relational invariant (i.e., property that holds over all members of a category; Kittur et al., 2004, 2006). Jung and Hummel (2009, 2011) provided additional evidence that relational learning requires some kind of invariant in order to succeed. These findings suggest that featural and relational learning rely not only on qualitatively different forms of mental representation (namely, features vs. relations; see, e.g., Hummel, 2010; Hummel \& Holyoak, 1997, for a discussion of the difference) but also that they rely on qualitatively different kinds of learning algorithms (e.g., associative learning in the featural case and something more akin to structured intersection discovery in the relational case; Jung \& Hummel, 2009, 2011).

The current experiment provides additional evidence for this sharp distinction between featural and relational category learning. In the current experiment, featural learning was impeded by a visual dual task (i.e., one that might be expected to interfere with visual feature processing as required for featural learning) but not by a verbal dual task. Relational category learning, in sharp contrast, was interfered with by a verbal dual task (which has been shown to interfere with relational processing; Waltz et al., 2000), but not by a visual dual task. This double dissociation between visual vs. verbal dual task interference on the one hand and featural vs. relational category learning on the other adds to the growing evidence that these two kinds of category learning rely on qualitatively different and dissociable learning systems.

# The Effects of Repeated Sequential Context on Recognition Memory 

George Kachergis, Gregory E. Cox, and Richard M. Shiffrin \{gkacherg, grcox, shiffrin\}@indiana.edu<br>Department of Psychological \& Brain Science / Cognitive Science Program<br>Bloomington, IN 47405 USA

#### Abstract

Many people have had the experience of knowing what song will play next on an album (even one heard only a few times). Conversely, many people fail to recognize an acquaintance encountered in an unfamiliar context. Associations can likely form simply because items appear nearby in time, and not only due to semantic similarity. Using surprise recognition testing, we examine the automatic storage of associations between successively encountered words on a list of incidentally studied words. Many modern memory models assume storage of such associations, but with little evidence as yet (e.g., Cox \& Shiffrin, 2012; REM-II Mueller \& Shiffrin, 2006). We find evidence for sequential associations, which are further improved by shared semantics or study context. We also find improved accuracy and response time for old words preceded by old words, and for new words preceded by new words - regardless of the previous response.

Keywords: recognition; episodic memory; temporal context; sequential association; priming

## Introduction

We have all had the experience of knowing what song will play next on an album that we have listened to several times, even without having looked at the list of songs. Conversely, we have also had the experience of seeing an acquaintance in a new context and not immediately recognizing them. Without realizing it, we often form associations between co-occurring events in a context, and memory is strengthened if the context reoccurs. In general, associates stored together help us remember if they are present at test. When any event is experienced there are a host of potential associations that make up the contextwhen and where and with what other things did the event happen to me? The memory and its context, and the retrieval of both, are termed episodic memory. The current study investigates the formation and retrieval of one type of context: the other words in a presented sequence of words. A critical factor in this research is the existence of source confusion. For example, given a recognition test of a word, test word familiarity is partly governed by the familiarity of the previous test word. At both study and test we confuse features of nearby events. For example, Jacoby and Whitehouse (1989) found in a recognition experiment when unstudied words were preceded by a subliminal prime ( 50 or 35 ms ) of the same word, people were more likely to incorrectly endorse the word as a studied one (i.e., false alarm). When the prime was a different unstudied word than the target, false alarms decreased for the 50 ms primes, but oddly not for 35 ms primes. In contrast, for liminal primes ( 200 or 600 ms ), a studied prime decreases hits for a
matching target, and an unstudied prime reduces false alarms to a matching target.

The ROUSE-Responding Optimally with Unknown Sources of Evidence - model of short-term priming (Huber, Shiffrin, Lyle, and Ruys, 2001) incorporates feature leakage from the prime to the target, leading to biased responses. However, ROUSE's decision rule has a discounting mechanism that attempts to correct for leakage: underdiscounting explains why primed words are chosen after passive priming, and over-discounting accounts for foil preference after active priming. Although ROUSE was applied mainly to identity and orthographically similar primes, semantic priming and leakage of semantic features also occur, and all these features should (with some probability) be incorporated in the storage of the next few events, and in the test probe of the next few tests. This might suggest episodic-recognition context effects would match those in perceptual recognition, but Malmberg and Annis (2012) investigated sequential dependencies in recognition and found patterns that did not seem to match those found in perceptual experiments. We will investigate this issue in some detail in this research.

We examine the storage of associations between adjacent words in a studied list, and how memory for a studied word is affected at test by the presence of its study-list neighbor. When people expect a memory test, they will form explicit associations between nearby items using a variety of coding schemes. Since our main interest is in automatic and nonstrategic storage and retrieval, we limit explicit associative strategies by using an incidental study task: participants make alternating pleasantness/animacy judgments at study.

Evidence for temporal associations have been found in recall following explicit attempts to remember. Participants are serially shown individual, unrelated words (e.g. 'crow', 'bottle', 'house', ...) and then asked to recall words from the list in any order. Given that a participant recalls a word (e.g. 'bottle'), the next word they recall is very likely to be the next word that was presented (e.g. 'house'; Kahana, 1996). In recognition tests, participants are shown words one at a time, some from the studied list, and some new, and asked to indicate those studied. A positive recognition response is thought to occur when the test word seems sufficiently familiar, via a fast and automatic parallel search of memory, or when its study event is recalled explicitly, typically via a slow and strategic process (Malmberg, Holden \& Shiffrin 2004). Models such as REM and TCM explicitly have a role for word context. We seek to understand such effects when study is incidental.

## Experiment 1

This study explores the automatic formation and retrieval of associations in recognition memory between temporally proximal events. Specifically, we varied the relation of two successive words at study for incidental judgments, and explored the effect when words related to these were tested successively, each for separate judgments of presence during study. For example, if "banana" is followed by "chair" at study, is "chair" recognized better or differently at test when preceded by a test of "banana"? The words in this example are semantically unrelated, but some of the adjacent words were made to be semantic associates.

The conditions we used included identical repeats, i.e. the same successive words at study and test, the case probably most likely to produce recognition benefits. In another condition the context word itself does not repeat, but its meaning does: The forward migration of matching semantic features at both study and test could produce improved recognition. In addition, meaning could be altered by the meaning of a recent word. For example, bank might be encoded as an earthen side if preceded by river, but encoded as a monetary institution if preceded by money. Table 1 shows examples of each condition, as well as the possible features that the preceding word (cue) may contribute to the target word at test: Familiarity (F) if the cue was a studied word; Semantics (S) if the cue is semantically related to the target; and Context (C), if the cue was also the target's study neighbor.

| Cue Type | Study | Test | F | S | C |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Same, Related | cash bank | cash bank | 1 | 1 | 1 |
| Same Sense | cash bank | robber bank | 1 | 1 | 0 |
| Different | cash bank | river bank | 1 | $1^{*}$ | 0 |
| Sense |  |  |  |  |  |
| Different, | cash bank | sloth bank | 1 | 0 | 0 |
| Unrelated |  |  |  |  |  |
| Same, | sloth bank | sloth bank | 1 | 0 | 1 |
| Unrelated | sloth bank | glass bank | 1 | 0 | 0 |
| Unrelated | $\ldots$ bank | lamp bank | 0 | 0 | 0 |

Table 1: Features (Familiarity, Semantics, Context) that the cue may contribute to the target at test in each condition. *=related in the lexicon.

## Subjects

Participants were 57 undergraduates at Indiana University who received course credit for participating.

## Stimuli \& Procedure

We selected 40 common polysemous words (e.g., diamond) and their two strongest forward associates for each meaning (e.g., ruby/emerald and spade/ace) from the free association norms (Nelson, McEvoy, and Schreiber, 1998). For each participant, the 40 polysemes are assigned randomly to one of five conditions. In the Same, Related (SR) condition, the strongest associate of the dominant
meaning is presented just prior to the polyseme at both study and test (e.g. ruby-diamond). In the Same, Unrelated (SU) condition, an unrelated word is presented just prior to the polyseme at both study and test (e.g. lawn-diamond). The remaining conditions all have the strongest associate of the dominant meaning immediately prior to the polyseme at study, and a word that was studied elsewhere presented prior to the polyseme at test. In the Same Sense (SS) condition, a different associate from the same meaning was presented prior to the polyseme at test (e.g. emeralddiamond). In the Different Sense (DS) condition, the strongest associate from the other meaning was presented prior to the polyseme at test (e.g. spade-diamond). Finally, in the Different, Unrelated (DU) condition, an unrelated word was presented prior to the polyseme at test (fruitdiamond), for comparison to SR.

These 40 pairs of words are shuffled among 80 common filler words to compose a study list of 160 words. At study, each word was rated for either animacy or pleasantness, in an alternating fashion, in order to induce belief that this was the primary task and to reduce explicit encoding of successive words in identical ways. Each word was presented for 900 ms , followed by $2,000 \mathrm{~ms}$ of prompting for a response (which was not recorded), followed by 800 ms of blank screen before the next word was presented. After the study list was completed, participants were instructed that they would now perform a recognition test for the words they had just studied. The 160 studied words were randomly shuffled among 160 new words for surprise yes/no recognition testing. In order to reduce the use of strategic and explicit recollection we required participants to respond to the old-new test task within 700 ms . Slow responses elicited a "Too slow!" feedback message. Feedback on correctness was given on each test trial in Experiment 1.

## Results \& Discussion

Of the 60 subjects, 12 were removed for having a mean accuracy not significantly above chance (.522). Of the remaining responses, $2.8 \%$ were removed for being faster than 150 ms . The remaining 13,397 responses were analyzed using mixed-effects logistic regression, which is more appropriate than ANOVAs for analyzing accuracy (Jaeger, 2008). As regressors, we used the features that the cue may contribute to the target (see Table 1): Familiarity, Semantics, and Context. The logistic regression (see Table 2) shows that each of the three factors increase the odds of recognizing the target, with Semantics being the strongest cue ( $O R=2.16$ ), followed by Context $(O R=1.60)$, and finally Familiarity (OR=1.09).

| Factor | Coefficient | $Z$ | odds | p-value |
| :--- | :---: | :---: | :---: | :---: |
| (Intercept) | 0.40 | 9.67 | 1.49 | $<.001$ |
| Familiarity | 0.09 | 2.52 | 1.09 | $=.01$ |
| Context | 0.47 | 4.95 | 1.60 | $<.001$ |
| Semantics | 0.77 | 9.57 | 2.16 | $<.001$ |

Table 2: Logistic regression coefficients for Experiment 1.
Shown by condition in Figure 1, participants were most likely to respond old to old items in the SR condition, followed by the SS and DS conditions, then the SU condition, and finally the DU condition. The SR and SU findings imply that automatically encoded temporal context affects recognition, although we cannot say how much of the effect is due to a bias shift vs. a performance shift (because the design did not have equivalent conditions of cuing preceding new trials). We note in particular that the presence of a semantic relationship between the polyseme and the previous word at study (DU) or at study and test (SS, DS) increases the probability of giving an old response. From these results, it is clear that automatic associations are formed between both related and unrelated temporally proximal items. We also infer that familiarity accruing to the preceding test item tends to make the next test word seem familiar.

Figure 1: "Hits', p(old|old), for polysemous conditions in Exp. 1 (with feedback).

## Experiment 2

In Experiment 1, in contrast to traditional recognition memory experiments, we provided corrective feedback after each response at test. It may be that participants used the feedback signal from the previous trial to classify their feeling of familiarity and strategically used it on the next trial in any of several ways. Thus, in Experiment 2 we did not provide accuracy feedback at test.

## Subjects

Participants were 57 undergraduates at Indiana University who received course credit for participating.

## Stimuli \& Procedure

The same stimuli and procedure were used in Experiment 2, except at test there was no accuracy feedback given.

## Results

Of the 57 subjects, 4 were removed for having a mean accuracy not significantly above chance (.522). Of the
remaining responses, $1.8 \%$ were removed for being faster than 150 ms . The remaining 15,275 responses were analyzed using multilevel logistic regression. As in Experiment 1, we found positive effects of Semantics ( $\mathrm{OR}=1.84$ ), Context ( $\mathrm{OR}=1.51$ ), and Familiarity ( $\mathrm{OR}=1.25$; see Table 4). Thus, we have evidence for all of these three cues influencing the proximal trial, with and without feedback, when responses are limited to within 700 ms . In both experiments, semantics had the strongest effect, followed by context, and then familiarity.

| Factor | Coefficient | $Z$ | odds | p-value |
| :--- | :---: | :---: | :---: | :---: |
| (Intercept) | 0.40 | 7.03 | 1.49 | $<.001$ |
| Familiarity | 0.22 | 5.77 | 1.25 | $<.001$ |
| Context | 0.41 | 4.00 | 1.51 | $<.001$ |
| Semantics | 0.61 | 7.17 | 1.84 | $<.001$ |

Table 4: Logistic regression coefficients for Experiment 2.
Figure 2 shows the probability of a "hit" (old to an old test item) by condition for the polysemous manipulations in Exp. 2, which look much like those in Exp. 1. The only qualitative difference is that Same Sense was higher than Different Sense in Exp. 2, whereas a trend in the opposite direction was found in Exp. 1. Even given this difference, the experiments-with and without feedback-had much the same results.

Figure 2: "Hits" for polysemous conditions in Exp. 2 (without feedback).

The previous results, from both studies, were those for the carefully balanced conditions. However there also many filler items that were studied and tested, and many new items tested. Analyses of these items and their sequential effects are taken up in the next section.

## Further Sequential Analysis

Analyses of the filler words and new words showed a more general sequential context effect. We analyzed all of the data in both experiments using mixed-effects logistic
regression, trying to predict correct responses (old for old, new for new) as a function of the current item's oldness, the previous item's oldness, the correctness of the response to the previous item, and feedback (i.e., Experiment).

| Factor | Coeff | $Z$ | p-value |
| :--- | :---: | :---: | :---: |
| (Intercept) | 0.29 | 4.31 | $<.001$ |
| Prev. Correct | 0.37 | 5.39 | $<.001$ |
| Previous Old | 0.13 | 1.53 | $=.13$ |
| Current Old | 0.37 | 4.60 | $<.001$ |
| Feedback | 0.16 | 1.73 | $=.08$ |
| PrevCorr*PrevOld | -0.58 | -0.86 | $=.39$ |
| PrevCorr*CurOld | -0.66 | -4.19 | $<.001$ |
| PrevOld*CurOld | 0.08 | 0.67 | $=.51$ |
| PrevCorr*Feedback | -0.12 | -1.37 | $=.17$ |
| PrevOld*Feedback | -0.52 | -4.49 | $<.001$ |
| CurrOld*Feedback | -0.47 | -4.30 | $<.001$ |
| PrevCorr*PrevOld* | 1.06 | 6.88 | $<.001$ |
| CurrOld |  | $<.001$ |  |
| PrevCorr*PrevOld* | 0.50 | 3.43 | $=.07$ |
| Feedback |  |  |  |
| PrevCorr*CurrOld* | 0.26 | 1.85 | $<.001$ |
| Feedback |  |  |  |
| PrevOld*CurrOld* | 1.00 | 6.01 | $<.001$ |
| Feedback |  |  |  |
| PrevCorr*PrevOld* | -0.89 | -4.22 |  |
| CurrOld*Feedback |  |  |  |

Table 3. Coefficients for accuracy in both experiments.
Being correct on the previous trial increases the odds of being correct on the current trial (previous: $\mathrm{M}_{\text {corr }}=.64$, $\mathrm{M}_{\text {incorr }}=.61$ ). The odds of being correct on the current trial also increase if the previous trial was an old (i.e. studied) word rather than a new (i.e. unstudied) word (prev old $\mathrm{M}=$ .64 , prev new $M=.61$ ). There is no significant effect of the current item's familiarity. There was a significant interaction of previous correctness and the current item type, showing that if a new cue was misidentified as old, subjects were much worse at the current trial (. 59 vs. .64). Most strikingly, there was a significant interaction of the cue's and target's familiarity: old targets were more likely to be identified after an old cue (Old|Old $=.73$, Old|New $=.56$ )regardless of the response to the cue-and new items were similarly more likely to be correctly identified as new after a new cue (New $\mid$ New $=.64$, New $\mid$ Old $=.54$ ).

Figure 3 displays correct rejection of unstudied (New) items and recognition of studied (Old) items as a function of the previous trial's familiarity and response correctness for Exp. 1 (with feedback). Figure 4 displays the same information for Exp. 2.

Figure 3: Proportion of correct responses for unstudied (New) items and studied (Old) items by panel, broken down according to the studied/unstudied status of the item on the previous trial, as well as the correctness of the response on the previous trial. Note that New|(Previous New) items are more likely to be correctly rejected than New|(Previous Old), regardless of the correctness of the response on the previous trial. Similarly, Old|Old accuracy is greater than Old|New.

Previous Incorrect ○

Figure 4: Without feedback, almost the same pattern is evident: Old|Old responses are more accurate than Old|New responses, regardless of correctness on the previous trial. New|(New,Correct) responses are better than New|(Old,Correct), but New|(New,Incorrect) trends lower than $\mathrm{New} \mid$ (Old, Incorrect), breaking the pattern.

We also investigated the 18,023 correct response times using log-linear mixed-effects regression. Shown in Table 4, there was a significant main effect of the previous item's oldness (Previous Old), and a significant interaction of previous oldness with current oldness (PrevOld*CurOld). The mean correct RT when the previous item was old was 506 ms vs. 504 ms when the previous item was new. When
the current item is new, Ss were faster after new items ( 504 ms ) than old items ( 526 ms ). When the current item is old, Ss were faster after old items $(490 \mathrm{~ms})$ than new items ( 507 ms ). This corroborates the accuracy fluency finding, showing an advantage when the current item is the same oldness as the previous item. There was also a marginally significant interaction of previous response correctness, previous oldness, and feedback.

| Factor | Coeff | $t$ | p-value |
| :--- | :---: | :---: | :---: |
| (Intercept) | 497.26 | 65.24 | $<.001$ |
| Prev. Correct | 6.05 | 1.52 | $=.13$ |
| Previous Old | 21.44 | 4.20 | $<.001$ |
| Current Old | -3.20 | -0.69 | $=.49$ |
| Feedback | 0.07 | 0.01 | $=.99$ |
| PrevCorr*PrevOld | -10.05 | -1.58 | $=.11$ |

Table 4. Coefficients for correct RTs in both experiments.

In summary, in an incidental-study recognition memory task with fast responding, we found that the oldness of the prior tested word affects the response time and accuracy on this word. When the current test word is studied, having seen a studied word on the previous trial makes you, on average, faster and more accurate on the current trial - regardless of your response on the previous trial. The accuracy effect happened with and without feedback, so the responses cannot merely be driven by feedback. Seeing a studied word reinstates context features from the study list, and those features contribute to the correct recognition on this trial. For unstudied items preceded by other unstudied items, there is no reinstated context from the previous trial to discount. The need for discounting may explain why correct responses for unstudied items preceded by studied items were drastically slower than for unstudied items preceded by unstudied items.

## Discussion

In two recognition memory experiments with time-limited responses-limiting the role of recollection-we found evidence that associations form between incidentallystudied items. Although oldness and semantics can also serve to increase the likelihood of correct recognition, enhanced recognition due purely to sequential context was also observed.

## Context Effects

Roughly additive priming effects were found for oldness (familiarity), semantics, and sequential context. Although many models could account for one or even two of these effects straightforwardly, additional assumptions would be required to account for all three. We begin by making a common assumption in memory modeling that study events are encoded as a set of features and that recognition decisions are made on the basis of a comparison of a probe-also consisting of a set of features-to each stored trace in memory with "old" responses given if this comparison is strong enough (e.g., Hintzman, 1988; Murdock, 1992; Shiffrin \& Steyvers, 1997; Nelson \& Shiffrin, in press). We make the further assumption that some features sampled during the preceding trial are able to "leak" into the probe features present on the current trial. The same leakage is assumed to occur at study, with features of recent items being present in short term memory during the encoding of a subsequent item, and hence joining that item's stored trace (implemented by Nelson \& Shiffrin, in press).

Thus, because the memory trace contains some features from the preceding study item, preceding it by the same item at test leads to a stronger match between the test probe and the memory trace. The same account explains the positive but smaller priming when the preceding test item is semantically related-some of the semantic features overlap, but not the many physical features that also overlap when identity priming is used.

Priming due to oldness or semantics independent of sequential context requires yet more modeling assumptions, for which we turn to the dynamic model of recognition of Cox \& Shiffrin (2012). This model was able to account for the Jacoby-Whitehouse illusion by assuming, as we have thus far, that primes (in this case, previous test items) contribute some features to the current test probe, at least initially (see Cox, Lewis \& Shiffrin, under review, for more details). As more features are sampled and added to the probe, its match to memory evolves over time. If the probe begins with no features at all, the match to memory tends to go down slightly with the first few features sampled, regardless of whether the test item was studied or not. This is because, even if the test item is a target, it will tend not to match most of the other studied items and these mismatches outweigh the single target match until a sufficient number of features are sampled. Thus, after a few features have been sampled, the match for a target test will tend to increase while the match for a foil test will tend to continue to
decrease. If, however, a few features are present at the start of the trial, these initial negative steps are avoided for both targets and foils, leading to a bias to say old. This bias is proportional to the similarity between the prime and the test item. Thus, an old unrelated item will lead to a slight bias, and a semantically related item will lead to a larger bias, as observed in the present studies.

## Old/New Effects

This mechanism is qualitatively consistent with the observed effects of oldness and correctness of the previous trial in the no-feedback condition. If the preceding item is new, it will tend to contribute features that do not match anything on the list, minimizing the similarity not just with the current test item, but with all the traces in recent memory, leading to a lower tendency to respond "old" than if the preceding item had been old. All else being equal, if we assume that the decision on the preceding trial reflects the quality of evidence provided by the test item on the preceding trial, the effect of the oldness of the previous test item should interact with correctness. For example, if the previous trial was a false alarm, then although the previous item was new, it had to contain enough old features to lead the participant to judge it as old. This account then predicts that the effect of the oldness of the previous test item on the current trial is mainly a function of whether the participant thought the previous item was old, manifesting as a crossover interaction between oldness and correctness on the previous trial.

This is the pattern observed in the no-feedback condition, and is consistent with the idea that there is little or no discounting (a la ROUSE; Huber, et al., 2001) of previous item features in that condition. This interaction is absent from the feedback condition, however: one is still more likely to make an "old" response when the previous item was old, but correctness does not have a large effect on responses to old items; rather, correctness only seems to affect responses to new items, with incorrect responses on the previous trial leading to an overall bias to respond "old" on the current trial. In terms of ROUSE's discounting mechanisms, these data suggest that participants might engage in discounting when the previous trial was incorrect, but they only discount new features. One problem with this account, of course, is that it is unclear whether "old" and "new" features can be identified and differentially discounted. Another problem is that there is no clear reason why participants would only discount new features since doing so only leads to more errors.

An alternative explanation in terms of response criteriae.g., requiring more evidence to respond after an errordoes not hold up either, since that would predict increased accuracy after an error, the opposite of what is observed here. In short, although current models of memory might account for most of the results reported here, the old/new effects in the feedback condition seem to require additional mechanisms that will require further research to elucidate.

Further questions include: What is the effect of using lures that were not studied, but are semantically related to
the polyseme, as cues? If an associate of the nondominant meaning is the cue at study, does it still provide an advantage? If the associate is presented after the polyseme at study, is the association still formed?

In the world, things that occur nearby in time (or space) are often related, and if these relations can be remembered they may prove important. Having shown that automatic associations are formed-even between unrelated items-in recognition memory, much work remains to be done to determine how these associations are represented in memory, and what other forms of context they capture.

#### Abstract

Previous research has found that people can use word-object co-occurrences from ambiguous situations to learn word meanings (e.g., Yu \& Smith, 2007). However, most studies of cross-situational learning present an equal number of words and objects, which may simplify the problem by, for example, encouraging learners to use assumptions such as each word going with one object. This paper presents several conditions in which the number of words and objects do not match: either additional objects appear at random, or objects appear sometimes without their intended words. These manipulations do generally hurt learning in comparison to balanced conditions, but people still learn a significant proportion of word-object pairings. The results are explored in terms of statistics of the training trials - including contextual diversity and context familiarity-and with the uncertainty- and familiarity-biased associative model. Parametric differences between conditions hint at hidden cognitive constructs.

Keywords: statistical learning; cross-situational learning; language acquisition

## Introduction

Human infants learn words quite quickly despite many challenges facing them, including uncertainty and ambiguity in the language environment. Recent research has studied how learners may acquire word meanings from regularities in the co-occurrence of words and referents (e.g., objects). Such cross-situational statistical word learning relies on two assumptions: 1) that spoken words are often relevant to the visible environment, and 2) that learners can to some extent remember the co-occurrence of multiple words and objects in a scene. Thus, as words and their intended referents are observed in different situations over time, learners can apprehend the correct word-object mappings. Relying only on the regularity of the linguistic environment and basic memory and attention processes, this may be an important method of learning nouns for infants, and even adult travelers in a foreign country.

In adult cross-situational learning studies (e.g., Yu \& Smith 2007), participants are asked to learn the meaning of alien words by watching a series of training trials. On each trial learners see an array of unfamiliar objects (e.g., four sculptures) and hear pseudowords (e.g., stigson, bosa). The meaning of each pseudoword is ambiguous on a given trial, because although each word refers to a single onscreen object, the intended referent is not indicated. In a typical learning scenario, participants attempt to learn 18 wordobject pairings from 27 trials, with four words and four objects given per trial. In this design, each word-referent pair is presented six times over the five-minute training period. Learning a correct word-object pairing requires
some form of accumulation of word-object co-occurrences. When tested on each word and given four trained objects to choose from, participants chose the correct object for half of the 18 words, on average (Yu \& Smith, 2007).

However, learning environments in the real world are likely not as simple: there may be objects present that go unnamed, some spoken words (e.g. articles) do not refer to particular objects, and object names may be spoken when the intended object is not visible. These forms of noise likely interfere with learning to some extent. When a word is heard without the object it previously co-occurred with several times, is a learner to map it to a new object? What if that object already has a name? Conversely, when an object is seen, but the word it previously occurred with is not heard, will learners lose certainty about the old mapping, and even associate a new word with it?

In this study, we take baseline conditions from $\mathrm{Yu} \&$ Smith (2007) that present an equal number of words and objects on each trial and either add or remove words or objects in a systematical way in order to change various cooccurring statistics that learning may rely on. We investigate several critical factors that matter to learning, such as conditional probability of words given objects during learning, final test probability, and contextual diversity-the number of other pairs each pair appears with (Kachergis, Yu, \& Shiffrin, 2009b). Following Fazly, Alishahi, and Stevenson (2010), we also investigate additional two factors - age of exposure (i.e., when a pair first appears) and context familiarity (the mean frequency of the objects a given pair appears with). Not only are these factors likely to influence how well people learn, but likely so will the fact that the trials contain an unequal number of words and objects. Previous studies have also typically presented an equal number of words and objects on each trial, which may induce participants to only consider 1-to-1 mappings (although see Vouloumanos, 2008 as well as mutual exclusivity investigations: Kachergis, 2012; Ichinco, Frank, \& Saxe, 2009; Yurovsky \& Yu, 2008).

Finally, we use a recent associative model of crosssituational learning (Kachergis, Yu, \& Shiffrin, 2012) to shed light on differences between the conditions. The model assumes that learners have access to both their familiarity and their uncertainty about the word-object pairings present on a given trial, and that attention competes for uncertain stimuli and for already-strong pairings. This model matches adult behavior in a number of previous cross-situational experiments (Kachergis, 2012; Kachergis, Yu, \& Shiffrin, 2013).

## Experiment

Participants were asked to learn 18 word-referent pairs from a series of individually ambiguous training trials using the cross-situational word learning paradigm (Yu \& Smith, 2007). Each training trial was comprised of a display of two or more novel objects and two or more spoken pseudowords, depending on condition. With no indication of which word refers to which object, on a single trial, learners can only guess at the correct word-referent mappings. However, since words always appear on trials with their intended referents, the correct pairings may be learned over the series of trials.

In this study, many conditions were created by manipulating training conditions from Yu and Smith (2007)-the $2 \times 2$ (i.e., 2 word-object pairs per trial), $3 \times 3$, and $4 \times 4$ conditions- to introduce different types of noise which is arguably more in line with real-world learning, such as a non-referential word, an unnamed object, or both. In every condition, participants experienced a series of training trials with a total of 18 intended word-object pairs. The same pair was never allowed to appear in neighboring trials in conditions, as previous studies have shown such temporal contiguity improves learning (Kachergis, Yu, \& Shiffrin, 2009a; Kachergis, Yu, \& Shiffrin, 2013). In the baseline $\mathbf{2 \times 2}$ ( 54 trials), $\mathbf{3 \times 3}$ (36 trials), and $\mathbf{4 \times 4}$ ( 27 trials) conditions, each word and object appear 6 times. Every time a given object is present, the intended word is presented ( $p(\mathrm{w} \mid \mathrm{o})=1)$, and every time a given word is presented, the intended object is present $(p(\mathrm{o} \mid \mathrm{w})=1)$. Most conditions in Table 1 were built from these three baseline conditions. We manipulate the number of words and objects per trial, thus changing their frequency. This also changes the probability of hearing the word for a given object on a trial (in Table 1,

Trial $p(\mathrm{w} \mid \mathrm{o}))$. The probability of seeing an object given that its label was heard was always 1 (Trial $p(\mathrm{o} \mid \mathrm{w})$ ). Test $p(\mathrm{o} \mid \mathrm{w})$ in Table 1 shows the probability of guessing the intended object for a given word after experiencing all of the training.

In the $2 \times 4$ condition, words appeared 6 times and objects 12 times, so on each trial the probability of hearing the intended word for a given object is $p(\mathrm{w} \mid \mathrm{o})=.5$. In the $2 \times 3$ condition, objects appear 9 times, making $\mathrm{p}(\mathrm{w} \mid \mathrm{o})=.67$. In the $\mathbf{2 x 4}$ condition, each word appears 6 times and each object appears 12 times. In the $\mathbf{3 x 3}+\mathbf{1 w} / \mathbf{o}$ condition, an additional random word and object were shown on each trial. In the $\mathbf{4 x 4}+\mathbf{2 w} / \mathbf{o}$ condition, two additional random words and objects were shown per trial. In the $\mathbf{3 x 4}$ condition, each word appears 6 times, each object 8 times $(p(w \mid 0)=.75)$. In the $3 \times 41 / .5$ condition, words appear 6 times, and 12 objects appear only with their words $(p(0, w)=1)$, while 6 objects appear 12 times $(p(\mathrm{w} \mid \mathrm{o})=.5)$. In the $\mathbf{3 \times 4} \mathbf{1 / . 6 6}$ condition, words appear with their objects 6 times $(p(\mathrm{w} \mid \mathrm{o})=1)$, but 12 objects appear 3 additional times $(p(\mathrm{w} \mid \mathrm{o})=.66)$ without their words. In the $3 \times 4+60$ condition, 18 word-object pairs cooccur 6 times, and 6 additional objects occur as noise.

The $1 \times 3$ condition divided each trial of the $3 \times 3$ condition into 3 trials with one word and 3 objects, and shuffled the trials so no objects (or words) repeated trial-to-trial. Thus, words appeared 6 times, and objects 24 times $(p(\mathrm{w} \mid \mathrm{o})=.33)$. The $1 \times 4$ condition divided the $4 \times 4$ trials as $1 \times 3$ did for $3 \times 3$, meaning that objects appeared 24 times $(p(\mathrm{w} \mid \mathrm{o})=.25)$.

Calculated for each item per condition, Table 1 also shows the average "Age" of Exposure (trial the pair first appears), Context Familiarity (defined by Fazly, Alishahi, and Stevenson (2010) as the mean co-occurrence with all other pairs across exposures), and Context Diversity (the number of unique pairs a pair co-occurs with over training).

Table 1. Summary of conditions in the Experiment.

## Subjects

Participants were undergraduates at Indiana University who received course credit for participating. The number of participants in each condition are shown in Table 1 (Num. Subjs. column). None had participated in previous crosssituational experiments.

