The mean score on the delayed post-test (after participants generated explanations) was .704 , \(\mathrm{SD}=.299\). Participants in the visual group improved significantly from the immediate post-test \((\mathrm{M}=.822, \mathrm{SD}=.208), \mathrm{F}(1,125)=51.24, \mathrm{p}<.01\), Cohen's \(d=1.27\). Participants in the verbal group also showed significant increases from the immediate post-test \((\mathrm{M}=.631, \mathrm{SD}=.273), \mathrm{F}(1,125)=15.796, \mathrm{p}<.05\), Cohen's \(d=71\).

A comparison of the delayed post-test scores between groups found significant differences. Figure 3 shows scores on the post-test by group and spatial ability. Participants
generating visual explanations \((\mathrm{M}=.822, \mathrm{SD}=.208)\) scored higher on the post-test than participants generating verbal explanations \((\mathrm{M}=.631, \mathrm{SD}=.273), \mathrm{F}(1,125)=19.707\), \(\mathrm{p}<.01\), Cohen's \(d=.88\). In addition, high spatial participants ( \(\mathrm{M}=.824, \mathrm{SD}=.273\) ) scored significantly higher than low spatial participants \((\mathrm{M}=.636, \mathrm{SD}=.207), \mathrm{F}(1,125)=19.94\), \(\mathrm{p}<.01\), Cohen's \(d=.87\) (Figure 4-12). The results of the test of the interaction between group and spatial ability was not significant. A separate analysis comparing performance on multiple choice questions and free response questions did not show any differences between visual and verbal groups or between low and high spatial ability groups.

\section*{Discussion}

The results of Experiment 2 supported those of Experiment 1: learner-generated visual explanations provided an advantage over learner-generated verbal explanations. Visual explanations resulted in higher scores on the post-test for both low spatial and high spatial participants.

No difference was found between low and high spatial participants in the amount of structural information contained in the explanations, but high spatial participants included more function, were more likely to use specific examples, and scored higher on the delayed post-test.

An interesting finding of Experiment 2 was that the use of arrows significantly correlated with scores on the delayed post-test. How does their use lead to greater understanding? Arrows were most often used to label structure, or to label an action. They were also used to differentiate an initial versus and ending state, to show change. Previous research has shown arrows to serve a number of purposes. Notably, studies have shown the addition of arrows able to convey functional information in a structural diagram (Heiser \& Tversky, 2006). While the purpose of this study was to examine student-generated explanations, these results support those of previous work that shows when arrows are used in diagrams in a way that encourages the development of mental models, they become more effective.

\section*{Conclusion}

Experiment 1 showed that learning about a physical bike pump and generating visual explanations was primarily a benefit to low-spatial ability participants. The measures of learning (from a true/false post-test) were of course limited, and it is possible that higher-order learning by high spatial ability participants was not revealed. Experiment 2 showed that viewing a class lesson on chemical bonding and generating visual explanations benefited both low and high spatial ability students, although to different degrees (high spatial ability participants scored significantly higher on the post-test). In the generation of visual explanations, learners use the information they gather from new material to create internal representations that become richer with the integration of verbal and non-verbal representations, forming a mental model that then informs and direct the creation of visual explanations. Learners with high spatial ability are more adept at forming and manipulating mental images; this may make the generation of visual explanations easier for them. Learners with low spatial ability may find the task difficult, but may be able to be more successful with generating visual explanations if support is provided.

Together, the results from the two experiments support the use of learner-generated visual explanations as a learning strategy in science. Future studies should explore how this strategy mediates the comprehension of concepts presented in physical models, experiments, and textbooks, and posttest performance. Students live in a macroscopic world, where objects have mass and occupy space. Understanding "invisible" processes in science, then, presents a challenge. Generating visual explanations through drawing is likely an underused method of monitoring and supporting students' understanding of scientific concepts.

\begin{abstract}
In times of globalization, differences between cultures and in the interpretation of linguistic terms can lead to misunderstanding in communication. The present study focuses on the influence of cultural dimensions, especially uncertainty avoidance, on the interpretation of verbal probability expressions. It is hypothesized that uncertainty avoidance has an effect on the interpretation of uncertainty expressions. Therefore, Spanish and German participants were asked (1) for uncertainty avoidance and (2) to estimate numerical equivalents for 12 verbal probability expressions (e.g., possible). The estimation data were modeled using fuzzy membership functions. Results neither show differences in uncertainty avoidance nor in the interpretation of the probability expressions between these two languages. Possible reasons and future research perspectives are discussed.
\end{abstract}

Keywords: Uncertainty Avoidance, Linguistic Terms, Probability Expressions, Fuzzy Membership Functions.

\section*{Introduction}

In times of the most severe economic crisis the European Union ever experienced the following situation is likely to happen: Imagine economic experts from Spain and Germany discussing about the risk of a financial breakdown of Spain's banks in the near future: Expert 1 argues: "I am sure that we will have a crash next year." and expert 2 responds: "It's possible but I am still optimistic. Probably we can manage it." In many social interactions between persons or groups of different countries the language for communication might not be the native language of the speakers (e.g., Spanish or German) but a foreign one (such as English). Nevertheless, one is likely to "think" in terms of the own language, choose words that express the own intention best and then "translate" them into the foreign language. But given the vagueness of natural languages (e.g., Teigen \& Brun, 2003; Budescu, Karelitz \& Wallsten, 2003; Bocklisch, Bocklisch \& Krems, 2010; 2012) and potential cultural differences (e.g., Hofstede, 1980; 2001; Hofstede, Hofstede, \& Minkov, 2010) we can not necessarily be sure that the translation reflects the meaning precisely and therefore, communication partners may misunderstand each other. The example described above is prototypical for situations in which forecasts and decisions
have to be done under uncertain circumstances. Often, the decision makers express their beliefs using verbal probabilities such as "probable" or "possible". There is a risk of miscommunication because of the considerable variation of people's interpretation of the meaning of linguistic terms (LTs) (e.g., Karelitz \& Budescu, 2004). Further, misunderstandings may lead to wrong decisions with undesirable consequences. Therefore, avoiding misunderstandings and improving interpersonal communication is highly relevant in a globalized world.

The present paper highlights the questions (1) if LTs (probability expressions) of different languages (Spanish vs. German) are interpreted differently by native speakers and (2) whether there exists a cultural influence on the LTs interpretation, namely, concerning the dimension of uncertainty avoidance (Hofstede, 1980). Methodologically, we use fuzzy membership functions (MFs) to formalize and compare the vague meaning of the LTs (e.g., Bocklisch, Bocklisch \& Krems, 2012).

\section*{Culture and Language}

One influential paradigm in intercultural research is Hofstedes model of cultural differences. In its original form (Hofstede, 1980), he differentiated four cultural dimensions on which cultures vary and, therefore, may be compared: individualism/collectivism, power distance, uncertainty avoidance and masculinity/femininity. Concerning the investigation of probability expressions, we consider the third dimension "uncertainty avoidance" (UA) as especially interesting and, therefore, focus on UA in the following. In short, UA is determined by the extent to which members of a society become nervous or insecure about situations that seem to be unpredictable, unstructured and uncertain.

There are already evidences that culture and language are important concerning the interpretation of LTs, for instance, Doupnik and Richter (2003) already found differences in the interpretation of German and English uncertainty expressions between native speaking auditors in two cultural areas, namely, America and Germany. We will focus on two languages, Spanish and German, which developed in the same European cultural region. According to Hofestede (2001), Spain and Germany are both countries with high UA values and, at the same time, differ remarkably in UA \(\left(\mathrm{UA}_{\text {Spain }}>\mathrm{UA}_{\text {Germany }}\right)\). In our study we (1) expect to replicate Hofstedes results and find high UA scores for both
languages as well as significant differences. Furthermore, we hypothesize that the probability expressions should be interpreted differently. We expect that because the context seems to influence the meaning of expressions (e.g., Weber \& Hilton, 1990). We think that culture may be determined as a very global form of context. Therefore, if the scores of \(\mathrm{UA}_{\text {Spain }} \neq\) UA Germany the LTs might also be interpreted differently.

\section*{Numerical Translation of Linguistic Terms}

To determine the meaning of LTs researchers have developed procedures for the numerical translation of verbal expressions (e.g., Simpson, 1944; Beyth-Marom, 1982; Budescu, Karelitz \& Wallsten, 2003; Bocklisch, Bocklisch \& Krems, 2010; 2012). Generally, results of these studies show (1) that mean estimates for linguistic expressions are similar and that they have stable meaning (Simpson, 1944 and Hakel, 1968). At the same time there exists large interindividual variability in the interpretation of verbal expressions (for reviews see Pepper, 1981; Teigen \& Brun, 2003). Another important outcome is (2) that fuzzy set theory (Zadeh, 1965) proved especially useful for describing the vague meaning of LTs by modelling them using fuzzy MFs (e.g., Zimmer, 1984; Budescu \& Wallsten, 1995; Budescu et al., 2003, Bocklisch et al., 2012).

We used the two-step translation procedure outlined in Bocklisch et al. (2012) for the numerical translation of the probability expressions. This procedure also uses fuzzy MFs to model the empirical estimates of participants. MFs are truth value functions. In this study, the membership value \((\mu)\) represents the degree of truth that a numerical estimate fulfils a specific criterion represented by a LT (e.g., the numerical probability "in 70 of 100 cases" belongs to the linguistic probability expression probable). We use a standardized \(\mu\) ranging from 0 (no membership) to 1 (full membership). Furthermore, the procedure has been proven useful for the translation of LTs (e.g., probability expressions: Bocklisch et al., 2010; symptom intensities in medical contexts: Bocklisch, Stephan, Wulfken, Bocklisch \& Krems, 2011; and frequency expressions: Bocklisch et al., 2012), and as basis for evaluating and choosing verbal response labels for questionnaire scales (e.g., for the StateTrait Anxiety Inventory (STAI-T) see Bocklisch, Bocklisch \& Krems 2011). It includes (1) an empirical estimation method in which participants assign typical, minimum and maximum correspondence numbers to presented words, and (2) a fuzzy approach for the analysis of data and the generation of MFs - specifically, parametric MFs of the potential type. This procedure is very efficient as only three numerical values are estimated, and is easily understood because the semantic meaning of estimation points is implicitly clear to participants (e.g., minimum and maximum correspondence values \(=\) borders of LTs meanings). Semantic comprehensibility, as such, makes participants' estimates understandable even if they have no theoretical knowledge of the concept of fuzzy membership.

Such intuitive understanding is also advantageous when an estimation method is used for participants not highly trained in estimation tasks. For more details concerning the theoretical justification or parameter estimation see Bocklisch (1987) or Bocklisch, Groß, Bocklisch and Krems (submitted).

\section*{Method}

\section*{Participants}

We collected data of 147 German participants ( 51 males) with an average age of \(27.5(S D=9.9)\) and 21 Spanish participants (12 males) with a mean age of 34.8 ( \(S D=\) 12.9). All subjects were native speakers. Four (German sample) vs. one (Spanish sample) persons were raised bilingual. Most of the participants were students and the German students received course credits for participation.

\section*{Design, Material and Procedure}

The study was quasi-experimental employing an online questionnaire in two languages (Spanish vs. German). The material was carefully constructed to make sure that both questionnaire versions were equivalent in meaning, especially concerning the 12 probability expressions (see Table 1) that were presented in the questionnaire in a random order. The 12 LTs were chosen from a pool of 47 probability expressions gained from a literature review and dictionaries. These 12 words are rather unambiguous in meaning and are frequently used in both languages. The translation from German to Spanish was done independently by two Spanish that also speak German very well (international C1 and B2 level). The questionnaire had four main parts: (1) a short introduction, (2) the estimation part for the translation of the probability expressions (Bocklisch et al., 2012), (3) the uncertainty avoidance scale including ten items (e.g., "I would like to have more control about the future.") (Mealy, Stephan, Abalakina-Paap, 2006; see also Fahmie, 2012) and (4) a few questions concerning demographic data.

\section*{Results}

\section*{Uncertainty Avoidance}

We found UA scores of \(M_{\text {German }}=38.8\left(S D_{\text {German }}=7.0\right)\) and \(M_{\text {Spanish }}=39.5\left(S D_{\text {Spanish }}=5.8\right)\) and, therefore, no significant differences \((t(166)=-.425, p=0.67)\).

\section*{Meaning of Linguistic Terms}

The results for the meanings of LTs are structured starting with descriptive statistics of the data, and then the fuzzy MFs and discriminatory power values ( \(d p\) ) indicating how similar the MFs and, hence, the meaning of the LTs are. As outlined in Bocklisch et al. (2012, p.148), we present descriptive statistics and MFs for purposes of completeness and comparison, even though we believe that MFs are more suitable for describing the meaning of vague LTs. We have
to emphasize that statistical and fuzzy analyses are two approaches that should be understood independently, because fuzzy MFs, by definition, do not refer to probability theory and statistics. Although some parameters of our MF type can be interpreted statistically (e.g., representative values \((r)=\) the arithmetic mean), a MF is not a probability density function and conventional requirements (i.e., the integral of the variable's density is equal to 1 ) are not valid.
Descriptive Statistics. Table 1 shows a comparison of the descriptive statistics (i.e., means and standard deviations) for the Spanish and German LTs. The minimal and maximal estimates were used for modelling of the MFs and are not reported here.

The order of the means of the typical estimates (equals \(r\) of the MFs, see below) presented in Table 1 is the same for the Spanish and German LTs and even the numerical values are very similar. The largest difference is 12.5 for probable.
(MFs shapes) in both languages. For instance, the MFs for possible (MF 7) are almost congruent.

Furthermore, we find the same pattern as reported in Bocklisch et al. (2010 and 2012) that MFs of LTs at the scales borders (e.g., impossible) are smaller in extent and, therefore, more precise in meaning compared to mid-scale LTs (e.g., possible). MFs 8 and 12 (probable and certain) show the largest differences. This is also confirmed by the \(d p\) s (see Table 1). For MFs 12 (certain) \(d p=0.71\) reaches the threshold of a remarkable difference while all other \(d p\) s are smaller than 0.5.

Table 1: Descriptive Statistics (Typical Estimates) and Discriminatory Power Values ( \(d p\) )
\begin{tabular}{lllllll}
\hline Probability Expressions & \multicolumn{4}{l}{ German } & \multicolumn{2}{l}{ Spanish } \\
English Translation (Original in German / Spanish) & \(M\) & \(S D\) & \(M\) & \(S D\) & \(d p\) \\
\hline 1 & Impossible (Unmöglich / Imposible) & 1.53 & 2.93 & 0.50 & 1.24 & 0.44 \\
2 & Very improbable (Sehr unwahrscheinlich / Muy improbable) & 7.48 & 4.98 & 8.95 & 7.41 & 0.16 \\
3 & Improbable (Unwahrscheinlich / Improbable) & 14.24 & 8.29 & 13.71 & 9.18 & 0.05 \\
4 & A small probability (Wenig wahrscheinlich / Poco probable) & 19.79 & 10.14 & 18.38 & 11.63 & 0.08 \\
5 & Uncertain (Unsicher / Inseguro) & 28.21 & 15.04 & 27.52 & 19.11 & 0.04 \\
6 & Maybe possible (Vielleicht möglich / Tal vez posible) & 36.69 & 16.54 & 35.24 & 15.53 & 0.10 \\
7 & Possible (Möglich / Posible) & 52.04 & 13.49 & 52.86 & 9.43 & 0.05 \\
8 & Probable (Wahrscheinlich / Probable) & 71.64 & 13.62 & 59.14 & 15.26 & 0.35 \\
9 & Rather certain (Ziemlich sicher / Bastante seguro) & 82.89 & 10.99 & 82.86 & 9.43 & 0.09 \\
10 & Very probable (Sehr wahrscheinlich /Muy probable) & 85.96 & 8.76 & 85.60 & 9.42 & 0.17 \\
11 & Highly probable (Höchstwahrscheinlich / Altamente probable) & 87.16 & 10.66 & 85.75 & 7.48 & 0.27 \\
12 & Certain (Sicher / Seguro) & 94.22 & 8.93 & 98.30 & 3.23 & 0.71 \\
\hline
\end{tabular}

Fuzzy Membership Functions. Figure 1 shows the potential MF for both the German and Spanish probability expressions. The MFs' peaks (marked with a vertical line), indicating the highest membership ( \(r\) ), are identical to the means shown in Table 1. Dps of the MFs are shown in Table 1. According to Bocklisch et al. (2012; p.149), \(d p\) values are defined by the overlapping area of two MFs and is standardized by taking values between 0 (MFs are identical) and 1 (no overlap at all). By definition, the larger the overlap, the smaller the \(d p\), and the more similar the meanings of the verbal expressions are. Concerning the interpretation of \(d p\), values \(\geq 0.7\) suggest that the MFs are considerably different (because overlap is \(<30 \%\) ).

For reasons of clarity and comprehensibility, the LTs with odd numbers are shown in the upper part and even numbers in the lower part of Figure 1. The MFs positions and shapes show that the meaning of a certain LT is highly similar regarding its typical meaning ( \(r \mathrm{~s}\) ) as well as vagueness

\section*{Discussion}

The results show that there is (1) no significant difference in the UA between Spanish and German participants. Hence, we could replicate only parts of Hofstedes results (Hofstede, 2001): Spain and Germany are both countries with high UA. But our results do not show remarkable differences between Spain and Germany in UA as we hypothesized according to Hofstede (2001). Concerning (2) the interpretation of probability expressions we did not find differences in the MFs between the Spanish and German sample except for LT certain and, by tendency, for probable. This is a surprise because we did not expect that the MFs of the Spanish and German LTs are so similar because the languages do not origin from the same language family. But in regard to the cultural background it seems reasonable and goes along with the idea that UA and interpretation of probability LTs may be connected. For future studies we suggest to collect data from a more representative sample. Especially the Spanish sample of this study was rather small.

\section*{Membership}

\section*{Membership}

Figure 1: Fuzzy MFs of Spanish and German LTs

Furthermore, a comparison of languages from cultures with larger differences in UA (e.g., Asian vs. European cultures) would be interesting to test the hypothesis whether UA influences the interpretation of LTs because the larger the differences in UA the more differences in LTs MFs should be.

As an additional result it was possible to compare the data of Bocklisch et al. (2010) that used the same translation procedure and the results of the German sample for seven LTs (see Table 2). The \(r\) s (means of the typical values) are almost identical (largest difference is 3.96 for probable) meaning that we could replicate their findings very good using the fuzzy MF approach.

Table 2: Comparison of Representative Values of German Sample and Bocklisch et al. (2010)
\begin{tabular}{lcc}
\hline \begin{tabular}{l} 
Probability Expressions \\
(Original German)
\end{tabular} & \begin{tabular}{c} 
German \\
Sample
\end{tabular} & \begin{tabular}{c} 
Bocklisch, et \\
al. (2010)
\end{tabular} \\
\hline Impossible & 1.53 & 1.44 \\
Very Improbable & 7.48 & 5.53 \\
Improbable & 14.24 & 11.68 \\
Possible & 52.04 & 51.49 \\
Probable & 71.64 & 67.68 \\
Very Probable & 85.96 & 83.95 \\
Certain & 94.22 & 96.28 \\
\hline
\end{tabular}

The results encourage the application of fuzzy MFs in technical, cognitive and language interaction systems. Concerning the methodological possibilities of MFs the implementation in technical systems can easily be done by implementing the parametric description that underlies the MFs. We see a high potential for this methodology for future research and application, for instance, in the field of intercultural communication.

\title{
Why 100 Once Is Worse Than 10 Times 10: Dread Risks versus "Continuous" Risks
}

\begin{abstract}
People tend to react more strongly to a dread risk, a rare event that kills many people at once, than to a continuous risk, a relatively frequent event that kills many people over a longer period of time, even when both cause the same number of fatalities. This different reaction to the dread risk is often considered a bias, but we show that it is an ecologically rational strategy. In a series of simulations, we found evidence that dread risks affect the population more severely over time than continuous risks causing the same number of fatalities. This holds particularly true when the risks affect children and young adults who would have produced future offspring if they had survived longer.
\end{abstract}

Keywords: dread risk; continuous risk; risk perception; ecological rationality

\section*{Introduction}

Imagine two different risky events: One threatens to kill 100 people at once; the other threatens to kill 10 people every year over a period of 10 years. The first event represents a dread risk, a rare event that kills many people at once, such as a pandemic, an earthquake, or a terrorist attack. The second event represents a continuous risk, a relatively frequent event that kills many people over a longer period of time, such as diabetes, air pollution, or car accidents. Which of the two risks is more severe? Both events kill the same number of people and differ only with respect to the time frame. Yet, people react much more strongly to dread risks than to continuous risks, in terms of both perception and avoidance behavior (Gigerenzer, 2004, 2006; Slovic, 1987).

For instance, in reaction to the 9/11 terrorist attacks (a typical dread risk), many Americans avoided air travel and switched to their cars without considering that the risk of dying in a car accident (a continuous risk) is larger than the risk of an airplane terrorist attack, and even of dying in an airplane accident in general (Sivak \& Flannagan, 2003). The avoidance of flying and the elevated use of cars increased the number of fatal highway crashes after the \(9 / 11\) attacks (Gaissmaier \& Gigerenzer, 2012).

People's higher sensitivity to dread risks compared with continuous risks is often considered a bias: If the continuous risk causes the same number of fatalities, it should not be perceived as less dreadful. In this paper we offer an
alternative explanation to the assumption of biased minds and argue that a stronger reaction to dread risks is ecologically rational, because dread risks actually cause a larger cumulative reduction in the population size.

\section*{Previous Accounts}

Different hypotheses have been proposed to explain why people fear dread risks more than continuous risks. First, the psychometric paradigm (Slovic, 1987) suggests that high lack of control, high catastrophic potential, and severe consequences account for the increased risk perception and anxiety associated with dread risks. Second, people might lack knowledge about the statistical information underlying risks (Gigerenzer, Mata, \& Frank, 2009), in particular about the large number of fatalities caused by continuous risks. Third, because people estimate the frequency of a risk by recalling instances of its occurrence from their social circle or the media, they may overvalue relatively rare but dramatic risks and undervalue frequent, less dramatic risks (Hertwig, Pachur, \& Kurzenhäuser,2005; Lichtenstein, Slovic, Fischhoff, Layman, \& Combs, 1978). Fourth, according to the preparedness hypothesis, people are prone to fear events that have been particularly threatening to survival in human evolutionary history (Öhman \& Mineka, 2001). Given that in most of human evolutionary history people lived in relatively small groups, rarely exceeding 100 people (Hill et al, 2011; Lee \& DeVore, 1968), a dread risk, which kills many people at once, could potentially wipe out one's whole group. This would be a serious threat to individual fitness, as being in a group reduces predation risk, helps with finding food and hunting, and increases survival chances when injured (Dunbar \& Schultz, 2007; Krause \& Ruxton, 2002). In line with this hypothesis, Galesic and Garcia-Retamero (2012) found that people's fear peaks for risks killing around 100 people and does not increase if larger groups are killed.

\section*{A population-based perspective}

A different perspective reveals that dread risks lead to significantly worse short- and medium-term consequences than continuous risks, even if they do not eliminate a whole group. Thus, we focus not only on the overall number of
immediate fatalities, as in previous accounts, but also on (a) the population size over time, and (b) the role of the age group that is affected by the risky event. Note that a fatal event strikes twice: it kills a number of people immediately, and it reduces the number of future offspring by reducing the number of their potential parents. A risk that affects children and young adults will have stronger negative effects on future group growth than a risk that affects group members who are past their reproductive period. Dread risks such as pandemics, terrorist attacks, or nuclear accidents are more likely to strike children and young adults compared to many continuous risks such as diabetes, cancer, heart attack, or household accidents, which affect primarily older people (Statistisches Bundesamt Deutschland, 2012). For example, the H1N1 pandemic in 2009 was more likely to infect younger people, whereas older people were relatively immune, probably due to previous exposure to a similar virus strain (ECDC, 2009).

Hypothesis We hypothesize that dread risks cause larger cumulative losses on the population level than continuous risks. More specifically, we hypothesize that the number of people-years lost because of a dread risk is larger than the number of people-years lost because of a continuous risk, in particular when the event affects the younger age groups. People-years correspond to the number of people who live 1 year in the population. Hence, by killing a large number of children or young adults at once, dread risks not only deprive the society of their contribution in subsequent years, but they also remove the potential contribution of the offspring the victims could have had if they had survived longer.

To illustrate this hypothesis, consider first a very simplified example. Imagine a population of 40 people, uniformly distributed across four age groups:

Children and adolescents, aged 0-19 years: Pre-fertile generation that may produce offspring in the future.

Young adults, aged 20-39 years: Fertile generation that currently produces offspring.

Older adults, aged 40-59 years: Post-fertile generation.
Elderly adults, aged 60-79 years: Post-fertile generation.
Further assume that the population growth is constant and that every year each young adult produces exactly one offspring. This implies that the number of children at time point \(i, t_{i}\), corresponds to the number of young adults at time point \(i-1, t_{i-1}\). Moreover, at every \(t_{i}\) a generation shift takes place, so that the number of young adults at \(t_{i+1}\) corresponds to the number of children at \(t_{i}\), and so on for the other groups. Moreover, all elderly adults at \(t_{i-1}\) will be dead at \(t_{i}\). In the absence of any dread risk or continuous risk, the population is constant over time with \(N_{\text {total }}=40\) (see Figure 1).

What happens if a dread risk occurs at \(t_{1}\) that kills \(50 \%\) of the young adults (i.e., 5 young adults)? At \(t_{1}\), the total population is reduced to \(N_{\text {total }}=35\left(N_{\text {children }}=10, N_{\text {young adults }}=\right.\) \(\left.5, N_{\text {older adults }}=10, N_{\text {elderly adults }}=10\right)\). At \(t_{2}\) the population is further reduced to \(N_{\text {total }}=30\left(N_{\text {children }}=5, N_{\text {young adults }}=10\right.\),
\(N_{\text {older adults }}=5, N_{\text {elderly adults }}=10\) ), because the number of newborn offspring is smaller due to the fewer young adults. Finally, the population size settles at \(N_{\text {total }}=30\), with continuous fluctuation within the respective groups.

What happens if a continuous risk, a disease, occurs at \(t_{1}\) that kills five young adults over a period of five time steps (one young adult at every \(t_{\mathrm{i}}\), from \(t_{1}\) to \(t_{5}\) )? Note that the total number of fatalities directly caused by the risk is the same as in the dread risk scenario (i.e., 5). The total population is reduced to \(N_{\text {total }}=39\) at \(t_{1}\) and continues to decline until \(t_{6}\), where it finally corresponds to the size of the population hit by the dread risk.

In sum, the continuous risk takes five more generations to affect the population as severely as the dread risk. The difference in the cumulative losses caused in the population by the dread versus continuous risk, can be calculated by determining the area between the curves representing the difference in the cumulative population sizes of the two conditions (i.e., the difference in people-years over time). In the example in Figure 1, this integral is 20, meaning that the population hit by the dread risk lost 20 people-years more than the population experiencing the continuous risk.

Figure 1: Development of the population size when no risky event is present (baseline), and when a continuous risk (1 individual killed from t1 to t ) or a dread risk (5 individuals killed at t1) event occurs. A dread risk leads to a more immediate impact on cumulative population size that lasts longer compared with the continuous risk.