## Stimuli

Each training trial consisted of an array of 2-4 uncommon objects (e.g., sculptures) and 2-4 spoken pseudowords, depending on condition (see Table 1). The computergenerated pseudowords are phonotactically-probable in English (e.g., "bosa"), and were spoken by a monotone, synthetic female voice. The words and objects used for each condition were drawn from a set of 72 words and 72 objects.

Training for each condition consisted of between 27 and 108 trials. Each training trial began with the appearance of two to four objects (differing by condition) which remained visible for the entire trial. After 2 s of initial silence, each word was heard (1s per word, with 2 s of silence after each).

## Procedure

Participants were told they would see a series of trials with some objects and alien words, but that the words would be presented in random order. They were also told that their knowledge of which words belong with which objects would be tested at the end.

After each training block, participants' knowledge of word-object mappings was assessed using 18-alternative forced choice (18AFC) testing: on each test trial a single word was played, and the participant was instructed to choose the appropriate object from a display of all 18 trained objects. Each of the 18 words was tested once in a random order.

## Results \& Discussion

As shown in Fig. 1, all of the conditions had mean performance significantly above chance (18AFC chance $=$ .056). The $2 \times 2$ baseline condition had by far the highest performance ( $M=.79$ ). Adding another object to each trialwithout it's intended word-harmed learning ( $2 \times 3$ : $M=.56$ ). $2 \times 4$ adds yet another object, further decreasing both Trial $p(\mathrm{w} \mid \mathrm{o})$ and Test $p(\mathrm{o} \mid \mathrm{w})$, resulting in even lower performance $(M=.30)$. Adding an extra pair ( $3 \times 3+1 \mathrm{w} / \mathrm{o}$ ) or two ( $3 \times 3$ $+2 \mathrm{w} / \mathrm{o}$ ) is even more harmful ( $M=.17, M=.10$, resp.); it both lowers Test $p(\mathrm{o} \mid \mathrm{w})$ and creates more possible pairings to consider on each trial. For another example, the $1 \times 3$ and 1 x 4 conditions are identical in all of the other factors except that there were 1 word and 3 objects in the $1 \times 3$ condition ( 0.33 ) but 1 word and 4 objects in the $1 x 4$ condition ( 0.25 ). This one change caused a dramatic performance difference from $M=.53$ to $M=.19$. Meanwhile, it may not seem like there is a dramatic difference between the $1 \times 3$ and $2 \times 3$ conditions. All this suggest that given multiple factors that can be used to characterize statistical information in training data, and the flexibly of human statistical learning systems, it is difficult to pull apart all of the effects in terms of conditionsespecially in the 3 -word and 4 -word conditions-as a
change in one factor is often correlated with changes in several other factors (e.g., contextual diversity and context familiarity).

Figure 1: Mean accuracy by training condition. Performance was variable, but all conditions were above chance (18AFC=.056). Error bars show +/-SE.

To better understand the effects of the various factors, we fit a logistic mixed-effects regression model to the trial-level accuracy data using the lme4 package in R (Bates and Maechler, 2010; R Development Core Team, 2010). Mixed logit models are more appropriate for forced-choice data than ANOVAs, especially when different conditions yield different amounts of data, as in the present experiment (Jaeger, 2008). The model included subject as a random factor, and Trials/Condition, Word Frequency, Object Frequency, Trial $p(\mathrm{w} \mid \mathrm{o})$, Test $p(\mathrm{o} \mid \mathrm{w})$, Contextual Diversity, Age of Exposure, and Context Familiarity as fixed factors. All of these factors were scaled to remove collinearity. Shown in Table 2, there was a significant negative intercept, showing that participants were less likely to choose the correct answer than the incorrect answer. Trials/Condition and Test $p(\mathrm{o} \mid \mathrm{w})$ both had significant, large positive coefficients (. 75 and .78 ), showing that longer training periods were better, as well as stronger correct associations-both of which occur more in the conditions with fewer pairs per trial (i.e., $2 \times 2$ rather than $4 \times 4$ ).

| Factor | Coefficient | $Z$ | p-value |
| :--- | :---: | :---: | :---: |
| (Intercept) | -0.75 | -9.20 | $<.001$ |
| Trials/Cond | 0.75 | 4.57 | $<.001$ |
| Word Freq | -0.10 | -0.92 | $=.36$ |
| Obj Freq | -0.58 | -2.75 | $<.01$ |
| Trial $p$ (w\|o) | -0.14 | -0.88 | $=.38$ |
| Test $p(\mathrm{o} \mid \mathrm{w})$ | 0.78 | 5.67 | $<.001$ |
| Cont. Fam. | 0.20 | 2.82 | $<.01$ |
| Age of Exp | -0.08 | -1.93 | $=.05$ |
| Cont. Div. | 0.17 | 2.24 | $<.05$ |

Table 2. Summary of logistic regression results.

Word frequency did not contribute significantly to correctness, but object frequency had a negative coefficient, showing that additional repetitions of an object on trials without the intended word indeed inhibited learning of that object. Trial $p(\mathrm{w} \mid \mathrm{o})$ was not a significant predictor of accuracy; it seems the other (partially-correlated) factors better capture the variance. Context Familiarity and Contextual Diversity both have significant positive coefficients (. 20 and .17). Though they are correlated ( $r=.56$ ), these two factors both help people learn words. Age of Exposure had a marginally significant negative coefficient (-.08), showing that earlier-appearing pairs are indeed a bit more likely to be learned.

In total, these results offer a look at the factors that influence cross-situational word learning, and an estimate of their relative magnitudes. We now apply a recent associative model of cross-situational word learning to see whether it can account for word-learning in these noisy environments, and to see whether the recovered parameters yield any additional insight.

## Model

To better understand how the condition demands differ, we introduce an associative model of cross-situational word learning proposed by Kachergis, Yu, and Shiffrin (2012a).

The model assumes that learners do not equally attend to all word-object pairings on a trial (i.e., store all cooccurrences). Rather, selective attention on a trial is drawn to strengthen associations between words and objects that have co-occurred previously. This bias for familiar pairings competes with a bias to attend to stimuli that have no strong associates (e.g., as a novel stimulus). The competing familiarity and uncertainty biases allow the model to exhibit fast mapping, since a novel word-novel object combination will demand more attention, and mutual exclusivity: a novel word will only become weakly associated with an alreadyknown referent (Kachergis, Yu, \& Shiffrin, 2012). For example, suppose word $w_{l}$ and object $o_{l}$ have appeared together and are thus somewhat associated, while $w_{7}$ and $o_{7}$ are novel. Given a trial with both pairs: $\left\{w_{1}, o_{1}, w_{7}, o_{7}\right\}, w_{1}-o_{1}$ demands more attention than $w_{7}-o_{1}, w_{1}-o_{7}$, or $w_{7}-o_{7}$, since $w_{l}-o_{l}$ is stronger than baseline. However, attention is also pulled individually to $w_{7}$ and to $o_{7}$, since both of these novel stimuli have no strong associates. Uncertainty is measured by the entropy of each stimulus' association strengths. Because of the high joint uncertainty of $w_{7}$ and $o_{7}$, more attention is given to the association $w_{7}-O_{7}$. Thus, attention is mostly divided between $w_{I}-o_{I}$ and $w_{7}-O_{7}$, although the other pairings will be strengthened a bit.

Formally, let $M$ be an $n$ word $\times n$ object association matrix that is incrementally built during training. Cell $M_{w, o}$ will be the strength of association between word $w$ and object $o$. Strengths are subject to forgetting (i.e., general decay) but are augmented by viewing the particular stimuli. Before the first trial, $M$ is empty. On each training trial $t$, a subset $S$ of $m$ word-object pairings appears. If new words and objects are seen, new rows and columns are first added.

The initial values for these new rows and columns are $k$, a small constant (here, 0.01).

Trial-to-trial, association strengths decay and then a fixed amount of associative weight, $\chi$, is distributed among the presented word-object associations and added to the strengths. The rule used to distribute $\chi$ (i.e., attention) balances a bias for attending to unknown stimuli with a bias for strengthening already-strong associations. When a word and referent are repeated, extra attention (i.e., $\chi$ ) is given to this pair: a prior knowledge bias. Stimuli with no strong associates also attract attention, whereas pairings between uncertain objects and known words, or vice-versa, draw little attention. Stimulus uncertainty is measured by entropy $(H)$, which is 0 when the outcome of a variable is certain (e.g., a word appears with one object, and has never appeared with any other object), and maximal $\left(\log _{2} n\right)$ when all of the $n$ possible object (or word) associations are equally likely (e.g., when a stimulus has not been observed before, or if a stimulus were to appear with every other stimulus equally). In the model, on each trial the entropy of each word (and object) is calculated from the normalized row (column) vector of associations for that word (object), $p\left(M_{w}\right)$, like so:

$$
H\left(M_{w, \cdot}\right)=-\sum_{i=1}^{n} p\left(M_{w, i}\right) \cdot \log \left(p\left(M_{w, i}\right)\right)
$$

The update rule for allocating attention and adjusting strengths for the stimuli presented on a trial is:

$$
M_{w, o}=\alpha M_{w, o}+\frac{\chi \cdot e^{\lambda \cdot(H(w)+H(o))} \cdot M_{w, o}}{\sum_{w \in S} \sum_{o \in S} e^{\lambda \cdot(H(w)+H(o))} \cdot M_{w, o}}
$$

In this equation, $\alpha$ is a parameter governing forgetting, $\chi$ is the weight being distributed, and $\lambda$ is a scaling parameter governing differential weighting of uncertainty and prior knowledge (familiarity). As $\lambda$ increases, the weight of uncertainty (i.e., the exponentiated entropy term, which includes both the word's and object's association entropies) increases relative to familiarity. The denominator normalizes the numerator so that exactly $\chi$ associative weight is distributed among the potential associations on the trial. Only decay operates for stimuli not on the current trial. After training, a learner is tested with each word and chooses an object from $n$ alternatives in proportion to the association strengths of each alternative to that word.

In sum, this associative model learns trial-by-trial by distributing attention in a way that corresponds with both our intuitions about word-learning-using competing biases for familiar pairings and uncertain stimuli-and a number of empirical findings. Three parameters ( $\chi, \alpha$, and $\lambda$ ) were fit using $\log$ likelihood to each individual's choices in each training condition. The model achieved quite a good fit to the data, with $R^{2}=.98$. Figure 2 shows mean model performance for individuals' model fits by condition. Figure 3 shows individuals' mean performance in each condition versus the model's performance. Next, we investigate the
parameter values for each condition to see what they tell us about the cognitive effects of different types of noise.

Figure 2. Model performance closely matches human performance (Fig. 1) and variability in the Experiment.

Figure 3. Individual performance versus model fit: the model was capable of closely matching the behavior of most participants.

We first looked at correlations between each parameter and performance. $\chi$ was positively correlated with learning (Pearson's $r=.72, t(494)=22.74, p<.001$ ), which is consistent with our interpretation of $\chi$ as a learning rate; how much associative weight can be distributed per trial. $\lambda$ was negatively correlated with performance ( $r=-.22, t(494)=-$ $5.04, p<.001$ ): greater focus on uncertain stimuli seems to harm learning, at least in the conditions of this Experiment. $\lambda$ and $\chi$ were also negatively correlated ( $r=-.20, t(294)=-$ 4.64, $\mathrm{p}<.001$ ), meaning that uncertainty-focused learners tended to have slower learning rates. All other correlations were $<|.03|$, and not significant.

We also investigated whether there were differences in parameters by condition. Ideally, the parameters of a cognitive model should be cognitively interpretable. For
example, in our model, $\chi$ is for now a learning rate per trial, but should likely depend on how many possible associations there are on a trial and how much time there is to consider them. If systematic differences in particular parameters were required to fit performance in some of the conditions, then we may be able to pinpoint which factors learning rate and memory decay depend on, and redefine them in more meaningful units. An ANOVA by condition for each parameter showed significant differences for all three parameters $(\chi: \mathrm{F}(12,482)=11.63, p<.001 ; \lambda: \mathrm{F}(12,482)=2.13$, $p=.01 ; \alpha: \mathrm{F}(12,482)=2.70, p<.01)$. Table 3 shows the mean parameters found for each condition. We emboldened the highest mean values for each parameter and italicized the lowest in order to highlight the conditions with unusual mean parameter values.

For $\chi$, the $2 \times 2$ condition has the highest value (19.47), and this condition also yields the highest performance in humans. $2 \times 2$ also has the lowest $\lambda$ (i.e., more focus on familiarity) and $\alpha$ (i.e., faster decay), the latter of which may mitigate the high learning rate a bit. Conditions with the next-highest learning rates- $2 \times 3$ (9.87) and $1 \times 3$ (10.32)-had the next-highest performance (.56 and .52). $1 \times 3$, along with $1 \times 4$ also had the highest mean $\alpha=.94$ (memory fidelity). These two conditions have the shortest trials (5s), along with the fewest possible associations: only one word and three or four objects. The conditions with the lowest learning rates, $3 \mathrm{x} 4(\chi=.35)$ and $1 \mathrm{x} 4(\chi=.47)$, have fairly low performance (. 19 and .19). The short trial time for the 1 x 4 condition may not give subjects enough time to pick out the single correct pairing.

| Condition | Correct | $\chi$ | $\lambda$ | $\alpha$ |
| :--- | :---: | :---: | :---: | :---: |
| $2 \times 2$ | 0.79 | $\mathbf{1 9 . 4 7}$ | 5.0 | 0.85 |
| $2 \times 3$ | 0.56 | 9.87 | 6.9 | 0.92 |
| $2 \times 4$ | 0.30 | 1.73 | 9.3 | 0.88 |
| $3 \times 3+1 \mathrm{w} / \mathrm{o}$ | 0.17 | 0.91 | 8.6 | 0.89 |
| $4 \times 4+2 \mathrm{w} / \mathrm{o}$ | 0.10 | 3.01 | 8.7 | 0.87 |
| $3 \times 3$ | 0.43 | 6.30 | 6.1 | 0.90 |
| $1 \times 3$ | 0.52 | 10.32 | 7.3 | $\mathbf{0 . 9 4}$ |
| $3 \times 4$ | 0.19 | 0.35 | 7.5 | 0.89 |
| $3 \times 4+6 \mathrm{o}$ | 0.27 | 5.07 | $\mathbf{9 . 2}$ | 0.89 |
| $3 \times 41 / .5$ | 0.22 | 0.99 | 8.0 | 0.92 |
| $3 \times 41 / .66$ | 0.21 | 1.58 | $\mathbf{9 . 1}$ | 0.88 |
| $4 \times 4$ | 0.31 | 2.80 | 7.9 | 0.87 |
| $1 \times 4$ | 0.19 | 0.47 | $\mathbf{9 . 1}$ | $\mathbf{0 . 9 4}$ |

Table 3. Mean of best-fitting parameters for each condition. The largest and smallest mean values of each parameter are emboldened and italicized, respectively.
In the $3 \times 4$ condition, there are again more objects than words, and many possible associations. The other $3 \times 4$ conditions also had low performance and low learning rates,
except for $3 x 4+60$, in which participants may have had little difficulty ignoring the extraneous objects (which are less confusing since they are occur infrequently, and never with a consistent name). It is hard to see a pattern in $\lambda$, the relative focus on uncertainty vs. familiar pairings (roughly, explore vs. exploit). We do not yet have any reason to believe $\lambda$ should remain fixed; learners may well change it-implicitly or strategically-depending on task demands. Moreover, previous investigations found that $\lambda$ has little effect on the shape of learning curves (Kachergis, $\mathrm{Yu}, \&$ Shiffrin, 2012b).

## Discussion

In the language environment, many objects in a scene may go unlabeled, whether they are novel or familiar. For the sake of simplicity, previous studies of cross-situational learning presented an equal number of words and objects on each trial, and a word's intended referent was always present (and vice-versa; e.g. Yu \& Smith, 2007; Kachergis, Yu, \& Shiffrin, 2009a, 2009b). In this study, we presented learners with a variety of conditions with different kinds and degrees of statistical noise (e.g., extra objects, mismatched words and objects). Although performance varied widely in different conditions, learners performed significantly above chance in all conditions.

To better understand what factors influence learning, we measured various statistics about items in each condition, and tried to predict learning from these statistics. Greater contextual diversity-how many pairs a pair appears with during training, context familiarity-the average frequency of pairs a pair appears with, trials per condition, and overall strength of the correct pairing all significantly improved the odds of learning a pair. Being exposed to a pair earlier in training improved learning of that pair, but being exposed to an object more often inhibited learning, because in this study extra occurrences of an object were likely to be noise (e.g., appearing on a trial where it goes unnamed). These conditions and measures provide important constraints for word-learning models, as well as demonstrating that crosssituational learning is robust under a variety of types of noise.

We applied a recent associative word-learning model to these data, and found that it could account for individuals' behavior in each of the conditions. We investigated the average parameter values for individuals in each condition, and found that they differed. The learning rate parameter was strongly linked to overall performance, and was high when there were few pairings to consider on each trial (e.g., $2 \times 2,1 \times 3$ )-unless most of them were noise, and presented quickly (e.g., $1 \times 4$ ). There less memory decay in conditions with very one word per trial, and thus few associations ( $1 \times 3$, $1 \times 4$ ), although the most decay occurred in the $2 \times 2$ condition, but that was balanced by the fast learning rate. Overall, we have a somewhat clearer idea of what the model's parameters do under different noise conditions, but we do not yet have a wholly satisfactory psychological interpretation of them.

In summary, cross-situational learning is robust under a many noise conditions that more closely resemble situations learners may encounter in the real world than in previous studies. Moreover, we have presented a large dataset that we hope will inspire new experiments to test the limits of crosssituational learning, and will constrain and inform modeling efforts.

# The role of thinking-aloud instructions and prior domain knowledge in information processing and source evaluation during Web search 

Yvonne Kammerer (y.kammerer@iwm-kmrc.de)<br>Knowledge Media Research Center, Schleichstr. 6, 72076 Tuebingen, Germany<br>Peter Gerjets (p.gerjets@iwm-kmrc.de)<br>Knowledge Media Research Center, Schleichstr. 6, 72076 Tuebingen, Germany

#### Abstract

This paper examines the impact of thinking-aloud (TA) instructions as well as of individuals' prior domain knowledge on information processing and source evaluation during Web search on a health-related topic. With regard to TA instructions, prompted instructions that entailed evaluation prompts (as used in some previous Web search studies) were compared to neutral instructions (in line with the standards defined by Ericsson \& Simon, 1993) and to a silent condition. To measure participants' $(\mathrm{N}=44)$ information processing and source evaluation we used a rich multi-method approach including eye-tracking methodologies, log file data, and verbal protocols. Results indicate that prompted TA instructions as compared to neutral instructions significantly increased participants' verbal reflections on information quality and on structural aspects of Web pages, given that participants possessed at least a moderate level of prior domain knowledge. In addition, prompted instructions resulted in less linear viewing sequences on the search engine results pages than the silent condition. Finally, the higher participants' prior domain knowledge the more intensely they scrutinized the search results presented by the search engine and the smaller were their average pupil sizes, which indicated lower cognitive load. The significance of the results is considered in light of methodological as well as educational implications.

Keywords: Web search; source evaluation; prior domain knowledge; thinking-aloud instructions; eye tracking

## Introduction

In recent years, the World Wide Web (WWW) has evolved into a major information resource offering easy access to billions of Web pages on almost any topic. However, as anyone can publish virtually any information on the WWW, the quality of Web pages can vary widely. That is, misleading and low-quality Web pages, for example, in the field of medicine and health care, are as common as those providing neutral, high-quality information. Hence, to avoid the selection and use of doubtful or even false information, it is important that Web users themselves critically evaluate the quality of information they retrieve from the Web.

Previous empirical findings about Web users' source evaluation as indicated by verbal reports, however, are inconclusive. Whereas some studies indicate that Web users mainly evaluate search results and Web pages only based on the topical relevance or their ranking in the search engine results page (e.g., Hargittai, Fullerton, Menchen-Trevino, \& Thomas, 2010; Savolainen \& Kari, 2006), others suggest that Web users are also concerned to a substantial extent
about information quality (i.e., the accuracy, authority, objectivity, or currency of information; e.g. Rieh, 2002; Tombros, Ruthven, \& Jose, 2005). According to Tombros et al. (2005) also the structure of Web pages (i.e., the clarity of the Web page or the organization of the information therein) is evaluated extensively.

The aim of the present paper was to identify potential reasons for the divergent findings. Specifically, we examined the impact of the instructions used in the studies as well as of participants' prior domain knowledge on information processing and source evaluation during Web search, using a rich multi-method approach including eye tracking methodologies, log file data, and verbal protocols.

## The Role of Prompted Thinking-Aloud Instructions

One reason for the divergent findings might be a methodological one, namely that in the studies by Rieh (2002) and Tombros et al. (2005) participants were instructed beforehand to explain what criteria they used to evaluate Web information (Tombros et al., 2005) or to select good or credible information during Web search and to explain their evaluation processes in the form of postsearch interviews including specific evaluation-related questions (Rieh, 2002).

According to the seminal work by Ericsson and Simon (1993) and the meta-analysis by Fox, Ericsson, and Best (2011), however, procedures for verbal reporting are only nonreactive (i.e., do not alter thought processes and task performance) when instructions to think aloud are given in a neutral way, by instructing participants to verbalize their thoughts per se. In contrast, procedures that entail describing or explaining thoughts and actions - as it was the case in the studies by Tombros et al. (2005) and Rieh (2002) - are significantly reactive, altering participants' course of cognitive processing and leading to higher task performance than silent conditions. Hence, the instructions used by Tombros et al. (2005) and Rieh (2002) might have increased participants' awareness of the necessity of critically evaluating the information retrieved during Web search. Indirect evidence for this assumption comes from the studies by Hargittai et al. (2010) and Savolainen and Kari (2006) that used neutral thinking-aloud (TA) instructions and only found few utterances related to information quality or structural aspects of Web pages. A first aim of the present study, thus, was to further prove this assumption by directly comparing participants' verbal utterances when given TA
instructions entailing explicit prompts to explain what criteria they used to evaluate search results and Web pages (hereinafter referred to as prompted thinking-aloud) with neutral TA instructions (in line with Ericsson \& Simon, 1993).

Furthermore, previous research that directly compared participants' information processing while thinking-aloud (with neutral or prompted instructions) to a silent condition, showed that with prompted TA instructions that entailed explanation prompts participants who had to solve a series of information tasks on a Website explored the information more extensively than when they worked in silence (Hertzum, Hansen, \& Andersen, 2009). That is, in the former case participants showed a more distributed visual exploration of the screen (i.e., they searched or scanned more across the screen), scrolled more frequently within Web pages, and navigated to more Web pages than in the silent condition. Between the neutral TA instructions and the silent condition, in contrast, only few marginal differences were found. With the present study we aimed at expanding these findings to a Web search scenario including multiple Websites being accessed via a search engine results page (SERP), with participants either receiving prompted TA instructions (including evaluation prompts), neutral TA instructions, or working in silence.

## The Role of Prior Domain Knowledge

Referring to the Elaboration Likelihood Model (ELM; Petty \& Cacioppo, 1986) from persuasion research, Metzger (2007) postulates that the extent to which Web users engage in source evaluations is dependent both on their motivation (which might be increased by evaluation prompts), but also on their ability (e.g. their prior domain knowledge). In this regard it should be noted that participants in Rieh's (2002) study reported to use their prior domain knowledge to evaluate information quality, indicating that they possessed a certain amount of prior knowledge on the search topics. Importantly, previous research has not only shown differences in source evaluations between domain experts and novices, but also between groups of novices varying in their level of prior domain knowledge. For example, a casestudy by MaKinster, Beghetto, and Plucker (2002) that investigated undergraduate students' Web search on a complex science topic through postsearch interviews that entailed evaluation-related questions indicated that students with moderate domain knowledge scrutinized search results more thoroughly, by examining the titles, the page excerpts, and the URLs of the search results, than low-knowledge students. In addition, Bråten, Strømsø, and Salmerón (2011) found that when reading multiple documents dealing with a science-related topic undergraduates with low knowledge on the subject matter trusted the different documents to the same extent irrespective of the type of source, whereas students with higher knowledge judged an article from a company with vested interests about the addressed issue as less trustworthy than the other documents. According to Bråten et al. (2011) a possible explanation for the
undifferentiated or lacking trustworthiness evaluations of low-knowledge readers is that they have to invest more cognitive effort in comprehending the content of the documents than readers with higher domain knowledge. As a consequence, low-knowledge readers might have less cognitive resources available to engage in evaluations that go beyond content. Thus, another central aim of our study was to further examine the effects of prior domain knowledge on information processing and source evaluation during Web search as well as potential interactions between prior domain knowledge and TA instructions.

## Hypotheses of the Present Study

Given the theoretical considerations and prior empirical findings our hypotheses were as follows:

First, with respect to the evaluation of information quality and structural aspects of Web pages as indicated by verbal utterances, we hypothesized that prompted TA instructions would increase the number of respective verbal utterances during Web search as compared to neutral instructions, but only when participants' possessed a certain level of prior knowledge (cf. Metzger, 2007) (H1). Low-knowledge participants' quality-related and structure-related verbal utterances should not be increased due to participants' lack of cognitive resources (cf. Bråten et al., 2011).

Second, based on the findings by Hertzum et al. (2009) we hypothesized that prompted TA instructions as compared to a silent condition would result in a more distributed scanning behavior on SERPs (H2) and a significant increase in Web pages selected from the SERPs during Web search (H3). In contrast, neutral instructions should only result in slight changes in regard to these measures as compared to a silent condition.

Third, according to the case-study results of MaKinster et al. (2002) we hypothesized that the higher participants' domain knowledge the more thoroughly they would scrutinize the search results, as indicated by longer total fixation times (H4). Finally, based on the theoretical assumption provided by Bråten et al. (2011) we hypothesized that the lower participants' domain knowledge, the more cognitively demanding the Web search would be for them, which should result in larger mean pupil sizes (H5) which is known to be an indicator of increased cognitive load (for review e.g. see Hyönä, Tommola, \& Alaja, 1995; Wang, 2010).

## Method

## Participants and Design

Participants ${ }^{1}$ were 44 undergraduates ( 18 male, $M=25.02$ years, $S D=3.68$ ) from different majors at a large German

[^108]university, who were rewarded with either course credit or payment. Participants had normal or corrected to normal vision. They reported to use Google as their primary search engine and judged their computer- and Web search experience and skills between intermediate and high ( $M=$ $3.50, S D=0.67,4$ items, on a scale from $1=$ very low to $5=$ very high, Cronbach's $\alpha=.78$ ).

Thinking-aloud condition served as a between-subjects factor, with participants being randomly assigned to a neutral TA condition, a prompted TA condition, or a silent condition. Neutral instructions to think aloud were worded in line with the standards described by Ericsson and Simon (1993), that is "Please think aloud during your Web search, that is, verbalize everything that comes to your mind." In contrast, the prompted TA instructions were similar to the instructions used, for instance, by Tombros et al. (2005) or Rieh (2002) including evaluation prompts, that is "Please think aloud during your Web search, that is, mention the evaluation criteria you apply to select search results and to assess Web pages." In the silent condition participants performed the task silently.

There were no differences between the three conditions regarding participants' age $\left(\chi^{2}(2, N=44)=2.24, p=.33\right)$, gender $(F<1)$, or computer- and Web search experience and skills $(F<1)$.

As a second factor participants' self-reported prior knowledge on the subject matter of the task (i.e., diets and nutrition) was assessed (see 'Measures' for details) and used as a continuous between-subjects factor.

## Tasks and Web Materials

Participants were given the task of seeking information on the WWW about two competing weight loss methods, namely low carb(ohydrate) diets and low fat diets, in order to give informed advice to a fictitious overweight friend who wants to lose weight by changing her diet.

To complete the experimental task, which was limited to 20 minutes, participants were provided with three prefabricated Google-like SERPs (with ten search results each), retrieved for the search terms "low fat", "low carb", and "low carb versus low fat". Participants were instructed to access all three SERPs during their Web search. They could access all 30 Websites corresponding to the list of search results presented on the SERPs, but were not allowed to generate new search results by changing the search terms. All search results and Websites were relevant to the search topic in regard to the content of information provided, but differed with regard to the type of sources including Websites provided by scientific institutions, journalists, industry and companies, and laypeople.

## Measures

Self-reported prior domain knowledge To assess participants' prior knowledge on diets and nutrition, participants were administered a questionnaire with eight statements that had to be rated on five-point scales ( $1=$ totally disagree; $5=$ totally agree); example items are "I
know more about diets and nutrition than my family and friends" or "I can describe the concept of low carb diets". Cronbach's alpha was .87 for the eight items. The range of participants' prior domain knowledge was 1 to 4.38 ( $M=$ $2.48, S D=0.70$ ). There were no differences between the three experimental conditions regarding participants' prior knowledge on diets and nutrition $(F<1)$.

## Dependent variables

Participants' thinking-aloud protocols (in the prompted and neutral TA conditions) were segmented at a small grain size: Each sentence or utterance preceded and followed by a pause was considered a separate segment. According to the studies by Rieh (2002) and Tombros et al. (2005) utterances were coded as information quality when participants on SERPs or Websites reflected on whether (or not) the information is good, valid, credible, or current, or the source provides trustworthy, reliable, or official information, and as structure of Web pages when participants addressed the clarity of a Web page or the organization of the information therein (cf. Tombros et al., 2005). Besides, utterances addressing the topical relevance (i.e., utterances on SERPs or Websites about whether or not the information matches with the search topic) were coded (e.g., Savolainen \& Kari, 2006). Two raters familiar with the search task and the Web materials scored $30 \%$ of the protocols. Interrater reliability computed on this subsample of protocols yielded a Cohen's kappa of .76. Disagreements were resolved through discussion between the raters. One rater scored the remaining protocols.

In addition, for participants of all three conditions their viewing and selection behavior on the SERPs were analyzed. Eye movements and mouse clicks were recorded by a 50 Hz Tobii 1750 remote eye-tracking system supported by the software ClearView 2.7.1.

To analyze participants' eye-tracking data, for each of the ten search results on a SERP a polygonal area of interest (AOI) was defined around the search result (covering the title, the excerpt, and the URL), in order to determine for how long and in which order a participant was looking at a search result. The minimum fixation duration was set to 100 milliseconds with a fixation radius of 30 pixels. On this basis, the total fixation time of each search result, that is, the overall amount of time participants scrutinized a search result to decide whether to click on it or not, was calculated. Second, as a measure of distributed viewing behavior across the screen (cf. Hertzum et al., 2009) participants' viewing sequences on the SERPs, that is, the order in which the search results on a SERP were inspected, were computed, by comparing them with a perfectly linear sequence from top to bottom (search result 1, search result 2, search result 3 , search result 4 , etc.) by means of the Levenshtein distance (cf. Josephson \& Holmes 2002). Levenshtein distance values were transformed into a similarity percentage: A higher similarity percentage indicated more linear top-tobottom viewing sequences. The similarity percentages were averaged across the three SERPs. Third, participants' mean
pupil size (in mm ) during task processing was computed (averaged across eyes).

Furthermore, based on the mouse click recordings, the number of Websites participants' accessed during their Web search was analyzed (cf. Hertzum et al., 2009).

## Procedure

Participants were tested in individual sessions of approximately one hour. The lighting conditions were kept constant during all examinations. Before participants started on the search task, control variables and self-reported prior domain knowledge were assessed. Furthermore, participants received some general instructions about the Web search experiment as well as the TA instructions according to their experimental condition. Next, they performed a practice task (structured in the same way as the subsequent main task) for approximately five minutes to get acquainted with the Web search environment and with the TA method. After the practice task, participants received the instruction for the main task (i.e., the request of the fictitious friend). Then, they were calibrated on the eye-tracking system using a nine-point calibration and started their Web search. In the two TA conditions, whenever participants stopped verbalizing their thoughts, the experimenter reminded them (after 5 seconds) to keep thinking aloud or to mention the evaluation criteria, respectively. After 20 minutes participants were asked to stop the task. Subsequent to their Web search, they had to decide which of the two weight loss methods they would recommend. However, in the present study only process measures during Web search were analyzed.

## Results

ANCOVAs with TA conditions (neutral, prompted, and silent) and prior domain knowledge (z-scored) as well as an interaction term between TA conditions and prior domain knowledge were conducted. Significant interaction effects between TA condition and prior domain knowledge were probed according to the procedure outlined by Aiken and West (1991). Table 1 shows means and standard errors for the dependent variables.

## Verbal Utterances

With respect to verbal utterances about topical relevance neither TA condition nor prior domain knowledge had a significant effect and there was no significant interaction between the two factors (all $F \mathrm{~s}<1.90, p \mathrm{~s}>.18$ ).

With respect to verbal utterances about information quality the ANCOVA showed a significant effect of TA condition $\left(F(1,25)=10.95, p=.003, \eta_{\mathrm{p}}^{2}=.30\right)$ and of prior knowledge $\left(F(1,25)=6.22, p=.02, \eta_{\mathrm{p}}{ }^{2}=.20\right)$. These effects were qualified by a significant interaction between the two factors $\left(F(1,25)=4.62, p=.04, \eta_{\mathrm{p}}{ }^{2}=.16\right)$. Simple comparisons according to the procedure outlined by Aiken and West (1991) revealed that, consistent with the predictions of $H 1$, only high-knowledge participants (i.e., 1
$S D$ above the sample mean) and moderate-knowledge participants (i.e., at the sample mean) expressed more information-quality utterances during prompted TA than during neutral TA $(\beta=.80, t(25)=3.85, p=.001$ and $\beta=$ $.48, t(25)=3.31, p=.003$, respectively). In contrast, lowknowledge participants (i.e., $1 S D$ below the sample mean) did not significantly differ in the two TA conditions ( $\beta=$ $.16, t(25)=0.79, p=.44)$. In addition, in the prompted TA condition prior knowledge was significantly positively related to the number of information-quality utterances ( $\beta=$ $.67, t(25)=3.30, p=.001$ ), whereas in the neutral TA condition it wasn't $(\beta=.05, t(25)=0.24, p=.81)$.
With respect to verbal utterances regarding the structure of Web pages the ANCOVA showed similar effects: a significant effect of TA condition $(F(1,25)=13.69, p=$ $.001, \eta_{\mathrm{p}}^{2}=.35$ ), a marginal effect of prior knowledge ( $F(1$, 25) $=3.49, p=.07, \eta_{\mathrm{p}}^{2}=.12$ ), and a significant interaction between the two factors $\left(F(1,25)=6.01, p=.02, \eta_{\mathrm{p}}^{2}=.19\right)$. Simple comparisons revealed that only high-knowledge participants and moderate-knowledge participants expressed more structure-related utterances during prompted TA than during neutral $\mathrm{TA}(\beta=.89, t(25)=4.34, p<.001$ and $\beta=$ $.53, t(25)=3.70, p=.001$, respectively). In contrast, lowknowledge participants did not differ in the two TA conditions ( $\beta=.17, t(25)=0.85, p=.41$ ). In addition, as for the information-quality utterances, in the prompted TA condition prior knowledge was significantly positively related to the number of structure-related utterances ( $\beta=$ $.62, t(25)=3.07, p=.01)$, whereas in the neutral condition it wasn't $(\beta=-.08, t(25)=-0.41, p=.69)$.

## Eye-Tracking and Mouse Clicks

With regard to the linearity of participants' viewing sequences on the SERPs, as measured by the similarity percentages of participants' string to a linear top-to-bottom string, the ANCOVA showed a significant main effect of TA condition $\left(F(2,38)=6.19, p=.01, \eta_{p}{ }^{2}=.25\right)$. Bonferroni post-hoc tests revealed that in line with the predictions of H 2 , in the prompted TA condition participants' viewing sequences were significantly less linear than in the silent condition ( $p=.004$ ). The differences between the neutral TA condition and the silent condition were only marginally significant ( $p=.08$ ). The two TA conditions did not differ significantly ( $p=.89$ ). Prior knowledge had no effect on participants' viewing sequences and there was no interaction with TA conditions (both $F \mathrm{~s}<$ 1).

Regarding the total fixation time of each search result the ANCOVA showed a significant main effect of prior knowledge $\left(F(1,38)=4.00, p=.05, \eta_{\mathrm{p}}{ }^{2}=.10\right)$. In line with the predictions by H 4 , the higher participants' domain knowledge, the more intensely they scrutinized the search results to decide whether or not to click on them. TA conditions had no effect $(F<1)$ and there was no interaction with prior knowledge $(F(1,38)=1.52, p=.23)$.

Table 1: Means (and standard errors) of the dependent variables as a function of thinking-aloud (TA) conditions.

|  | Thinking-aloud condition |  |  |
| :--- | :---: | :---: | :---: |
| Dependent variables | Prompted instructions | Neutral instructions | Silent condition |
| \# utterances about topical relevance | $6.92(1.21)$ | $4.51(1.26)$ | NA |
| \# utterances about information quality | $12.11(1.55)$ | $4.74(1.60)$ | NA |
| \# utterances about structure of Web pages | $5.52(0.84)$ | $1.05(0.87)$ | NA |
| \% linearity of viewing sequences on SERPs | $62.11(3.90)$ | $68.10(4.10)$ | $81.40(4.00)$ |
| total fixation time (in s) of each search result | $3.02(0.35)$ | $3.03(0.36)$ | $2.62(0.36)$ |
| mean pupil size (in mm) | $3.71(0.10)$ | $3.86(0.11)$ | $3.58(0.10)$ |
| \# Websites accessed (in \%) | $47.14(4.09)$ | $52.91(4.30)$ | $42.49(4.20)$ |

With regard to participants' mean pupil size during task processing, after controlling for participant's average eye-to-screen-distance (which had a strong positive effect on pupil size, $\left.F(1,37)=7.89, p=.01, \eta_{\mathrm{p}}^{2}=.18\right)$, the ANCOVA showed a significant effect of prior knowledge $(F(1,37)=$ $5.87, p=.02, \eta_{\mathrm{p}}^{2}=.14$ ). In line with the predictions by $H 5$, less prior domain knowledge was associated with larger pupil sizes. Besides, there was no significant effect of TA conditions $(F(2,37)=1.71, p=.20)$, nor a significant interaction with prior knowledge $(F<1)$.

With regard to the number of Websites participants accessed during Web search, the ANCOVA showed no significant main effect of TA conditions $(F(1,38)=1.51, p$ $=.24)$, but of prior knowledge $\left(F(1,38)=5.40, p=.03, \eta_{\mathrm{p}}{ }^{2}\right.$ $=.12$ ). This effect was qualified by a significant interaction with TA conditions $\left(F(2,38)=7.11, p=.002, \eta_{p}{ }^{2}=.27\right)$. Simple comparisons revealed that participants with high prior knowledge accessed significantly more Websites in the prompted TA condition than in the silent or neutral TA condition $(\beta=.45, t(38)=2.26, p=.03$ and $\beta=.53, t(38)=$ 2.32, $p=.03$, respectively), which did not differ significantly $(\beta=.09, t(38)=0.42, p=.68)$. Thus, the assumptions of $H 3$ are at least partly confirmed. However, other than expected, low-knowledge participants accessed significantly more Websites in the neutral TA condition than in the silent or prompted TA condition $(\beta=.51, t(38)=$ $2.41, p=.02$ and $\beta=.72, t(38)=3.65, p=.001$, respectively), which did not differ significantly ( $\beta=.21$, $t(38)=0.97, p=.34)$.

In addition, in the prompted TA condition prior knowledge was significantly positively related to the number of selected search results $(\beta=.93, t(38)=4.13, p<$ .001), whereas in the silent and neutral TA condition no significant relationship with prior knowledge were found ( $\beta$ $=-.38, t(38)=-1.66, p=.11$ and $\beta=.25, t(38)=1.17, p=$ .25 , respectively).

## Discussion and Conclusion

With the present study we sought to examine the impact of TA instructions - especially of "prompted" TA instructions that entail evaluation prompts as used in some previous studies (e.g. Rieh, 2002; Tombros et al., 2005) - as well as of prior domain knowledge on participants' information processing and source evaluation during Web search.

First, with regard to verbal utterances about information quality and the structure of Web pages, in line with $H 1$, our study showed that prompted TA instructions (i.e., to mention the evaluation criteria applied to select search results and to assess Web pages) as compared to neutral TA instructions (i.e., to verbalize everything that comes to their mind) significantly increased participants' verbal reflections on information quality and on structural aspects of Web pages, given that participants possessed at least a moderate level of prior knowledge on diets and nutrition. In contrast, irrespective of the instructions given, students with no or little prior domain knowledge only rarely expressed such utterances. Thus, to conclude, the findings by Rieh (2002) and Tombros et al. (2005) seem to have resulted from a combination of prompted TA instructions and a certain level of prior domain knowledge of the participants. Utterances about topical relevance, on the contrary were expressed by all participants to a similar extent, irrespective of prior knowledge or instructions. That is, the evaluation of whether or not a search result or a Web page addresses the search topic seems to be a default process that guides every Web search task.

Second, with regard to the effects of prompted or neutral TA instructions on participants' information processing during Web search as compared to a silent condition, in line with $H 2$ and the findings by Hertzum et al. (2009) about Web page inspection, we found that the prompted instructions resulted in less linear, that is, more distributed viewing sequences on the SERPs. That is, instead of simply following the list order (a typical effect on SERPs) participants examined the search results in a rather free way. This can be seen as an indication of own evaluations, instead of simply relying on the order presented by the search engine. Between the neutral TA instructions and the silent condition, in contrast, only marginal respective differences were found (cf. Hertzum et al., 2009). With regard to the number of Websites accessed during Web search the results showed a more complex pattern than expected. For participants with rather high prior knowledge similar effects were found as in the study by Hertzum et al. (2009), namely that participants in the prompted TA condition accessed more Websites than in the other conditions (in line with H3). However, for participants with a moderate level of prior knowledge no differences were
found between conditions, and participants with low prior knowledge accessed more Websites with neutral TA instructions than with prompted instructions or when working in silence. A post-hoc explanation for the latter finding might be that low-knowledge participants in the neutral TA condition were overwhelmed by the situation and did not really know what to say and to do and, thus, simply selected (almost) all Websites.

Third, with regard to further effects of prior knowledge, in line with H 4 we found that the higher students' selfreported prior knowledge on diets and nutrition the more intensively they scrutinized the search results on the SERPs to decide whether to select them (cf. MaKinster et al., 2002). Furthermore, in line with $H 5$ participants with lower prior knowledge across conditions had increased pupil sizes, which is an indicator of increased cognitive load. This effect provides further evidence for the assumption proposed by Bråten et al. (2011) that low-knowledge users have to employ more cognitive effort in order to comprehend the content of the Web pages than Web users with higher domain knowledge. As a consequence, they seem to lack cognitive resources to engage in evaluations that go beyond content. This is also indicated by the fact that in both TA conditions low-knowledge users hardly ever verbally reflected on the information quality or on the structure of Web pages. Future research should examine these effects in greater detail, analyzing more detailed moment-to-moment changes in participants' pupil sizes and using withinsubjects task variations.

In sum, from a methodological perspective, the present findings indicate that prompted TA instructions increase participants' verbal reflections on information quality and on structural aspects of Web pages, and, therefore, might overestimate, users' spontaneous reflections about these issues. Yet, from an educational point of view the findings of the present study suggest that simple evaluation instructions that prompt Web users to evaluate search results and Web pages have the potential to increase their awareness about the necessity to critically evaluate the information found on the Web - given that they possess a certain amount of prior knowledge on the subject matter of the search task at hand. In order to improve source evaluations of searchers with no or little prior domain knowledge, however, more comprehensive instructional support seems to be required that also includes measures to reduce individuals' cognitive burden during task processing. Furthermore, when the WWW is used as a research tool in formal learning settings (e.g., in school), it seems advisable that the teacher first provides some general information on the topic before students start with their Web search.

#### Abstract

Previous work has identified a distributed, network of neural systems involved in appraising the value of rewards, such as when winning $\$ 100$. We hypothesized that involvement of intraparietal sulcus (IPS) in this network is specialized for processing numeric rather than monetary value. To test our hypothesis, we manipulated numeric magnitude and units to construct a range of economic rewards (e.g., $+\$ 1,+100 \phi$ ) in response to simple decisions. Consistent with our hypothesis, BOLD activity in IPS was related to changes in numeric magnitude, independent of monetary value, whereas activity in OFC was associated with monetary value, independent of numeric magnitude. Finally, by using representation similarity analysis, we found that the information represented in IPS and OFC was more consistent with the patterns expected if representations of numeric magnitudes or monetary values, respectively, were in a compressive scale. Together, these findings show the importance of numerical cognition for understanding how the brain processes monetary rewards.

Keywords: monetary rewards; IPS; OFC; fMRI, representation similarity analysis, numerical cognition

## Introduction

Humans are continuously faced with choices, often involving incommensurable options. When choosing among options for a romantic date, for example, it is not clear how to compare the esthetic pleasure of a movie with the gustatory pleasure of a nice dinner. Making decisions apparently requires computing the value of each option in some way that would register the difference in values (Montague, King-Casas \& Cohen, 2006).

Economic models have long assumed that humans behave 'as if' they compute value for each option in a common mental currency (i.e., subjective value), and experiments on the distributed neural correlates of valuation (i.e., valuation network) suggest that this assumption may be correct (Kable \& Glimcher, 2009; Padoa-Schioppa \& Asad, 2006, 2008; but see Vlaev, et al., 2011; Tremblay \& Schultz, 1999; Seymour et al., 2007; Nieuwenhuis et al., 2005).

One of the sources of information that comprise this common mental currency is the magnitude of the reward. Being rewarded two cookies feels better than being
rewarded just one. A special case of using magnitude for valuation is the use of monetary rewards. By using money, dissimilar goods can be compared on the same scale (e.g., dollars or cents) and can be described with just one value, its numeric magnitude (e.g., +300 or -300 ).

Although translation of value into a numeric scale has many benefits, it may also come with a price. Numeric magnitude, like luminance and loudness, has a compressive psychophysical scale (Fechner, 1860/1966; Weber, 1846/1948; Dehaene, 1997). Thus, the difference between 10 and 15 appears larger than the difference between 120 and 125.

The compressive nature of numerical judgments is important because it may play a large role in how the brain tracks monetary value and makes economic decisions (Furlong \& Opfer, 2009; Peters et al., 2008). Indeed, "unit effects" on decision-making have been known for many decades. For example, Kahneman and Tversky (1981) observed that participants were willing to trade 20 minutes of their time to save $\$ 5$ on a $\$ 15$ calculator, but not on a $\$ 125$ jacket, even though in both cases they are trading 20 minutes of their time for the same amount of money (i.e. $\$ 5)$. Although, these effects can be explained by assuming that subjects pay more attention to the proportional gains, the compressive function of numeric representations might provide another explanation. Because larger numerals have smaller psychological distances between them, the difference between a $\$ 125$ and $\$ 120$ jacket is subjectively less than the difference between a $\$ 15$ and $\$ 10$ calculator.

In this paper, we were interested in why neural activation also appears to devalue marginal monetary gains. Specifically, we addressed whether the neural response to increasing quantities of money are caused by increases in objective monetary value (the value hypothesis), by increases in the numeric magnitude used to represent the magnitude of the monetary reward (the number hypothesis), both, or neither. This issue is important because neuroeconomists typically assume that the brain areas responsible for processing monetary rewards are not affected by the magnitudes of the numerals that represent the rewards, but this assumption has never been tested.

## The Valuation Network: Neural Correlates of Monetary Value

Research in the field of neuroeconomics has suggested the existence of a neural valuation network. This network computes the subjective value of options under consideration and uses that valuation to make choices. The most critical brain areas associated with economic value are the orbitofrontal cortex (OFC)/ventromedial prefrontal cortex (VMPFC), striatum, anterior cingulate cortex (ACC), and posterior parietal cortex (PPC) (Glimcher, 2009; Kable \& Glimcher, 2009). In theory, the function of this valuation network is to integrate the multiple value dimensions of an option to provide a one-dimensional scale of subjective value according to which choices can be ranked for future decisions.

Of critical importance for this paper are the roles of OFC and PPC. Both studies in monkeys and humans have consistently shown the importance of OFC in the valuation process. There are, however, different ways in which that value can be represented. Although some studies have found neurons in OFC that are associated with absolute value (Paddoa-Schioppa \& Assad, 2006, 2008; Tom et al., 2007), other studies have found that other neurons in OFC are also associated with relative value with adaptive scaling (Kennerley, Behrens \& Wallis, 2011; Tremblay \& Schultz, 1999).

Parietal cortex activity related to valuation processes has been located in the lateral inferior parietal cortex (LIP) of monkeys and intraparietal sulcus (IPS) - its human homologue (Clithero, Carter, \& Huettel, 2009; Kable \& Glimcher, 2009; Platt \& Glimcher, 1999). For instance, using pattern classification techniques, activity in IPS was related to the value of options, and it was even able to distinguish between intertemporal and probabilistic valuations (Clithero et al., 2009). Also, their data suggest that IPS is critical for the initial stages of valuation by representing and integrating the information necessary for computation of economic value in OFC and the striatum. Also, activation of IPS has recently been related to the outcome of monetary rewards, but not to the outcome of social rewards (Lin, Adolphs \& Rangel, 2011). This result is important since it shows that the presence of (numeric) magnitude information in the reward presented may be a critical component of the value representation in IPS.

However, the meaning of magnitude in the studies reviewed is ambiguous. Because numeric magnitude and value magnitude typically go hand in hand, it is not possible to know if the increases in activation in IPS (or OFC) are related to an increase in the value of the reward or in the numbers used to represent that value. Moreover, there is strong evidence that suggests that IPS is a central area in the processing of numeric information (Arsalidou \& Taylor, 2011 for a meta analysis). Therefore, we suggest - as an alternative hypothesis - that while OFC does process reward value, the role of IPS in these studies is to process the numeric magnitudes of the rewards being considered. If true, the activity of the valuation network would be
susceptible to manipulations of numeric magnitude even when these manipulations do not change the objective monetary value of the rewards.

## Present Study

Recently, Furlong and Opfer (2009) provided a method to discern between these two possibilities at the behavioral level. Although economic theories assume that the magnitude of the numbers should not affect economic behavior, Furlong and Opfer showed that in fact numeric magnitude and not economic value explained the degree of cooperation of participants in a prisoner's dilemma task. The device used to prove this point was exceedingly simple. By manipulating the unit of the rewards between dollars and cents, it was possible to achieve rewards with the same objective economic value while drastically changing the numeric magnitude associated with the same reward (e.g. \$1 $=100 \not \subset$ ). This simple manipulation makes it possible to provide participants with a variety of rewards in such a way that allows to parametrically vary numeric magnitude and economic value independently.

To test whether IPS processes numeric magnitude or economic value, we conducted a functional magnetic resonance imaging (fMRI) study that was designed to introduce linear transformations to the magnitudes of rewards. In order to properly disambiguate the effects of numeric magnitude from those of monetary value on the valuation network, we developed a scratch-off lottery game in which we could manipulate the units (between dollars and cents) of the monetary rewards given to participants.

## Method

## Participants

Seventeen adults participated (mean age 22.2, range 18-41; 10 female). All were right-handed, had normal or corrected-to-normal vision and reported no neurological problems. One participant was excluded for failing to complete the task and complaints of headaches during scanning.

## Design and Procedure

Participants were recruited to play a lottery game; $\$ 15$ was guaranteed for playing plus the chance to earn $\$ 0$ to $\$ 20$ more depending on the value of tickets uncovered during the experiment. To uncover extra money, participants had to choose between two covered tickets (represented as two gray rectangles on a computer screen) by pressing one of two buttons on a button box. After choosing a ticket, the amount of extra money earned (or lost) would be revealed. Participants had only one second to choose a ticket lest the choice be made for them; were 25 tickets missed during the session, all extra money would be forfeit.

Unbeknownst to participants, the lottery was rigged in several ways to optimize data for our experiment. First, the sequence of rewards and the jittered intertrial interval were presented in a pseudo-random order, determined by a custom MATLAB script (Poldrack, 2011) that optimizes
contrast efficiencies of fMRI event-related designs. Jittered intertrial intervals varied from 2 s to 8 s and were derived from a pseudoexponential distribution (mean ITI $=4 \mathrm{~s}$ ). The optimization routine was created for each of the 5 individual runs, and order of runs varied randomly between subjects. Thus, participants had no actual control of the amount of money they received.

Critically, values of tickets came from all possible combinations of 5 numbers (i.e., $0,1,3,100,300$ ), 2 units (i.e., dollars and cents) and 2 valences (i.e., win and loss). Combined, these components yielded a range of 17 possible tickets: $(-1 \phi,-3 \phi,-100 \phi,-300 \phi,-\$ 1,-\$ 3,-\$ 100,-\$ 300,0$, $+1 \phi,+3 \phi,+100 \phi,+300 \phi,+\$ 1,+\$ 3,+\$ 100,+\$ 300)$. To control for number of digits and position of units, rewards were presented such that valence signs always appeared in the leftmost position, units rightmost, and numbers between with three digits and one dot (e.g., "- $1.00 \not \subset "$ ".

The experiment consisted of 5 fMRI runs of 8 minutes each. Each run contained 57 trials, 51 trials corresponding to 3 repetitions of each of the 17 different tickets, and 6 extra tickets. Extra trials were added because equal repetitions of all tickets would yield no net gain thereby earning participants no extra money. Instead, the lottery was rigged so all participants earned an extra $\$ 10.50$ from the 30 extra tickets distributed randomly over the 5 runs.

## fMRI Scanning Parameters

Imaging data was collected on a Siemens Tim MAGNETOM Trio 3T MRI scanner. For registration of images, we used a T1-weighted MPRAGE sequence (TR = $1900 \mathrm{~ms} ; \mathrm{TE}=4.68 \mathrm{~ms}$ ). In each run, we acquired 237 whole-brain T2* weighted echo planar images (TR = $2100 \mathrm{~ms} ; \mathrm{TE}=25 \mathrm{~ms}$; flip angle $90^{\circ}$ ). The first 4 volumes of images were discarded to allow for stabilization of the scanner. Parameters of functional scans were selected to minimize susceptibility problems associated with imaging of prefrontal cortex (PFC).

## Data Analysis

fMRI data were analyzed using FEAT 5.98 (FMRI Expert Analysis Tool) from FSL toolbox (www.fmrib.ox.ac.uk/fsl). Preprocessing of data consisted of brain extraction, motion correction, spatial smoothing with a 5 mm (FWHM) Gaussian kernel, and registration to standard MNI space.

Statistical analyses were conducted with a whole-brain GLM parametric analysis in which parametric regressors were created to model wins and losses separately to account for the different subjective value functions predicted by prospect theory (Kahneman \& Tversky, 1979). Specifically, activity for each trial was modeled using units (i.e. dollars = 1 , cents $=-1$ ) and numbers (i.e. $1,3,100,300$ ) as regressors:

BOLD(wins) $=$ Units(wins) + Number(wins) + (Number(wins) * Units(wins))
BOLD $($ losses $)=$ Units $($ losses $)+$ Number(losses $)+$ (Number(losses) * Units(losses))
Where the Number*Units interaction corresponds to the objective monetary value of each ticket. In addition to these regressors of interest, motion correction parameters from

MCFLIRT motion correction procedure were also included in the models as regressors of no interest. Whole brain statistical analyses were performed using a multi-stage approach to implement a mixed-effects model treating participants as random-effects. Regressors of interest were constructed by convolving a boxcar function representing the onset time of the stimulus, the magnitude of the parametric regressor and its duration with a canonical double-gamma (HRF). All reported results in the following section were assessed for cluster-wise significance ( $\mathrm{P}<$ 0.05 , FWE-corrected) using a defining threshold of $Z>2.3$.

## Results

## Behavioral Results

To ensure that participants were paying attention to the task, they were instructed to choose a lottery ticket within 1 s of their onset on the screen. The typical participant was very attentive and only missed 3.88 tickets (range $0-11$ ).

## Imaging Results

The experimental design of this study allowed examining the effects of manipulating numeric magnitude, units and valence on neural activity. Wins and losses were modeled separately in agreement with prospect theory (Kahneman \& Tversky, 1979). For space reasons, we will only describe results concerning winning trials.

## Win Trials

As predicted by the number hypothesis, we found that bilateral activation of IPS was related to increases in numeric magnitude, but not to increases in monetary value. The activation clusters associated with the number parametric regressor extended to adjacent areas in lateral occipital cortex, inferior temporal gyrus, superior parietal lobule and angular gyrus. Also, we found significant clusters in middle frontal gyrus. (Fig. 1). Further, no clusters showed a negative relation between number and neural activation. These patterns are consistent with the literature on number processing (Arsalidou \& Taylor, 2011) and show the importance of numeric information in the processing of monetary rewards. Further, these findings contradict the idea that the role of IPS in the valuation network is to compute economic value (Glimcher, 2009).

Conversely, activity in bilateral OFC, insula, inferior frontal gyrus, ACC, VMPFC, angular gyrus, and lateral occipital gyrus, (Fig. 2) was associated with increases in monetary value. These results are consistent with what is known about the neural correlates of absolute value (Kable \& Glimcher, 2009; Padoa-Schioppa \& Assad, 2008).

Activity associated with the units regressor (i.e. greater activity for dollars than for cents) was found in areas of bilateral OFC, insula, VMPFC, paracingulate cortex, ACC, and left striatum (Fig. 1). Here, areas that show significant relations with receiving rewards in dollars overlap with the areas associated with increases in monetary rewards. This overlap makes sense because - all else being equal -

Figure 1: Regions for which activation was significantly modulated by numeric magnitude (red), monetary value (blue), dollars (yellow) and cents (green) of winning tickets.
changing the unit of the received lottery ticket from cents to dollars entailed a 100 -fold increase in monetary value. Conversely, areas of left postcentral gyrus, anterior IPS, and right lateral occipital gyrus showed greater activity for cents than for dollars. Following a similar logic, a change from dollars to cents - holding the amount of money constant entailed a 100 -fold increase in numeric magnitude. However, as can be seen in Fig. 1 and unlike in the previous case, the areas in posterior parietal cortex that showed significant BOLD activity related to cents do not overlap with the areas associated with increases in numeric magnitude.

Evidence that PPC activation is associated with numeric magnitude adds to the current literature of the neural correlates of valuation by pointing out an important confound present in all studies of valuation that have used monetary rewards. Several of these studies have reported IPS activity and as a result have suggested that PPC is directly implicated in the network that computes economic value (Ballard \& Knutson, 2009; Clithero et al., 2009; Hare, et al., 2011; Lin, et al., 2011; Louie, et al., 2011; Nieuwenhuis, et al., 2005; Platt \& Glimcher, 1999). However, the present results suggest that the involvement of IPS in the valuation network is related to the processing of numeric magnitude information and not to economic value.

Conversely, signatures of absolute monetary values were obtained in OFC, VMPFC, striatum and ACC. In these areas, the magnitudes of the numbers used to represent the economic values did not affect the representation of economic value. These results are consistent with the previous literature (Kable \& Glimcher, 2009) since these are all major areas of the suggested neural network charged with processing economic value. Combined, the findings from winning tickets are in agreement with the idea that there are in fact multiple valuation networks that may have different properties.

## Representation Similarity Analysis

An important question underlying this study is whether brain regions like IPS or OFC treat $100 ¢$ more like $\$ 1$ (same economic value) or like $\$ 100$ (same numeric value). One way to answer this question is to examine how the

Figure 2: Regions of OFC, VMPFC and insula for which activation was significantly modulated by increases in monetary value for winning tickets.
information of interest is represented in a particular brain area. Here, the main goal is not just to detect activation, but to characterize the information present in the particular area (Kriegeskorte \& Bandettini, 2007). Representation similarity analysis (RSA; Kriegeskorte, Mur \& Bandettini, 2008) is one kind of multivariate approach to fMRI data analysis that tries to accomplish this. RSA aims to find correspondences between the relations among stimuli, and the relations between the patterns of brain activation in a particular brain area in response to the same stimuli. Therefore, RSA can be applied to the present problem, since it can provide an answer to the question of whether a given brain area treats the full matrix of monetary rewards more like the numerical representation of those rewards or more like a sequence of distinct monetary values.

Furthermore, we were interested in comparing multiple theories of how the brain patterns of activity elicited by the full set of stimuli might be related. For the purposes of this study, RSA allowed us to compare the patterns of brain activity from anatomical regions of interest (ROI's) to the patterns expected if the given brain area processes numeric magnitude (both in linear and logarithmic scales), or monetary value (both in linear and logarithmic scales). Additionally, by using RSA we were able to check if positive and negative rewards were treated equally or not.

To conduct RSA, we computed dissimilarity matrices (DSMs) among all presented stimuli for the patterns of activity in each ROI, as well as for each theoretical model. Once these DSMs were obtained, Spearman correlations were computed between the ROIs and the model DSMs. This analysis allowed us to rank order the ROI-model similarities (Fig. 3).

As can be seen in Fig. 4, the DSM obtained from IPS activation was more similar to the DSM expected if the information represented were numeric magnitude in a log scale. Conversely, the DSM obtained from OFC activation was more similar to the DSM expected if the information represented were monetary value in a log scale (Fig. 4). These results not only are consistent with the GLM results presented in the previous section, but also provide important additional information regarding the details of the neural

Figure 3: Middle: Single subject IPS dissimilarity matrix (DSM); Top Left: Absolute-magnitude Log Number DSM;
Top Right: Log Number DSM; Bottom Left: Absolutemagnitude Log Monetary Value DSM; Bottom Right: Log Monetary Value DSM. In RSA the brain DSM is correlated with Spearman correlations to the model DSMs to provide a rank order of which model matches better the brain data.
representations. In particular, the results from RSA show that both numeric magnitude in IPS, and monetary value in OFC are represented in compressive scales.

## Discussion

We proposed that the neural response to monetary rewards could be accurately predicted by the cognitive components of valuation. One such component, the processing of numeric magnitude, seemed likely to be especially important, though previous studies had not controlled it systematically. We thought this an important oversight: because the function relating objective numeric magnitudes to subjective magnitudes is compressive, a similar relation might exist in the neural response to monetary rewards.

The results presented in this paper generally confirm this hypothesis. In particular, when winning money of varying amounts, IPS activity was strongly associated with the numeric - and not monetary - value of the rewards. In contrast, activity of OFC, insula, ACC and VMPFC was strongly associated with the monetary - and not numeric value of rewards. Further, RSA showed that numeric information in IPS and monetary value in OFC are represented in a compressive scale.

The fact the IPS was associated with increases in numeric magnitude and not to monetary value provides a new way to understand previous studies about the valuation network (Ballard \& Knutson, 2009; Clithero et al., 2009; Hare, et al., 2011; Louie, et al., 2011; Nieuwenhuis, et al., 2005). In these studies IPS activity was interpreted as processing monetary value, but our results suggest that it is better understood as processing numeric information. Moreover, this conclusion is strengthened by the fact that IPS has been continuously associated with processing of numeric and mathematical information (Arsalidou \& Taylor, 2011).

On the other hand, the finding that activity in OFC,

Figure 4: Spearman correlations between model DSMs and group-averaged DSM for IPS (left) and OFC (right).

ACC, VMPFC, and insula was related to monetary value, is consistent with a wealth of studies that have established strong relations between these areas and the process of monetary value (Cunningham et al., 2009, Glimcher, 2009, O’Doherty, et al., 2003; Padoa-Schioppa \& Assad, 2008). Thus, it seems that though the value hypothesis applies to OFC, the number hypothesis applies to the IPS.

Our results from RSA suggest that both numeric magnitude on IPS and monetary value in OFC are represented in compressive scales. An interesting question that should be explored further is whether the information is first compressed in one area (e.g., OFC uses the already compressed numerical information from IPS when processing monetary rewards) or whether information is compressed in both areas independently. Thus, performing effective connectivity analyses such as dynamic causal modeling (Friston et al., 2003) could provide useful information about the interactions between these brain areas.