\section*{Simulation Set 1}

In the first set of simulations, we assumed a small population size, similar to groups in which people lived throughout most of evolutionary history (Lee \& DeVore, 1968). We manipulated whether the population growth rates
were constant, increasing, or decreasing, and which age group was exposed to a dread or to a continuous risk.

\section*{Method}

We set the total population to 160 people. The individuals were distributed equally across 80 years (i.e., there were 2 individuals for each age at t0) and across four age groups, as in the illustrative example above. Between conditions, we manipulated (a) whether a dread or a continuous risk occurred, (b) the population growth rate, and (c) which age group was hit by the risk. The risk simulated was either a dread risk that immediately killed \(50 \%\) of the population of the age group hit, or a continuous risk that killed the same total number of people in the same age group over a period of 10 years. The population growth rate was manipulated by setting the birth rate to either 0.05 (constant population), 0.075 (increasing population), or 0.025 (decreasing population). All individuals would die naturally after their 79th year. The risk hit only children, only young adults, only older adults, or only elderly adults.

In total there were 24 scenarios. Each scenario was simulated 500 times, and we calculated for every time point the average population size within the simulations. We analyzed each scenario by comparing the log difference in cumulative people-years between the dread risk condition and the continuous risk condition after 25,50, 75 and 100 years.

\section*{Results}

Figure 2 shows the results for the log difference in cumulative people-years depending on the population growth rate and the hit group after \(25,50,75\), and 100 years. A zero value indicates no difference in cumulative peopleyears between the dread risk and continuous risk; a negative value indicates a higher loss in cumulative people-years in the dread risk condition, and a positive value a higher loss in the continuous risk condition.

When children and young adults were hit by the risks, the effect was stronger and lasted for the entire 100-year-range simulated. When older and elderly adults were hit, the difference between dread and continuous risks was weaker, decreased over time, and sometimes even became positive.

Figure 2. Log difference in people-years lost because of continuous and dread risk, by age group hit by the risk, separately for A. constant, B. increasing and C. decreasing populations. The dread risk killed \(50 \%\) of a specific age group at once; the continuous risk the same total number of people over a period of ten years. A negative value of the difference indicates that the loss in people-years is larger for the dread risk; a positive value that the loss is larger for the continuous risk.

In sum, the results show that the dread risk affected the cumulative population size more strongly for most scenarios, particularly when it hit children or younger adults. The objective of this first set of simulations was to evaluate the impact of a dread and a continuous risk on
small samples that would reflect the sample size of social circles. With a second set of simulations we investigated the effects of such risks on a much larger population of the size of the U.S. population in 2010.

Figure 2: Log difference in people-years lost because of continuous and dread risk, by age group hit by the risk, separately for A. constant, B. increasing and C. decreasing populations. The dread risk killed \(50 \%\) of a specific age group at once; the continuous risk the same total number of people over a period of ten years. A negative value of the difference indicates that the loss in people-years is larger for the dread risk; a positive value that the loss is larger for the continuous risk. Results show that dread risks lead to larger losses in people-years across time compared with continuous risks, in particular when children and young adults are affected.

\section*{Simulation Set 2}

\section*{Method}

We set the population size to the actual U.S. population size in 2010 (Howeden \& Meyer, 2011) with the respective age
distributions \({ }^{1}\) and population growth rates. As in Simulation Set 1, we manipulated which age group (children, young adults, older adults, elderly adults) was hit by the risk. The risk killed either \(20 \%\) of the hit group, or the same total number of people over 10 years.

We again ran 500 simulations for each scenario, calculated the averaged population size of the dread risk and continuous risk and plotted the log integrals after 25, 50, 75, and 100 years.

\section*{Results}

Using real U.S. data, we found support for the findings of the previous simulations. The differences between the cumulative population hit by dread versus continuous risks occurred across all conditions and lasted over, at least, 100 years. Independent of which age group was affected, the dread risk led to a higher loss in people-years than the continuous risk (Figure 3). Loss was highest when children and young adults were hit by the risk.

Although our simulations are simplified and ignore death rates for different age groups, fluctuations in population growth rates, immigration and migration, gender differences, and fluctuations in disease, they illustrate the rationale of our hypothesis. Moreover, sensitivity analyses showed that the conclusions do not change when the continuous risk is distributed over a longer period or when the number of fatalities is larger or smaller.

Figure 3. Log difference in people-years lost because of continuous and dread risk, based on the US population. The dread risk killed \(20 \%\) of a specific age group at once; the continuous risk killed the same total number of people over a period of 10 years. Results show that the dread risk leads to a larger loss in people-years over time across all age groups. The loss was largest when children and young adults were affected.

\footnotetext{
\({ }^{1}\) The statistics only provided population size for age groups. For instance, 20,201,362 children \(<5\) years old lived in the United States in 2010. For simplicity, we assumed an equal distribution of the children across \(0-4\) years.
}

\section*{Discussion}

People's stronger reaction to dread risks compared with continuous risks is often perceived as a bias. This result proposes a new perspective against which the current hypotheses accounting for people's perception and reaction to dread risks might be reconsidered.

We showed through two different sets of simulations that this is in fact an ecologically rational strategy. The effect of dread risks compared with continuous risks is amplified twice: First by killing more people at a specific point in time, and second by reducing the number of children and young adults who would have potentially produced offspring. Hence, this effect is particularly strong when children and young adults are hit which is often the case for dread risks (e.g., earthquakes, terrorist attacks, pandemics). This result is also in line with findings suggesting that people are more concerned about risks killing younger, and hence more fertile, groups (Wang, 1996).

There are important practical implications of this finding. For instance, from a public policy perspective, an appropriate reaction to dread risks would be to stimulate increase in birth rates and/or immigration to counterbalance the stronger loss in population size.

In sum, people's fear and stronger risk perception of dread risk, compared to continuous risks, should not be considered an irrational bias, an emotional overreaction to a dramatic event. In fact, people's intuition seems to capture the objective severity of the two different risks.

\begin{abstract}
Past research suggests that spatial configurations play an important role in graph comprehension. The present study investigates consequences of this fact for the relative utility of graphs and tables for interpreting data. Participants judged presence or absence of various statistical effects in simulated datasets presented in various formats. For the statistical effects introduced earlier in the study, performance was better with graphs than with tables, while for the effect introduced last in the study, this trend reversed. Additionally, in the later sections of the study, responses with graphs, but not tables, reflected increasing influence from the presence of stimulus features which had been relevant earlier in the study, but were no longer relevant. The findings suggest that graphs, relative to tables, may better facilitate perception of complex relationships among data points, but may also bias readers more strongly to favor some perspectives over others when interpreting data.
\end{abstract}

Keywords: representations; graphs; tables; mathematics; statistics; human factors

\section*{Introduction}

Humans have devised a variety of different formats for externally representing information. Often, the same information may be represented in multiple representations that are informationally equivalent, in that each may be reconstructed perfectly on the basis of any other. Despite such equivalence, different representations may support performance of specific cognitive tasks at different levels of efficiency. Such differences have important implications for the selection and design of external representations.

The present study explores such differences with respect to graphs and tables, two of the most commonly-employed representational formats for quantitative information in a variety of fields. The relative advantages of graphs and tables have been the subject of extensive research. Tables appear to be at least as effective as graphs with respect to point reading tasks, which require one to estimate or read off individual data points (Meyer, Shamo, \& Gopher, 1999; Porat, Oron-Gilad, \& Meyer, 2009; Vessey \& Galletta, 1991). However, graphs have often shown advantages for tasks involving complex relationships between multiple data points, such as estimating or comparing differences between points (Schonlau \& Peters, 2012; Vessey \& Galletta, 1991), projecting trends (Meyer et al., 1999), and detecting changes in function parameters (Porat et al., 2009).

Models of graph comprehension (Carpenter \& Shah, 1998; Ratwani, Trafton, \& Boehm-Davis, 2008) suggest a possible explanation for the latter findings. According to
these models, spatial configurations of data points are the raw material on which graph comprehension processes operate. Importantly, some configurations may be directly perceived as basic visual features (Pomerantz \& Portillo, 2012), allowing relationships between points to be "read off" directly without first encoding each point separately (Carpenter \& Shah, 1998; Porat et al., 2009). For example, distances between points may be used to determine or estimate differences in the values they represent, without the need to encode those individual values at all (Pinker, 1990). Thus, in graphs, spatial configurations can act as cues for recognizing relationships between data points. Because such cues are unavailable or less salient in tables, this property of graphs can account for their observed advantages in conveying relationships among data points.

Many studies comparing task performance with graphs and tables have employed univariate datasets (Meyer et al., 1999; Porat et al., 2009). Consideration of bivariate data introduces another difference between graphs and tables. In graphs of bivariate data, there is a representational asymmetry between the two independent variables, in that one is often laid out along a spatial axis, typically the x -axis, while the other is typically represented by a non-spatial visual feature such as line color or thickness. For tables, on the other hand, such representational asymmetry is reduced, because the levels of both independent variables are laid out along spatial axes, albeit horizontal in one case and vertical in the other.

Can such representational asymmetries as exist in graphs of bivariate data lead to performance asymmetries in tasks involving one or the other variable? A few studies have provided evidence in the affirmative (Carpenter \& Shah, 1998; Shah \& Freedman, 2011). For example, Shah and Freedman (2011) found that when asked to interpret graphs of bivariate data, participants were more likely to describe main effects of the variable depicted in the legend than of that depicted on the \(x\)-axis, and were more likely to describe interaction effects as moderating effects of the legend variable on the effect of the x-axis variable than vice versa.

Such representational asymmetries in graphs, together with the intuition that these asymmetries are reduced in tables, suggest that performance asymmetries between tasks relating to one or the other independent variable in bivariate data should be greater for graphs than for tables. While a few studies have compared performance with graphs and tables on tasks involving bivariate data (Schonlau \& Peters, 2012; Vessey \& Galletta, 1991), the specific issue of how
display format affects performance asymmetry between tasks has not been directly investigated.

Consideration of multiple tasks introduces the possibility of transfer, in which experience with one task affects subsequent performance on other tasks. Such transfer could be positive or negative, depending on whether previouslylearned skills are correctly adapted for novel tasks, or applied without adaptation despite being inappropriate. Differences in the methods used to comprehend data in different formats, such as greater reliance on spatial configurations in graphs than in tables, could cause differences in ease of adaptation to novel tasks. Consistent with this possibility, Porat et al. (2009) found evidence of greater negative transfer between tasks for tables than for graphs of univariate data. However, it is unclear whether, and to what extent, these findings may generalize to other tasks, and in particular, to tasks involving bivariate data.

A related issue is how best to promote future positive transfer, and reduce negative transfer, when instructing learners to perform particular tasks. Educational theories (e.g. Ainsworth, 2006) suggest that incorporating multiple representations into instruction may be one path to these goals. Learners who integrate knowledge from multiple representations to form unified internal concepts are likely to show more robust and flexible learning. Analogy research suggests that comparison is a powerful tool to facilitate such integration and thus encourage positive transfer. For example, Gentner, Loewenstein, and Thompson (2003) found that management students who compared case studies illustrating a negotiation technique were more likely to apply the technique to novel cases. Considering these two lines of research together suggests that comparing graphs and tables illustrating a concept may encourage learners to learn the concept in a more abstract way, and thus to apply and adapt them more flexibly when faced with novel tasks.

The preceding discussion suggests several questions, which were investigated in the present study. First, for tasks focusing on one or the other variable in bivariate datasets, does graphical presentation lead to greater performance asymmetry than tabular presentation with respect to the depicted variables? Second, do graphs or tables show more positive (or less negative) influence of previous task practice on novel task performance? Third, does comparing graphs and tables during training promote such positive transfer (and/or reduce negative transfer)?

\section*{Method}

Participants received tutorials on different types of statistical effects in the context of \(2 \times 2\) factorial designs with one ex-perimentally-manipulated variable, or "treatment factor," and one observed variable, or "secondary factor." The first two tutorials involved, respectively, main effects of the treatment factor and interaction effects of the two factors. Each tutorial explained how to judge the presence of the given effect in graphs and tables. Each tutorial was followed by a test requiring participants to judge whether the given effect was present in a series of graphs and tables.

The first two tutorials and tests were followed by a third tutorial and test pertaining to main effects of the secondary factor. This test required participants to perform the same task as for main effects of the treatment factor, namely marginalizing over one of the two factors, and differed only in which factor was to be marginalized. Comparing performance across test sections allowed us to tell whether the size of performance asymmetries across tasks differed by representational format. Further, the first two tutorials explained explicitly how to determine whether the given effects were present. By contrast, the third tutorial, regarding main effects of the secondary factor, did not. Thus, the third test provided a measure of transfer to a novel task following practice with other related tasks. The tests following each tutorial also included stimuli in a verbal format which was not shown during training. Performance with these stimuli served as a measure of knowledge transfer to a task involving a novel representation.

\section*{Participants}

Participants were \(\mathrm{N}=127\) undergraduate students from the Indiana University Psychology Department who participated in partial fulfillment of a course requirement.

\section*{Materials}

A set of tables, graphs, and text passages representing possible outcomes of a fictional study were developed for use as test stimuli (Figure 1). The study involved a drink taste test with two binary independent variables, drink flavor and participant age group, and one continuous dependent variable, taste rating. Drink flavor is referred to as the "treatment factor," and age group as the "secondary factor."

Each stimulus represented a dataset comprising one taste

Figure 1. Test stimuli in (a) graph, (b) table, and (c) verbal format for a single dataset.
The pictured dataset shows a treatment effect and a treatment \(\times\) secondary interaction, but no secondary effect.
rating for each combination of factor levels. 2 datasets were generated for each combination of presence or absence of effects of the treatment factor, secondary factor, and their interaction, yielding 16 datasets. Each effect appeared in exactly half of the datasets, and no effect was correlated with any other. 3 stimuli were created for each dataset by presenting the data in each of 3 formats: table (Figure 1a), graph (Figure 1b), and verbal (Figure 1c), yielding 48 stimuli. The secondary factor always appeared on the horizontal axis of the graphs and tables, while the treatment factor was laid out vertically in the tables and the graph legends, but these orientations were reversed in the verbal stimuli.

Another fictional study, involving effects of cognitive enhancement drugs on test scores of males and females, was devised as a basis for examples to be shown in the tutorials. Analogous to our terminology for the test stimuli, drug is referred to as the treatment factor and sex as the secondary factor. As for the test stimuli, 3 effects of these factors were possible: treatment effect, secondary effect, and treatment \(\times\) secondary interaction. For each effect, 2 datasets were developed: a "positive" dataset, which had the effect, and a "negative" one, which did not. Using the same conventions as for the test stimuli, one graph and one table were created for each dataset, yielding 4 examples for each effect.

\section*{Procedure}

The experiment was divided into 3 sections, one for each effect. Each section consisted of a tutorial, followed by a test, for the given effect. The sections were always presented in the same order, namely (1) treatment effect, (2) interaction effect, and (3) secondary effect. The tutorials and tests were presented via a computer interface.

The tutorials for treatment and interaction effects followed the same structure. First, participants were shown a brief description of the cognitive enhancer study, together with 2 of the 4 examples for the given effect shown side-byside, and asked to judge whether or not the examples showed the given effect. Second, they were told that the presence of the effect depended on certain values, i.e. difference in drug scores when marginalizing over sex in the case of treatment effect, or difference of differences between drugs for each sex in the case of interaction effect. They were required to calculate and compare the relevant values, and were then told in which example(s) the effect was present, using the calculated values as justification \({ }^{1}\). Next, participants were asked to compare the two examples. Finally, the above procedure was repeated for the remaining 2 examples for the given effect.

The tutorial for secondary effects followed the same pattern as those for treatment and interaction effects, except that participants were not told which values they should calculate in order to judge the presence of secondary effects. Instead, after selecting which of the example(s) they thought

\footnotetext{
\({ }^{1}\) Participants were informed that normally a statistical test would be required, but for simplicity, they were to make their judgments using the standard that differences were significant if greater than or equal to 5 , and not significant otherwise.
}
showed effects of the secondary factor, they were asked to state how they thought the judgment should be made. They were given no feedback on their responses to this question.

Each participant was assigned randomly to one of three training conditions, which determined which examples were shown together in the tutorials. (1) In the Comparing Representations condition, the two positive examples, i.e. one graph and one table, were shown together first, followed by the two negative examples, again one graph and one table. (2) In the Contrasting Examples condition, the positive and negative examples in table format were shown together first, followed by the positive and negative examples in graph format. (3) In the Control condition, the positive table and negative graph examples were shown together first, followed by the negative table and positive graph examples.

The Comparing Representations condition directly implemented the idea, described in the introduction, of encouraging learners to compare different representations of the same information. The Contrasting Examples condition was intended as a pedagogically plausible alternative approach that employed the same materials, and involved the same amount of training, but did not afford the above opportunity for comparison of different representations. The Control condition was intended as a baseline with the same materials and same amount of variation across examples as the other two conditions, but with the examples paired in a way not expected to be useful for learners. \(\mathrm{N}=42\) participants were assigned to Comparing Representations, \(\mathrm{N}=41\) to Contrasting Examples, and \(\mathrm{N}=44\) to Control.

Each tutorial was followed by a test. Participants were shown a description of the taste test study and told that they would need to judge whether or not the effect about which they had just learned was present for various outcomes of the study. For each trial, one test stimulus appeared and remained onscreen until a response was received. No feedback was given. Each test stimulus was presented once per test section, in random order, for a total of 48 trials.

The experiment may be viewed online at http://perceptsconcepts.psych.indiana.edu/experiments/dwb/ MRIS_02/experiment_demo_live.html.

\section*{Results}

Mean accuracy on test trials was 66\%, and ranged from 25\% to \(100 \%\). Accuracy was significantly higher than chance, i.e. \(50 \%\), for all test sections and stimulus formats.

Accuracy scores were submitted to a \(3 \times 3 \times 3\) mixed ANOVA with training condition as a between-subjects factor, and test section and stimulus format as within-subjects factors. The main effect of training was not significant, \(F(2,124)=1.82, p=.166\), nor were any of its interactions with other factors. The main effect of section was significant, \(F(2,248)=23.67, p \approx .000\), indicating that accuracy was highest in the treatment section (74\%), lower in the interaction section (69\%), and lowest in the secondary section (63\%). There was a marginal main effect of format, \(F(2,248)=2.82\), \(p=.061\), qualified by a significant section \(\times\) format interaction, \(F(4,496)=11.54, p \approx .000\). Accuracy scores by test and
format are shown in Figure 2. In the treatment and interaction sections, accuracy was highest for graphs, lower for tables, and lowest for verbal, while in the secondary section, accuracy showed the opposite trend.

Figure 2: Accuracy by Test Section and Format. Error bars indicate standard errors.

Several of our research questions relate to graphs and tables only. Thus, the above analysis was repeated with the data from verbal stimuli excluded. The interaction of format with section was still significant, \(F(2,248)=3.61, p=.029\). While accuracy decreased across the three sections for both graphs and tables, it decreased more for graphs (treatment: \(77 \%\), interaction: \(71 \%\), secondary: 61\%) than for tables (treatment: 75\%, interaction: 69\%, secondary: 63\%).

Response times for test trials were analyzed using the same ANOVA model structure. The results strongly resembled those for accuracy. No significant effects involving training were found, \(p \mathrm{~s}>.25\). The main effects of test section and format were both significant, \(F(2,248)=63.78\), \(p \approx .000\) for section and \(F(2,248)=40.69, p \approx .000\) for format, as was their interaction, \(F(4,496)=3.04, p=.017\). Response times by section and format are shown in Figure 3. Responses sped up over the course of the three test sections. Responses were, overall, faster for graphs than for tables and verbal, but these differences were more pronounced in the treatment section than in the later sections.

Figure 3: Response Time by Test Section and Format. Error bars indicate standard errors.

Just as for accuracy, the analysis of response time was repeated using for graph and table trials only. The main effect of format was significant, \(F(1,124)=53.41, p \approx .000\), but the interaction of format with section was not, \(F(2,248)=.913\), \(p=.403\). Thus, response times were faster for graphs (6209 ms ) than for tables ( 7230 ms ) across all three sections.

Accuracy scores reflect the differing utilities of graphs and tables for task performance in different test sections, but give little insight regarding the mental processes underlying task performance. One way in which the latter might differ is the degree of influence exerted by different stimulus features. Each test stimulus was determined by presence or absence of treatment, interaction, and secondary effects, which may be viewed as three binary features. In each test section, only one feature was relevant, but the two irrelevant features may also have influenced responses. For example, in the secondary effect section, only the presence/absence of secondary effects was relevant, but a participant who had not adequately differentiated the three effects might give a positive response to a stimulus exhibiting treatment and interaction effects, even if no secondary effect was present. Thus, it could be useful to understand the influences of relevant and irrelevant features on responses for different stimulus formats and test sections.

To this end, a measure of the degree \(I_{x, s}\) to which the presence of effect \(x\) influenced responses in the test section regarding effect \(s\) was calculated as follows:
\[
I_{x, s}=P\left(R=+\mid E_{x}=+, S=s\right)-P\left(R=+\mid E_{x}=-, S=s\right)
\]
\(R=+\) signifies a positive response, \(E_{x}=+\) and \(E_{x}=-\) signify, respectively, the presence and absence of effect \(x\), and \(S=s\) signifies that the test section concerns effect \(s\). Thus, \(I_{x, s}\) represents the difference in probability of a positive response regarding effect \(s\) when effect \(x\) is present, relative to when effect \(x\) is absent. For a perfect responder, we would have \(I_{x, s}=100 \%\) when \(x\) is relevant, i.e. \(x=s\), and \(I_{x, s}=0 \%\) when \(x\) is irrelevant, i.e. \(x \neq s\). In other words, perfect responses would reflect total influence of relevant features and zero influence of irrelevant features.

Influence \(I_{x, s}\) was calculated separately for each participant, stimulus format, effect \(x\), and test section \(s\). The pattern of results for relevant features closely resembled those for accuracy, and thus are not reported here. The results for irrelevant features are shown in Figure 4. The mean of \(I_{x, s}\) in these cases was \(18 \%\), and was significantly greater than \(0 \%\) for all combinations of format and test section. Thus, participants were significantly biased towards positive responses by the presence of irrelevant features.

The data for influence \(I_{x, s}\) over all cases where \(x \neq s\) were analyzed using the same ANOVA model structure as for accuracy and response time. No significant effects involving training condition were found, \(p \mathrm{~s}>.12\), nor was the main effect of test section significant, \(F(2,248)=0.86, p=.423\). However, a significant main effect of format was found, \(F(2,248)=5.68, p=.004\), indicating that irrelevant features had the most influence for graphs (20.5\%), less for tables
(18.7\%), and least for verbal format (17.4\%). This effect was qualified by a format \(\times\) test section interaction, \(F(4,496)=8.61, p \approx .000\). As shown in Figure 4, the influence of irrelevant features increased over test sections for graphs, stayed about the same for tables, and decreased for verbal stimuli. Separate ANOVAs conducted using the data for each format alone found a significant effect of test section on influence \(I_{x, s}\) for graphs, \(F(2,248)=8.41, p \approx .000\), but not for tables or verbal stimuli, \(p s>.38\).

Figure 4. Influence \(I_{x, s}\) for \(x \neq s\), i.e. for irrelevant features. Error bars indicate standard errors.

\section*{Discussion}

In the first two sections of the study, participants were trained to judge whether treatment and interaction effects were present in bivariate data, and then tested on their ability to do so when the data was presented in graphical, tabular, or verbal format. In both sections, responses were faster and more accurate for graphs than for tables. Judging the presence of either effect requires assessing complex relationships between data points, i.e. comparing averages of pairs of data points for treatment effects or differences between pairs of data points for interaction effects. The advantage shown by graphs over tables is thus consistent with the general view that complex relationships among data points are more easily assessed in graphical than in tabular format (Meyer et al., 1999; Porat et al., 2009; Schonlau \& Peters, 2012; Vessey \& Galletta, 1991).

Accuracy was lower in the secondary effect section than in the previous two sections. This result is not surprising, considering that participants were not told how to judge the presence of secondary effects. However, interestingly, the effect of format on accuracy was reversed in this section. What might have caused this reversal? One possible explanation, detailed below, involves transfer. Specifically, low accuracy with graphs in the secondary effect section may have reflected negative transfer from the previous sections that was absent, or reduced, in the case of tables.

To flesh out this possibility, we consider how experience of the earlier sections of the study might have affected performance in later sections. In the earlier sections, participants were trained in explicit calculation methods to judge the presence of treatment and interaction effects. With
graphs, however, their judgments may have relied in part on visual patterns. For example, a sideways " \(v\) " shape in the graphs (Figure 1a) could be a useful cue for the presence of both treatment and interaction effects. Reliance on such visual patterns may have led to the creation of automatic visual routines (Ullman, 1984) that could support quick judgments regarding presence or absence of effects without, or before, performing the relevant calculations. Importantly, such routines, once acquired in the earlier sections of the study, might continue to be used in the later sections.

Thus, visual routines associating responses with visual patterns are one mechanism by which experience of the earlier sections might influence performance in the later sections. Importantly, this account predicts that such influence would be greater for graphs than for tables. Visual patterns are believed to play an important role in graph comprehension (Carpenter \& Shah, 1998; Pinker, 1990), but are much less salient in the case of tables. Moreover, the above mechanism could lead to negative transfer. Because visual patterns that were relevant earlier become irrelevant, even misleading, later, continuing to rely on them could hurt performance. For example, having learned in the first two sections to give positive responses when seeing the sideways "v" shape (Figure 1a), participants might continue to do so in the secondary effect section, even though that shape actually indicates the absence of a secondary effect. In sum, the above account predicts greater negative transfer for graphs than for tables in the later sections of the study.

Support for this explanation comes from our analysis of influence of irrelevant features on responses. In general, such influence was greater for graphs than for tables. More important for our present purpose, such influence increased over the course of the study for graphs, exactly as would be expected if responses in later sections were influenced by visual patterns which had proven useful in earlier sections. By contrast, influence of irrelevant features did not change over the course of the study for tables, as one would expect given the lesser salience of visual patterns in tables.

An alternate explanation for the reversal, in the secondary effect section, of relative accuracies for graphs and tables involves variation in the intrinsic difficulty of recognizing different effects in different formats. Specifically, for graphs, treatment and interaction effects may have been relatively easy to detect, and secondary effects relatively difficult, while for tables, there may have been less variation in the ease of detecting the various effects. This possibility is consistent with the hypothesis, stated in the Introduction, that performance asymmetry between tasks should be greater for graphs than for tables, due to greater representational asymmetry between variables in the former case. It is also consistent with Shah and Freedman's (2011) abovementioned finding that spontaneous interpretations of bivariate graphs tend to focus on main effects of the legend variable (in our study, the treatment factor) rather than the x axis variable (in our study, the secondary factor).

However, two aspects of our results cannot easily be explained in terms of variation in intrinsic task difficulty. The
first is the observed pattern of response times. Although accuracy in the secondary effect section was lower for graphs than for tables, reaction times showed the opposite trend, i.e. faster responses for graphs. These faster responses are consistent with reliance on automatic visual routines, as described above, but less consistent with the assumption that the task was more difficult to perform with graphs. Second, variation in intrinsic task difficulty cannot explain why influence of irrelevant features increased over the study for graphs, but not for tables. However, this effect is predicted by the first account given above.

While available evidence favors the first over the second account, further research could more definitively disambiguate between them by placing the secondary effect section at the beginning, and the treatment effect section at the end. If the first account, in terms of learned visual routines, is correct, then whichever section comes last should show negative transfer for graphs. If the second account, in terms of intrinsic task difficulty, is correct, then performance on the secondary effect section should be worse for graphs regardless of when it is encountered.