Combined with the effects that numeric information have on economic behavior (Furlong \& Opfer, 2009; Peters et al., 2008), the implications of these findings can be far reaching. The fact that simply changing the numerical magnitude of a reward (without altering at all the monetary value) can create these stark effects on the neural valuation network and in particular in IPS - implies that individual differences in IPS should predict differences in decisions that involve monetary information. Therefore, people who suffer dyscalculia or neurological disorders that affect the functionality of parietal cortex (such as Williams or Turner Syndrome) may be at risk for deficits in economic decisionmaking.

For example, Peters and collaborators (2008) found that individual differences in both numeracy and number sense had an impact on the use of numeric information on economic decisions. Activity in IPS in response to monetary value can provide a neural link to this line of research.

Finally, the fact that both numeric magnitude and monetary value are represented in a compressive scale suggests that more attention has to be paid at the way we present monetary information when important decisions have to be made. For example, recent political discussions about deficit reduction deal with extremely large numeric
magnitudes. The compressive scales that we use to represent money imply that it is very likely that decisions made with very large values would not be consistent with the decisions made in an equivalent situation with smaller numeric magnitudes. If monetary values are treated differently when only the numbers used to represent them are different, people might be easily deceived in supporting proposals that go against their own preferences.

# The Funny Thing About Incongruity: A Computational Model of Humor in Puns 

Justine T. Kao ${ }^{1}$ (justinek @ stanford.edu), Roger Levy ${ }^{2}$ (rlevy @ucsd.edu), Noah D. Goodman ${ }^{1}$ (ngoodman@stanford.edu)<br>${ }^{1}$ Department of Psychology, Stanford University. ${ }^{2}$ Department of Linguistics, UC San Diego.

Abstract<br>Researchers showed the robot ten puns, hoping that one of them would make it laugh. Unfortunately, no pun in ten did.

#### Abstract

What makes something funny? Humor theorists posit that incongruity-perceiving a situation from different viewpoints and finding the resulting interpretations to be incompatiblecontributes to sensations of mirth. In this paper, we use a computational model of sentence comprehension to formalize incongruity and test its relationship to humor in puns. By combining a noisy channel model of language comprehension and standard information theoretic measures, we derive two dimensions of incongruity-ambiguity of meaning and distinctiveness of viewpoints-and use them to predict humans' judgments of funniness. Results showed that both ambiguity and distinctiveness are significant predictors of humor. Additionally, our model automatically identifies specific features of a pun that make it amusing. We thus show how a probabilistic model of sentence comprehension can help explain essential features of the complex phenomenon of linguistic humor.

Keywords: Humor; language understanding; probabilistic models

## Introduction

Humor plays an essential role in human interactions: it has important positive effects on children's development (Frank \& McGhee, 1989), success in the work place (Duncan et al. 1990), coping with illness and traumatic events (Gelkopf \& Kreitler, 1996), and marital satisfaction (Ziv \& Gadish, 1989). Indeed, in a study on gender differences in desired characteristics of relationship partners, both men and women rated sense of humor as more important than physical attractiveness and earning potential (Stewart et al., 2000). In this paper, we are interested in understanding how this fundamental and ubiquitous phenomenon works from the perspective of cognitive science. What makes something funny? How might defining characteristics of humor shed light on the ways in which the mind processes and evaluates information?

A leading theory of humor posits that incongruityperceiving a situation from different viewpoints and finding the resulting interpretations to be incompatible-contributes to sensations of mirth (Veale, 2004, Forabosco, 1992, Martin, 2007; Hurley et al., 2011; an idea that dates to Kant's theories about laughter and the sublime (Veatch, 1998). Although there is disagreement about whether incongruity alone is sufficient, most theorists accept that incongruity is necessary for producing humor: as Veale (2004) states, "Of the few sweeping generalizations one can make about humor that are neither controversial or trivially false, one is surely that humor is a phenomenon that relies on incongruity." However, definitions of incongruity are often ambiguous and difficult to operationalize in empirical research. In this paper, we use a computational model of language understanding to formalize a notion of incongruity and test its relationship to humor.

Language understanding in general, and particularly humor, relies on rich commonsense knowledge and discourse understanding. To somewhat limit the scope of our task, we focus on applying formalizations of incongruity to a subset of linguistic humor: puns. Writer and philosopher Henri Bergson defined a pun as "a sentence or utterance in which two ideas are expressed, and we are confronted with only one series of words." This highlights the fact that one sentence must evoke two different interpretations in order to be a pun, which aligns with the concept of incongruity as a requisite of humor.

We develop our model on homophone puns-puns containing words that sound identical to other words in the English language-because the space of possible interpretations of a homophone pun is relatively constrained and well-defined. An example helps to illustrate:

## "The magician got so mad he pulled his hare out."

This sentence allows for two interpretations:
(a) The magician got so mad he performed the trick of pulling a rabbit out of his hat.
(b) The magician got so mad he (idiomatically) pulled out the hair on his head.

If the comprehender interprets the word "hare" as itself, he will arrive at interpretation (a); if he interprets the word as its homophone "hair," he will arrive at interpretation (b). The sentence-level differences between interpretations (a) and (b) can thus be approximated by the two interpretations of the observed word "hare." In general, distinct interpretations of a homophone pun hinges on one phonetically ambiguous word, allowing the two lexical forms of the homophone word to stand in for competing interpretations of the entire sentence.

Critically, even though the example we gave was a written pun and the reader sees the word "hare" explicitly on the page, the "hair" interpretation is still present and even salient in the context of the sentence. Here we explore the idea that puns such as these arise and are funny when they are due to noisy-channel processing. Noisy channel models of sentence processing posit that language comprehension is a rational process that incorporates uncertainty about surface input to arrive at sentence-level interpretations that are globally coherent (Levy, 2008; Levy et al., 2009). Comprehenders can thus consider multiple word-level interpretations ("viewpoints") to arrive at more than one interpretation of a sentence, each coherent but potentially incongruous with each other. The notion of incongruity thus fits naturally into a noisy channel model of sentence comprehension.

Our purposes for developing a formal model of linguistic humor are two-fold. First, we wish to formalize the concept
of incongruity and test assumptions adopted by leading theories in humor research. Secondly, we aim to show that a noisy channel of language processing allows for flexible context selection and sentence comprehension that gives rise to sophisticated linguistic and social meaning such as humor.

## Model

Incongruity is a property of the interpretations derived from a sentence. In order to formalize incongruity, we first describe a probabilistic model of sentence comprehension. Our model aims to infer the topic of a sentence (a coarse representation of its meaning) from the observed words. Unlike previous such models, however, we take a noisy channel approach, assuming that the comprehender maintains uncertainty over which words reflect the sentence topic and which are noise. From this model we derive two quantities that may contribute to humor: ambiguity and distinctiveness. Intuitively, if the resulting interpretation is unambiguous, then no incongruity exists and the sentence is unlikely to be funny. However, since many ambiguous sentences are not funny (e.g. "I went to the bank"), ambiguity alone is insufficient. This is because the interpretations of such sentences are not supported by distinct topical subsets of the sentence (or "viewpoints"). In other words, there must be a set of words in the sentence that support one interpretation and a set that supports the other, and these two sets must be different or "distinct" from each other in order to evoke a sense of incongruity.

Assume our sentence is composed of a vector of content words $\vec{w}=\left\{w_{1}, \ldots, w_{i}, h, w_{i+1}, \ldots, w_{n}\right\}$, including a phonetically ambiguous word $h$. We will use a simple generative model for $\vec{w}$ (see Figure 1): given the latent sentence topic $m$, each word is generated independently by first deciding if it reflects the topic (the indicator variable $f_{i}$ ). If so it is sampled based on semantic relevance to $m$; if not it is sampled from a fixed unigram prior over words. We thus view the sentence as a mixture of topical and non-topical words. Similar approaches have been used in generative models of language to account for words that provide non-semantic information, such as topic models that incorporate syntax (Griffiths et al. 2005). Our model is motivated by the important role that semantic priming plays in lexical disambiguation during sentence processing (Seidenberg et al. 1982; Burke \& Yee, 1984); while ignoring the other non-semantic factors of interpretation (which may also be important).

We make the simplifying assumption that the plausible candidate topics $m$ of the sentence correspond to the potential interpretations of the homophone word $h$, which are constrained by phonetic similarity to two alternatives, $m_{1}$ and $m_{2}$. For example, in the magician pun described above, $h$ is the phonetically ambiguous target word "hare," and $m_{1}$ and $m_{2}$ are the candidate interpretations hare and hair. The two potential topics of the sentence can be identified by the two interpretations hare and hair. This assumption reduces the ill-defined space of sentence meanings to the simple proxy of alternate spellings for phonetically ambiguous words.

Figure 1: Generative model of a sentence. Each word $w_{i}$ is generated based on the sentence topic $m$ if the indicator variable $f_{i}$ puts it in semantic focus; otherwise it is generated as noise (from a unigram distribution).

Using the above generative model, we can infer the joint probability distribution $P(m, \vec{f} \mid \vec{w})$ of the sentence topic $m$ and the indicator variables $\vec{f}$ that determine whether each word is in semantic focus. This distribution can be factorized into:

$$
\begin{equation*}
P(m, \vec{f} \mid \vec{w})=P(m \mid \vec{w}) P(\vec{f} \mid m, \vec{w}) \tag{1}
\end{equation*}
$$

The two terms on the right-hand side are the basis for our derivations of measures for ambiguity and distinctiveness respectively. Ambiguity means the presence of two similarly likely interpretations and can be quantified as a summary of the distribution $P(m \mid \vec{w})$. Distinctiveness measures the degree to which two interpretations are supported by "distinct" viewpoints of the sentence, which we represent as the divergence between sets of words that are in semantic focus given the two values of $m$; it can be quantified as a summary of the distribution $P(\vec{f} \mid m, \vec{w})$. Together, these two measures constitute our formalization of incongruity.

Ambiguity Let $M$ denote the distribution $P(m \mid \vec{w})$, a binomial distribution over the two meaning values $m_{1}$ and $m_{2}$ given the observed words. If the entropy of this distribution is low, this means that the probability mass is concentrated on only one meaning, and the alternative meaning is unlikely given the observed words. If entropy is high, this means that the probability mass is more evenly distributed among $m_{1}$ and $m_{1}$, and the two interpretations are similarly likely given the contexts. The entropy of $P(m \mid \vec{w})$ is thus a natural measure of the degree of ambiguity present in a sentence. We compute $P(m \mid \vec{w})$ as follows:

$$
\begin{align*}
P(m \mid \vec{w}) & =\sum_{\vec{f}} P(m, \vec{f} \mid \vec{w})  \tag{2}\\
& \propto \sum_{\vec{f}} P(\vec{w} \mid m, \vec{f}) P(m) P(\vec{f})  \tag{3}\\
& =\sum_{\vec{f}}\left(P(m) P(\vec{f}) \prod_{i} P\left(w_{i} \mid m, f_{i}\right)\right) \tag{4}
\end{align*}
$$

We approximate $P(m)$ as the unigram frequency of the words that represent $m$. For example, $P(m=$ hare $)$ is approximated
as $P(m=$ "hare"). We also assume a uniform probability that each words is in focus-hence $P(\vec{f})$ is a constant. As for $P(m \mid \vec{w})$, note that it is driven in part by the semantic relationship between $m$ and $\vec{w}$ and in part by the prior probability of $m$, which we approximate using the unigram probability of the words $m_{1}$ and $m_{2}$. From the generative model,

$$
P\left(w_{i} \mid m, f_{i}\right)= \begin{cases}P\left(w_{i}\right), & \text { if } f=0 \\ P\left(w_{i} \mid m\right), & \text { if } f=1\end{cases}
$$

Once we derive $P(m \mid \vec{w})$, we then compute its entropy as a measure of ambiguity.

Distinctiveness We next turn to the distribution over focus sets, given sentence topic. This may be computed as follows:

$$
\begin{equation*}
P(\vec{f} \mid m, \vec{w}) \propto P(\vec{w} \mid m, \vec{f}) P(\vec{f} \mid m) \tag{5}
\end{equation*}
$$

Since $\vec{f}$ and $m$ are independent, $P(\vec{f} \mid m)=P(\vec{f})$.
Let $F_{1}$ denote the distribution $P\left(f \mid m_{1}, \vec{w}\right)$ and $F_{2}$ denote the distribution $P\left(f \mid m_{2}, \vec{w}\right) . F_{1}$ and $F_{2}$ represent the distributions over semantic focus sets assuming the sentence topic $m_{1}$ and $m_{2}$, respectively. We use a symmetrized Kullback-Leibler divergence score $D_{K L}\left(F_{1} \| F_{2}\right)+D_{K L}\left(F_{2} \| F_{1}\right)$ to measure the distance between $F_{1}$ and $F_{2}$. This score measures how "distinct" the semantic focus sets are given $m_{1}$ and $m_{2}$. A low KL score would indicate that meanings $m_{1}$ and $m_{2}$ are supported by similar subsets of the sentence; a high KL score would indicate that $m_{1}$ and $m_{2}$ are supported by distinct subsets of the sentence.

## Evaluation

By generating a large corpus of sentences involving the same words and measuring subjective funniness of each sentence we can evaluate the contribution of each of our quantitative measures, ambiguity and distinctiveness, to humor. We evaluate our model and measures on a set of 235 sentences, consisting of 65 puns, 40 "de-punned" control sentences that are matched with a subset of the puns, and 130 non-pun control sentences that match the puns in containing the same phonetically ambiguous words.

## Materials

We selected 40 pun sentences from a large collection of puns on a website called Pun of the Day, which contains over one thousand puns. Puns were selected such that the ambiguous item is a single phonetically ambiguous word, and no two puns in the collection have the same ambiguous item. To obtain more homophone pun items, a research assistant generated an additional 25 pun sentences based on a separate list of homophone words.

We constructed 40 sentences to be minimally different from the pun sentences that we collected from "Pun of the Day," which we will call de-punned sentences. A second research assistant who was blind to the hypothesis was asked to replace one word in each of the pun sentences (without
changing the homophone word itself) so that the sentence is still grammatical but is no longer a pun. This resulted in sentences that differed from the pun sentences by one word each.

The 130 non-pun sentences were chosen to match each pun sentence on its ambiguous word as well as the alternative homophone. The sentences were taken from an online version of Heinle's Newbury House Dictionary of American English (http://nhd.heinle.com/). We selected sample sentences included in the definition of the homophone word. This design ensured that puns, de-punned, and non-pun sentences all contain the same set of phonetically ambiguous words. Table 1 shows example sentences from each category.

| Type | Example |
| :--- | :--- |
| Pun | The magician got so mad he pulled his hare out. |
| De-pun | The professor got so mad he pulled his hare out. |
| Non-pun | The hare ran rapidly across the field. |
| Non-pun | Some people have lots of hair on their heads. |

Table 1: Example sentences from each category

## Human ratings of semantic relatedness

As described in the model section, computing our measures requires the prior probabilities of meanings $P(m)$ (approximated as the unigram probabilities of the words that denote the meanings), the prior probabilities of words $P(w)$, and the conditional probabilities of each word in the sentence given a meaning $P(w \mid m)$. While we computed $P(w)$ and $P(m)$ directly from the Google Web unigram corpus, $P(w \mid m)$ is difficult to obtain through traditional topic models trained on corpora due to data sparsity. However, since each meaning we consider has a single word as proxy, we may approximate $P(w \mid m)$ using an empirical measure of the semantic relatedness between $w$ and $m$, denoted $R(c, m)$. We use $R(c, m)$ as a proxy for point wise mutual information between $c$ and $m$, defined as follows:
$R(w, m)=\log \frac{P(w, m)}{P(w) P(m)}=\log \frac{P(w \mid m)}{P(w)}=\log P(w \mid m)-\log P(w)$
We assume that human ratings of relatedness between two words $R^{\prime}(w, m)$ approximate true relatedness up to an additive constant $z$. With the proper substitutions and transformations,

$$
\begin{equation*}
P(w \mid m)=e^{R^{\prime}(w, m)+z} P(w) \tag{6}
\end{equation*}
$$

To obtain $R^{\prime}(w, m)$ for each of the words $w$ in the stimuli sentences, we recruited 200 subjects on Amazon's Mechanical Turk to rate distinct word pairs on their semantic relatedness. Since it is difficult to obtain the relatedness rating of a word with itself, we used a free parameter $r$ and fit it to data. Function words were removed from each of the sentences in our dataset, and the remaining words were paired with each of the interpretations of the homophone sequence (e.g., for the pun in Figure 1, "magician" and "hare" is a legitimate word pair, as well as "magician" and "hair"). This resulted in 1460

Figure 2: (a) In the example pun (top), two candidate meanings of $h$ are each more related to a subset of the content words. In the non-pun, only one candidate meaning is more related. (b) Content words are similarly related to both candidate meanings in puns; more related to alternative meanings in de-puns; more related to observed meanings in non-pun. (c) Funniness varies across the sentence types in a pattern that reflects the balance of relatedness to candidate meanings shown in (b).
distinct word pairs. Each subject saw 146 pairs of words in random order and were asked to rate how related each word pair is using a scale from 1 to 10 . The average split-half correlation of the relatedness ratings was 0.916 , indicating that semantic relatedness was a reliable measure.

Figure 2 a) shows the relatedness of each content word with the two homophone interpretations for two example sentences. In the top sentence, which is a pun, the word "magician" is rated as significantly more related to "hare" than it is to "hair", while the word "pulled" is rated as significantly more related to "hair" than it is to "hare." In the bottom sentence, which is a non-pun, all words except the neutral word "through" are more related to the word "hare" than to "hair."

Figure 2b) shows the average relatedness ratings of words and the two homophone interpretations across the three types of sentences. In pun sentences, the average relatedness of words to the two homophone interpretations are not significantly different. In the de-punned sentences, the average relatedness of words to the alternative meaning is significantly higher than to the observed meaning. In the non-pun sentences, the average relatedness of words to the observed meaning is significantly higher than to the alternative meaning. These analyses suggest that relatedness ratings for the two candidate meanings capture the presence or absence of multiple interpretations in a sentence. It further supports our model's prediction that ambiguity of meaning and the distinctiveness of supporting context words can help distinguish among the three types of sentences.

## Human Ratings of Funniness

We obtained funniness ratings of the 235 sentences from 100 subjects on Amazon's Mechanical Turk. Each subject read roughly 60 sentences in random order, counterbalanced

|  | Estimate | Std. Error | p value |
| :--- | ---: | ---: | :--- |
| Intercept | -0.699 | 0.180 | $<0.0001$ |
| Ambiguity | 1.338 | 0.245 | $<0.0001$ |
| Distinctiveness | 0.183 | 0.053 | $<0.0001$ |

Table 2: Regression coefficients using ambiguity and distinctiveness to predict funniness ratings
for the sentence types, and rated each sentence on funniness and correctness. The average split-half correlation of funniness ratings was 0.83 . Figure 2 (c) shows the average funniness ratings of puns, de-punned, and non-pun sentences. Pun sentences are rated as significantly funnier than de-punned sentences, and de-punned sentences are rated as significantly funnier than non-pun sentences $(F(2,232)=$ 415.3, $p<0.0001$ ). Figure 2 (b) and Figure 2 (c) together suggest that the balance of relatedness between the two interpretations is a predictor of funniness.

## Results

Following the derivations described in the model section and using the relatedness measures described above, we computed an ambiguity and distinctiveness value for each of the 235 sentences. Our model has two free parameters-the additive constant $z$ in equation (6) and the constant $r$ that indicates the relatedness of a word with itself -which we optimized using $R^{2}$ in the linear regression summarized in Table 2 As predicted, ambiguity differs significantly across sentence types $(F(2,232)=25.42, p<0.0001)$ and correlates significantly with human ratings of funniness across the 235 sentences ( $r=0.33, p<0.0001$ ). Furthermore, distinctiveness scores differ significantly across sentence types as well $(F(2,232)=5.76, p<0.005)$ and correlates signifi-

| $m 1$ | $m 2$ | Type | Sentence and Semantic Focus Sets | Amb. | Disj. | Funniness |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| hare | hair | Pun | The magician got so mad he pulled his hare | 0.570 | 3.405 | 1.714 |
|  |  | De-pun | The professor got so mad he pulled his hare out. | 0.575 | 2.698 | 0.328 |
|  |  | Non-pun | The hare ran rapidly through the fields. | 0.055 | 2.791 | -0.400 |
|  |  | Non-pun | Most people have lots of hair on their heads. | $2.76 E^{-5}$ | 3.920 | -0.343 |

Table 3: Semantic focus sets, ambiguity/disjointedness scores, and funniness ratings for two groups of sentences. Words in red are in semantic focus with $m_{1}$; green with $m_{2}$; blue with both. Semantic focus sets for all sentences can be found at http://www.stanford.edu/~justinek/Pun/focusSets.html

Figure 3: Standard error ellipses of ambiguity and distinctiveness across sentence types. Puns score higher on ambiguity and distinctiveness; de-puns are less supported by distinct focus sets; non-puns have low ambiguity.
cantly with human ratings of funniness ( $r=0.21, p<0.005$ ).
A linear regression showed that both ambiguity and distinctiveness are significant predictors of funniness. Together, the two predictors capture a modest but significant amount of the variance in funniness ratings $\left(F(2,232)=20.86, R^{2}=\right.$ $0.145, p<0.001$; see Table 27. Using both ambiguity and distinctiveness as dimensions that formalize incongruity, we can distinguish among puns, non-puns, and de-punned sentences, as shown in Figure 3 Figure 3 shows the standard error ellipses for each of the three sentence types in the two-dimensional space of ambiguity and distinctiveness. Although there is a fair amount of noise in the predictors (likely due to simplifying assumptions, the need to use empirical measures of relatedness, and the inherent complexity of humor) we see that pun sentences tend to cluster at a space with higher ambiguity and distinctiveness. While de-punned sentences are also high on ambiguity (e.g. it is ambiguous whether the word "hare" in "The professor got so mad he pulled his hare out" should be interpreted as hair), they tend to have lower distinctiveness measures. Non-puns score the

Figure 4: Funniness contours smoothed using a 2-D Loess regression with ambiguity and disjointedness measures as predictors. Sentences become funnier as they move to high ambiguity and distinctiveness space.
lowest on ambiguity with moderate distinctiveness measures.
Figure 4 shows the funniness contours in the twodimensional ambiguity-distinctiveness space smoothed using a 2-D Loess regression. Not only do the three types of sentences differ along the two dimensions, but sentences become funnier as they increase in ambiguity and distinctiveness. These results suggest that our measures of incongruity capture an important aspect of humor in pun sentences.

Beyond predicting the funniness of a sentence, our model can also tell us which particular features of a pun make it amusing. By finding the most likely semantic focus sets $\vec{f}$ given each latent meaning variable $m$ and the observed words, we can identify words in a funny sentence that are critical to producing incongruity and humor. Table 3 shows the most likely semantic focus sets given each meaning for two groups of sentences. Sentences in each group contain the same pair of candidate meanings for the target word $h$. However, they differ in measures of ambiguity, distinctiveness, and funniness. Words in the most likely focus sets given $m_{1}$ are in red; words in the most likely focus sets given $m_{2}$ are in green; and
words in the most likely focus sets of both meanings are in dark blue. We observe that visually, the two pun sentences (which are significantly funnier) have more distinctive and balanced sets of focus words for each meaning than other sentences in their groups. De-punned sentences tend to have fewer words in support of $m_{1}$, and non-pun sentences tend to have no words in support of the interpretation that was not observed. Moreover, imagine if you were asked to explain why the two pun sentences are funny. The colorful words in each pun sentence-for example, the fact that magicians tend to perform magic tricks with hares, and people tend to be described as pulling out their hair when angry-are what one might intuitively use to explain why the sentence is a pun. Our model thus provides a natural way of not only formalizing incongruity and using it to predict when a sentence is a pun, but also to explain what aspects of a pun make it funny.

## Discussion

Researchers in artificial intelligence have argued that given the importance of humor in human communication, computers need to generate and detect humor in order to interact with humans more effectively (Mihalcea \& Strapparava, 2006). However, most work in computational humor has focused either on joke-specific templates and schemata (Binsted, 1996; Kiddon \& Brun, 2011) or surface linguistic features that predict humorous intent (Mihalcea \& Strapparava, 2006, Reyes et al., 2010). Our work moves beyond these approaches and directly utilizes a model of sentence comprehension to derive theory-driven measures of humor.

While the measures we developed account for a significant amount of variance in funniness ratings, there are several ways to improve our model of language in order to more accurately capture the subtleties of linguistic humor. By making the simplifying assumption that semantic association drives sentence comprehension, we disregarded the sequential structure of language that is often important for understanding a pun. For example, "The actors had one great movie after another. They were on a role." scores high on funniness but low on our measures because it leverages the idiomatic expression "on a roll" to boost the interpretation roll. Since our bag-ofwords model does not account for word sequences, the measures we derive fail to fully capture the incongruity of many pun sentences that contain idiomatic expressions. In future work, we aim to incorporate information about the sequential structure of a sentence to further improve our language model and measures of incongruity.

In this paper, we showed how a basic model of sentence comprehension can illuminate incongruous sentence interpretations with rich social and linguistic meaning. Although our task in this paper is limited in scope, we believe that it represents a step towards developing models of language that can explain complex phenomena such as humor. From the perspective of language understanding, such phenomena can serve as probes for developing models of language that account for the subtleties of linguistic behavior. We hope that
our work contributes to research in humor theory, computational humor, and language understanding, with the aim to one day understand what makes us laugh and build robots that appreciate the wonders of word play.

#### Abstract

Mimicry and imitation are crucial mechanisms of social learning and rapport. Further, mimicry informs essential social judgments formed not only by the interacting party but also by third-party observers. How sophisticated are observer's inferences from mimicry? We examined this in the context of observers' use of mimicry to judge trustworthiness. Participants observed a dyadic interaction in which a target mimicked or did not mimic a model. Prior to observation, the model's honesty was earlier defamed, or praised, in front of some, but not other, targets. Observers always knew the model's reputation. Observers also knew which targets were aware of the model's reputation. Results suggest that observers' use of mimicry in trust judgments is very sophisticated It reflects not just the presence of mimicry, but also the model's moral reputation and, critically, knowledge of the target's awareness of the model's reputation. This sophistication leads observers to rate targets as trustworthy when they mimic untrustworthy models, but only when the observers know that the model reputation is unknown to the target.

Keywords: Mimicry; Imitation; Inference, Social Judgment; Trust

## Introduction

Mimicry is an essential part of the human social repertoire that is inexorably bound up to basic social processes of empathy, bonding, and in-group formation (Churchland, 2011; Kashima, 2008; Lakin \& Chartrand, 2003; Lakin, Jefferis, Cheng, \& Chartrand 2003; Preston \& De Waal, 2002). We have greater rapport with those who mimic us
(Bernieri 1998), and are more prosocial after being mimicked (Lakin, Jefferis, Cheng, \& Chartrand, 2003). Interestingly, many of these effects occur without participants' consciousness of mimicry (Chartrand \& Bargh, 1999).

To date, the mimicry literature has focused on the interacting dyad (for a review, see Chartrand \& van Baaren, 2009). However, the social context of mimicry often includes many interacting parties. Here, human observers can use information about who mimics whom to make social judgments. This was shown in a recent series of experiments by Kavanagh, Suhler, Churchland, and Winkielman (2011). Participants (observers) viewed videos of one-on-one interviews, and evaluated the interviewee's competence. In some videos the interviewee mimicked the interviewer's gestures (leg crossing, chin-rubbing) and in the other videos the interviewee did not mimic. Additionally, the attitude of the interviewer towards the interviewee was manipulated: in some videos, the interviewers were cordial to the interviewee and in others they were condescending to the interviewee.

The results showed that the impact of mimicry on the observers' (participants') judgments of interviewees' competence depended on whom the interviewee mimicked. When the interviewer was rude to the interviewee, mimicking interviewees were rated as significantly less competent than non-mimicking interviewees. When the interviewer was cordial to the interviewee, mimicking
interviewees were rated as non-significantly more competent. Finally, when the interviewer was cropped out of the videos, thus preventing participants from noticing synchronous movements, all of the above effects disappeared. Despite these effects, participants showed a lack of conscious awareness of mimicry in debriefings.

Thus mimicry, when done in the wrong context, can negatively affect observers' judgments of our competence. But this research leaves open two important questions, which will addressed presently.

## How Complex are Inferences From Mimicry?

The above-discussed judgments by observers can be seen as relatively "sophisticated", as they took the attitude of the model (interviewer) towards the mimic (interviewee) into account. Observers clearly did not simply equate mimicry with competence. This seems to show that information gleaned from mimicry is integrated with broader social information in a subtle manner.
However, an alternative "non-intelligent" interpretation of these findings is that gestural mimicry simply enhances the perceived similarity between the interacting parties. As a result, negative attributes of the model (e.g., rudeness or cordiality) "rubbed off" on the mimic but not on the nonmimic. This can be explained as a relatively simple associationist inference that a target person who behaves like the model probably shares further traits with the model (Andersen, Moskowitz, Blair \& Nosek, 2007), or as a reflection of observers' belief that mimicry functions as a means of enhancing perceived similarity (Over \& Carpenter, 2012).

On the other hand, much research argues that mimicry itself is a complex, and even intelligent, process. Mimicry generation (despite its unconscious origins) depends on the context and social relationship between the mimicker and the model. People reduce their mimicry or even engage in anti-mimicry when interacting with a partner who is disliked, represents an out-group, or has different goals (Bourgeois \& Hess, 2008; Likowski, Muehlberger, Seibt, Pauli, \& Weyers, 2008; McIntosh, 2006; Stel et al., 2010). It would thus seem maladaptive for perceivers to interpret mimicry in a context-free manner.

## Mimicry, competence, and trust

It is also interesting and important to understand whether perception of traits other than competence can be influenced by perceived mimicry. Competence is one of the two main dimensions of social judgment (Judd et al., 1995). The other dimension is trust, which is critical to group cohesion, relationships, and most social transactions. Indeed, mimicry is posited to be part of the process of developing empathy and interpersonal trust (Bavelas, Black, Lemery, \& Mullett, 1987), and been called "social glue" (Lakin \& Chartrand, 2003). Thus, the connection between mimicry and trust is of obvious interest.

The link between mimicry and trust is particularly important in situations where an observer watches an interaction involving a person with a persuasive agenda. It has been shown, for example, that children imitate others more when they are attempting to persuade them to do unpleasant things, such as eat unappetizing foodstuffs, rather than enjoyable things (Thelen, Miller, Fehrenbach, Frautschi, \& Fishbein, 1980). Mimicry has also been shown to be an effective technique in adult negotiations (Maddux, Mullen, \& Galinsky, 2008). In short, it is important, and also novel, to explore how mimicry influences third-party inferences about trust.

## Present Study

The goals of the present study were twofold. First we examined whether third-party judgments about mimicry result from a simple assumption of trait similarity between similarly behaving individuals (i.e., the transference or "rub off" effect described above), or whether they instead reflect more nuanced social inferences. In particular, we tested whether observers' inferences about the target's trustworthiness reflected not only the presence/absence of mimicry between the target and the model, and the model's past trust-relevant behavior, but also, critically, the observer's knowledge of the target's epistemic state with regard to the model's past behavior. If mimicry inferences are indeed complex, observers should be sensitive to whether the mimicker "knows" about the model's reputation-related behavior. This is not unlike sensitivity that observers, even relatively young children, show to the epistemic state of an actor in "theory-of-mind" tests (Premack \& Premack, 1995).
Secondly, we explicitly attempt to show that mimicry can influence third-party observers' impressions of the trustworthiness of dyad members. We do this by directly influencing participants' impressions of the trustworthiness of one of the dyad members (the interviewer), and then testing whether mimicry (and the mimic's epistemic state) moderates the extent to which this reputation carries over to the other member (the interviewee).
The current paradigm was based on the previous work on third-party observation (Kavanagh et al. 2011), with some important changes. Participants again observed interviews and made social judgments about interviewees. Interviewees either mimicked or did not mimic their interviewer (model). Additionally, in the current study, participants also had to play an economic "trust" game (Berg, Dickhaut, \& McCabe, 1995) with interviewees.