Another question investigated in our study was whether comparing graphs and tables of the same data during training, as in the Comparing Representations condition, would facilitate learning and transfer. However, this prediction was not confirmed. Accuracy showed no effect of training condition, suggesting that the Comparing Representations condition was not more effective overall. Nor did accuracy show any interaction of training condition with either format or section, suggesting that the Comparing Representations condition did not produce any particular benefits for transfer, either to a novel format, i.e. verbal, or to a novel effect type, i.e. secondary effect.

Importantly, this negative finding does not address the issue of whether the use of multiple representations during instruction can benefit learners, because multiple representations were included in all of our training conditions. However, our findings do suggest that the specific technique of comparing different representations of the same data may not produce any incremental learning benefit. This finding stands in contrast to the considerable learning benefits that can result from comparing semantically different instantiations of the same concept (Gentner et al., 2003).

In conclusion, our findings are consistent with previous research in finding an advantage for graphs over tables for tasks involving complex relationships between data points. Theories of graph comprehension suggest that salient visual patterns in graphs may underlie this advantage. However, a novel finding of the present study is that such visual patterns may not always be helpful. In particular, when performing novel tasks, graph readers may focus on visual features which were relevant to previous tasks, and have difficulty shifting perspective to focus on features which were previously irrelevant. By contrast, such shifts of perspective may be relatively easier with representational formats in which visual patterns are less salient, such as tables. These considerations suggest that graphical presentation may be pref-
erable for performing well-practiced tasks which are known in advance, while tabular presentation may be most suitable when performing or learning to perform unfamiliar tasks.

\begin{abstract}
We examined lexical choice and variability in referring expressions during direction-giving to pedestrians. The Walking Around Corpus comprises an experimentally parameterized collection of spontaneous spoken dialogues produced by 36 pairs of people communicating by mobile telephone; it provides both a testbed for lexical entrainment "in the wild" as well as a resource for pedestrian navigation applications. A stationary partner (the Giver) directed a mobile partner (the Follower) to walk about 1.8 miles, to 18 destinations on a medium-sized campus. Givers viewed a map marked with target destinations, labels, and photos. Followers carried a cell phone with GPS and a digital camera in order to photograph the destinations they visited; Givers monitored Followers' progress as a cursor on a map display. Immediately after the navigation task, Followers returned to the lab and both were tested individually on their spatial ability and memory for the destinations. Next, the Experimenter attempted to interfere with any conceptual precedents they had established by giving Followers printed copies of the photos they had just taken and prompting them (sometimes with competing labels) to identify each destination. Finally, each pair participated in 6 rounds of a more traditional referential communication lab task to repeatedly match duplicate copies of the Follower's pictures of the destinations. Results include significant rates of lexical entrainment, evidence for partner-specific conceptual pacts, and that joint navigation efficiency is affected by directiongivers' spatial ability. The Walking Around Corpus is available to the research community.
\end{abstract}

\section*{Introduction}

Speakers make many expressive choices in conversation, leading to enormous variability in spontaneous speech. These choices emerge not only from their individual proclivities and the availability of words in memory, but also from collaboration with conversational partners (Clark \& Wilkes-Gibbs, 1986). There is much less variation within than between conversations; speakers are more likely to continue using the same term with the same addressee than with a new addressee (Brennan \& Clark, 1996). Studies of referential communication in laboratory settings show that
lexical choice is influenced not only by precedent (what a speaker has said previously) and strength of precedent (e.g., how often a referent has been discussed), but also by partner (whether the precedent was established with the current partner or a different one) but that it can be maintained via interactive cues provided during grounding (ibid).

We have proposed that lexical entrainment marks two speakers' beliefs that they are referring to the same thing; in fact, breaking a conceptual pact, such as hearing a speaker inexplicably abandon an entrained-upon expression for a new expression when referring to the same referent, results in slower comprehension than hearing the same new expression from a different (new) partner (Metzing \& Brennan, 2003; Matthews, Lieven, \& Tomasello, 2010). A conceptual pact does not reflect a rigid mapping between expression and referent, but emerges instead from a flexible, temporary agreement arrived at with an interactive partner to take a particular perspective on the referent; as such, it is highly dependent on context. Although there is evidence that the partner associated with a conceptual pact is represented by a cue in memory (Horton, 2007; Horton \& Gerrig, 2005), this does not pre-empt an expression and referent from being easily associated with a different partner (Barr \& Keysar, 2002; Brennan \& Clark, 1996), nor does having an existing conceptual pact with a partner inhibit a new expression-referent association from being encoded with that partner when the pragmatic context changes (ibid).

Lexical entrainment has been demonstrated in adults (Brennan \& Clark, 1996; Clark \& Wilkes-Gibbs, 1986; Garrod \& Anderson, 1986) and in children (Matthews et al., 2010); in experts and in novices (Isaacs \& Clark, 1987); in native and native/non-native conversations (Bortfeld \& Brennan, 1997); and for lexicalized and non-lexicalized referents (Gergle, Kraut, \& Fussell, 2013; Schober \& Carstensen, 2010). It has also been measured in statistical analyses of the transcripts of speech corpora (e.g., Nenkova, Gravano, \& Hirschberg, 2008's studies of the Switchboard and Columbia Games corpora, and Stoyanchev \& Stent, 2009's from Let's Go, a real-world bus information system). In laboratory studies of referential communication and lexical choice, we and others have demonstrated effects of psycholinguistic processing in interactive dialogue contexts,
attempting to gain sufficient control to test hypotheses while modeling spontaneous interaction in conversational contexts. However, the question sometimes arises as to whether dialogue in non-laboratory contexts may be too noisy to show the same sorts of effects (Stoyanchev \& Stent, 2009).

In this project, we examine lexical entrainment and conceptual pacts both outside of and inside the laboratory.

\section*{The Walking Around Project}

\section*{Design and Materials}

Visual Context Manipulation Visual evidence relevant to a collaborative task has been shown to affect task strategies, to incrementally shape the form and content of spontaneous utterances, and to enable partners to shift the initiative or distribute the responsibility for grounding utterances (see Brennan, 2004 for discussion).

The amount of visual context provided to the stationary direction-giving partner during the navigational task was varied as a between-pairs and within-destinations factor. For half of the target destinations, the direction-giver saw only a close-up photo of the target (Figure 1) along with its numbered location on a map; for the other half, they saw the close-ups plus extra visual context (Figure 2). Each pair was assigned to either List 1 or List 2, with Givers seeing minimally illustrated targets in List 1 or extra visual context in List 2, and vice versa.
Because the mobile partner in the navigation task had rich visual information from being present within the local context, while the stationary partner had global information about the target location but less information about its visual appearance and relative local landmarks, we predicted that additional visual context for the stationary partner would help them align their knowledge, making presentation and acceptance phases of the directions more efficient jointly. On the other hand, such knowledge might be unnecessary for direction-givers who knew campus well (assessed during the final questionnaire).

\section*{Methods}

Task Sequence Pairs of volunteers did a sequence of five tasks during a 2 -hour session: (1) a collaborative navigation task in which one partner followed the other's directions in order to visit 18 pre-chosen destinations on campus, (2) a timed mental rotation test of spatial ability, (3) individual recall tests of their memory for the locations they had discussed, (4) showing the Experimenter the photos taken of the destinations (done by the mobile partner only) during which the Experimenter provided competing labels for some of the destinations, (5) 6 rounds of a referential communication task in which pairs matched identical copies of this set of photos (switching director-matcher roles halfway through, with the mobile partner acting as director for the first three rounds and the stationary partner as director for the last three), and (6) a questionnaire, completed individually. This sequence of tasks enabled us
to examine lexical choices within and across different interactive and solitary contexts; the spatial ability test provided the opportunity to examine the impact of this individual difference on strategies and performance.

Status of Corpus Project The corpus being released to the research community includes 36 digitally recorded spoken dialogues (with associated data on individual differences and experimental parameters). The navigational dialogues from these pairs have all been transcribed in detail (including disfluencies and pauses, along with time stamps). A full article in preparation will present data on the content and sequencing of referring expressions and navigation strategies. Here, we report findings from the post-navigation recall test, entrainment data from the 6 -round referential communication task, and effects of spatial ability.

Figure 1: Close-up views of 10 targets seen by Givers ( \(L\) to \(R\), top to bottom): Patriotic faces, Mushroom house, Outside chalkboard, Ship sculpture, Sorority rock with girl, Spaceship label, Goldfarb plaque, Cylindrical cement structure, Cedar plaque, Warning sticker

\section*{Subjects}

54 pairs of Stony Brook students were recruited from the Psychology Subject Pool or via flyers on campus to participate with another person in a task involving a nature hike or walking around campus. All identified as native speakers of English, all but two pairs were strangers, and all gave informed consent. As they arrived, they were asked whether they preferred to walk around or remain indoors; roles were assigned according to their preferences.
Because the sessions involved so many tasks (with the inevitable risks of equipment failure, bad weather, and subjects who either failed to complete the navigation task or who disregarded instructions and ran errands during the
session), and since inclusion of the navigation dialogues in the final corpus required both members of a pair to sign an additional release form, 18 of the 54 sessions could not be included in the Walking Around corpus. However, a total of 49 pairs completed most or all of the matching rounds, so contributed usable data for the current analyses. Subjects received their choice of either 2 research credits that could be used to fulfill a course requirement, or \(\$ 9\) per hour.

The student assigned to the role of direction-Giver (G) remained inside the lab with a landline phone to direct the student assigned as Follower (F) to locations on campus.

Figure 2: Extra visual context provided to Giver (without highlight) for selected targets from Fig. 1: Spaceship label, Warning sticker, Sorority rock with girl, Patriotic faces.

\section*{Procedure}

The sequence of tasks unfolded as follows:
(1) The goal of the collaborative navigation task was for \(F\) to visit and identify each target destination in order, and to take a photograph documenting the destination. F was provided with a digital camera and a mobile phone with GPS, but no information about the destinations, and so had to rely entirely on G's directions and descriptions. G used an interactive web interface displaying a custom Google Map of the relevant portion of Stony Brook's campus, with 18 target destinations marked and numbered in the order in which they were to be visited by F. By clicking on each numbered destination on the map, \(G\) could view the associated pop-up photograph(s) and label (Table 1 lists the labels provided to G). In addition, the same photographs and labels were provided as hard copy in a binder, with the materials for one destination visible per page. The map interface also displayed a cursor generated by F's mobile phone's GPS tracking, providing G with visual evidence of F's location on campus, updated every few seconds.
(2) Immediately following the navigation task, \(F\) returned to the lab, where both F and G were tested individually for their spatial ability via a timed paper and pencil mental rotation test (Card Rotation Test-S-1 [Rev.] by Educational

Testing Services, 1962, 1975).
(3) Then each partner was tested individually for their memory for the destinations. A SuperLab program on a laptop randomly selected and displayed 36 pictures of campus destinations, one at a time; half of these were the close-ups of the eighteen target destinations from the navigational task (as in Figure 1), and the other half depicted destinations the partners had not seen. Each partner was instructed to indicate within five seconds whether the destination was old (discussed or visited in the navigation task) or new. If a partner recognized the destination as old, the program allowed 30 seconds for typing its name into an expanding textbox. This task aimed to probe for the most available conceptualization (presumably, related to the one they had grounded with the partner during the navigational study completed only a few minutes earlier).
(4) Next, the Experimenter attempted to interfere with any conceptual precedents or pacts the pair may have established by giving F printouts of the photos F had just taken and having F identify them one by one; for some, the Experimenter deliberately used different labels than had been originally provided to \(G\) (see Table 1).

Table 1: Influences upon G and F, prior to matching task
\begin{tabular}{|l|l|}
\hline \begin{tabular}{l} 
Label provided to Giver \\
(screen and binder):
\end{tabular} & \begin{tabular}{l} 
Expression addressed to \\
Follower (by Exptr)
\end{tabular} \\
\hline Cedar plaque & Lebanon plaque \\
\hline Goldfarb plaque & Stickball plaque \\
\hline Patriotic faces & Profiles plaque \\
\hline Warning sticker & Watertower sticker \\
\hline Mushroom house & Brown brick structure \\
\hline Outside chalkboard & Physics chalkboards \\
\hline Ship sculpture & Engineering sculpture \\
\hline Spaceship label & SUNYLab label \\
\hline Cylindrical cement structure & T-shaped cement block \\
\hline Sorority rock with girl & Sorority rock with the moon \\
\hline
\end{tabular}
(5) After this, the partners re-joined one another to participate in 6 rounds of a referential communication task in which they repeatedly matched identical sets of pictures of the 18 destinations. The pictures used in this phase consisted of the actual photos taken by F while walking around and were printed in grey-scale, on \(8.5 " \mathrm{X} 11\) " paper. G and F sat at separate tables, back-to-back; F played the role of director for the first 3 rounds with G as matcher, and they switched roles for the last 3 rounds. To begin each round, each partner's set of pictures was shuffled randomly, with the director's arranged as a stack from which to view and describe one picture at a time, and the matcher's spread out on the table so that the matcher could identify and stack each one in the same order as the director's. Partners were told to accurately order their pictures as quickly as possible; the experimenter intervened if they made a matching error or tried to peek at each other's pictures.
(6) Partners filled out a questionnaire asking about their familiarity with campus, whether they knew each other, their length of time at SBU, whether they drive or live on
campus, their confidence in their own sense of direction and ability to read maps, and any other information they wanted to volunteer as relevant. Then they were debriefed.

\section*{Coding and Examples}

Entrainment coding We coded the content of referring expressions that both partners used in the 6 rounds of the matching task, including whether F's and G's expressions had converged by Round 6 ( F was director and G was matcher for Rounds 1-3, with G as director and F as matcher for rounds 4-6). We coded only the 10 target destinations for which the Experimenter provided an expression to F before the matching task, where the expression was distinct enough to compete with G's given label (illustrated in Figure 1 and listed in Table 1).