Critically, in the current study, the interviewer exhibited the same neutral behavior in all videos - that is, she was not directly cordial or directly rude to the target, as in Kavanagh et al. (2011). Rather, subjects' perceptions of the interviewer were manipulated by an experimental confederate (also posing as a subject) who relayed a story. The interviewer was depicted as trustworthy to half of subjects, and as untrustworthy to the other half.

Participants' understanding of whether they and the interviewees had common knowledge of the interviewer was also manipulated. We did this by having some of the interviewees be present as "subjects" in the waiting room, along with the actual participant. There they also heard either the praising or defamatory story about the interviewer. Other interviewees were not among the subjects in the waiting room. Thus, the observers knew that some interviewees, having heard the story, were aware of the interviewer's high/low trustworthiness, but that other interviewees, having not heard the story, were not aware of the interviewer's high/low trustworthiness.
This step was motivated by the moral psychology literature, as well as philosophical and legal perspectives on responsibility more broadly, which suggest that observers take into account an agent's mental states (e.g., intent, deliberation, knowledge) when determining culpability for right/wrong actions (Suhler \& Churchland, 2009). Importantly, it seems that such considerations are relatively automatic (Young \& Saxe, 2009).
The current paradigm allows for a test of the sophisticated inference hypothesis of mimicry. If mimicry (similar movements) simply leads dyad members to be seen as similar, then observers should judge interviewees mimicking the trustworthy interviewer more favorably than interviewees mimicking the untrustworthy interviewer, regardless of the interviewee's state of knowledge about the interviewer's trustworthiness/untrustworthiness. However, the sophisticated inference account generates a more nuanced set of predictions in the context of trust-related situations.
The most straightforward prediction is that mimicking a trustworthy interviewer should benefit interviewees who are personally knowledgeable about his or her trustworthiness. This prediction should be offered with the caveat that work within the dyad has shown that some level of mimicry is expected in a normal face-to-face interaction (Dalton, Chartrand, \& Finkel, 2010) and so it may be that very strong mimicry would be required in order to "make a positive impression" on the viewer.

Figure 1: Experimental Conditions

The second and perhaps more interesting prediction is that mimicking an untrustworthy interviewer may benefit interviewees who are not knowledgeable about his or her misdeeds. After all, for the observer, when an innocent mimics an undesirable individual (i.e., shows affiliative behavior toward an undeserving party), the mimic should be seen as a particularly trusting (or naïve) and prosocial individual. All this should result a three-way interaction between mimicry (present/absent), trustworthiness (positive/negative), and knowledge (present/absent).

## Method

Participants and Procedure. 123 UCSD undergraduates participated for class credit. Upon arrival in the lab, subjects were greeted by the experimenter, who consulted a list and then told them that they would be in the rater condition and placed in a waiting room marked "rater condition." Another waiting room, clearly visible, was marked "interviewer condition" (this language was chosen to minimize ingroup effects by emphasizing situational assignment to the interviewee role). See Figure 1 for timeline (panel A) and spatial schematic (panel B). Several minutes before the supposed experimental start time, the confederate (henceforth "the gossip") who would be used to manipulate opinions about the trustworthiness of the interviewer was brought to the waiting room posing as another subject. Two other confederate "subjects" (confederate interviewees), who would eventually be transferred to the interviewee condition, entered the room one at a time right around the supposed experimental start time. This made their entrance (i) noticeable by subjects and (ii) minimized their chances of being engaged in conversation by subjects. After the last confederate arrived, the experimenter then fetched another confederate ("the interviewer"), introduced her to the subjects, and while the interviewer stood on, told the subjects (accurately) that they would see four interviews and then would play with the interviewees an economic game in which the trustworthiness of one's partner would be crucial to success. Subjects were also (deceptively) told that interviews would take place live in the interview room and that the video would be broadcast to computer screens in the rating rooms via the local intranet. After all these instructions, the experimenter left to take the interviewer to the interview room.

While the interviewer was gone, "the gossip" loudly told a story meant to either erode or build the participants' trust in the interviewer. In the praise condition the gossip recounted that the interviewer had driven to his home to return a lost wallet intact. In the defamation condition, participants were told that the interviewer was a friends' roommate who avoided paying all bills and shunned any communication.

After sufficient time, the interviewer returned and said that the experiment was ready to start but that two "subjects" currently in the rater condition would need to be transferred to the interviewee condition. The confederate interviewees were chosen for transfer and taken to the
interview room, while subjects and the gossip were escorted to small rooms equipped with a computer.

The computer portion of the experiment (see Figure 1, right panel) consisted of viewing and responding to 4 videos of interviews with 4 interviewees, all of whom were paired with the confederate interviewer. At the start of the computer portion, participants also viewed a detailed explanation of the Trust Game (see below). To back up the experimenter's cover story that the videos were in fact live, a screen of variable duration saying simply "waiting for live feed" in slowly flashing text was added to each video. Each subject now saw two interviewees (knowledgeable interviewees) who had heard the same story that they did, and two that did not (non-knowledgeable interviewees). Within each of these knowledge conditions, videos were arranged so that one member mimicked the interviewer and one did not. Mimicry was implemented as is standard in the literature, with neutral gestures (e.g., chin rubbing and leg-crossing) and no differences between verbal or meaningful nonverbal content.

Participants provided Likert scale (7-point) ratings for each interviewee on trustworthiness. As a behavioral measure, subjects also indicated how much money (from \$0 to 10) they would entrust with the target in the investor game (Berg et al., 1995). In this game, the participant is endowed with $\$ 10$ and can transfer some amount of this endowment to the target. This money is then tripled, and a partner could (if scrupulous) then return some money back to the participant. Participants also rated targets on control dimensions of competence, likability, and friendliness. Finally, as a manipulation check, participants also rated the interviewer herself on the same measures. Postexperimental funneled debriefing was also performed to check for conscious awareness of mimicry, belief that videos were live, and skepticism towards the waiting room manipulation (gossip).

Manipulation-Checks Analysis of debriefing questionnaires revealed that 20 participants were suspicious of the waiting room manipulation. A further 6 participants were excluded because they personally knew one of the confederates, and 1 participant was excluded because they noticed mimicry. The final sample thus consisted of 96 participants (59 females and 37 males) who were, on average, 20.23 years old ( $S D=1.58$ ).
We tested how participants perceived the interviewer as function of reputational manipulation (praise/defamation) and as a function of interacting with a mimicking or nonmimicking interviewee. Across all dependent measures, a 2 x 2 MANOVA revealed only a main effect of reputation, with no ME or interactions with mimicry on any measures. Specifically, in the Trust Game probe, participants were willing to give the interviewer more money in the praise condition $[M=4.8$ vs. $3.17, F(1,94)=10.30, p=.002]$. They also rated the interviewer as more trustworthy $[M=5.05 \mathrm{vs}$. 3.67, $F(1,94)=21.5, p<.001]$. In the praise condition, the interviewer was also rated as significantly more likeable
( $F=15$ ), competent ( $F=5.1$ ), and marginally more friendly ( $F=3.8$ ), all $p s<.05$. However, of the 4 ratings, the trust rating was particularly strongly influenced, as reflected in the 2-way interaction of reputation by rating type, $[F(3,94)$ $=5.9, p=.01]$. In short, our manipulation was very successful in changing the perception of the interviewer (model), with the effects particularly pronounced on the trust-related dimensions.

## Results

As described above, the "sophisticated inferences from mimicry" hypothesis predicts that evaluations made by third-party observers should vary as a function of the reputation of the model, presence or absence of mimicry by the target (interviewee), and the observer's knowledge about whether the target is aware of the reputation of the model (interviewer). Our central prediction was the observers would take the target's epistemic state into account. This should lead to the inferences that are more than simply a function of the goodness/badness of the model, as predicted by an associationist/rub-off account.

Because our reputational manipulation (praising vs. defamatory story) targeted the model's trustworthiness, we chose trustworthiness ratings, and monetary investment as our critical DVs. We analyzed these variables as a function of reputation (praise/defamation), knowledge (informed/ignorant), and mimicry (presence/absence), using a 3-way, mixed-models MANOVA.

We first focused on the trustworthiness rating (Figure 2) There were no significant main effects or interactions in the knowledgeable condition (all Fs < 1). Critically, in the ignorant condition, we found a 2-way interaction of reputation and mimicry $[F(1,93)=5.87, p=.02$. Simple effects (two-tailed) showed that ignorant participants who mimicked bad (untrustworthy) models were perceived as mo

re trustworthy than participants who did not mimic bad models ( $p<.06$ ), and as more trustworthy than ignorant participants who mimicked good (trustworthy) models ( $p<$ .10). Overall, this pattern resulted in a significant 3-way interaction $[F(1,93)=4.58, p=.03]$. We also found a main effect of knowledge, such that targets who witnessed the reputational manipulation were rated as more trustworthy
than targets who did not $[F(1,93)=11, p<.01]$. This effect (also seen on other ratings, as discussed below) presumably reflects that participants were personally familiar with targets in the knowledge, but not the ignorant, condition.

On the investment measure of trust, we also found a 2way interaction of reputation and mimicry $[F(1,94)=5.41$, $p=.02$ ]. Simple effects (two-tailed) showed that when ignorant participants mimicked bad models, they were perceived as marginally more trustworthy than participants who did not mimic bad models ( $p<.12$ ), and as more trustworthy than ignorant participants who mimicked good models ( $p<.01$ ). There were no significant effects in the "knowledgeable" condition (all Fs < 1). Overall, this pattern resulted in a 3-way interaction $[F(1,94)=3.42$, $p=.07]$. No other main effects or interactions were reliable.

Other ratings. Similar analyses were conducted on other ratings that were not directly related to trust. Analyses revealed a main effect of knowledge, such that "knowledgeable" targets were rated as overall friendlier ( $p<$ .01 ) and more competent than "ignorant" targets ( $p<.05$ ). As mentioned above, this effect may be due to participants' personal familiarity with targets in the knowledge condition (due to having spent time with them in the waiting room). Critically, none of the other ratings showed the 3-way interaction involving mimicry, reputation and knowledge (Fs $<1$ ). This suggests that observers’ inferences were restricted to the relevant trust-related dimensions that were relevant to our praising/defaming story manipulation.

## Discussion

Our central question was whether third-party observers' inferences from mimicry are simple or sophisticated. Thus, we tested whether such inferences take into account not only the presence or absence of mimicry, but also the reputation of the model and the target's knowledge about the model. We examined these third-party inferences of mimicry in the context of morality-related judgments of trust - an important social dimension.
Overall, our results support the idea that inferences made about third-party dyad members on the basis of observed mimicry are nuanced. Specifically, participants' judgments of trustworthiness reflected (i) whether the target mimicked,
(ii) the reputation of the person they mimicked, and also (iii) whether the target was aware of their model's reputation. As such, the results speak against the hypothesis that third party judgments of mimics reflect simple "rub-off", where the mimic is merely assigned traits of the model. More generally, our results suggest that people can integrate their perception of rapport with higher level social information. Critically, this higher level information includes knowledge about the target's epistemic state.
The observed 3-way interaction was largely driven by the fact that ignorant interviewees benefited from mimicking the untrustworthy interviewer. As we suggested earlier, this could reflect observers' perception that mimicry is an affiliative, courteous social behavior, so extending it, unknowingly, to an undeserving party is demonstrating a particularly trusting, perhaps gullible personality disposition. However, we feel this explanation should be tested explicitly in future extensions.
Another question for future research is why knowledgeable targets were not seen as more trustworthy after mimicking a trustworthy model. Targets were also not "blamed" for mimicking a model they knew to be bad. One possibility, consistent with the trust literature is that people do not give moral credit or blame for social courtesy (mimicry) when such courteous behavior is expected (Wojciszke, 2005). As mentioned, past work shows that some level of mimicry is expected in a normal social interaction (Dalton et al., 2003).
Another possibility is that mimicry effects disappeared in the knowledgeable condition because the targets had previously been personally encountered in the "waiting room" portion of the experiment. As mentioned, this brief acquaintance non-specifically enhanced several judgments, including trust, friendliness, and competence. Familiarity may also have caused these targets actions' to be judged in a more "charitable" manner. It may also be related to the fact that people make more situational inferences about acquaintances and more dispositional ones about strangers.
Also noteworthy is that, as expected, there was no decrement in competence ratings when targets mimicked a "defamed" interviewer. We believe this is because, unlike previous work (Kavanagh et al, 2011) interviewers were never directly condescending to the interviewee in this study. This contextualizes previous work, in which interviewees who mimicked to interviewers who condescended directly to them were seen as less competent. This provides further evidence that inferences from mimicry are subtle and situated. Though the full extent and nature of such inferences is not entirely clear, the results are the first to point towards the integration of unconsciously processed embodied signals with epistemic (e.g. Theory of Mind) knowledge.

#### Abstract

How individuals think about opposing or paradoxical categories influences their social relationships. We found that Chinese managers were more likely than US managers to categorize attempts to outperform others as an instance of both competition and cooperation. Further, the Chinese managers were more likely than the US managers to perceive a given working relationship as being both cooperative and competitive. The two findings were linked: culturally-guided beliefs about whether the cooperation-competition paradox should be integrated or kept separate influenced how individuals understood their social relationships. More broadly, the implication is that category membership and relations between categories are guided by cultural influences distinct from the particulars of the categories themselves that normally enter into cognitive science research on categories. In addition, those categorization choices are consequential for the network of social relationships individuals form.

Keywords: Categories; paradox; cooperation; competition; culture; relationships; China.

## Introduction

"[O]ur two countries gain far more when we cooperate with one another than when we descend into an unhealthy competition."

Hillary Clinton, US Secretary of State, Beijing, September 5, 2012, at a joint press conference with Chinese Foreign Minister Yang Jiechi.

Choices to engage in cooperation and competition are fundamental to a wide range of social life, ranging from diplomacy between nations down to working relationships between individuals. Actors form competitive relationships as they seek to maximize their own outcomes and form cooperative relationships as they seek to achieve group goals. Further, most actors, most of the time, have mixed motives-they are concerned with both their individual
outcomes and their group's outcomes. Yet it is not clear whether and why actors might choose to engage in both cooperation and competition.

We will suggest that categories play a key role in the choice to engage in both cooperation and competition. As a result, we raise new issues in the study of culture, categories, and complex social relationships. The specific account that we develop centers on what we term paradoxical categorization, or the classification of a single situation as a member of both of two opposing categories. In our case, the paradoxical categorization of interest is the classification of a situation as both an instance of cooperation and an instance of competition. We show that culture influences whether individuals engage in paradoxical categorization. Then we show that paradoxical categorization predicts whether managers have working relationships that are both cooperative and competitive.

## Paradoxical Cultural Categories

Multiple streams of work are now challenging longstanding assumptions about the relation between cooperation and competition, and they are converging to make the joint use of cooperation and competition an important question. One such longstanding assumption in research on cooperation and competition, also implicit in the quote from Secretary Clinton, is that cooperation and competition are separate. Cooperation and competition have long been defined as mutually exclusive types of relationship (Deutsch, 1949), mutually exclusive types of behavior (Komorita \& Parks, 1996), and mutually exclusive types of motivation (McClintock \& Allison, 1989). However, there are now multiple proposals about why cooperation and competition could be integrated (e.g., Brandenberger \& Nalebuff, 1996; Van de Vliert, 1999), suggesting that cooperation and competition can co-occur.

Another longstanding assumption in research on cooperation and competition (Fulop, 2004), also implicit in
the quote from Secretary Clinton, is that cooperation and competition are the same for everyone. However, it is now clear that, for example, individuals in the United States and China view cooperation differently (Keller \& Loewenstein, 2011), and that individuals in Hungary and Japan view competition differently (Fulop, 2004). There are also strong theoretical arguments suggesting that the relation between cooperation and competition likely differs across cultures (Chen, 2008): Western cultural philosophies (e.g., US, UK, Australia) seem to emphasize the separation of cooperation and competition and East Asian cultural philosophies (e.g., China, Japan, Korea) seem to emphasize the integration of cooperation and competition. Accordingly, culturallyguided beliefs may affect when and why individuals choose to engage in both cooperation and competition.

A third longstanding assumption in research in cooperation and competition (Stanne, Johnson \& Johnson, 1999), but that Secretary Clinton's quote rejects, is that there is only one kind of competition. Instead, there appear to be distinct consequences to healthy or appropriate competition, such as the attempt to outperform others, and unhealthy or zero-sum competition, such as the attempt to sabotage others (Stanne et al., 1999). Different kinds of competition may be differently compatible with cooperation. That is, the overall semantic relation between cooperation and competition may be antonymic (Herrmann, Conti, Peters, Robbins, \& Chaffin, 1979), as noted in both American (Merriam-Webster, 2006) and Chinese (He, 2009) thesauruses. However, even if the categories as a whole are antonyms, it is an open question as to whether the two categories may still overlap and share members.

We generate a new account of the relation between cooperation and competition consistent with the three new possibilities just discussed. Our starting point is to conceptualize cooperation and competition as cultural categories (Atran, Medin \& Ross, 2005; Douglas, 1986; Keller \& Loewenstein, 2011). Through social interactions, people learn the conventions in their culture (Millikan 2005) for categorizing interpersonal situations and relationships as cooperative and as competitive. The question then is why an individual might categorize an item as being both cooperative and competitive. Two influences seem key: beliefs about paradoxes and contradictions, and the type of interpersonal situation.

There is ample evidence that individuals who are members of Chinese culture are more likely than members of American culture to hold dialectical beliefs (SpencerRodgers et al, 2010), meaning they tend to tolerate contradictions, expect change, and seek to integrate paradoxes. One consequence is that Chinese individuals tend to be more likely than American individuals to engage in paradoxical categorization. For example, they are more likely to categorize themselves as both shy and outgoing (Spencer-Rodgers, Boucher, Mori, Wang \& Peng, 2009) and as both happy and sad (Bagozzi, Wong \& Yi, 1999).

These general tendencies should apply to cooperation and competition. To be clear, we are not claiming that a general
tendency towards dialecticism, derived from one's culture, predicts a willingness to believe that any competitive situation is also a cooperative situation, or even more starkly, that Chinese individuals always engage in both cooperation and competition and American individuals never do. Rather, we are suggesting that dialecticism licenses individuals to grant that cooperation and competition could co-occur. Specifically, a general tendency towards dialecticism, derived from one's culture, should predict an individual's willingness to categorize a seemingly contradictory situation with features of both cooperation and competition as being both cooperative and competitive, rather than being forced to pick one or the other.

The key situations with features of both cooperation and competition are acts of healthy competition, such as attempts to outperform another person. If attempts to outperform others are interpreted as efforts to gain higher relative standing (a key feature of competitive behavior, Johnson \& Johnson, 1989), these efforts could be classified as competitive. If attempts to outperform others are also seen as efforts to advance group gains (a key feature of cooperative behavior, Tyler \& Blader, 2000) then they have the potential to be classified not only as competitive but also as cooperative. By contrast, acts of unhealthy competition, such as attempts to sabotage another person, are unlikely to be seen as incorporating any feature of cooperation (they lower group gains; Stanne et al, 1999), but are likely to be seen as competitive (they are efforts to gain higher relative standing). Thus, paradoxical categorization could occur for attempts to outperform others but is unlikely for attempts to sabotage others.

Taken together with the prior point about culture, the full prediction is that because individuals who are members of East Asian cultures are more likely than individuals from Western cultures to hold dialectical beliefs, they should be more likely to generate the paradoxical categorization that attempts to outperform others are acts of both cooperation and competition.

## Paradoxical Social Relationships

Most research on social relationships has described a stark choice between cooperative colleagues giving each other advice versus rivals battling to get ahead (e.g., Burt, 1987). Yet just as researchers examining the same data can radically disagree concerning whether cooperation or competition represents the best explanation of observed patterns (Kilduff \& Oh, 2006), individuals also sometimes struggle to comprehend the meaning of their colleagues' actions. We see people inventing terms like "coopetition" and "frenemies" to account for such complex social relationships.

Individuals are embedded in networks of cooperative working relationships as they collaborate with others. But people are also embedded in networks of competitive relationships as they vie for status and resources (Burt, 1992; Lazega \& Patterson, 1999). Because social relationships are complex (Ingram \& Zou, 2008), an
individual could have relationships that are both cooperative and competitive. When are relationships likely to be recognized as both cooperative and competitive? Two concerns seem to be key: the frequency of interaction and paradoxical categorization.

We focus on managers' working relationships, as a subset of social relationships. In managerial work contexts, frequency of interaction typically implies that individuals engage in reciprocal patterns of sharing knowledge (McAllister, 1995). In addition, managers who work together frequently are also more likely to have their performance compared (Brown et al, 1998) and to contend for resources (Burt, 1992). Thus, working together frequently is likely to provide the opportunity for individuals to experience and to reciprocate acts of cooperation and acts of competition.

The cycles of reciprocated behaviors that individuals experience in their social relationships should guide how they interpret those relationships (Gouldner, 1960; Koster \& Sanders, 2006). So, for example, if individuals experience others sharing knowledge, they may interpret those acts as cooperation and reciprocate with cooperative behaviors of their own, leading them to characterize their relationship as cooperative. Accordingly, if managers' working relationships involve frequent contact, then this should provide the potential for developing relationships that are both cooperative and competitive.

Frequent interaction only provides the potential for forming working relationships that are both cooperative and competitive because individuals might tend to reciprocate mainly one as opposed to both kinds of behavior. Consistent with our earlier arguments, we suggest that individuals from different cultural groups and with differing cultural categories should differ in how they resolve the paradoxical tension (Miron-Spektor, Gino, \& Argote, 2011; Smith \& Lewis, 2011) of encountering opportunities for, or behaviors indicating, both cooperation and competition.

If Chinese individuals are more likely than American individuals to categorize attempts to outperform others as instances of both cooperation and competition, then this may indicate a more general willingness to integrate and reciprocate both cooperation and competition. That is, Chinese individuals may be more likely than American individuals to experience someone attempting to outperform them, perceive it as cooperative and competitive, and reciprocate with acts of cooperation as well as acts of (presumably healthy) competition. In contrast, American individuals may be more likely than Chinese individuals to experience someone attempting to outperform them, perceive it as competitive and not cooperative, and reciprocate with acts of competition and non-cooperation. The end result is a difference in the frequency of experiencing both cooperation and competition within the same working relationship. Thus, paradoxical categorization should predict whether, for those working relationships with frequent interaction that allow for developed chains of
reciprocity, individuals are likely to characterize those working relationships as both cooperative and competitive.

In the study that follows, we examined Chinese and American managers for their beliefs about the paradoxical categorization of cooperation and competition. A week later, we gathered their evaluations of their working relationships. We expected that Chinese managers would be more likely than American managers to endorse paradoxical categorization and to characterize their frequent working relationships as both cooperative and competitive.

## Methods

## Participants

A total of 111 managers in the United States and 139 managers in China participated in the study. The American managers were, on average, 29 years old and the Chinese managers were about 31 years old. The American managers ( $76 \%$ ) and the Chinese managers ( $63 \%$ ) tended to be male. All participants had earned college degrees and had at least three years of full-time work experience. Within each sample, each major industry, including technology, services, and manufacturing, was represented. Participation in the study was voluntary.

## Procedure and Materials

Time 1 Survey Participants listed up to 24 people within their organization with whom they had an ongoing working relationship (as in, for example, Chua, Ingram, \& Morris, 2008). Participants then completed a categorization task, as described below. Finally, participants provided demographic information about themselves and information about their organization.

Categorization task The categorization task followed protocols developed within cognitive anthropology (see Weller, 2007 for a review). Using a separate sample from the main study, we asked 40 participants from China and 40 participants from the United States to describe situations that indicated competition. We used existing data on cooperation from Keller and Loewenstein (2011). We created 25 items describing situations that were mentioned by members of both cultures as either cooperative or competitive. All items were in Chinese in China and in English in the US. To ensure language equivalence, we engaged in a coding, translating and back-translating process by coders not informed about the purposes of the study (Brislin, 1970).

The key items concerned outperforming (5 items), sabotaging ( 4 items) and knowledge sharing ( 2 items). We included an additional 14 filler items to reduce demand effects. The 25 situations were presented to participants three separate times; once each for whether the situation could be categorized as cooperation, as competition and as commitment (to provide a filler between the cooperation and competition categorization tasks). Half the participants rated situations for cooperation first and competition third,

Table 1: Categorization of situations as cooperation and competition

|  |  | Knowledge Sharing | Sabotaging | Outperforming |
| :--- | :--- | :---: | :---: | :---: |
| USA | Cooperation | $3.83(1.40)^{*}$ | $1.53(0.55)^{*}$ | $3.10(0.73)$ |
|  | Competition | $2.25(1.32)^{*}$ | $4.22(0.70) *$ | $4.16(0.42) *$ |
| China | Cooperation | $3.98(1.18)^{*}$ | $1.61(0.51)^{*}$ | $3.62(0.55) *$ |
|  | Competition | $2.01(1.01)^{*}$ | $4.12(0.64) *$ | $4.26(0.46) *$ |

Standard deviations are in parentheses.

* $\mathrm{p}<.01$ from one-way t -tests ( $\min \mathrm{df}=110, \min \mathrm{t}=13$ ) for differences from 3, with above 3 indicating cooperation or competition, and below 3 indicating non-cooperation or non-competition.
and half rated situations in the reverse order. We found no effects of order of presentation.

Time 2 Survey One week later, participants evaluated each working relationship they had listed on the Time 1 survey. They rated the level of competition, cooperation, and the frequency with which they worked together, as well as other information beyond the scope of the current paper. The order of presentation of the questions about cooperation and competition was counterbalanced, and we found no effects of the order of presentation.

## Measures

Categorization Participants rated knowledge sharing, sabotaging, and outperforming situations twice on scales from $1=$ non-cooperative/ non-competitive and $5=$ cooperative/ competitive.

Paradoxical categorization We used participants' ratings of how cooperative outperforming situations were as a measure of paradoxical categorization. We found similar patterns if we use measures based on their ratings of both cooperation and competition.

Frequent interaction Working relationships with "at least daily" interaction were coded as a working relationship with frequent interaction.

Paradoxical working relationships Participants rated each working relationship on a 5-point scale for cooperation ( $1=$ very non-cooperative, $2=$ slightly non-cooperative, $3=$ neither cooperative nor non-cooperative, $4=$ slightly cooperative, and $5=$ very cooperative) and a similar scale for competition. A working relationship that was rated a 4 or 5 on both the "cooperative" and "competitive" scales was coded as a working relationship that had both cooperation and competition.

Number of working relationships Participants could have reported up to 24 working relationships and we included the number they listed as a control variable.

Demographic Variables Age and gender were included as control variables because they commonly influence interactions within organizations.

## Results

## Categorization data

Table 1 shows the means and standard deviations for the categorization of each situation type (knowledge sharing, sabotaging and outperforming) for respondents from the US and China. As expected, Chinese managers and American managers categorized knowledge sharing as cooperative and non-competitive and sabotaging situations as competitive and non-cooperative. Both Chinese and American managers categorized outperforming situations as competitive. Finally and most critically, Chinese managers categorized outperforming situations as cooperative $(M=3.62, S D=$ 0.55 ) whereas American managers did not $(M=3.10, S D=$ $.73), t(249)=6.35, p<.01$. Thus, Chinese managers showed greater willingness than American managers to engage in paradoxical categorization.

## Working relationship data

Table 2 reports hierarchical non-linear logistic regression models predicting paradoxical working relationships. We found no effects of gender, age, and number of ties (second level control variables) or cultural group (a second-level variable). As expected, frequent interaction predicted paradoxical working relationships (a first-level variable; $\mathrm{B}=$ $.77, \mathrm{SE}=.15$ ). Also as expected, there was an interaction between cultural group and frequent interaction ( $\mathrm{B}=.73$, SE $=.30)$, as Chinese managers $(M=.20)$ reported that more of their frequent interaction relationships were paradoxical working relationships than did American managers ( $M=$ .14), $t(2342)=3.38, p<.01$.

Paradoxical categorization helped to explain the effect of cultural group. Paradoxical categorization predicted paradoxical working relationships (a second-level variable; $\mathrm{B}=.05$, $\mathrm{SE}=.01$ ). When including paradoxical categorization with cultural group, frequent interaction and the interaction of cultural group and frequent interaction, the effect of the interaction was still significant yet reduced (B $=.51, \mathrm{SE}=.30$ ). A bootstrapped test of an indirect effect of the interaction of cultural group and frequent interaction on

Table 2: Predictors of Paradoxical Working Relationships

|  | Controls |  | Cultural Group |  | Frequent Contact |  | Interaction |  | Paradoxical categorization |  | Full Model |  |

Note: bold if $\mathrm{p}<.05$.
paradoxical working relationships through paradoxical categorization found support, estimating an effect of 0.04
( $95 \%$ CI: 0.01-0.07). Therefore, the influence of Chinese culture on paradoxical categorization is linked to the particular likelihood of Chinese managers' having paradoxical working relationships among their frequent interaction partners.

## Discussion

Chinese managers, relative to American managers, were more likely to categorize outperforming situations as both cooperative and competitive, and in turn were more likely to describe working relationships with frequent interaction as both cooperative and competitive. Simultaneously cooperative and competitive working relationships were not randomly distributed rare occurrences. For those who categorized outperforming situations as both cooperative and competitive (a set of mostly Chinese and some American managers), the median manager worked every day with two people with whom they both cooperated and competed. Yet for those who did not categorize outperforming situations as both cooperative and competitive (a set of mostly American and some Chinese managers), the median manager did not work with anyone with whom they both cooperated and competed. Thus, cultural support for paradoxical categorization, combined with enabling social situations, shape the social experience of cooperation and competition and, more broadly, opportunities for paradoxical working relationships.

Part of the account is about the influence of culture on categorization. Our account, drawing on prior literature, was that cultural philosophies can provide a basis for dialecticism. Dialectical beliefs then enable paradoxical categorization. In related research, we have documented the mediating role of dialectical beliefs in the link between cultural group membership and paradoxical categorization.

The robustness of the link between culture and paradoxical categorization is suggestive of the importance of studying culture to studying categories. The nature of the relation people perceive between categories, and category membership itself, is not just a function of the features or properties of the categories, their members, or the categories to which they are associated (e.g., Goldstone, 1996). Whether attempts to outperform others are instances of cooperation is ambiguous and appears to be resolved by principled social convention.

The more general implication is that attempts at studying category membership and relations among categories without considering cultural influences has the potential to be misleading. Part of individuals' understandings of categories-which tends not to be the focus of cognitive science research-is shaped by cultural use of the specific category and the culturally normative views about categories more generally. Studying artificial categories is wonderfully useful, as is studying concrete object categories that are fairly consistent across cultural communities. Cooperation and competition are not typical of the categories cognitive science researchers tend to study (they are relational categories; Gentner \& Kurtz, 2005). Yet cooperation and competition are arguably among the most frequently used categories in social life, and relational categories more generally account for much of our expert knowledge. The culturally-guided aspects of these categories' meanings are, therefore, highly consequential and so worthy topics of study.

Cultural factors shape categories because category use is so often social. In the current case, beliefs about categories are linked to perceptions of relationships. In other work, we also show that these beliefs about cooperation and competition predict behavior in a workgroup context. These perceptions and behaviors are consequential. People's choices are guided by how they perceive others, and those
perceptions can be self-reinforcing because of reciprocity. For example, a direct implication of the findings in this paper are that general cultural beliefs about paradoxes could, by shaping categories and relations between categories, shape the networks of social relationships that comprise our lives.

# Minimally Supervised Learning for Unconstrained Conceptual Property Extraction 

Colin Kelly (colin.kelly@cl.cam.ac.uk), Anna Korhonen (anna.korhonen@cl.cam.ac.uk)<br>Computer Laboratory, University of Cambridge<br>15 JJ Thomson Avenue, Cambridge, CB3 0FD, UK<br>Barry Devereux (barry@csl.psychol.cam.ac.uk)<br>Centre for Speech, Language, and the Brain, University of Cambridge Downing Street, Cambridge, CB2 3EB, UK

#### Abstract

We present a highly performant, minimally supervised system for the challenging task of unconstrained conceptual property extraction (e.g., banana is fruit, spoon used for eating). Our technique employs lightly supervised support vector machines to acquire promising features from our corpora (Wikipedia and UKWAC) and uses those features to anchor the search for plausible unconstrained relations in our corpus. We introduce a novel backing-off method to find the most likely relation for each concept/feature pair and produce a number of metrics which act as potential indicators of true relations, training our system using a stochastic search algorithm to find the optimal reweighting of these metrics. We also introduce a human semantic-similarity dataset; our output shows a strong correlation with human similarity judgements. Both our gold standard comparison and direct human evaluation results improve on those of previous approaches, with our human judgements evaluation showing a significant 20 percentage point performance increase.

## Introduction

Recent theories in cognitive psychology attest a propertybased, distributed and componential model of conceptual representation for concrete concepts (e.g., elephant, screwdriver) in the brain (Farah \& McClelland, 1991; Tyler, Moss, Durrant-Peatfield, \& Levy, 2000; Randall, Moss, Rodd, Greer, \& Tyler, 2004). To explore the validity of these theories, researchers employ real-world knowledge taken from property norming studies where human volunteers are asked to list properties for concepts. McRae, Cree, Seidenberg, and McNorgan (2005) performed the largest such study to date, collecting properties for over 500 concrete nouns (we call these the 'McRae norms'). Some example properties from these norms can be found in Table 1.

However, as has been widely discussed (Murphy, 2002; McRae et al., 2005), these studies suffer from a number of weaknesses. For example, human participants often underreport certain properties, even when they are facts presumably known by the volunteers: though all participants are likely to have known that animals have hearts, has heart is not reported as a property for any animal concept. Similarly, is animal is listed as a property of all animals in the norms while breathes is only cited as a property for whale. A related issue is inconsistency across similar concepts: has legs is listed as a property of leopard but is absent for tiger.

Our task is to automatically extract such conceptual representations from large text corpora using NLP techniques. We

Table 1: Top ten properties from McRae norms with production frequencies for knife and pig.

| knife | pig |  |  |
| :--- | :--- | :--- | :--- |
| is sharp | 29 | an animal | 21 |
| used for cutting | 25 | lives on farms | 20 |
| is dangerous | 14 | is pink | 20 |
| has a handle | 14 | has a tail | 17 |
| has a blade | 11 | has a curly tail | 15 |
| a weapon | 11 | has a snout | 12 |
| a utensil | 9 | eaten as bacon | 11 |
| made of steel | 8 | oinks | 9 |
| is serrated | 8 | is fat | 8 |
| found in kitchens | 8 | is dirty | 8 |

hope to extract features for a given concept as well as those features' relationship with that concept; specifically, we aim to extract properties in the form of concept relation feature triples (e.g., knife used for cutting, pig lives on farm), where both the relation and the feature are unconstrained. Our task is particularly challenging because while we seek a very specific 'type' of information (namely, conceptual properties), there is an enormous amount of variation across the features and relations of properties which exhibit such characteristics.

Previous approaches to our specific conceptual property extraction task (Baroni, Murphy, Barbu, \& Poesio, 2009; Devereux, Pilkington, Poibeau, \& Korhonen, 2009; Kelly, Devereux, \& Korhonen, 2010, 2012) have been successful to varying degrees, however each has suffered from limitations. Baroni et al., for example, did not explicitly offer relations between their extracted concepts and features. The relations extracted by the Devereux et al., system were rather unsophisticated, with the relation corresponding to the verb found along the grammatical relation path linking concept to feature. The Kelly et al. (2010) system had reasonable performance but was founded on manually constructed rules and relied heavily on WordNet for its feature selection.

The system of Kelly et al. (2012) approached this task as one of relation classification. The relations generated were derived directly from its training set; it was therefore unable to posit new or unseen relationships between its extracted concepts and features. We believe their feature output, however, was promising and we extend and enhance their feature extraction method in the first component of our own system.

Our system works by first employing a wealth of lexical, syntactic and semantic machine-learning attributes to train a support vector machine for feature-extraction. Unlike other
approaches, we make heavy use of unlabelled training data, rendering our system only very lightly supervised. Next, we return to our unlabelled corpus to find relations for the extracted features, using a novel, probabilistically motivated backing-off technique. In doing so, we are not constrained by relations found in the McRae norms: our method allows for the extraction of any relation.

## Data

## Recoded norms

We used the same set of recoded norms employed by Kelly et al. (2012) to train our system. This set, containing 510 concepts in total, is a coding of an anglicised version ${ }^{1}$ of the McRae norms into a uniform concept relation feature format, where each feature and concept contain one word; the relation slot can contain one or more words.

## Corpora

We used Wikipedia and the more general UKWAC corpus (Ferraresi, Zanchetta, Baroni, \& Bernardini, 2008), containing English-language webpages, as corpora. Together these offered a suitable balance of general and encyclopaedic text. We used the C\&C-parser (Clark \& Curran, 2007) to extract grammatical relations (GRs) and part of speech (POS) information from sentences, allowing us to construct a GR-POS graph for each. We trained our system on the corpora individually and in combination.

## Chunking

We also used chunked versions of our two corpora. Chunking is a technique which identifies the constituent blocks of a sentence (verb phrase, noun phrase, prepositional phrase, etc.). To chunk our corpora, we used the Apache OpenNLP 1.5 suite (Baldridge, 2005), using the Tokenizer, POS Tagger and Chunker tools. The various components of the suite were trained using models supplied with the OpenNLP package.

## Method

We trained our system with 466 of the 510 concepts in the anglicised McRae set to fix our training parameters and evaluated with the remaining 44 concepts, those in the ESSLLI expansion set (Baroni, Evert, \& Lenci, 2008) (discussed later).

## Feature derivation

In the first stage we focussed on extracting terms relevant to our concepts in order to generate a promising set of features, similar to those found in our norms.

Machine learning attributes Support vector machines (SVMs) are non-probabilistic binary linear classifiers which take a set of input data and predict, for each given input, which of two possible classes it corresponds to. This works by plotting training data points in a high-dimensional space and separating them with a hyperplane which has the largest

[^109]distance (or margin) to the nearest training data points of each class. This plane is subsequently used to classify unseen data points. SVMs can also be extended to the multi-class case.

We trained an SVM by constructing paths through each sentence's GR-POS graph from the concept to prospective features and used the GR path labels, POS tags, relation verb instances and path-length as machine learning attributes. We augmented this (mostly syntactic) set of machine learning attributes to incorporate additional semantic and lexical information: bigrams and concept/feature clusters. ${ }^{2}$ The intuition behind this was that similar types of concepts/features (as exhibited by cluster membership) might also exhibit similar types of relationships (e.g., 'tool' concepts and used for relations); the aim was to enable the SVM to detect the regularities that exist in the relationships between different semantic classes of concepts and features.

Every possible attribute across the training set corresponded to a distinct dimension of the vector space. The majority of the co-ordinates of the training data points took binary values depending on whether the dimension's corresponding attribute appeared in the path (except the clustering and path-length attributes which took integer values). Each training data point was labelled with its relation (or 'class').
Learning instances We applied the SVM Light software ${ }^{3}$ (Joachims, 1999) to our learning attributes to extract an SVM score (the sum of absolute values of the decision function values, which can be interpreted as a measure of confidence of the SVM in its classification) for each concept-feature pair. We also calculated log-likelihood (LL) (Dunning, 1993) and pointwise mutual information (PMI) (Church \& Hanks, 1990) statistics across the top 200 returned concept-feature pairs for each concept.

Previous work has ignored a large amount of potentially instructive training data by only examining sentences which link entities explicitly found in the training set. However, the use of 'negative' information could prove informative and therefore we trained on all GR-POS paths linking one of our concepts to any potential feature term ${ }^{4}$ in each sentence. The size of our training set was 5.52 million instances for the Wikipedia corpus and 20.07 million instances for the UKWAC corpus. ${ }^{5}$ As we were unaware of the nature of the relationship between these concept/feature terms, we labelled these unknown training paths as unknownrel.

Our system was therefore only very lightly supervised: only $6.8 \%$ of the UKWAC input and $8.7 \%$ of the Wikipedia input to the system was labelled with relations drawn from the McRae norms. Consequently, our SVM classified every

[^110]concept/feature pair into the unknownrel relation class. We therefore ignored the relation output from this stage of the system, instead using the top 200 returned concept/feature pairs ranked by their SVM scores as input to the next stage. In this way, we were interpreting a higher-rated SVM score as a proxy for the likelihood that a feature would have some kind of relationship with the concept at hand.

## Relation extraction

The underlying hypothesis of our relation extraction stage was that if we found sequences of chunks in our corpus sentences which were anchored at each end by a known concept and feature (from the previous stage), and those chunks' labels matched the labels of our chunked property norms, then we could use the surface text of the chunk(s) between the anchors as the relation in our concept relation feature format.
Chunk pattern selection To decide which patterns of chunks were likely to be indicative of property norm relations, we turned to our training set. We passed the full text of the non-ESSLLI McRae norms through the chunker, and manually examined the output for chunk label patterns likely to indicate relations.

Using this output, we created a ruleset for selecting sentence fragments (chunk sequences) which were similar in structure to our property norms. We called a sequence of three labelled chunks a three-chunk, a sequence of four chunks a four-chunk, etc. We employed the first four most frequent label combinations (NP VP NP; NP VP PP NP; NP VP ADJP; and, NP VP ADVP) to form our ruleset; together these covered $95.6 \%$ of the three- and four-chunk label patterns generated from our training set. By using the NP VP PP NP-labelled four-chunks we were able to extract multi-word, prepositional verbs (e.g., worn on, used for) as potential relations: previous approaches to our task have not attempted this.

Chunk pre-selection We needed to select those chunks most relevant to our relation extraction task. To do this we passed through our chunked corpus, generating sets of 3 and 4 sequential chunks and pre-selecting those which were relevant to our concepts. Our criterion for relevancy at this stage was that the final term contained within the first chunk, when lemmatised, corresponded to a training concept.

Chunk to triple conversion Having pre-selected our chunks we generated triples from the chunk text. For threechunks we did this by simply taking the final term in the first, second and third chunks and lemmatising each to give our concept, relation and feature terms respectively. For fourchunks we followed the same process for the first and fourth chunks to yield our concept and feature. To extract the relation we took the final term of the second (VP) chunk and compounded it with the final term of the third (PP) chunk; the only exception to this was if the POS of the final term of the second chunk was VBG, in which case we lemmatised that term and compounded it with the third chunk's final term. For example:

- [NP Mirrors_NNS] [VP are_VBP found_VBN] [PP in_IN] [NP the_DT bedroom_NN] became mirror found in bedroom
- [NP Most_JJS cats_NNS] [VP have_VBP] [NP furry_NN tails_NNS] became cat have tail
- [NP The_DT microwave_NN] [VP was_VBD running_VBG] [PP on_IN] [NP electricity_NN] became microwave run on electricity

## Relation selection

The third stage of our system worked by taking each con-cept-feature pair from both the SVM and chunking output, and finding the best relation for that pair from the chunking output to generate a triple. It also assigned to that triple a number of metrics relating to its constituent parts, their relative frequency and association scores.

We assumed that each concept-feature pair had one corresponding relation. We called the set of extracted triples generated by Stage 2, $T$ (with triples $(c, r, f) \in T$ ) and the set of all extracted relations from Stage $2, R$. For each concept, we also generated a final potential feature set, $F_{c}$, which, for a given concept, was the union of the top 200 features from Stage 1 (ranked by their SVM score) and the top 200 features from Stage 2 (ranked by their frequency in the extracted relations, but excluding features which appeared only once).

We defined Concept Feature Frequency (CFF) to be the number of times a concept, $c$, and feature, $f$, co-occurred across our extracted relations:

$$
\begin{equation*}
\operatorname{CFF}(c, f)=\sum_{r \in R} \operatorname{freq}(c, r, f) \tag{1}
\end{equation*}
$$

We also calculated a Distinct Relation Score which measured the number of distinct relations linking $c$ to $f$ :

$$
\begin{equation*}
\operatorname{DRS}(c, f)=\left|D_{c, f}\right| \text { for } D_{c, f}=\{r:(c, r, f) \in T\} \tag{2}
\end{equation*}
$$

We next wanted to choose relations for our various con-cept-feature pairs, $(c, f) \in C \times F_{c}$. We did this in three steps.

Step 1 For each concept, $c$, and feature, $f$, we iterated through all relations relating to that pair and calculated an Exact Match Score:

$$
\begin{equation*}
\operatorname{EMS}(c, f)=\max \{\operatorname{freq}(c, r, f): r \in R\} \tag{3}
\end{equation*}
$$

If $\operatorname{EMS}(c, f)>0$ then we selected as our best relation, $\hat{r}$, the relation corresponding to that score. If there was more than one relation with the same score, then we chose the least common (i.e., that which had the lowest frequency across all our relations). If $\operatorname{EMS}(c, f)=0$ then we left $\hat{r}$ undefined.

Step 2 Our first step only retrieved a relation if there was an exact match amongst our relation extraction output.

If there wasn't, we took a split approach; given a particular concept, $c$, and feature, $f$, we calculated separate probabilities across all our relations of $c$ occurring with each relation, and of $f$ occurring with each relation. We then calculated for each relation, $r$, a combined score for the combination of $c$, $r$ and $f$ by multiplying the constituent probabilities together. Our pairwise combination score was defined:

$$
\begin{equation*}
p(c, r)=\sum_{f \in F} \frac{\operatorname{freq}(c, r, f)}{\operatorname{freq}(c) \cdot \operatorname{freq}(r)} \tag{4a}
\end{equation*}
$$

$$
\begin{gather*}
p(r, f)=\sum_{c \in C} \frac{\operatorname{freq}(c, r, f)}{\operatorname{freq}(r) \cdot \operatorname{freq}(f)}  \tag{4b}\\
\operatorname{PCS}(c, f)=\left\{\begin{array}{l}
p(c, \hat{r}) \cdot p(\hat{r}, f) \text { if } \hat{r} \text { defined } \\
\max \{p(c, r) \cdot p(r, f): r \in R\}
\end{array}\right. \tag{4c}
\end{gather*}
$$

If we had not already selected a best relation, $\hat{r}$, then we defined it as the relation, $r$, which corresponded to this pairwise combination score. Again, if there was more than one relation with the same score, then we chose the least common.
Step 3 Our final step assigned relations to concept/feature pairs which lacked an exact mutually linking relation. This occurred around $17 \%$ of the time and was usually due to both the concept and feature terms being relatively low frequency. ${ }^{6}$

To achieve this, we backed-off to semantic feature clusters: we defined $f_{\star}$ as the cluster for feature $f$, and $F_{\star}$ as the set of all feature clusters, and defined our Feature Cluster Score, $\operatorname{FCS}\left(c, f_{\star}\right)$, analogously to our Pairwise Combination Score, merely substituting all instances of $f$ for $f_{\star}$. Our best relation, $\hat{r}$, was defined as the relation corresponding to this FCS.

## Reweighting

In our system's fourth and final stage we used the metrics derived above to assign an overall score for each triple using a weighting of parameters; we used our training set to derive the most optimal values for these parameters. We normalised our various metrics so that they all lay between 0 and 1 .

Our relation selection stage had already fixed a relation, $\hat{r}$, for each concept and feature. Hence we calculated for each of our triples $t=(c, \hat{r}, f)$ an overall score:

$$
\begin{align*}
\operatorname{score}(t)= & \beta_{\mathrm{PMI}} \cdot \operatorname{PMI}(t)+\beta_{\mathrm{LL}} \cdot \mathrm{LL}(t)+\beta_{\mathrm{SVM}} \cdot \operatorname{SVM}(t) \\
& +\beta_{\mathrm{CFF}} \cdot \mathrm{CFF}(t)+\beta_{\mathrm{DRS}} \cdot \operatorname{DRS}(t)+\beta_{\mathrm{EMS}} \cdot \operatorname{EMS}(t)  \tag{5}\\
& +\beta_{\mathrm{PCS}} \cdot \operatorname{PCS}(t)+\beta_{\mathrm{FCS}} \cdot \operatorname{FCS}(t)
\end{align*}
$$

We wished to optimise our parameters for superior feature F-score performance against our training set. We employed a stochastic process to find best-possible values for our training parameters, using a random-restart hill-climbing algorithm, repeated 1000 times and selecting the output (and $\beta$ values) offering the best F-score across these iterations.

This process offered a reasonable approximation of the best possible F-scores our system could produce and their corresponding $\beta$ values; following this process, our best F-scores were $0.2739,0.2803$ and 0.2996 for our Wikipedia, UKWAC and combined corpora respectively.

## Evaluation

We evaluated our system using gold standard, human semantic-similarity and direct human evaluations.

## Gold standard evaluation

We began by comparing our top twenty output using the ESSLLI gold standard set. This 'expansion' set comprises the top

[^111]Table 2: Our best precision, recall and F-scores against the synonym-expanded ESSLLI norms across our corpora, found using the training $\beta$ parameters.

| Relation | Corpus | Prec. | Recall | F |
| ---: | :--- | :--- | :--- | :--- |
| With | Wikipedia | 0.1131 | 0.2265 | 0.1509 |
|  | UKWAC | 0.1000 | 0.2005 | 0.1335 |
|  | Combined | 0.1214 | 0.2431 | 0.1620 |
|  | Kelly et al. | 0.1238 | 0.2493 | 0.1654 |
|  | Wikipedia | 0.1214 | 0.2431 | 0.1620 |
|  | UKWAC | 0.1048 | 0.2101 | 0.1398 |
|  | Combined | 0.1298 | 0.2598 | 0.1731 |
| Without | Wikipedia | 0.2798 | 0.5603 | 0.3732 |
|  | UKWAC | 0.2560 | 0.5132 | 0.3416 |
|  | Combined | 0.2798 | 0.5606 | 0.3733 |
|  | Kelly et al. | 0.2417 | 0.4847 | 0.3225 |

ten lemmatised properties for each of 44 concepts from the recoded McRae norms, together with a feature expansion set generated for each concept relation feature triple. One of the reasons for using this set is that McRae et al. normalised their features by channelling synonymous properties into a single representation. The ESSLLI set undoes some of these normalizations, expanding the feature terms to a set of synonyms. In this way, loud, noise and noisy (for example) can all be counted as matches against the property is loud. The relations were not expanded.

Our results can be found in Table 2. We also assessed our system using the full text of the relations found in the original McRae norms as additional 'relation synonyms'; these augmented results can be found under the 'With (aug.)' relation heading. We have exceeded the performance of Kelly et al. (2012) (best F-score of 0.1654 ) with a best overall F-score of 0.1731 for the combined corpus.

We also note that performing these evaluations on the top ten properties returned further improved the situation (perhaps unsurprising since the ESSLLI set contains only ten properties per concept); for example, evaluating our top ten triples against the relation synonyms set returned a precision of 0.2215 for the combined corpus. Furthermore, the precision on the combined corpus for the top ten evaluation of features-only was 0.4409 , surpassing Baroni et al. (2009) who offer a best score of 0.239 on the same evaluation.

## Human-generated semantic similarity

Comparison with the ESSLLI gold standard is still an incomplete evaluation: not all conceptual properties for a given concept are contained therein, and lexical variation can mark valid relations as wrong. Furthermore, one of the primary advantages of our computational approach is its ability to extract a large number of properties for a given concept. Hence, we introduced an alternative approach to calculate how semantically meaningful our output was by evaluating the triples' capacity to predict human-rated similarity between words.

We asked five native English speakers to rate the similarity of 90 concept pairs, where concepts in the pairs were all drawn from the ESSLLI set. The raters were given instructions explaining the task and then presented with each concept pair, one by one, a scale of 1 to 7 and asked to rate how

Table 3: Pearson correlation ( $r$ ) results with confidence intervals between our $V_{\text {Human }}$ vector and our similarity vectors $V$ (with dimensionality $D$ and derived from the top $n$ properties) from our system.

| Relation | V | $n$ | D | $r$ | Conf. Int. |
| :---: | :---: | :---: | :---: | :---: | :---: |
| With | Wikipedia | 20 | 654 | 0.598 | [0.446, 0.716] |
|  | UKWAC |  | 712 | 0.629 | [0.486, 0.740] |
|  | Combined |  | 692 | 0.671 | [0.539, 0.771] |
|  | Wikipedia | 300 | 3585 | 0.693 | [0.568, 0.787$]$ |
|  | UKWAC |  | 3442 | 0.683 | [0.555, 0.780$]$ |
|  | Combined |  | 3380 | 0.723 | [0.606, 0.809] |
| Without | Wikipedia | 20 | 478 | 0.720 | [0.603, 0.807] |
|  | UKWAC |  | 456 | 0.754 | [0.649, 0.832] |
|  | Combined |  | 475 | 0.742 | [0.632, 0.822 ] |
|  | Wikipedia | 300 | 7324 | 0.782 | [0.685, 0.851] |
|  | UKWAC |  | 8698 | 0.806 | [0.719, 0.868] |
|  | Combined |  | 8727 | 0.807 | [0.721, 0.869] |
| WithWithout | McRae |  | 410 | 0.785 | [0.691, 0.854] |
|  |  |  | 355 | 0.787 | [0.693, 0.855$]$ |
|  | LSA |  | 300 | 0.708 | [0.586, 0.798] |

similar the two concepts were.
To compare our system with these ratings we constructed a vector space of dimension $D$, where $D$ was the number of distinct properties across our triples. For each of our 44 concepts, we generated a concept-score vector with non-zero entries by inserting the triple scores, $\operatorname{score}(t)$, into their correct entries in the concept-score vector. We then constructed a $44 \times 44$ symmetric pairwise similarity matrix across our concepts by calculating the cosine similarity between their concept-score vectors. From this we extracted a similarity vector, $V$, for our 90 pairwise comparisons.

We calculated twelve such matrices (using the top twenty and top 300 extracted triples, across three corpora and excluding and including the relation term). We also generated two such matrices using both the feature-heads and the full text of the McRae property norms, using the norm production frequencies as entries in each concept's vector, as well as comparing our ratings with LSA-predicted (Landauer, Foltz, \& Laham, 1998) similarities. ${ }^{7}$ Our results are in Table 3. ${ }^{8}$

Our systems' performance, evaluating with and without relation and when using the top twenty triples, was comparable to LSA (correlation 0.708) with average correlations across our corpora of 0.754 and 0.671 respectively. Including the top 300 extracted triples brought our correlations up to 0.807 and 0.754 respectively, an extremely strong result given that the average Pearson coefficient of correlation across the five judges (considering all pairwise combinations) was 0.820 .

## Human evaluation

In our final evaluation, we asked two native English speaking human judges to assess the accuracy of our triples. Following the methodology of Devereux et al. (2009), we asked them to classify output triples for 15 concepts into four categories: 'correct' (c), 'plausible' (p), 'related' (r) and 'wrong'

[^112]Table 4: Inter-annotator agreement and judgements for our extraction system applied to our three corpora.

| Corpus |  | Audge | A | B | Avg | c/p |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | \(\left.\begin{array}{c}Kappa <br>

(Agree)\end{array}\right]\)
(w). Our judges were unaware of the aims of the evaluation. We concatenated their ratings using the methodology of Devereux et al. ${ }^{9}$ however our instructions reflected the fact that, unlike previous systems, our output contained prepositional relations and we therefore did not wish our volunteers to allow for absent prepositions. This evaluation offers an important insight into the viability of our method as a property extraction system. Our results are in Table 4, and Table 5 shows a sample of our output and the corresponding judgements.

It is clear that our best results were again in the combined corpus, where an impressive $71.3 \%$ of our returned triples were marked as either plausible or correct with a Kappa (Fleiss, 1971) score of 0.7229 indicating substantial agreement between annotators. This constitutes a major improvement over Kelly et al. (2012) who evaluated on the same set of concepts and whose corresponding score was just $51.1 \%$.

## Discussion

As the first system to offer viable unconstrained property norm-like extraction, this paper brings research into conceptual property extraction to the next level. Our system employs both full parsing and chunking to extract features and relations respectively and introduces a novel multi-step backingoff method for relation selection. Our gold standard performance exceeded that of previous approaches, and our human evaluation indicated that we have outperformed the system of Kelly et al. (2012) by a significant margin. We also introduced a semantic similarity evaluation for this task, showing a strong Pearson correlation of 0.754 with human ratings when employing just 20 extracted properties per concept, with the correlation rising to 0.807 when using 300 properties. In this latter case, the predicted similarities were almost as correlated with human judgements as the human judgements are with each other.

Potential criticisms of our system include the fact that our chunk to triple conversion process won't necessarily always yield a true reflection of the sentence's original meaning. It is, for example, possible for the final chunk to contain adjectives which modify the final noun. These could have importance from a conceptual representation perspective (e.g., features such as long neck for giraffe has long neck). Also, the modifying portion of a chunk may be semantically significant, altering the final term's meaning (e.g., a tea bag is quite different from a bag). It should be possible to have more gen-

[^113]Table 5: Judges' assessments of the top twenty extracted relation/feature pairs (combined corpus) for two concepts.

eral chunk to triple extraction (e.g., by using a larger corpus to mitigate the sparsity associated with multi-word terms).

Finally, a major issue is our lack of comprehensive training/testing data; our norms are incomplete insofar as there were a large number of 'correct' properties absent from our gold standard. In future work we hope to implement largescale evaluation of our system's output (e.g., using Amazon Turk) which would allow us to rapidly obtain large amounts of human-generated feedback. We could then use activelearning to introduce a feedback loop of human-annotation to better pinpoint inaccurate features or relations. Feedback which strongly indicated that certain properties were uninteresting could prove invaluable in getting even closer to a conceptual structure-like representation of concepts.

## Acknowledgments

This research was supported by EPSRC grant EP/F030061/1 and the Royal Society University Research Fellowship, UK. We are grateful to McRae and colleagues for making their norms publicly available, and to the anonymous reviewers for their comments and feedback.

#### Abstract

Are observed links between musicality and non-native speech sound processing due to superior sensory processing of temporal, pitch, and spectral information, which benefits both musical and linguistic processing? Native English speakers discriminated Norwegian tonal contrasts, non-linguistic puretone analogues, Norwegian vowels, and short tones differing in temporal, pitch and spectral characteristics. Musicality was measured using Gordon's (1989) Advanced Measures of Musical Audiation (AMMA). After controlling for effects of sex, non-verbal IQ and previous language learning experience, the link between AMMA scores and tonal contour discrimination was partially mediated by pitch acuity. In addition, tonal contrast, pitch contour and vowel discrimination were predicted by temporal and spectral acuity. No independent effects of musical training were found. Thus, links between musicality and non-native speech sound processing appear to be mainly due to superior temporal, pitch or spectral acuity, which, in turn, may play somewhat different roles in processing different speech sounds.

Keywords: Non-native phoneme processing; temporal acuity, pitch acuity; spectral acuity; musicality; tonal contrast; vowel contrast.

## Introduction

A number of studies have documented links between musicality and the ability to discriminate non-native speech sounds (Delogu, Lampis, Belardinelli, 2006, 2010; Marie, Delogu, Lampis, Belardinelli \& Besson, 2011; Slevc \& Miyake 2006; Wong, Skoe, Russo, Dees \& Kraus, 2007). These studies typically use complex psychometric measures of musical aptitude, which leaves open the question as to which specific sub-components of musical aptitude are associated with non-native speech sound processing. Tests like the Wing test (Wing, 1968) or Gordon's Advanced Measures of Musical Audiation (AMMA) (Gordon, 1989) rely on working memory for musical and rhythmic phrases as well as on the ability to discriminate subtle differences in pitch, timbre, intensity, and rhythm. It is not clear which of these sub-components of musical aptitude are linked to non-
native sound processing, especially because different types of acoustic information may be important for distinguishing different types of speech sounds. Specifically, the perception of vowels, which differ in spectral information associated with the first and second formants, should be most strongly predicted by sensitivity to timbre. In contrast, the perception of consonants, which are often distinguished by temporal information such as Voice Onset Time or formant transitions, should benefit from sensitivity to rapid temporal changes. Finally, lexical tones require sensitivity to pitch and, to the extent that they encompass differences in pitch contour, also sensitivity to temporal information. Thus, different aspects of auditory sensory acuity may be important for the processing of different types of non-native speech sounds. So far, the relationship between musicality and non-native speech sounds processing has been quite consistently established for tonal contrasts (Marie, Delogu, Lampis, Belardinelli \& Besson, 2011; Slevc \& Miyake, 2006; Wong, Skoe, Russo, Dees \& Kraus, 2007), but the findings are less clear for phonological contrasts (Delogu, Lampis \& Belardinelli, 2006, 2010).

A primary aim of this study was therefore to examine the specific contributions of temporal, pitch, and spectral acuity to the processing of different non-native speech sounds, and to determine whether general measures of musical aptitude can explain additional variance in non-native speech sound processing above what is explained by these basic sensory processes. To this end, we examined both a tonal and a vowel contrast that exist in Norwegian, a language unfamiliar to our participants. Many dialects of Norwegian have lexical tone such that rising and falling-rising pitch accents distinguish minimal pairs of segmentally identical bi-syllabic words. For example, 'Hammer', spoken with the rising tone, is a Norwegian proper noun while 'hammer', spoken with the falling-rising tone, denotes the tool. These contrasts encompass temporal changes in fundamental frequency in the range of several hundreds of milliseconds. Norwegian also contains a vowel contrast not present in English, the /i/ - /y/ contrast. The existence of these Norwegian contrasts offers the possibility to use linguistic
stimuli rather than isolated synthesized segments, which may be processed in ways that differ from processing of natural linguistic materials. Moreover, to control for differences between linguistic and non-linguistic stimuli, we also used the extracted pure-tone analogues of the Norwegian tonal contrasts as stimuli.

Musicality is a complex construct encompassing musical aptitude as well as musical expertise (Nardo \& Reiterer, 2009). Studies comparing non-native speech sound processing between musicians and non-musicians (Marie et al., 2011; Wong et al., 2007) suggest that musical practice hones abilities such as sensory acuity, working memory, or attentional control, which may transfer to the linguistic domain. However, it is also possible that certain sensory or cognitive abilities benefit both musical and linguistic processing. To see whether musical expertise incurs benefits for non-native speech sound processing in addition to benefits associated with superior auditory sensory acuity, we also examined whether the duration of musical training would explain variance in non-native speech sound processing over and above measures of musical aptitude.

## Method

Native speakers of English completed AX discrimination tasks for non-native tonal and vowel contrasts, as well as for synthesized sounds differing in temporal, pitch, and spectral characteristics. Musical aptitude was tested using Gordon's AMMA (Gordon, 1989). To control for non-verbal intelligence we administered Cattell's Culture Fair Intelligence Test (Cattell \& Cattell, 1973). Music and language background questionnaires inquired about length of musical training and number of languages learned at home or at school, and elicited self-ratings of proficiency in each language (L2 and L3).

## Participants

One hundred and three native speakers of American English ( 58 women, 45 men ) aged 19-22 years participated in the study. Three participants failed to provide L3 proficiency self-ratings, and one participant failed to provide pitch discrimination data. These participants are missing from analyses including these variables.