Lexical convergence (as evidence for entrainment) was coded for each of the 10 pictures using moderately strict criteria (adapted from Brennan \& Clark, 1996 and Bortfeld \& Brennan, 1997), as follows: if all of the content morphemes (nouns, adjectives) in the expressions spoken by the director (G) in Round 6 were included in any expressions from Rounds 1-3 (where F was director), or were also spoken or confirmed (e.g., by a backchannel or verbal acknowledgment) by F (the matcher) in Rounds 4-5, that counted as convergence.

Examples By these criteria, the expression "mushroom house" (used by a particular G as director in Rounds 4-6) was coded as not convergent with "mushroom hut" (which the F partner had used throughout Rounds 1-3) because F never used "house" and G never used "hut").

It has been shown many times that entrained-upon expressions become more efficient with repeated referring, so by this criteria, "mushroom" produced during Round 6 was coded as a convergent, shortened form of "brick mushroom" from Rounds 1-3.

Our coding ignored the order of propositional content, as well as the appearance of proxy terms (e.g., "thingy" in "mushroom thingy" or "blah blah" in "environmental blah blah" were considered to be like a wild card or variable, replaceable with other terms). Note that we did not include prepositions or other function words in the coding, so "moon rock girl" was coded as convergent with "girl on the rock with the moon."

However, when \(G\) introduced a new propositional morpheme in Round 6 that F had not used or acknowledged in Rounds 1-5, we coded this as a distinct expression (and a failure to entrain), such as in the following example, for which the given label was Ship sculpture, and the Experimenter's term was Engineering sculpture. (Note: in this and other examples, matchers did not always verbally respond, but would often just identify and arrange a picture.)

\section*{Round 1 F : boat structure}

G: boat structure?
F: yeah, the- in front of the Engineering building

Round 2 F: structure in front of Engineering building, the boat
Round 3 F: structure in front of Engineering building
Round 4 G : wire ship, *the*
F: *what?*
G : in front of the-
F : Engineering building?
G: yeah
F: okay
Round 5 G: the ship thing, in front of Engineering
Round 6 G: wire ship
(Pair 13, \#13)
In the example above, F's "boat structure" was never taken up by G, and G's "wire" was never confirmed by F.

Note that when pairs failed to entrain on a referring expression by Round 6, this did not mean that the expressions they used were unrelated. In some cases, they had all but converged in the 5 th round, but introduced an element new to their conversation in the 6th round (which could not count as entrainment by our strict criteria). This is the case with the next example (note also that in the navigation task, \(G\) had told \(F\) that he hated this particular object because he had run into it on his bicycle as a child):

Round 1: F: the cylinder you ran into
Round 2: F: the cylinder you ran into
Round 3: F: cylinder you ran into
Round 4: G: cylinder
F: cylinder
Round 5: G: cylinder
Round 6: G: cement
(Pair 54, \#15)
Note that for this destination, both the label given in the binder and the Experimenter's term had included "cement" (see Table 1). Like other behaviorally expressed products of human memory, conceptual pacts are subject to interference.

In other cases where pairs did not entrain, they sometimes appeared to be in the process of converging on a conceptual pact that was still a bit unstable, having included all of the same elements but in partial combinations during the 6 rounds, with F never producing or accepting all of the propositions in G's final expression.

However, at other times, F and G did express distinct, competing conceptualizations (possibly expressing disagreement), such as when F repeatedly used "submarine" in Rounds 1-3 and G subsequently used "spaceship" on Rounds 4-6, with neither comment nor discussion. Such dueling perspectives rarely led to errors in the matching task, but they do illustrate that pairs did not always succeed in entraining on a stable perspective.

Some gave explicit evidence that they were monitoring the sources of the content they expressed, both from walking around and from hearing competing terms from the Experimenter. In this example (coded as entrainment), F refers explicitly to both:

Round 1: F: the thing I couldn't find, that really tall, I think
she \(<\) the Experimenter \(>\) described it as a watertower, the really tall thing that was by G: - the helium (tank)?
F: yeah, yeah, yeah
Round 2: F: the helium tank, I think you said
Round 3: F: helium, tank, or
Round 4: G: the helium tank
Round 5: G: helium tank
F: () tank
Round 6: G: helium tank
(Pair 30, \#6)
Other Influences on Perspective Taking We also coded the extent to which the expressions in Round 6 included content that was (a) originally provided in the label provided to G in the binder for the Walking Around task, (b) spoken to F by the Experimenter after the recall test and before the matching task, or (c) "other", or not provided in (a) or (b). We predict that "other" content of the referring expressions will reflect conceptualizations and expressions that the pair discussed during the navigation task, as here:
Round 1: F: the T-shaped structure that you thought looked like a thumbtack
Round 2: F: T-shaped structure, thumbtack
Round 3: F: the thumbtack scri-, structure
Round 4: F: thumbtack
Round 5: F: thumbtack
Round 6: F: thumbtack
(Pair 49, \#15)
Because we have not yet coded all of the destinationrelevant expressions produced in over 30 hours of recorded navigation sessions, we cannot yet quantify the influence of that task on the expressions pairs used later on. So for the purpose of the current analyses, we use these proxies:
- Often, G began describing a destination in the Walking Around task by first proposing the label given for that target in the destination binder. So for the current analyses, we used the initial labels from G's binder as an estimate of the conceptualization first proposed by G and often elaborated, modified, or renegotiated and replaced as F walked around.
- Likewise, we considered content from alternative expressions directed at F by the Experimenter as potentially interfering with conceptual pacts established while walking around (especially due to the recency of that label, heard immediately before the matching task).
- Finally, content coded as "other" was hypothesized as having as its potential source the perspectives negotiated by the partners while walking around.

\section*{Results and Discussion}

Effects of Spatial Ability The time it took a given pair to complete the Walking Around task was correlated with G's mental rotation ability, \(\mathrm{r}=-.42, \mathrm{p}=.004\). Walking Around time was not reliably correlated with F's mental rotation ability, \(r=-.24, p=.111\).

Entrainment while Matching By Round 6, there was evidence of lexical entrainment \(74.8 \%\) of the time, with individual pairs entraining on perspectives for \(33 \%\) to \(100 \%\) of destinations, and particular target destinations showing entrainment by \(54 \%-95 \%\) of the pairs.

This represents a rather strong degree of entrainment considering that conceptual pacts are theorized to be flexible across contexts, and the multiple contexts in our study differed substantially from one another (e.g., during the matching task, G viewed F's photos for the first time, and now needed to compare and distinguish the destinations alongside one another. Brennan \& Clark's (1996) lab experiments showed \(56 \%-71 \%\) entrainment (this did not include expressions where one was a shortened version of the other, but the task context was far more uniform).

Hybrids When several perspectives are in the air, one highly effective strategy is to hybridize them. In the next example, G first read warning sticker in the binder. While walking around, F proposed a big water tank or something, while G proposed diamond shaped sticker. Later, F heard watertower from the Experimenter. In the matching rounds, each accommodated the other:

Round 1: F: the watertower with the triangle, diamond I mean
Round 2: F: watertower, with the diamond, the colors
Round 3: F: the watertower with the diamond
Round 4: G: the, the watertower sign, triang-, diamond, with the colors
Round 5: G: the watertower sign, warning sign
Round 6: G: the diamond watertower sign (Pair 49, \#6)
Memory for Destinations \& Labels G was more accurate than F in correctly recalling the destinations discussed in the navigation task (responding "yes" to old items), \(90.6 \%\) to \(80.4 \%, t(47)=3.69, \mathrm{p}=.001\). G was also marginally faster to respond than \(\mathrm{F}, t(47)=1.72, \mathrm{p}<.10\). This makes sense, as the contexts in which G encoded the destinations were consistent with the context of recall (memory prompts were the same closeup photos from the binder, and G had ample time to look at them as F walked around).

Convergence of Recalled Terms with Given Label After responding "yes" in the recall test, the G partner produced an expression with the identical content as the F partner \(41.7 \%\) of the time. The fact that this was so much lower than their entrainment rate in the matching rounds highlights the difference between individual memories and collaboratively-achieved perspectives.

The expression \(G\) recalled had all the same propositional content as the given (binder) label \(37.5 \%\) of the time, and a somewhat shorter label \(20.4 \%\) of the time. So \(57.9 \%\) of the time, the label G recalled matched the one G started out with (we do not call this convergence "entrainment" since it does not emerge from interpersonal interaction). G’s recalled label added propositional content to the given label
only \(2.2 \%\) of the time (even though they often created hybrid labels later when interacting with F in the matching rounds). This is striking, as it suggests that when they encoded the given label as precedent, they did so very strongly. The rest of G's recalled expressions (30.9\%) included no content from the given label.

Figure 3: Proportions of matching rounds that included content from labels initially given to G (in G's binder) or spoken to F (by the Experimenter). The discontinuities between Rounds 3 and 4 reflect a change in speaker roles ( \(F\) directed Rounds 1-3, and G directed Rounds 4-6).

Influence of Experimenter's Label Finally, we consider whether \(F\) designed referring expressions with \(G\) in mind by quantifying the interference from expressions addressed by the Experimenter to F just before the matching rounds. Figure 3 shows that when \(F\) was director (R1-R3), some content from those expressions made it into the expressions F proposed to \(G\) (note: this does not yet take into account a baseline for how often such terms were used while walking around). If F chose referring expressions egocentrically or based on recency alone, rather than designing them for G, then the black bars in Figure 3 would be much higher.

\section*{Conclusions}

The Walking Around Corpus and associated data from this project demonstrate how spontaneous referring expressions in conversation are shaped by partner-specific influences and interaction, as well as by other factors that include prior conceptualizations, spatial ability, and recent interference from another speaker. We are analyzing the referring expressions from the corpus to further explore evidence for entrainment in real world contexts, as well as to address applied questions. The corpus may be applicable to spoken dialogue applications; although GPS-based spoken dialogue systems for cars are now standard, such systems have not yet been optimized for pedestrians. This corpus is available to others for research purposes (contact the first author).

\title{
Tracking Persons Over Time is Tracking What?
}

\author{
Andrew Brook (andrew_brook@carleton.ca) \\ Department of Philosophy and Institute of Cognitive Science \\ Carleton University, Ottawa ON K1S 5B6 Canada
}

\begin{abstract}
Tracking persons, that is, determining that a person now is or is not a specific earlier person, is extremely common and widespread in our way of life and extremely important. If so, figuring out what we are tracking, what it is to persist as a person over a period of time, is also important. Trying to figure this out will be the main focus of this paper. (This paper will introduce a theme on tracking persons in Topics in Cognitive Science.)
\end{abstract}

Keywords: tracking persons; personal identity; personal identity - psychological criteria.

Tracking persons, that is, determining that a person now is or is not a specific earlier person, is extremely common and widespread in our way of life and extremely important. If so, figuring out what we are tracking, what it is to persist as a person over a period of time, is also important. Trying to figure this out will be the main focus of this paper.

I will begin with three preliminary points.
1. Philosophers call persisting as the person one is over time, i.e., what we are tracking when we track persons over time, personal identity. This is an unfortunate term, not least because the term 'identity' is now widely used to talk of features of personality, attitude to oneself, and the like. In this usage, it makes sense to talk of a strong identity, diffuse identity, identity crisis, etc., terms that make no sense in the philosophical context. For such reasons, I will generally speak of a person persisting or personal persistence.
2. Because of the possibility (in brain bisection operations, some say the actuality) of one person splitting into two people, by 'personal persistence' I do not mean a relationship that has to be one-to-one. (A charming depiction of one person becoming two is central to the film, To Be, by John Weldon (http://www.nfb.ca/film/to_be).) Likewise, it would appear that there can be degrees of persisting as oneself over time.
3. One might expect a paper on personal persistence to begin with at least a few comments on what a person is. That does not happen. The reason is that figuring out what we track or should track when we track persons also tells us a lot about what persons are.

\section*{1. Where tracking persons is central}

Tracking persons is at the heart of a great many social institutions, including
- Criminal law and punishment. Hence the effort that goes into determining that the person under arrest is the person who committed the crime.
- Obligations. You are now responsible only for obligations (contracts, promises, and the like) that you took on in the past.
- Property. You are now entitled to what you earlier owned. Sometimes, as in the case of educational policies, the changes to the person in the meantime can be massive.
- Credit. You are entitled to use only credit cards and the like approved for your use earlier. Hence photo ID.
- Insurance and benefits. The only benefits that you have now are ones that were assigned to you earlier (a very large issue in medicine in the United States). Likewise, you are entitled to recompense for harm done only if the harm was done to you or what belongs to you.
- Compensation. You are paid only for services you rendered or caused to be rendered earlier.
- Rewards. For example, you get the grade that your work earlier earned.

And so on. There seem to be two general principles behind tracking in these situations:
- Responsibility. A person is responsible only for what s/he, the same person, did (or caused to be done) in the past (a central feature of all western legal systems).
- Entitlement. A person is entitled to praise, benefits (including property), and compensation only for what \(\mathrm{s} / \mathrm{he}\) did in the past.

Tracking persons is even central to
- Interpersonal relationships. If you have just lost someone dear to you, your grief will not exactly dissipate upon being told, 'No problem. Your loved one had an identical twin who can do everything for you that \(\mathrm{s} / \mathrm{he}\) used to do.'

We even assume that we can track ourselves over time. Each of us, for example, has a:
- Special concern for one particular person's past. I might regret something you have done but I will not normally be ashamed of it (not normally because when I have a stake in your actions, by being your parent for example, I can feel ashamed of something you have done). And a,
- Special concern for one person's future, the person whom I believe will be me.

In short, tracking persons is central to much human social activity. (For further discussion of where we track persons in everyday life, see Shoemaker 2012.)