## Materials and Tasks

Advanced Measures of Musical Audiation (AMMA): Gordon's (1989) AMMA consists of 30 items, each of which comprises a short musical 'statement' followed after four seconds by a short 'answer' of the same length. These items contain either one or more tonal changes, or one or more rhythmic changes, but not both. Participants have to decide whether the phrases are the same or different. For 'different' items, participants are asked to decide whether the difference is a tonal or rhythm change. The test yields a tonal and rhythm score, as well as a composite score.
AX ('same-different') - tasks: All AX tasks comprised 32 'same' and 32 'different' trials. For the Norwegian tonal and vowel contrasts, 'same' trials comprised different
within-category instantiations obtained from repeated recordings of the same word.
Temporal Acuity. We synthesized eight 250 Hz sinusoidal carrier waves with an overall duration of 600 ms differing in amplitude envelope onset rise times, and otherwise devoid of segmental, spectral and pitch information. The onset of the amplitude envelope was faded in with rise times to reach maximum amplitude at $0 \mathrm{~ms}, 10 \mathrm{~ms}, 20 \mathrm{~ms}, 30 \mathrm{~ms}, 60 \mathrm{~ms}$, $70 \mathrm{~ms}, 80 \mathrm{~ms}$ and 90 ms . 'Different' trials comprised pairs of sounds differing in rise times by 60 ms (e.g. 0 ms vs. 60 ms or 10 ms vs. 70 ms etc.), centered around 45 ms , a value which has been reported as the category boundary between 'bowed' and 'plucked' sounds (Cutting \& Rosner, 1974).
Pitch Acuity. We created eight 500 ms pure tone sinusoidal carrier waves ranging from 100 to 3000 Hz in steps increasing by 100 Hz resulting in tones of $100 \mathrm{~Hz}, 200$ $\mathrm{Hz}, 400 \mathrm{~Hz}, 700 \mathrm{~Hz}, 1100 \mathrm{~Hz}, 1600 \mathrm{~Hz}, 2200 \mathrm{~Hz}$, and 3000 Hz , as well as contrasts with a frequency increased by $2 \%$ resulting in tones of $102 \mathrm{~Hz}, 204 \mathrm{~Hz}, 408 \mathrm{~Hz}, 714 \mathrm{~Hz}, 1122$ $\mathrm{Hz}, 2244 \mathrm{~Hz}$, and 3060 Hz . The cumulative increase was designed to create sound pairs that subjectively sampled the pitch range at roughly similar intervals, taking into account the non-linearity of pitch perception. For the 'different' trials, each sound was paired with its corresponding contrast sound resulting in pairs of 100 Hz vs. $102 \mathrm{~Hz}, 200 \mathrm{~Hz}$ vs. $204 \mathrm{~Hz}, 400 \mathrm{~Hz}$ vs. 408 Hz etc.)
Spectral Acuity. To test spectral acuity, we incorporated the pure tones created for the pitch acuity test into complex tones comprising low (e.g. 100 Hz or 200 Hz ), middle (e.g. 700 Hz or 1100 Hz ) and high (e.g. 2200 Hz or 3000 Hz ) frequencies. These frequencies were chosen to broadly mimic the fundamental frequency and the first two formants of speech, which are crucial for vowel perception. For 'different' pairs, one of the component tones was increased by $2 \%$, and this change affected either the middle or the high frequency. For example, a 'different' pair might include a complex tone consisting of frequencies of 100 Hz , 1100 Hz and 3000 Hz and a complex tone consisting of frequencies of $100 \mathrm{~Hz}, 1122 \mathrm{~Hz}$ and 3000 Hz .
Norwegian tonal contrast. Recordings by a male native speaker of Norwegian of eight minimal pairs of Norwegian words containing a contrast between rising and falling-rising tonal contours were taken from Kempe, Thoresen, Kirk, Schaeffler \& Brooks (2012). Four pairs contained short vowels in the first (stressed) syllable (mean length 64 ms ); the remaining four pairs contained long vowels (mean length 187 ms ). Crucially, words with rising and with falling-rising tones did not differ in length of the first vowel ( 118 vs. $133 \mathrm{~ms}, \mathrm{p}=.5$ ), overall word length ( 396 vs .417 $\mathrm{ms}, \mathrm{p}=.2$ ), and metric stress; thus, duration and stress could not be used as additional cues. Corresponding short and long vowel pairs were matched for their initial phoneme.

To ensure that a male advantage in the discrimination these tonal contrasts, as found in previous research (Kempe et al., 2012), was not an artifact of the male voice presenting the stimuli, we also created a female voice version of the stimuli. To control for indexical features, we submitted the
male voice stimuli to the voice gender change algorithm in PRAAT (Boersma \& Weenink, 2011) using a fundamental frequency of 220 Hz and scaling the first formant up by 20 $\%$. All results below are averaged over the male-voiced and the female-voiced version of the AX-task.
Pitch contour (non-speech analogue of tonal contrast). The non-speech equivalents of the Norwegian tonal contrast comprised sine waves with pitch contours extracted from the fundamental frequency modulation of both the malevoiced and the female-voice Norwegian tonal contrasts. These stimuli contained no information other than the pitch contour of the Norwegian tones. Again, results below are averaged over the male-voiced and the female-voiced version of the AX-task.
Norwegian vowel contrast. We used eight minimal pairs of Norwegian mono-syllabic words containing the vowel /i:/ or /I/ vs. /y:/ or /Y/, a contrast between high front unrounded and rounded vowels which does not exist in English. Recordings of a male native speaker of Norwegian were taken from Kempe et al. (2012). Four word pairs contained the short vowels $/ \mathrm{I} /$ and $/ \mathrm{Y} /$ (mean length 67 ms ), and the remaining four word pairs contained the long vowels /i:/ and $/ \mathrm{y}: /$ (mean length 150 ms ). On average both members of a minimal pair did not differ in vowel length ( 108 vs .108 ms , $\mathrm{p}=.9$ ); thus, duration could not serve as additional cue.

Other measures: Participants also completed Cattell's Culture-Fair Test of Nonverbal Intelligence, Scale 3, Form A (Cattell \& Cattell, 1973), a music background questionnaire on which they provided information about duration of musical training, and a language background questionnaire on which they indicated the number of languages learned, and rated their reading, writing, speaking and comprehension abilities in all languages on a scale from 1 (very poor) to 6 (native-like).

## Procedure

AX discrimination tasks were presented in three blocks, with the first block containing the temporal, pitch and spectral AX tasks, the second block containing the malevoiced and female-voiced tonal AX tasks as well as the vowel AX task, and the third block containing the two AX tasks presenting the extracted pitch contours of the malevoiced and female-voiced Norwegian tonal stimuli. The fixed block sequence ensured that variance due to order effects was not confounded with participant variance, although task order was counterbalanced within blocks. AMMA and Culture Fair Intelligence Test were interspersed between blocks with their order counterbalanced as well. Informed consent was obtained and background questionnaires were completed prior to any of the tasks.

In each of the AX-tasks, participants received eight practice trials with feedback, followed by 64 test trials without feedback. Within a trial, sound stimuli were separated by an inter-stimulus interval of 200 ms ; the intertrial interval was 500 ms . Participants were asked to press the ' $s$ ' key if they perceived the sounds to be the same and the ' $d$ ' key if they perceived them to be different.

## Results

Participants' performance on the AX-tasks was converted into A', a sensitivity measure that corrects for differences in response bias, and ranges from 0 to 1 , with 0.5 corresponding to chance. Table 1 shows performance with tonal contrasts, non-speech contour analogues, and vowels. As previous research had shown a male advantage for the processing of some non-native speech sounds (Kempe et al., 2012; Bowles, Silbert, Jackson \& Doughy, 2011), results are given for male and female participants separately. A 3 (Condition) x 2 (Sex) ANOVA yielded a main effect of Condition, $\mathrm{F}(2,202)=8.2, \mathrm{p}<.001$. Bonferroni-corrected post-hoc tests indicated that performance was superior for the vowels compared to both tonal conditions, all t's $>3.4$, all p 's $<.01$, which did not differ from each other, $\mathrm{p}=.7$. The main effect of Sex, $\mathrm{F}(1,101)=2.3, \mathrm{p}=.1$, and the interaction, $\mathrm{F}(2,202)=2.8$, p $=.06$, fell short of significance. This trend towards a male advantage in processing tonal contours, but not vowels confirms the previous findings (Kempe et al., 2012).

Table 1: Mean A' and standard deviations (in parentheses) for discrimination of Norwegian tonal contrasts, extracted pitch contours and Norwegian vowels.

|  | tonal contrast | pitch contour | vowel contrast |
| :--- | :--- | :--- | :--- |
| males | $0.781(0.103)$ | $0.790(0.087)$ | $0.800(0.101)$ |
| females | $0.748(0.097)$ | $0.747(0.104)$ | $0.802(0.102)$ |

Zero-order correlations between the predictors of nonnative speech-sound processing are provided in Table 2. Noteworthy findings involve a positive correlation between non-verbal intelligence and both AMMA scores, indicating that comparison of musical phrases relies to some extent on mechanisms shared with psychometric intelligence, such as working memory and cognitive control (Duncan, Emslie, Williams, Johnson \& Freer, 1996). Also, as expected, pitch and spectral acuity were positively correlated with both AMMA scores. In contrast, temporal acuity was not correlated with the AMMA scores, which may reflect the fact that the temporal processing relevant for music involves a longer time scale than the rapid temporal changes in the order of tens of milliseconds presented in our temporal acuity test. Instead, temporal acuity was positively correlated with non-verbal intelligence, confirming the documented link between rapid temporal auditory processing and psychometric intelligence (Rammsayer \& Brandler, 2007).
The results of multiple regression analyses of non-verbal intelligence, language background, sex (dummy-coded) and the musicality measures on performance with tonal contrasts, pitch contours and vowels are presented in Table 3 (upper panel). We found that non-verbal intelligence showed a trend towards a positive association with discrimination of tonal contours and non-linguistic pitch contours. As indicated above, there was also a statistically marginal male advantage for these stimuli. Crucially, the

AMMA rhythm score predicted performance with tonal contrasts, even if they were extracted and presented without linguistic information. For non-native vowels, only selfrated proficiency in L3 predicted performance. Thus, while tonal performance was related to musicality, vowel performance was not, confirming observations by Delogu et al. (2006; 2010). Note that there was no effect of musical training.

Next, we added temporal, pitch and spectral acuity to the model (lower panel of Table 3) to see whether auditory acuity explains the link between musicality and non-native tonal processing. All Variance Inflation Factors were below 3.8, suggesting that multi-collinearity was not a problem in this data set. For the tonal contrast, we found a significant effect of pitch acuity; the effects of temporal and spectral acuity fell short of significance. For the extracted pitch contour, we found a significant effect of spectral acuity; the effect of temporal acuity fell short of significance. For the vowel contrast, we found significant effects of temporal and spectral acuity. In other words, the data showed a tendency for temporal and spectral acuity to predict discrimination of all non-native speech contrasts while the predictive effect of pitch acuity was confined to the tonal contrasts.

To test explicitly whether the association of the AMMA rhythm score with the tonal and the extracted pitch contour contrasts was mediated by auditory acuity, we performed mediation analyses employing bootstrapping to estimate the $95 \%$ confidence intervals of the indirect effect using a procedure introduced by Hayes and Preacher (2013) for multiple predictor variables (SPSS-macro MEDIATE, http://www.afhayes.com/spss-sas-and-mplus-macros-andcode.html). A relative indirect effect is deemed to be statistically significant at $p=.05$ if these confidence
intervals do not include zero. This analysis revealed that the effect of the AMMA rhythm score on the tonal contrast was partially mediated by pitch acuity (the obtained lower and upper boundaries of the confidence interval were .0001 and .0048 , respectively). For the extracted pitch contour, there were no indirect effects.

Table 3: Standardized regression coefficients and proportion of variance accounted for in regression analyses with performance on tonal contrasts, pitch contours and vowel contrasts as criterion variables and sex, non-verbal intelligence, language background and musical ability measures as predictors at the first step (upper panel) and temporal, pitch and spectral acuity added at the next step (lower panel), ${ }^{* * *} \mathrm{p}<.001,{ }^{* *} \mathrm{p}<.01,{ }^{*} \mathrm{p}<.05,{ }^{\dagger} \mathrm{p}<.1$.

## Discussion

When different measures of auditory sensory acuity relevant to non-native speech-sound processing were added into a multiple regression model, they had an independent effect beyond effects of musical aptitude. For Norwegian tonal contrasts, the effect of musical aptitude was partially mediated by pitch acuity. For non-linguistic pitch contours and for vowels, performance was mainly predicted by temporal and spectral acuity rather than musical aptitude. This suggests that associations between musical aptitude and non-native speech-sound processing predominantly
arise from superior sensory processing encompassing the ability to make subtle distinctions in temporal, pitch, and spectral properties of the sounds. This finding is incompatible with claims that musical and linguistic processing exploits different cues-with language mainly relying on rapid temporal processing and music relying on processing of pitch and spectral information (Zatorre, Belin \& Penhune, 2002). By showing that musical aptitude contributes little to non-native speech sound processing beyond effects of temporal, pitch and spectral acuity, our findings underscore the importance of these basic sensory processes for both music and speech sound processing, and thereby support the idea of partially shared mechanisms (Patel, 2003; Strait, Hornickel \& Kraus, 2011). This is not to say that musical aptitude does not encompass other components that may or may not be shared with language; rather, we suggest that the links between musical aptitude tests and non-native speech sound processing reported in the literature may be due to basic temporal, pitch and spectral acuity to a significant degree.
Before sensory acuity measures were added to the regression model, effects of musical ability were found only for tonal contrasts and their non-linguistic analogues, but not for the phonemic vowel contrast. This confirms reports that the link between musicality and non-native speech sound processing is strongest for tonal contrasts (Delogu et al., 2006, 2010). Adding temporal, pitch and spectral acuity to the model qualified this picture: We had hypothesized that discrimination of tonal contrasts would be predicted by temporal as well as pitch and spectral acuity, whereas discrimination of vowel contrasts would be predicted mainly by spectral acuity. Indeed, for tonal contrasts and pitch contours this prediction bore out, although some effects fell short of significance. This confirms the previously observed role of temporal information, in addition to pitch and spectral information, in the processing of pitch contours, whether embedded in linguistic material or presented on their own (Kempe et al., 2012)-an important finding as researchers often conceive of lexical tones as predominantly involving pitch processing, even though lexical tones often entail changes of pitch and spectral information over time.
Counter to our prediction, we found that, along with spectral acuity, temporal acuity was also a significant predictor for vowel processing. This is surprising because we had carefully controlled for vowel length and metrical stress to exclude temporal information as an additional cue. Still, it is possible that participants were sensitive to subtle durational differences in other segments when trying to discriminate between the Norwegian words. Interestingly, performance with the vowel contrast was also significantly predicted by self-rating in an L3, which suggests that some of the languages participants studied later in life might have provided prior exposure to the $/ \mathrm{i} /-/ \mathrm{y} /$ vowel contrast, and this experience may have transferred to our stimuli. The effects of prior language experience notwithstanding, our findings suggest that both temporal and spectral acuity were
important predictors for the particular phonological contrast used in this study; the lack of a significant correlation of either AMMA scores with temporal acuity might explain why musical aptitude did not predict performance for this particular contrast.
More generally, our findings suggest that temporal, spectral and, to some extent, pitch acuity, underlie processing of a variety of non-native speech sounds. This adds an important facet to our understanding of speechsound processing in light of approaches that focus on rapid temporal auditory processing as the main sensory component underlying language (Goswami et al., 2002; Tallal, 1980). Moreover, subtle differences in the role of spectral, pitch, and temporal acuity in the processing of different phonemes might account for why links between musicality and non-native phoneme processing sometimes remain elusive (Delogu et al., 2006, 2010). For the tonal contrasts, on the other hand, the residual effects of musical aptitude may reflect shared working memory components (Williamson, Baddeley \& Hitch, 2010), in addition to sensory components, due to the somewhat longer duration of these stimuli. In addition, the finding that sensory acuity played a similar role in the processing of tonal contrasts and their non-linguistic analogues challenges the view that linguistic stimuli enjoy a special status with respect to basic sensory processing (Gandour et al., 2000)-a conclusion that needs to be verified through neuro-imaging studies.
The finding that the AMMA rhythm score was a better predictor of non-native tonal and pitch contour processing than the tonal score confirms similar findings with respect to non-native speech sound processing (Nardo \& Reiterer, 2009), as well as auditory working memory and reading performance in children (Strait et al., 2011). It appears that information related to repetitiveness, predictability and the sequential nature of sound sequences as measured by the rhythm score has greater diagnostic validity for detecting subtle changes in linguistic stimuli than information related to pitch differences.

A number of studies have conceptualized musicality as musical expertise and suggested that exposure to, and regular practice of music may hone sensory and cognitive abilities, which can subsequently benefit language processing (Marie et al., 2011; Wong et al., 2007). If this were correct one would expect experience with music, measured as number of years of musical training, to exert an independent effect on non-native speech sound processing. Musical training in our sample ranged from 0 to 20 years. Still, no independent effects of length of musical training on non-native speech-sound processing were found. Thus, our findings do not support the notion that musical expertise has independent effects over and above musical aptitude; rather, they suggest that auditory sensory acuity benefits performance both in the musical and the linguistic domain.

Finally, it is worth mentioning that our findings partially replicated the sex difference in non-native speech sound processing observed in previous studies (Bowles et al., 2011; Kempe et al., 2012). This sex difference was assumed
to be due to a general male advantage in rapid temporal auditory processing (Wittman \& Szelag, 2003) and temporal discrimination tasks (Rammsayer \& Troche, 2010), and, thus, should be found for processing of speech sounds that require rapid temporal auditory processing. Indeed, the difference in sensitivity for tonal contrasts and extracted pitch contours pointed towards a male advantage, although the effect fell short of statistical significance in the multiple regression analyses. In further support, a separate analysis for just the tonal and pitch contour stimuli yielded a main effect of sex, $F(1,101)=4.7, p<.05$. Surprisingly, however, the predicted male advantage was not observed for temporal acuity, $\mathrm{p}=.9$; instead, we found a male advantage in pitch acuity, $\mathrm{t}(101)=2.06, \mathrm{p}<.05$. This suggests that while a male advantage in processing of non-native tonal contrasts seems to be a robust phenomenon, future research may have to explore alternative explanations with respect to the underlying mechanisms.

In sum, our findings further illuminate the link between musical aptitude and non-native speech-sound processing by demonstrating that this link is largely explained by sensory acuity. Our results also suggest that temporal, pitch, and spectral acuity all contribute to the processing of a range of non-native speech sounds.

# Maximizing Students' Retention Via Spaced Review: Practical Guidance From Computational Models Of Memory 

Mohammad Khajah (mohammad.khajah@colorado.edu) Robert Lindsey (robert.lindsey@colorado.edu)<br>Michael Mozer (mozer@colorado.edu)<br>Department of Computer Science<br>University of Colorado<br>Boulder, CO 80309-0430

#### Abstract

During the school semester, students face an onslaught of new material. Students work hard to achieve initial mastery of the material, but soon their skill degrades or they forget. Although students and educators both appreciate that review can help stabilize learning, time constraints result in a trade off between acquiring new knowledge and preserving old knowledge. To use time efficiently, when should review take place? Experimental studies have shown benefits to long-term retention with spaced study, but little practical advice is available to students and educators about the optimal spacing of study. The dearth of advice is due to the challenge of conducting experimental studies of learning in educational settings where material is introduced in blocks over the time frame of a semester. In this paper, we turn to two established models of memory-ACT-R and MCM-to conduct simulation studies exploring the impact of study schedule on long-term retention. Based on the premise of fixed time each week to review, converging evidence from the two models suggests that an optimal review schedule obtains significant benefits over haphazard (suboptimal) review schedules. Further, we identify two scheduling heuristics that obtain near optimal review performance: (1) review the material from $\mu$-weeks back, and (2) review material whose predicted memory strength is closest to $\theta$. The former has implications for classroom instruction and the latter for the design of electronic tutors.

Keywords: spacing effect; memory model; ACT-R, MCM, optimization, learning, review

## Introduction

At every level of the educational system, from grade school through college through professional school, instructors and textbooks typically introduce students to new material in blocks. These blocks-sometimes called sections or units-represent conceptually coherent chunks of knowledge. For example, in a foreign language class, students may learn conversational skills concerning foods and restaurants one week, traveling the next week, and vacation activities the following week. In medical school, students may study vascular, pulmonary, and renal systems in consecutive months.

At the end of each block, teachers typically administer a quiz or assign a problem set to encourage students to master the material in the block. Because the students are rewarded for focusing on this task, they have little incentive at that moment to rehearse and practice material they have learned previously. As a result, forgetting is inevitable. Although anyone who has taught a
class appreciates the need for review, the time demands of review of old material must be balanced against the need to introduce new material, explain concepts, and encourage students toward initial mastery.

Achieving this balance requires an understanding of when students will most benefit from review. Reviewing material when it is fresh provides minimal benefit; however, waiting until material has been forgotten is also costly because the earlier study provides little benefit. A long history of research in experimental psychology has shown that the temporal distribution or spacing of study has a substantive impact on long-term retention. Selecting the ideal spacing of study can lead to nearly doubling retention of material on an educationally relevant time scale of a year (Cepeda, Vul, Rohrer, Wixted, \& Pashler, 2008). Evidence for the benefit of spaced study is found not only in the domain of declarative learning, but in conceptual understanding and cognitive skill acquisition (Carpenter et al., in press), and spacing manipulations have been shown to be effective in the classroom (e.g., Sobel, Cepeda, \& Kapler, 2011).

The goal of this paper is to leverage computer simulations to offer educators practical guidance about the optimal spacing of review in the context of a semesteror quarter-long class. In such a context, we assume that the class is divided into blocks, new material is introduced in each block, and some time during each block is allotted for review of old material. The issue at hand is what material should be reviewed and when. To state the issue formally, suppose that a semester consists of $B$ blocks, and in block $b, b=1 \ldots B$, the opportunity exists to review material from $N$ previous blocks, denoted $R_{b, n}, 1 \leq R_{b, n}<b$ and $n=1 \ldots N$. What review schedule, $\mathbf{R} \equiv\left\{R_{b, n}\right\}$, will maximize the students' memory for material following some retention interval $R I$ weeks after the end of the semester?

Conducting controlled experimental studies to answer this question is not feasible. Even if the opportunity is afforded for the review of only one $(N=1)$ block, the number of review schedules is $1 \times 2 \times \ldots \times(B-1)=$ $(B-1)$ !, and the combinatorics get worse for larger $N$. A typical high-school semester or a typical college quarter may have $B=10$ weeks of new material, for which $9!=362880$ possible review schedules exist.

Although the number of candidate schedules could be greatly pruned, it would be a significant undertaking to conduct an experimental study comparing even two alternative schedules over a time window spanning ten study blocks and a subsequent final evaluation.

Because of the difficulty in conducting multi-session studies over extended time periods, nearly all prior research on spacing has either focused on the case of two study sessions or spanned such a compressed time scale that its educational relevance is questionable. (Kang, Lindsey, Mozer, \& Pashler, submitted, offer a contrasting example.) Without recourse to controlled laboratory studies, one might conclude that cognitive science has little to offer educators beyond the qualitative advice to review material occasionally.

However, a trustworthy computational model can be used to optimize study, i.e., to search for the study schedule that will maximize student retention at some specified point or time window in the future. The cost of predicting performance with a computational model under a given study schedule is negligible relative to the cost of conducting a behavioral experiment. In past work, we've shown the potential benefits of optimizing study via a cognitive model (Lindsey, Mozer, Cepeda, \& Pashler, 2009). In the present work, we use models to explore a range of scheduling algorithms in order to identify both optimal schedulers and heuristic schedulers that well approximate the optimum in an extended classroom setting.

## Spaced Study And Memory Models

The spacing effect has been investigated for over a hundred years (Ebbinghaus, 1885/1964), and in additional to qualitative theories, many mathematical and computational models have been proposed to explain the phenomenon (e.g., Benjamin \& Tullis, 2010; Raaijmakers, 2003). However, two recent efforts have been fairly comprehensive in obtaining quantitative fits to data and both have shown promise in predicting the outcome of experimental studies: an extension of the ACT-R model of memory (Pavlik \& Anderson, 2005, 2008), and a model we developed called the Multiscale Context Model or MCM (Mozer, Pashler, Cepeda, Lindsey, \& Vul, 2009). We summarize the two models and then turn to using the models as a proxy for human performance to predict the optimal spacing of study. Lindsey et al. (2009) compared qualitative predictions of ACT-R and MCM in hypothetical situations, and the models gave some contrasting results. However, these earlier simulation studies did not explore the predictions of the models in a practical educationally relevant setting.

## ACT-R

ACT-R (Anderson et al., 2004) is an influential cognitive architecture whose declarative memory module is often
used to account for explicit recall following study. ACT$R$ assumes that a separate trace is laid down each time an item is studied, and the trace decays according to a power law, $t^{-d}$, where $t$ is the age of the memory and $d$ is the power law decay for that trace. Following $n$ study episodes, the activation for an item, $m_{n}$, combines the trace strengths of individual study episodes:

$$
m_{n}=\ln \left(\sum_{k=1}^{n} b_{k} t_{k}^{-d_{k}}\right)+\beta
$$

where $t_{k}$ and $d_{k}$ refer to the age and decay associated with trace $k$, and $\beta$ is a student- and/or item-specific parameter that influences memory strength. The variable $b_{k}$ reflects the salience of the $k$ th study session (Pavlik, 2007): larger values of $b_{k}$ correspond to cases where, for example, the participant self-tested and therefore exerted more effort.

To explain spacing effects, Pavlik and Anderson (2005; 2008) made an additional assumption: the decay for the trace formed on study trial $k$ depends on the item's activation at the point when study occurs:

$$
d_{k}\left(m_{k-1}\right)=c e^{m_{k-1}}+\alpha
$$

where $c$ and $\alpha$ are constants. If study trial $k$ occurs shortly after the previous trial, the item's activation, $m_{k-1}$, is large, which will cause trace $k$ to decay rapidly. Increasing spacing therefore benefits memory by slowing decay of trace $k$. However, this benefit is traded off against a cost incurred due to the aging of traces $1 \ldots k-1$ that causes them to decay further. The probability of recall is monotonically related to activation:

$$
p(m)=1 /\left(1+e^{\frac{\tau-m}{s}}\right)
$$

where $\tau$ and $s$ are additional parameters. In total, the variant of the model described here has six free parameters.

Pavlik and Anderson (2008) use ACT-R activation predictions in a heuristic algorithm for within-session scheduling of trial order and trial type (i.e., whether an item is merely studied, or whether it is first tested and then studied). They assume a fixed spacing between initial study and subsequent review. Thus, their algorithm reduces to determining how to best allocate a finite amount of time within a session. Although they show an effect of the algorithm used for within-session scheduling, we focus on the complementary issue of between-session scheduling. The between-session manipulation has a far greater impact on long-term retention (Cepeda, Pashler, Vul, Wixted, \& Rohrer, 2006).

## MCM

ACT-R is posited on the assumption that memory decay follows a power function. We developed an alternative model, the Multiscale Context Model or MCM (Mozer et al., 2009), which provides a mechanistic basis
for the power function. Adopting key ideas from previous models of the spacing effect (Kording, Tenenbaum, \& Shadmehr, 2007; Raaijmakers, 2003; Staddon, Chelaru, \& Higa, 2002) MCM proposes that each time an item is studied, it is stored in multiple item-specific memory traces that decay at different rates. Although each trace has an exponential decay, the sum of the traces decays approximately as a power function of time. Specifically, trace $i$, denoted $x_{i}$, decays over time according to:

$$
x_{i}(t+\Delta t)=x_{i}(t) \exp \left(-\Delta t / \tau_{i}\right)
$$

where $\tau_{i}$ is the decay time constant, ordered such that successive traces have slower decays, i.e., $\tau_{i}<\tau_{i+1}$. Traces $1-k$ are combined to form a net trace strength, $s_{k}$, via a weighted average:

$$
s_{k}=\frac{1}{\Gamma_{k}} \sum_{i=1}^{k} \gamma_{i} x_{i}, \text { where } \Gamma_{k}=\sum_{i=1}^{k} \gamma_{i}
$$

and $\gamma_{i}$ is a factor representing the contribution of trace $i$. In a cascade of $K$ traces, recall probability is simply the thresholded strength: $P($ recall $)=\min \left(1, s_{K}\right)$.

Spacing effects arise from the trace update rule, which is based on Staddon et al. (2002). A trace is updated only to the degree that it and faster decaying traces fail to encode the item at the time of study. This rule has the effect of storing information on a time scale that is appropriate given its frequency of occurrence in the environment. Formally, when an item is studied, the increment to trace $i$ is negatively correlated with the net strength of the first $i$ traces, i.e.,

$$
\Delta x_{i}=\epsilon\left(1-s_{i}\right)
$$

where $\epsilon$ is a step size. We adopt the retrieval-dependent update assumption of Raaijmakers (2003): $\epsilon=1$ for an item that is not recalled at the time of study, and $\epsilon=\epsilon_{r}$ $\left(\epsilon_{r}>1\right)$ for an item that is recalled.

The model has only 5 free parameters $\left(\epsilon_{r}\right.$, and 4 parameters that determine the contributions $\left\{\gamma_{i}\right\}$ and the time constants, $\left\{\tau_{i}\right\}$ ). MCM was designed such that its parameters could be fully constrained by data that are easy to collect-the function characterizing forgetting folllowing a single study session-which then allows the model to make predictions for data that are difficult to collect-the function characterizing forgetting following a study schedule consisting of two or more study sessions. MCM has been used to obtain parameter-free predictions for various results in the spacing literature.

## Methodology

## Model Parameterization

Different parameterizations of ACT-R and MCM are critical to accounting for a range of learning scenariosscenarios that encode the ability and background knowledge of students, the difficulty of material, the manner of

Figure 1: The 105 power-function forgetting curves used to represent a diversity of learning scenarios (i.e., learning tasks varying in material difficulty, student ability, manner of study, and potential interference.
study, and the degree to which previously learned material interferes with or facilitates the learning of new material. Because our goal is to obtain results that have some generality across scenarios, we simulate a wide range of scenarios and base our results on the average over scenarios. We summarize the many factors that comprise a scenario in terms of a forgetting curve, which specifies the probability that material learned in a single study session will be available at some later point in time. Figure 1 shows a family of 105 forgetting curves, all of which decay according to a power function of time. This family expresses a diverse range of naturally occurring degrees of forgetting.

For MCM, we search for model parameters that well approximate each forgetting curve. MCM has five free parameters, one of which $\left(\epsilon_{r}\right)$ was set based on previous simulations, and the other four of which directly determine and are fully constrained by the shape of the forgetting curve. For ACT-R, we fixed $b_{k}=1$, but because its remaining free parameters are not fully constrained by the forgetting curve, we used the parameterized MCM to generate data which was then used to fit ACT-R parameters, ensuring that matched parameter sets had a loose correspondence. The generated data consisted of two study sessions with intersession intervals ranging from minutes to weeks, and a subsequent final test days to months later. This procedure yielded 105 matched instantiations of MCM and ACT-R, reflecting a wide range of scenarios.

## Simulated Learning Experiment

We conducted separate simulations of MCM and ACT$R$ to model the performance of a student learning new material in each of $B=10$ weekly blocks. We assumed homogeneity of material in a block, allowing the block's material to be distilled into a single item for the purpose of the simulation. Initial study was simulated as a single training trial to the model, though this training trial - and the corresponding memory trace - is intended to correspond to the net effect of concentrated study over multiple trials by a student learner.

Review was included in the curriculum starting after a

Figure 2: (left, middle panels) Activation trace from MCM for 10 blocks of material for good and poor review schedules. (right panel) Predicted performance on cumulative exam as a function of week in semester for alternative review schedules.
$D$-week delay. Review consists of selecting one previous block's material and presenting it as a training trial to the model. We simulated the $(B-1)!/(D-1)$ ! distinct review schedules. We allowed $D$ to vary because when review begins earlier in the semester, the number of sensible review schedules significantly shrinks. For example, with $D=1$, the only option for week 2 review is week 1 ; this selection has consequences the next week because in week 3 , review of week 1 again adds little benefit, so a sensible option is to review week 2 ; and so forth.

To evaluate the effectiveness of a review schedule, mean recall accuracy over the $B$ blocks was assessed by querying the model with a final recall test following a retention interval of $R I$ weeks past the end of the semester.

## Alternative Review Schedulers

To summarize, we consider two models of human learning (ACT-R and MCM), 105 scenarios (model parameterizations), 3 retention intervals ( $R I=1,4,26$ weeks), and 3 review delays ( $D=1,2,3$ weeks), for a total of 1890 distinct combinations. For each combination, we conducted an exhaustive search through the set of distinct review schedules to determine the optimal schedule - the schedule that yields the highest average accuracy on the final test according to the model.