\section*{2. Current Tracking Practices}

The importance of tracking persons in our way of life is not matched by excellence in our tracking practices. The most common tracking practice uses facial similarity, whether in the form of eye-witness testimony in court (a practice that is not entirely reliable) or photo identification almost everywhere else now. Since two different people can look a lot alike, even entirely like in the case of identical twins, especially at a distance, and a single person can look very different in widely separated periods of life, tracking by facial similarity has its limitations.

Nonetheless, prosopagnosia, the inability to recognize faces, demonstrates how large a role tracking by facial appearance in fact plays. People with prosopagnosia cannot recognize people by face, therefore cannot tell whether they know a person before them or not. The result is that their lives are endlessly and embarrassingly complicated. To figure out whether they know a person before them, for example, they might have to get the person to speak.

Almost as common and equally limited is tracking by similarities in hand-writing, particularly signatures, a very common practice with contracts. In the legal system, similarity of fingerprints used to be the gold standard. It has been replaced by DNA sequencing, i.e., looking for similarities in the arrangement of molecule pairs in a particular stretch of DNA.

A common tracking practice with people we know but one that has received little attention is tracking by emotional reaction. We seem to have a distinctive emotional reaction to each person we know well. If a person before us triggers the distinctive reaction that we have to A and there are no countervailing factors (different gender, very different facial appearance and the like), this is a good reason for us to treat the person before us as A, the person to whom we have had the same reaction in the past.

One important piece of evidence for the importance of emotional reactions in tracking familiar people is the Capgras delusion. The Capgras delusion is the delusion that a person before one, a person whom one knows well and would normally care about, is an impostor. Despite the person before one looking like the familiar person, reacting
like the familiar person, expressing full and detailed memories of earlier events in the life of the familiar person - the person of course is the familiar person -, to someone in the throes of the delusion the familiar person is taken to be an impostor. (Capgras is usually accompanied by some form of major cognitive impairment such as severe schizophrenia.)

Neuroscience has not reached a settled view about what is going on the Capgras delusion but one widely held view is that, due probably to damage in the limbic system, the person suffering from the delusion has stopped reacting with the appropriate emotions to familiar, formerly liked or loved people. This is enough to convince the victim of the delusion that the person before him or her is not the person he or she knows and likes or loves. If this explanation is right, it would be evidence for the centrality of emotional reaction in reidentifying familiar people at a later time.

How well do our tracking practices relate to what matters in tracking persons? Not well. Return to fingerprints and DNA sequences. Let us suppose that the claims made for their uniqueness are right and the odds of two people having the same fingerprint or relevant DNA sequence are one in some billions. Would this tell us something valuable about what we want to track when we track a person? Even if fingerprints and DNA sequences were unique to each person, I don't think so.

The reason is that fingerprints and DNA are not what personal persistence consists in. They are merely features correlated with the person in question persisting. Again, suppose that the correlation is nearly perfect. Even here, knowing what a certain fingerprint is like or how a particular DNA sequence goes would tell us almost nothing about what being the bearer of that fingerprint or DNA sequence over time consists in. Indeed, knowing the fingerprint or sequence would tell us almost nothing about either their bearer in particular or what a person persisting in general consists in. Here is another way to put the same point: To know how well similarity of fingerprints or DNA correlate with the person before us being an earlier person, we need an answer to the question, correlate with what? What would it make the later person the earlier person?

\section*{3. Persons Over Time: What Interests Us?}

In the philosophical literature, two approaches to what must persist for a person to persist have dominated, the psychological approach and the somatic or bodily approach. On the psychological approach, the most frequent appeal is to the later person remembering events in the life of the earlier person in a particular way. However, psychological continuity of personality, abilities, and dispositions has also played a role. On the somatic or bodily approach, persistence of a functioning body or sometimes just a functioning brain has been front and centre.

It seems fairly clear that when we judge a person before us to be some earlier person, what primarily interests us are psychological factors. Even when somatic factors such as
facial similarity drive the judgment, it is because we take the somatic factor/s to be a reliable indication that the psychological factors of interest are present.

That psychological factors are what interest us can be shown in a number of ways. When we judge a person before us to be an earlier person, in the absence of special factors such a cognitive injury and dementia, we believe that the person before us will have a host of values, commitments, attachments, abilities, ways of viewing things, and so on so very similar to the same factors in the earlier person. Gaining this assurance is one of the reasons we track people. (We will return to this issue of psychological similarity.)
Another indication that psychological factors dominate is the way in which many people respond to brain bisection patients when, in special laboratory conditions, the body in question simultaneously does and disavows doing certain actions, responds to and disavows having heard certain requests, and so on. Many people (including Roger Sperry, who won a Nobel Prize for his work with brain bisection patients) take that it that, temporarily, two 'centres of consciousness' have appeared in these patients. Since there is only one body and brain throughout (albeit a brain whose corpus callosum has been severed in part or in whole), we cannot be making this judgment on somatic or even brain evidence and have to be making it on psychological factors, specifically, performance/lack of performance pairs.

A third argument is similar. When we learn about the idea of teletransportation (in Stars Trek episodes or whatever), the idea of a person being transported from one location to another without a single molecule of their body being transported makes instant sense to nearly everyone. For the idea to make sense, we have to be conceiving of the transfer as something psychological. (The same short film mentioned earlier, To Be by John Weldon, depicts teletransportation in a charming way.)

Finally, think of Kafka's Metamorphosis. In this story, the central character, Gregor Samsa, goes to sleep a human being and wakes up a 'monstrous vermin'. We have no trouble making sense of the idea that it is him, the very same person, who is now a bug. Yet the two bodies would not share any structure and not much if any matter.

Conclusion: What matters to us about personal persistence is something psychological. The next question is, what?

\section*{4. Memory}

What connects a later person to an earlier person when the earlier person persists as the later? Memory has a property that makes it a prime candidate. Unlike all other factors whether somatic or psychological, memory depicts events in the life of the earlier person. Its intentionality, to use that term of art, is backward-looking.

What kind of memory? Clearly we are not interested in short-term or working memory and we are not interested in procedural memory, memory of how to do things. What interests us is long-term declarative memory of some kind,
memory over substantial periods of time of what was the case. In the literature, three kinds of long-term declarative memory are distinguished:

Semantic memory (memory of facts, whether or not you were there)
Episodic memory (memory of events, usually with a requirement that you had witnessed the event)
Autobiographical memory (memory of events in one's own life, which can be both semantic and episodic)
However, this tristinction is not fine-grained enough for our purposes. For there are at least two kinds of autobiographical memory:
1. Remembering events in one's life 'from the inside', i.e., from the same point of view as the events were originally experienced. Thus one not only remembers an experience, a thought, or whatever, one remembers having the experience, the thought, or whatever. One not only remembers an action, one remembers doing the action. One not only remembers a feeling, one remembers having the feeling. And so on.
2. The rest - all the memories of events in one's life that are not from the standpoint of having lived them.
If I remember having had an experience, thought, feeling, it will appear to me that \(I\) had that experience, etc. I will appear to myself to be that person. And when I remember having had the experiences of an earlier person, or a series of person-stages tied together by a string of such memories, the appearance of the earlier person being me will be correct. Continuities and similarities can run from one person to another (Shoemaker, 2012, p. 12). However, I do not remember having others' experiences, etc. \({ }^{1}\) Absent some countervailing factor (such as reason to think that, for example, a memory transfer has taken place), if I have autobiographical memory 'from the inside' of having, doing, feeling a single earlier person's thoughts, experiences, actions and feelings, I am that person. That person has persisted as me.
Moreover, this suggestion about autobiographical memory 'from the inside' has more than intuitive appeal going for it, considerable though that is. We can use it to generate a nice theory of why we are responsible for earlier things we did and why we have a special concern for the future person who will be oneself.

Ask, why am I responsible for what I am doing right now?

Answer: Because I am the agent of the action - I experience myself from the standpoint of originating and doing the action.
And ask, why do I feel a special concern for me right now?
Answer: Because I will feel my pleasures and pains and other experiences - I experience them 'from the inside'. Likewise with plans and intentions. I put my plan in place, I act on my intentions. I merely observe the experiences, plans, and intentions of others

This suggests that I am responsible for an action of an earlier agent if I remember doing it and similarly for thinking, perceiving and feeling. Similarly, when I project my hopes and plans for my life onto a specific future person, when I feel special concern for a specific future person, I project onto and feel concern for the future person who will remember me as I am now 'from the inside'. A nice account. It flows directly from my account of remembering 'from the inside'.

\section*{5. Memory 'From the Inside' and Unified Consciousness}

There is a certain artificiality in what we have said about memory up to now. Contrary to the way I have written so far, we seldom remember having or doing or feeling individual experiences or actions. Usually what we remember about ourselves is far 'bigger' than that. Memories 'from the inside' are usually a kind of global representation:

Global representation - representing many objects as a single complex object.
What characterizes a global representation is that the representation of the elements of its object is united: One is aware of all the elements together, in a single conscious act, and one is aware of them not just as individual items but as a group.

To see how this works, consider representation of items that could be expressed by these sentences:
1. I am reading the words on the screen in front of me,
2. I am puzzled by your comments
3. I am enjoying the music I hear outside
4. I believe our agreement was to meet at 6:00
5. I thought I understood Kant's notion of the object
6. I wish the world were a fairer place

Here there are three different elements that could be united in a single global representation, (a) what I am representing, (b) the acts (act when unified) of representing them, and (c) myself as the subject doing the representing.

Similarly with memory. When I remember, for example, doing something, I nearly always also remember how I felt at the time, what I experienced at the time, the outcome of the action and how I felt about that, and so on. If so, my memory is a global representation that represents a unified group of earlier experiences and actions (see Raymont and Brook 2006)..

With this fuller description of memory, we can now give a fuller description of the relationship of memory to personal persistence. When we know the contents of a person's current global memory 'from the inside' of earlier experiences had, actions done, etc., and we track back and discover who had the global experience that is depicted in
the global memory, we know which earlier person the current person was.

Unified global experience and unified global memory 'from the inside' are a central part of what it is to be a (normal, cognitively intact) person. A persisting person is a series of global representations, each of which contains or contained memories of having thoughts and experiences, doing actions, feeling feelings 'from the inside', i.e., from the standpoint of having, doing and feeling them. Similarly, mutatis mutandis, for anticipating a future person as oneself. (This paragraph is my response to the wish discussed earlier for an account of what a person is.)

\section*{6. Problems with Memory}

So far, so good. But so far is not far enough. We do not ground judgments of personal persistence entirely on global autobiographical memory 'from the inside' and there are at least three challenges to the idea that we should do so.
1. In some cases, it appears that such memory is not necessary for personal persistence.
2. Some pressure can be put on the idea that it is always sufficient.
3. The kind of memory in question could in principle branch, go back to two or more earlier persons, or merge, two streams of memory becoming one.

Is memory necessary? Consider the most famous case in neuropsychology, Mr. H.M. (Henry Molaison, recently deceased). In the 1960s, to block epilepsy spreading from one hemisphere of his brain to the other, surgeons severed not just his corpus callosum but also the two halves of his hippocampus (and removed some other structures). This made it impossible for him to lay down new memories lasting more than about twenty minutes. Yet he was still taken to be a single, persisting person. No one questioned, for example, whether it was appropriate to continue to call 'him' by the same name or suggest that he was not the beneficiary of a pension plan created during the working life of the earlier person who had his name. Sacks (1970) discusses two cases with similar memory deficits.

To be sure, this attitude can be questioned. From the moment of the operation, HM was very different from people with normal memory. Post-operation, he never again entered a significant human relationship. (Even his care staff had to introduce themselves to him every morning.) He had no idea where he was and could not travel or even take a walk on his own. He had no knowledge of having had a life since the operation and so in one sense did not know who he was. If he had ever done anything that created entitlements or responsibility, he would have had no knowledge of having done so (so what would be the point of holding him responsible?). Thus he had no sense of accomplishment or failure, no pride in himself or guilt or shame, no sense of the trajectory of his life, no ... no ... no ... . And he could not plan a future for himself; his life did not have a planned or
desired trajectory. People with radical amnesia are very different from people with intact autobiographical memory.

Still, radical amnesia is not death. What makes memories 'from the inside' especially pertinent to personal persistence is that such memories depict, refer back to, earlier experiences and actions (and do so from the point of view of the person who had the original experience or did the original action). They do not, as we said, share this feature with any other kind of psychological state. However, they do share something else. Memories were caused by earlier experiences and actions.

Thus, memories are one kind of psychological continuity. When memory is missing, we can back off to other kinds of psychological continuity, ones that do not have backward intentionality. These can include continuitycarried similarities - HM, for example, had the same linguistic and arithmetic skills, the same knowledge of the world, the same manual abilities, and so on after the operation as before and the causes were primarily earlier events in the same body. Because HM is causally continuous with the body on whom the disastrous operation was performed, tracking his current causal continuities would lead us back to that body. We continue to find personal persistence even when memory is absent, I think, because we back off to these other kinds of causal continuity.

One very important non-memory causal continuity is continuity of plans, projects, and intentions. Usually I will have or have acted on much the same plans, life projects, etc., as I laid down for myself earlier and usually the main cause of having those plans, etc., now is that I laid them down for myself earlier. As we will see, continuity and discontinuity of such plans can make a difference in certain cases. I said that continuity of plans, etc., is a non-memory continuity and that is correct. However, they are usually carried from the past into the present in memories. Thus Mr. HM could not form any such plans, any that required him to remember them for more than half an hour at any rate. This is another and highly significant way in which he was radically unlike a person with normal memory.

Now our second question: Is global autobiographical memory 'from the inside' always sufficient for personal persistence? Cases where there has been massive personal change over time put some pressure on the idea. Let me sketch two real cases that certainly give one pause.