In addition, we considered various heuristic schedulers. Our goal is to identify heuristics that produce a close-to-optimal schedule. The two best heuristic schedulers were as follows. A $\mu$-back scheduler follows a simple rule: in week $i$, review material from week $\max (1, i-\mu)$. A $\theta$-threshold scheduler is motivated by Bjork's (1994) notion of desireable difficulty - that material should be restudied as it is on the verge of being forgotten. Using a memory model to determine the strength of each week's material, this scheduler selects the material whose recall probability closest to $\theta$. Because we use the same model for scheduling as we use for modeling the student, this scheduler offers a best-case use of the $\theta$-threshold. (We also explored several variants of the threshold scheduler which yielded poorer performance. One variant uses a scaled threshold rule whereby the threshold value is relative to the range of performance over all weeks' material. Another uses an asymmetric threshold where the selection is for material whose recall probability is close to the threshold on one side - either above or below.)

## Results

Figure 2 provides an intuition about the operation of our model-based scheduling. The left panel of the Figure shows ten curves, each representing the memory strength predicted by MCM for one block of material as a function of weeks into the semester. The color coding from red to blue indicates blocks $1-10$, respectively. In this example, block $i$ is introduced in week $i$ and is then reviewed in week $i+1$. As a result, the block gets a bump in strength in weeks $i$ and $i+1$, and then decays from that point on. The curves in the Figure represent the average over the 105 learning scenarios, and the ordinate of the graph shows the expected recall probability over these scenarios. The absolute probability is immaterial and is a consequence of the specific scenarios we simulate. However, relative probabilities matter. To emphasize this point, the middle panel of the Figure shows an activation trace for an arbitrary and somewhat bad review schedule. The right panel shows the same time history of activation, but averaged over the individual blocks to obtain a prediction of cumulative-exam performance (weighting all blocks equally) at a given time. The superiority of the one-back schedule (left panel) over the arbitrary (middle panel) is reflected in a higher average recall probability. Four weeks following the end of the 10 -week semester, the better review schedule achieves a $89.7 \%$ improvement in retention over no review, and a $16.1 \%$ improvement in retention over the poorer quality review schedule.

## Exhaustive Search Of Alternative Schedules

Figure 3 shows a set of curves that reflect the expected perfomance of all possible review schedules for a given simulation, sorted from worst to best. The average is taken over learning scenarios. Each graph shows three simulations, one per retention interval $(R I=1,4,26$ weeks). The top and bottom rows are simulations of MCM and ACT-R, respectively. The columns from left-to-right correspond to simulations in which review begins following weeks 1,2 , and $3(D=1,2,3)$. The colored squares on the left of each graph indicate the performance of a 'no review' condition for the retention interval of the corresponding color. Not surprisingly, all review schedules are superior to no review, and well-timed review is as much as $33 \%$ better than poorly-timed review.

Figure 3: Each curve is the sorted performance of all possible review schedules (The x-axis is an index over distinct review schedules). Each curve corresponds to one retention interval (RI). Top and bottom rows are simulations of MCM and ACT-R, respectively. The columns correspond to simulations in which review onset begins following weeks 1,2 , and 3 , respectively. Colored squares indicate the performance of a 'no review' schedule. Digits indicate the performance of the heuristic $\mu$-back scheduler, for $\mu=1,2,3$. The green disk (.) indicates the performance of the $\theta$ threshold scheduler for optimal $\theta$.

Figure 4: (a) Relative performance predicted by MCM and ACT-R for the $\theta$-threshold heuristic as a function of $\theta$ (for $D=1, R I=1$ ). (b) Relative performance of the 2-back schedule over all learning scenarios, sorted from best to worst (for $D=1, R I=1$ ). In both graphs, performance is relative to the exhaustive space of schedules.

## $\theta$-Threshold Heuristic Scheduler

The key result in Figure 3 concerns the performance of heuristic schedulers relative to the optimum schedule discovered by exhaustive search. For each curve, the location of the green disk indicates the relative ranking of the $\theta$-threshold schedule, for the best setting of $\theta$. The further to the right along the x -axis, the higher the ranking. The two models are consistent in predicting that the $\theta$-threshold scheduler is as good or nearly as good as the best schedule found by exhaustive search. Figure 4a shows how the predicted performance varies as a function of $\theta$ for the two models, for a delay of $D=1$ week and a retention interval of $R I=1$ week. The ordinate indicates the relative performance in the range defined by the complete space of schedules, where $100 \%$ and $0 \%$ correspond to the best and worst sched-
ules found by exhaustive search, respectively. Notably, the two models yield very similar curves, and although the $\theta$-threshold scheduler does not produce the very best schedule, it comes reasonably close. Notably, both MCM and ACT-R are consistent in indicating that a threshold in the neighborhood of $\theta=.4$ is best. We have shown the curve for $D=1$ and $R I=1$, but curves for the other values of $D$ and $R I$ are quite similar, and all have the same optimum for $\theta$.

The limitation of a threshold scheduler is that it requires an accurate model to predict memory strength as a function of time given some history of study. In our simulation, we've assumed that the model we use for determining memory strength - either MCM or ACT-R - is a veridical model of our (simulated) student. An important question for future research concerns how the accuracy of the model used for scheduling affects the performance of the $\theta$-threshold scheduler. However, it is clear that whatever model is used must take into account the history and spacing of past study, because the effect of distributed practice - as embodied in both MCM and ACT-R - is central to the difference in performance across review schedules.

## $\mu$-Back Heuristic Scheduler

Figure 3 also depicts the performance of the 1-, 2-, and 3 -back schedules, all of which do reasonably well across models, delays, and retention intervals. However, because ACT-R predicts the 1-back schedule to be inferior for $D=2,3$, and because MCM predicts the 3 -back schedule to be slightly worse for $D=1,2$, we suggest that the $\mu=2$, or the 2 -back schedule, might be adopted as a robust solution across conditions.

All results we've presented to this point are the average over the 105 learning scenarios. It's possible that
the $\mu$-back schedules work well on average but not for specific scenarios. To examine the performance of the 2-back schedule across scenarios, Figure 4b shows the performance in each scenario, sorted from best to worst. The curves for MCM and ACT-R are remarkably similar, and indicate that the 2-back schedule performs well for the majority ( $60-80 \%$ ) of scenarios we considered, further supporting our claim of its robustness.

## Discussion

In a metaanalysis of the experimental literature, the optimal spacing of study was found to grow monotonically with the retention interval (Cepeda et al., 2006). Although in past work we've shown that MCM and ACT-R both predict this characteristic, neither model strongly predicts that the best $\mu$ in the $\mu$-back scheduler should increase with the retention interval (Figure 3). Most likely, this inconsistency is due to the fact that as $\mu$ increases, the initial $\mu+1$ weeks of study become focused on the first week's material, and there are diminishing returns of this focus. Consequently, the benefits of increased spacing must be outweighed by the cost of illspent review time. This result suggests to us the importance of moving beyond laboratory studies of spacingtypically with two study sessions and a single block of material to be learned-to situations more reflective of real-world educational constraints, i.e., semesters in which multiple blocks of material are presented staggered in time and initial study must be interlaced with review.

Our results provide practical guidance to educators: To preserve learning beyond the end of a semester, a 2-back review schedule should generally be appropriate. Although classroom teachers do not have access to mathematical models of human memory, and therefore cannot exploit the $\theta$-threshold scheduler, we see great potential of incorporating model-based scheduling into electronic tutors used in synchronization with classroom instruction (Lindsey et al., in preparation). Indeed, such an approach opens the possibility to personalized review appropriate for a specific student rather than a one-size-fits-all approach. Our caveat in suggesting this approach is that it requires accurate psychological models of memory. Models based on intuition-as embodied in existing web-based flashcard apps-are unlikely to be adequate.

#### Abstract

Why do languages have the categories they do? It has been argued that spatial terms in the world's languages reflect categories that support highly informative communication, and that this accounts for the spatial categories found across languages. However, this proposal has been tested against only nine languages, and in a limited fashion. Here, we consider two new languages: Maijiki, an under-documented language of Peruvian Amazonia, and English. We analyze spatial data from these two new languages and the original nine, using thorough and theoretically targeted computational tests. The results support the hypothesis that spatial terms across dissimilar languages enable near-optimally informative communication, over an influential competing hypothesis.

Keywords: Spatial terms; semantic universals; informative communication; language and thought; semantic maps.

## Spatial categories across languages

Spatial terms across languages often pick out different categories, as illustrated in Figure 1. Yet at the same time similar or comparable categories often recur across unrelated languages.

Figure 1: 10 spatial scenes, as categorized in 2 languages: Tiriyó and Yélî-Dnye. Source: Levinson et al. (2003).

A central question in cognitive science is why languages have the categories they do - in this case, why spatial categories exhibit the constrained cross-language variation they do (Bowerman \& Pederson, 1992; Bowerman, 1996; Talmy, 2000; Levinson et al., 2003).

## Informative communication

Recently, an answer to this question has been proposed that is grounded in general communicative principles. Khetarpal, Majid, \& Regier (2009) argued that across languages, spatial categories are shaped by the need to support informative communication. On this view, the many different spatial systems observed across languages represent different means to this same end. This argument mirrors analogous arguments that have recently been advanced for the semantic domains of color (Regier, Kay, \& Khetarpal, 2007) and kinship (Kemp \& Regier, 2012), and also reflects a more general recent focus on informative communication as a central force that explains why languages take the forms they do (e.g. Fedzechkina, Jaeger, \& Newport, 2012; Piantadosi, Tily, \& Gibson, 2011).

Khetarpal et al. (2009) considered the 71 spatial scenes of the topological relations picture series or TRPS (Bowerman \& Pederson, 1992), illustrated in part in Figure 1, as named by speakers of 9 unrelated languages: Basque, Dutch, Ewe, Lao, Lavukaleve, Tiriyó, Trumai, Yélî-Dnye, and Yukatek (Levinson et al., 2003). Each of these languages groups TRPS scenes together into languagespecific spatial categories, and Khetarpal et al. (2009) asked whether these attested groupings support near-optimally informative communication. In a series of computational simulations, they asked whether each of these linguistic spatial systems supports informative communication better than a comparison class of hypothetical systems. They found that this is indeed the case. They concluded that spatial terms across languages reflect near-optimally informative spatial categories, and that this functional force may help to explain which spatial categories appear in the world's languages.

However, this earlier work is limited in three important respects. First, it considered data from only nine languages.

Such data are difficult and time-consuming to collect, and we are grateful to our colleagues at the MPI Nijmegen for sharing their data with us. Still, this is a very small sample, so it is possible that other languages would break the generalization made on the basis of these nine. Second, the earlier work tested the near-optimality claim against these nine languages in a narrow and limited way. Each language was compared to only 69 hypothetical systems that were intended to be comparable to it. Thus it is possible that many other, unexamined hypothetical systems may exist that are more informative than the attested system - again potentially breaking the generalization and undercutting the central theoretical claim. Third, the earlier work did not test the informativeness proposal against alternative explanations for constrained semantic variation.

Here we bring new data and analyses to bear on the claim that spatial categories across languages support informative communication, and that this force may account for the observed variation in spatial systems. The new data are from Maijiki, an under-documented language of Peruvian Amazonia, and English. The new analyses compare eleven languages (Maijiki, English, and the nine languages from Levinson et al., 2003) to much larger and more theoretically targeted sets of hypothetical systems. Critically, unlike the earlier analyses, the new analyses explicitly pit the claim of near-optimal informativeness against the competing and influential theoretical claim that semantic categories tend to pick out connected regions of conceptual or perceptual space (e.g. Croft, 2003; Haspelmath, 2003; Roberson, Davies, \& Davidoff, 2000; Roberson, 2005).

In what follows we first describe Maijiki and its spatial system, comparing it with that of English. We then lay out the hypotheses to be tested, our analyses of the eleven languages under consideration, and the results of these analyses. We conclude from these results that spatial systems across languages do indeed reflect near-optimally informative categories, and that this proposal is supported over the competing claim that categories pick out connected regions of conceptual or perceptual space. We suggest that the functional goal of informative communication may account for the wide but constrained variation found in spatial systems across languages.

## Maijiki

Maijiki is an under-documented Western Tukanoan language of Peruvian Amazonia, spoken in the departmento of Loreto, near the Colombian-Peruvian border. The language is spoken by approximately 100 individuals, of whom some 25 are Maijiki-dominant, although there are no monolingual speakers. The language is currently being documented as part of the Maijiki Project, a multi-year effort to produce a grammar, text collection, and dictionary of the language (Michael, Beier, \& Farmer, 2012). Maijiki is unrelated to the other languages that we consider in this paper.

The spatial system of Maijiki has only recently been investigated, and is described in detail by Neveu and

Michael (in preparation). Spatial meanings are conveyed in Maijiki by several means, including spatial adpositions and spatial verbs. For simplicity we focus on the major spatial adpositions, listed in Table 1 (tone marks are suppressed here and elsewhere in this paper).

Table 1: Spatial adpositions in Maijiki.

| Adposition | Approximate meaning |
| :---: | :--- |
| guibi | under |
| gunu | near an edge |
| imijai | on top or above |
| jeteruru | behind |
| sanu | inside at bottom |

The extensions of these Maijiki spatial adpositions are illustrated in Figure 2 below, as subsets of the full set of 71 scenes in the TRPS. Also shown for comparison are spatial categories in English. In each of the 71 scenes, the figure object is shown in orange, the ground object in black, and the corresponding spatial meaning is the spatial relation between the figure and the ground. As can be seen, the spatial categories of Maijiki differ from those of English. We seek general principles that help to determine which logically possible groupings of scenes constitute categories that are attested in the world's languages.

## Hypotheses

We consider two hypotheses, which our analyses pit against each other, using data from Maijiki, English, and the nine languages of Levinson et al. (2003).

## Near-optimally informative communication

The first hypothesis is the one sketched above: that spatial categories across languages appear as they do because these categories maximize or near-maximize the informativeness of communication. We take a communicative system to be informative to the extent that it supports accurate mental reconstruction by a listener of a speaker's intended meaning (cf. communication accuracy: Lantz \& Stefflre, 1964). This general idea, which also applies to other semantic domains, can be made concrete through the following communicative scenario.

A speaker has a particular spatial relation in mind, and wishes to communicate it to a listener. To that end, the speaker produces a spatial term that describes this spatial relation. The listener must then mentally reconstruct the original spatial relation that the speaker intended, from the term used. Because the listener knows only that the intended spatial relation falls in the general category named by the spatial term, the listener's mental reconstruction is the set of all spatial relations that are named by the term. We define the reconstruction accuracy to be the similarity of this mental reconstruction to the original intended spatial relation. In general, we hold that informative categories, and informative systems of categories, are those that support high reconstruction accuracy.

Figure 2: A semantic map showing spatial categories from Maijiki (red) and English (blue). Categories that appear in both languages are shown in black. Links connect scenes that are presumed to be universally related across languages. All displayed categories in both Maijiki and English pick out connected regions of the map.

We formalize these ideas as follows. ${ }^{1}$ Let $S$ be the set of all possible spatial relations (here approximated by the spatial scenes of the TRPS, or the subset of those scenes that are assigned names by a given language). Let $\operatorname{sim}(x, y)$ be the similarity between two spatial relations $x$ and $y$ (here, similarity is gauged empirically as described below, and ranges from $0=$ completely dissimilar to $1=$ maximally

[^114]similar). Let $s$ be the specific spatial relation the speaker intends to convey, let $t$ be the spatial term used to describe that spatial relation, and let $\operatorname{cat}(t)$ be the category or set of all spatial relations described by $t$, including $s$. Finally, let $\operatorname{era}(s)$ be the expected reconstruction accuracy of scene $s$, i.e. the similarity between the target spatial relation $s$ and the listener's reconstruction of that spatial relation, based on the speaker's spatial term $t$. This is the average, over all spatial relations $r$ in the same named category $\operatorname{cat}(t)$ as $s$, of the similarity between $r$ and $s$ :
\[

$$
\begin{equation*}
\operatorname{era}(s)=\frac{1}{|\operatorname{cat}(t)|} \sum_{r \in \operatorname{cat}(t)} \operatorname{sim}(r, s) \tag{1}
\end{equation*}
$$

\]

The overall expected accuracy of reconstruction, over all possible stimuli, is then given by:

$$
\begin{equation*}
R=\frac{1}{|S|} \sum_{s \in S} e r a(s) \tag{2}
\end{equation*}
$$

$R$ is a measure of how well a given communicative system supports informative communication. The first hypothesis we consider is that attested linguistic spatial systems will tend to exhibit high $R$, compared with hypothetical systems.

## The semantic map connectivity hypothesis

The second hypothesis we consider holds instead that attested categories pick out connected regions of a universal network of meanings called a semantic map (e.g. Croft, 2003; Haspelmath, 2003). Figure 2, in which we saw the spatial systems of Maijiki and English, is an example of a semantic map. Here the meanings are spatial meanings, represented by the spatial scenes of the TRPS. These spatial meanings are assumed to be universally available, and the links in the network represent presumed universally available connections between closely related spatial meanings. As we have seen, different languages often group these meanings into categories differently, and these language-specific groupings are also displayed in the map. Thus a semantic map represents both presumed universal semantic structure and language-specific parcelings of that structure.

The core idea behind a semantic map is that across languages, semantic categories will always pick out connected regions of the network. In other words, a category should correspond to a group of meanings (here, scenes) that are connected in the sense that one may travel from any meaning in the category to any other by repeatedly traversing links in the network. The semantic map in Figure 2 was inferred automatically (Regier, Khetarpal, \& Majid, in press) to accommodate, as connected regions, the spatial categories of the nine languages of Levinson et al. (2003). As can be seen, this network generalizes well to Maijiki and English: all the displayed Maijiki and English spatial categories also pick out connected regions of this map, although Maijiki and English were not considered in its construction. ${ }^{2}$ This fact suggests that the inferred universal structure of this semantic map, and the criterion of connectedness implicit in it, may in fact be an important constraint on semantic categories across languages. Similar ideas emphasizing the importance of connectedness as a determinant of what makes a good or natural category may also be found elsewhere (e.g. Levinson et al., 2003; Roberson, Davies, \& Davidoff, 2000; Roberson, 2005).

[^115]
## Goal of our analyses

It has been previously suggested (e.g. Croft, 2003: 138; Cysouw, 2001: 609; Regier et al., in press) that connectedness in a semantic map may be too loose a constraint on category shape, in part because it allows elongated categories with no clear central region; thus, semantic categories in actuality may tend to be more compact and coherent than is suggested by this constraint alone. However it has not yet been determined whether informativeness provides a better account of cross-language variation in semantic systems. The analyses we present below seek to answer this open question, by deliberately pitting informativeness and connectedness against each other.

## Analyses

We reasoned with the following predictions. The informativeness hypothesis predicts that attested linguistic spatial systems will support informative communication more effectively than almost all hypothetical systems - even if those hypothetical systems all pick out connected regions of a semantic map. The connectedness hypothesis in contrast does not make this prediction. Instead, on that hypothesis, it is connectedness rather than informativeness that plays a privileged role in determining which possible systems are actually attested - and so the informativeness of an attested linguistic spatial system should not tend to be any greater than the informativeness of other connected hypothetical systems.

For this reason, in our analyses we compared the informativeness of an actual linguistic spatial system with that of hypothetical variants, all of which correspond to connected regions of the semantic map of Figure 2. If informativeness is a major determinant of attested category systems, we expect the actual linguistic spatial system to support informative communication better than the connected hypothetical variants.

## Crawling a semantic map

We generated hypothetical connected variants of existing systems by randomly "crawling" a semantic map, by analogy with web-crawling - that is, through random graph traversal of a semantic map. We began with the semantic map in Figure 2, but with no labels assigned to the scenes. Then, for a given target language (e.g. English), we construct a hypothetical connected variant of that language as follows. Start by randomly selecting one the spatial terms in the language-call this term $t$ and the number of scenes associated with it $k$. Now randomly select one of the scenes in the graph and label it $t$. Then select another scene at random from the set of as-yet-unlabeled scenes directly connected to some scene already labeled $t$, and label that new scene $t$ as well; if there are no such scenes from which to select, the procedure terminates and begins again with no labels on any nodes. This step of extending the label $t$ to neighboring scenes is repeated until there are $k$ scenes
associated with $t$. The process as a whole is repeated for all terms in the language.

## Methods

We conducted semantic-map-crawling analyses separately for each of the eleven languages under consideration: Maijiki, English, Basque, Dutch, Ewe, Lao, Lavukaleve, Tiriyó, Trumai, Yélî-Dnye, and Yukatek. For each language, 2000 hypothetical connected variants were generated as described above, each with the same number of categories, and the same number of scenes per category, as the original. For each real or hypothetical spatial naming system, we calculated $R$, our measure of reconstruction accuracy, using equations 1 and 2 above. The categories $\operatorname{cat}(t)$ used to label specific scenes were determined by the naming system under consideration. The similarity of each pair of scenes $x$ and $y, \operatorname{sim}(x, y)$, was determined empirically by pile-sorting. Khetarpal et al. (2009) had asked speakers of English and Dutch to sort the TRPS scenes into piles on the basis of the similarity of the spatial relation portrayed, and they took the similarity of any two scenes to be the proportion of all their participants who sorted those two scenes into the same pile. ${ }^{3}$ We used the pile-sort-derived similarity judgments from that earlier study. For each language, we then compared the reconstruction accuracy $R$ for the language itself to the distribution of $R$ obtained for hypothetical connected variants of that system.

## Results

Figure 3 below presents the results of our analysis of Maijiki. The red line shows the informativeness $(R)$ of the Maijiki spatial adpositional system, and the blue histogram shows the frequency with which various values of $R$ were exhibited by hypothetical connected variants of Maijiki, obtained by randomly crawling the semantic map of Figure 2.

Figure 3: Informativeness of communication supported by the Maijiki spatial adpositional system (red line), compared with that supported by 2000 hypothetical variants derived by randomly crawling a semantic map (blue histogram).

The actual Maijiki system supports informative communication more effectively than any of the sampled

[^116]hypothetical connected variants. These results are consistent with the claim that languages tend to have highly informative spatial systems, and that informativeness is more relevant to the shape of such systems than is connectedness. Similar results from other languages would strengthen this conclusion.

Figure 4 below presents analogous results for English. Again, the actual English system supports informative communication more effectively than any of the sampled hypothetical connected variants.

Figure 4: Informativeness of communication supported by the English spatial system (red line), compared with that supported by 2000 hypothetical variants derived by randomly crawling a semantic map (blue histogram).

Finally, Table 2 below presents summary results of semantic map crawling analyses for all eleven languages we consider. In this case, the results are given numerically, as the proportion of hypothetical variants that the actual linguistic system scores higher than in $R$ (reconstruction accuracy). The results shown here for Maijiki and English summarize the results from the histograms displayed above; for the remaining nine languages, we present results in summary form only, to conserve space. In all cases, the actual linguistic system outperforms most of the sampled hypothetical connected variants, and in several cases it outperforms all of them.

Table 2: Summary results of semantic map crawling analyses for all languages considered in this study.

| Language | Result |
| :--- | :--- |
| Basque | $>99.95 \%$ |
| Dutch | $>100.00 \%$ |
| English | $>100.00 \%$ |
| Ewe | $>99.95 \%$ |
| Lao | $>96.20 \%$ |
| Lavukaleve | $>99.75 \%$ |
| Maijijki | $>100.00 \%$ |
| Tiriyó | $>100.00 \%$ |
| Trumai | $>100.00 \%$ |
| Yélî-Dnye | $>97.35 \%$ |
| Yukatek | $>99.95 \%$ |

In sum, each of the 11 languages considered supports informative communication more effectively than most sampled hypothetical variants of those systems - even when
the variants are connected regions of a semantic map. These results are consistent with the hypothesis that informativeness shapes category systems across languages, and that it does so more than connectedness in a semantic map.

## Conclusions

Our findings support the claim that spatial systems across languages reflect the need for informative communication. They do so based on new evidence, including evidence from an under-documented language, and on new large-scale analyses that directly pit informativeness against the competing claim that natural categories pick out connected regions of a semantic map.

These findings also leave a number of issues unresolved, suggesting directions for future investigation. Theoretically, our analyses have focused on the informativeness of a given system, by comparing that system to competitors of comparable complexity - thus deliberately controlling for, and not investigating, the complexity of these systems. A more complete account would investigate both informativeness and complexity, and the tradeoff between these two general forces (e.g. Kemp \& Regier, 2012). Empirically, eleven languages is still a small sample when considered relative to all existing languages. We feel that every new language considered adds important evidence, particularly under-documented languages such as Maijiki but consideration of more languages will allow more definitive conclusions.

Nonetheless, the present results lend substantial new support to the hypothesis that informativeness plays an important role in shaping spatial semantic systems across languages. In so doing, these results add to the current literature that suggests that the need for informative communication may be a key functional force that explains why languages have the forms that they do.

#### Abstract

Affect is important in motivated performance situations such as negotiation. Longstanding theories of emotion suggest that facial expressions provide enough information to perceive another person's internal affective state. Alternatively, the contextual emotion hypothesis posits that situational factors bias the perception of emotion in others' facial displays. This hypothesis predicts that individuals will have different perceptions of the same facial expression depending upon the context in which the expression is displayed. In this study, cardiovascular indexes of motivational states (i.e., challenge vs. threat) were recorded while players engaged in a multiissue negotiation where the opposing negotiator (confederate) displayed emotional facial expressions (angry vs. happy); the confederate's negotiation strategy (cooperative vs. competitive) was factorially crossed with his facial expression. During the game, participants' eye fixations and cardiovascular responses, indexing task engagement and challenge/threat motivation, were recorded. Results indicated that participants playing confederates with incongruent facial expressions (e.g., cooperative strategy, angry face) exhibited a greater threat response, which arises due to increased uncertainty. Eye fixations also suggest that participants look at the face more in order to acquire information to reconcile their uncertainty in the incongruent condition. Taken together, these results suggest that context matters in the perception of emotion.

Keywords: facial expressions, negotiation, context in emotion

## Introduction

Negotiation is relatively common in personal and professional settings. A child might ask a parent whether she can leave the dinner table. The parent might sternly command the child to finish her vegetables and the child could make a counter offer to finish the peas but not the broccoli. This could ensue into a strategic and emotionally charged social interaction.

Emotion is an important human factor in motivated performance situations (i.e., those that are self-relevant and therefore task engaging and require instrumental cognitive responses; Blascovich, 2008). Such interactions are rarely
affectively neutral; that is, they are associated with interactants' positive or negative emotional states. Clearly, negotiations represent motivated performance situations to interested partners. And, experimental negotiation tasks are no exception, including those involving real human players (Van Kleef, De Dreu, \& Manstead, 2004) and digital agents (i.e., player representations driven by computer algorithms, de Melo, Carnevale, \& Gratch, 2011).

The current work examines individuals' motivational responses, using physiological indexes, to emotionally expressive virtual characters in a multi-issue negotiation task. Specifically, we focus on the question of how situational context affects emotion perception from facial expressions. In person-to-agent negotiation tasks, experimenters often insert communicative cues such as agent facial expressions intended to strategically manipulate user's emotions. Agents that show emotion have now been used in several domains such as education, entertainment, training, therapy and commerce (for a review see Beale \& Creed, 2009). In a multi-issue negotiation task, de Melo and colleagues (2011) reported that participants made more concessions to a virtual human that displayed an angry facial expression compared to a happy facial expression.

Most research on the effects of virtual characters' emotional facial expressions has relied on subjective responses from participants (e.g., Beale \& Creed, 2009). However, given the evidence that emotion is processed via non-conscious pathways, perhaps more so than conscious pathways (Tamietto \& De Gelder, 2010), validated physiological measures related to affect should provide confirmation of the operation of non-conscious emotional processes involved in motivated performance tasks such as negotiation (Blascovich \& Mendes, 2010).

## Psychophysiological Measurement of Motivational States

Psychophysiological research is now a well-established technique to infer peoples' affective reactions to various situations (Blascovich, Vanman, Mendes, \& Dickerson,

Figure 1: The angry (left) and happy (right) facial expressions displayed by the virtual confederate.
2011). However, a lot of research involving peripheral physiological markers has been based on unitary physiological responses such as heart rate variability (Rienerman-Jones, Cosenzo, \& Nicholson, 2010) or electrodermal activity (Meehan, Insko, Whitton, \& Brooks, 2002) mostly as indexes for workload and stress.

Motivational research suggests that relying on unitary indexes can mask important processes. For example, the physiological indexes specified by the bio-psychosocial model (BPS; Blascovich, 2008) of challenge and threat provide a much more informative index of task motivation. Briefly, the BPS model is based on the neuroendocrine underpinnings (i.e., Dienstbier, 1989) of cardiovascular responses involving the sympathetic-adrenal-medullary (SAM) axis as well as the hypothalamic pituitary-adrenalcortical (HPA) axis.

Psychologically, challenge motivation occurs when an individual's consciously and unconsciously evaluated resources outweigh evaluated task demands. Threat occurs when resources are evaluated as not meeting task demands. Both states involve the activation of the SAM axis, while only the threat state involves both the axes.

Accordingly, activation of common SAM axis sympathetic neural and adrenal medullary endocrine processes affect cardiovascular responses underlying both challenge and threat including increased heart rate (HR) and increased ventricular contractility (VC; i.e., decreased preejection period or "PEP"), and task engagement. However, cardiac output (CO) and total peripheral resistance (TPR) differ depending on motivational state. A challenge state results in decreased TPR and an increase in CO, whereas a threat state leads little or no change or a decrease in CO and little or no change or an increase in TPR (Blascovich \& Mendes, 2010).

There is evidence that individuals' explicit responses in experimental tasks are not always congruent with underlying physiological markers (e.g., Blascovich, Mendes, Hunter, Lickel, \& Kowai-Bell, 2001). By utilizing the physiological markers specified by the BPS model of challenge and threat, one can identify motivational responses to a stimulus that are not typically accessible to a participant during a motivated performance situation.

## Theoretical Motivation and Research Questions

Previous work on cognition and emotion perception proposes that context matters when people decode others' emotions (Barrett, Mesquita, \& Gendron, 2011; Lanzetta \& Englis, 1989; Singer et al., 2006). In their review of the literature, Barrett and colleagues point out how the visual scene in a stimulus can give rise to different interpretations of an emotional state conveyed by a facial expression. A scowling face can convey anger or disgust depending on the body posture with which it is paired. Individuals' patterns of behavior can also serve as context cues that affect emotional processing.

Two similar individuals can give rise to different emotional responses in their interaction partners based on their behaviors and actions. For example, Singer and colleagues (2006) led participants to believe that confederate players in a Prisoner's Dilemma game were fair or not based on the confederates' game investment strategy. Experimenters then randomly cued participants that either the (fair/unfair) confederate or the participant herself would receive a painful shock. Participants exhibited more empathic neural activity (fronto-insular and anterior cingular cortex) when they observed a fair player receive a shock compared to the unfair player (Singer et al., 2006). This is compelling because the only difference between the individuals was the contextual information of their game playing strategy.

On the basis of this research (i.e., Barrett et al., 2011; Singer et al., 2006), we can infer that different contexts can shape the perception of emotion as well as give rise to different neurophysiological responses to facial expressions. In particular, it is possible that an experimental confederate that employs a fair strategy will be perceived differently as a function of whether the individual smiles or scowls. Similarly, a fair individual that smiles might be perceived differently compared to an unfair smiling individual. In this study, we utilized virtual humans as research confederates in order to manipulate their facial expressions and negotiation strategies while keeping other aspects of the interaction under experimental control.

The research question driving this work was: Do differences in virtual humans' emotional facial expressions coupled with their behavioral strategies in a negotiation task affect neuropsychological processes related to motivation and affect?

The contextual emotion hypothesis suggests that if the confederate's negotiation strategy affects perceptual process

Figure 2: The multi issue bargaining negotiation task interface with areas of interest.
of facial expressions, then individuals will show different responses to the same facial expression depending on context. Specifically, individuals will have a different cardiovascular response to angry faces when paired with a tough strategy compared to angry faces paired with soft strategies.