In 1941, one of Hitler's lieutenants, Rudolph Hess, flew to Scotland to try to negotiate a non-aggression treaty with England. (This would have left Hitler free to invade eastern Europe and the Soviet Union.) Hess was arrested as soon as he landed - and never lived outside a prison again. For many years, he was the sole inhabitant of last prison of the Allies in Germany, Spandau Prison in Berlin (the Soviet Union would not agree to his release), and so was effectively in solitary confinement. He died a very old man of 92 in 1987 (of either murder or suicide, theories vary). By the end, he was an embittered, cognitively-impaired shadow of his former self.

More recently, in 1998 Karla Faye Tucker was executed in Texas. She had taken part in a drug-fuelled murder at the age of 24 in 1983, so was in prison for close to \(40 \%\) of her life and nearly all her adult life. During her time in prison, she converted to Christianity and was not just a model prisoner but a counselor and mentor to other inmates. She even married the prison chaplain. In short, by the time she was killed, she could hardly have been more different than the out-of-control drug addict who took part in the murder.

Yet in both cases there was autobiographical memory and also psychological continuity and a single history, both psychologically and biologically. So all the tracking mechanisms that we normally use would lead us back to the same earlier person in both cases.

The trouble is, both cases raise the following question. Even though both people retained autobiographical memory and the usual continuities to the end, was there a sound basis at the time they died for taking the earlier person who bore their name, etc., at the time of their arrest, say, to have persisted as them? More directly, was there any justification for holding either of them responsible for what had been done by someone with the same name so many long years before?

Here is a basis for caution about how to answer these questions. Normally personal persistence carries with it persistence of character, life projects, and the like, so that if these things had been vicious earlier, they will be vicious now. And memory 'from the inside' will ensure that the later person knows about the earlier character - or at least the actions to which it gave rise. When character is no longer vicious, projects no longer malign, especially if accompanied by remorse or regret, the fact that the person nonetheless remembers his/her earlier character, projects, and actions 'from the inside' does not seem to matter as much.

And here the two cases differ. Tucker clearly fit the description of the paragraph above - but Hess did not. Tucker's character, life projects, and the like had been transformed. Hess, however, merely lost the power to act on his; he remained an unrepentant Nazi to his death. Thus, there would seem to be a better basis for continuing to hold Hess responsible for the actions of the triumphant young Nazi of old than for continuing to hold Tucker responsible for the actions of the earlier person who bore her name. (If so, it is a source of regret that Gov. Bush, as he was then, did not see things this way. Cases such as Hess and Tucker illustrate vividly that tracking persons can have profound ethical implications.)

Now the third question. What if a memories 'from the inside' lead back to two or more different people? Here there are two kinds of case, one where most of the memories originated in one person but a few originated in another, and one where the split is roughly equal.

In the first case, we could just ignore the aberrant memories, maybe by treating them as transferred somehow from another person. As to the second case, where
memories 'from the inside' originated in two different people about equally, we have grounds to hold that both people have persisted as the single current person with the memories. Because memories have a substructure of causal continuities and in our world the preponderant causal path carrying memory and other psychological continuities is within a body, memory transfer would take some very special technology.

\section*{7. ... And When There Is Little Or No Psychological Continuity Of Any Kind?}

There are also cases in which there is not just no memory but little or no psychological continuity of any kind, where nonetheless we take there to be a persisting person. Vegetative state patients are one kind of case. Newborns are a second. The relationship between me now as an adult and the newborn who was given my name decades ago is a third. (In the first two kinds of case, there is no psychological continuity. In the third, psychological continuity eventually developed but there is little or no psychological continuity running all the way back to the newborn.) How do we track persons in these cases?

Well, psychological continuities are causal continuities and some causal continuities exist in all three kinds of case. If materialism is correct, moreover, psychological continuities are one kind of bodily continuity. So we can, and do, fall back on other causal and bodily continuities such as looking alike, similarity of DNA, and a continuous causal history.

In summary, the pattern is this. When we have memory 'from the inside' and there are no countervailing factors, we stop there. When memories don't exist or have taken an unhelpful form, we back off to other psychological continuities. When psychological continuities are absent, we back off further, to non-psychological bodily continuities.

\section*{8. Practicalities}

Suppose that the story that we have told of what personal persistence consists in is at least roughly right. How would it connect to the tracking practices that we actually use, the ones that we laid out earlier? The answer is: At a conceptual level at least, not very tidily.

The problem is that in real life, it is often hard to gain knowledge of memories and other psychological continuities. To identify someone's memories, we need sophisticated skills in 'mind-reading' (assignment of psychological states to others) and considerable cooperation from the person in question. Such co-operation can, of course, be in short supply when you are trying to track people in the context of the criminal law, fraud, and
the like. So we resort to such things as facial appearance, fingerprints, and DNA pattern.

It may appear to be remarkable that such purely somatic factors work as well as they do for tracking what is, except in the rare special cases that we delineated in Stn. 7, a matter of psychological continuities. In fact, it is not. All the continuities we considered are underpinned by substantial causal continuities. Such continuities do not have to run though a single persisting body, as the very intelligibility of teletransportation shows. But in our world, they invariably do. For this reason, the rule, One persisting person per persisting body, works pretty well - and finding a reliable way to track persisting bodies over time is usually a pretty good way to track persisting persons. So facial similarity, fingerprints, and DNA sequences usually work pretty well. (For an excellent discussion of the relationships between cognition and the body, see Ismael 2007, Chapter 11, especially Section 5 .) \({ }^{2}\)

\({ }^{1}\) Bishop Joseph Butler claimed in the \(17^{\text {th }}\) century that we cannot by definition remember having an experience had by another. If so, being the same person is a requirement of the kind of memory we are discussing - and, of course, cannot be used to define or analyze it. Here I will just assume that we can define a form of memory that does not presuppose personal persistence.

\title{
Plausibility and Visualizability in Relational Belief Revision
}

\begin{abstract}
Belief revision is required when new facts are incompatible with existing beliefs. In the present experiment, participants changed their mind about the spatial and non-spatial relations between objects. The participants received information about relations, which were subsequently contradicted by irrefutable counterfacts. The task was to decide which of the initial relations to retain and which ones to give up. Previous experiments showed that these decisions are guided by the linguistic asymmetry between located (LO) and reference objects (RO). Reasoners have a strong preference to relocate the LO of the counterfactual relation. Our experiment explores whether this robust effect can be overwritten by the plausibility of revised beliefs; and how visualizability of problems affects revision. We found the LO-preference to be robust even when the resulting representation is implausible; and that revision is impeded when problems are easy to visualize. The results shed new light on relational belief revision in humans.
\end{abstract}

Keywords: Relational reasoning; Spatial reasoning; Belief revision; Mental models, Visual impedance

\section*{Relational Reasoning and the Revision of Beliefs}

Imagine you involuntarily put on some weight over the Christmas holidays. That is why, for the next couple of months, in order to get rid of the additional pounds, you consider nutrition which is low in fat and calories. You know that pasta, buckwheat, potatoes, and fruits are all low in fat, and further that potatoes are higher in calories than buckwheat is, and that pasta provides more energy than potatoes and fruits. Your ability to rank these, and even more, different types of food according to the amount of energy they provide enables you to conclude that fruits are a good choice when you want to pursue your aim of weight loss. This little example demonstrates that reasoning with relations is essential in our daily life. In fact, it is ubiquitous and it plays a vital role in higher cognitive processing, for instance, in planning and categorizing (Halford, Wilson, \& Phillips, 1998; 2010; Hummel \& Holyoak, 2005).

Now, imagine you learn about avocado fruits that they contain high amounts of fat. You presumably integrate this fact with ease into your knowledge base, although it is not coherent with what you thought you knew about fruits (that they were low in fat). The process of integrating nonconsistent pieces of information into already existing belief sets is referred to as belief revision (e.g. Gärdenfors, 1988; Elio \& Pelletier, 1997; Wolf, Rieger, \& Knauff, 2012).

Reasoners usually revise their beliefs about the state of the world when confronted with contradicting evidence. Indeed, we frequently encounter new facts that do not cohere with our beliefs. When the source of a new piece of information is reliable and the fact itself somewhat indisputable, we might consider taking it into account. In case we do, it entails that we update knowledge bases and revise current sets of beliefs.

Frequently, there are multiple ways in which the revision could be performed, implicating different decisions about which beliefs to maintain and which ones to discard. Consider your belief that fruits are a good choice when you want to lose weight: do you maintain it in the face of the fact that avocados are high in fat; or will you discard at least avocados from the diet menu? Do you still think of avocados as fruits after all? It is clear that belief revision is often accompanied by uncertainty and ambiguity.

The current study relies on recent work done in the field of relational belief revision. A recent finding in studies that looked at belief revision about spatial relations is that the revision is based on the variation of spatial mental models (Bucher, Krumnack, Nejasmic, \& Knauff, 2011; Krumnack, Bucher, Nejasmic, \& Knauff, 2011; Bucher \& Nejasmic, 2012; Knauff, Bucher, Krumnack, \& Nejasmic, 2013). Often, there are multiple (logically equal) alternatives for variations that would all re-establish consistency. However, human reasoners hold strong preferences for specific alternatives. These preferences can rely on linguistic cues provided by relational statements. The experiment presented here was designed to investigate whether reasoners still rely on these cues during revision, even when the resulting object relations are implausible. Furthermore, we compared reasoners' performance in problems that were easy to visualize and easy to spatially represent.

\section*{Preferences in Spatial Belief Revision}

Our recent experimental studies have focused on the revision of object arrangements. Imagine a person has reason to think that the objects \(\mathrm{X}, \mathrm{Y}\), and Z are arranged in this linear order. The spatial mental model that is constructed can be sketched as:
\[
X-Y-Z
\]

Let us assume the reasoner then learns from a reliable and trustworthy source that as an incontrovertible fact, "object Z is to the left of object \(X\) ". This fact is inconsistent with the
reasoner's model. In order to take the fact into account and - at the same time - keep changes to the model as little as possible, the reasoner can vary the model in two different ways: the X can be relocated; the Z can be relocated. These two alternatives are comparable, from a logical point of view.

The finding of recent studies is that reasoners encounter this ambiguity with clear and robust preferences. Preferred model revisions of the type introduced here are guided by cues provided by the conflicting statements. Binary relations - such as "Z left of X" - feature a functional asymmetry between the two objects, well known as distinction of figure and ground, target and anchor, or (the terminology used in the present context) "located" (LO; the "Z" in "Z left of X") and "reference" object (RO; the " X " in " \(Z\) left of \(X\) "). The asymmetry of LO and RO specifies the location of the LO relative to the location of the RO (Miller \& Johnson-Laird, 1976; Talmy, 1983; Landauer \& Jackendorff, 1993). Reasoners tend to perceive the RO's position as fixed and inflexible while the LO is considered to be more flexible and locatable.
The following example sketches a reasoner's characteristic preference for the revision of a horizontal linear arrangement of the objects \(\mathrm{X}, \mathrm{Y}\), and Z :

Arrangement: \(\mathrm{X}-\mathrm{Y}-\mathrm{Z}\)
Counterfact: Z is left of X ,
with \(Z\) as the \(L O\) of the counterfact and \(X\) as the \(R O\)
Revisions: (1) \(\mathrm{Z}-\mathrm{X}-\mathrm{Y}\)
(2) \(Y-Z-X\)

The revised arrangement (1) results from the relocation of the counterfact's LO relative to its RO and is usually the preferred revision. The logical equivalent but non-preferred alternative (2), results from the relocation of the RO relative to the LO. The LO-preference is a strong effect. Indeed, reasoners apply this principle in around \(90 \%\) of the problems of the described type (Bucher et al., 2011; Krumnack, Bucher, Nejasmic et al., 2011; Bucher \& Nejasmic, 2012; Knauff et al., 2013).
Note that abstract entities such as \(\mathrm{X}, \mathrm{Y}\), and Z are neutral with regard to the position within an arrangement. The same applies for objects such as fruits (apple, mango, orange) and tools (hammer, drill, pliers). Indeed these were the objects used in the experiments so far.

Here, as a novelty, we manipulated two factors: the plausibility of revisions and the visualizability of the statements. We used spatial and non-spatial relations of objects "that make sense", e.g. "an elephant is bigger than a fly". The statements used in the problems differed with regard to their visualizability, i.e. in their extent to which they provoke picture-like representations ("mental images").

The first question is: do reasoners still apply the LOprinciple when the revised model is implausible? In fact, reasoners often base their problem solutions on the plausibility of the content or on prior experiences within a
certain field (Newstead, Pollard, Evans, \& Allen, 1992; Klauer, Musch, \& Naumer, 2000; Evans, 2008, DeNeys, 2006; Knauff, Budeck, Wolf, \& Hamburger, 2010). These content effects show the strong tendency of reasoners to take into account what is meaningful or plausible. On the other hand, the LO-preference is a strong effect.

The second question is: does the visualizability of a problem modulate revision? Relations which are easy to visualize, impede reasoning (Knauff \& Johnson-Laird, 2002; Knauff, Fangmeier, Ruff, \& Johnson-Laird, 2003; Knauff \& May, 2006; Knauff, 2009). Mental images are considered to be irrelevant for reasoning itself but the inspection of the images appears to slow down thinking and makes it more prone to errors. This so-called visual impedance effect occurs complementary to the facilitating effect of spatial relations (Knauff, 2009; Knauff, 2013). Spatial belief revision is conceived as the manipulation of spatial mental models. The assumption for the current experiment is that models which are easy to mentalize as visual images should accordingly be harder to manipulate by a reasoner than models constructed from easy to spatially representable statements.

In order to prepare the manipulation of the experimental problems' visualizability, we conducted a pilot study.

\section*{Pilot study: the Visualizability of Statements}

Participants of the pilot study rated statements with regard to their visualizability. This procedure allowed the allocation of statements to categories: visual, neutral, and spatial.

\section*{Method}

30 volunteers ( 14 male; aged from 19 to 55) participated in the study. Each of them rated individually, 72 binary spatial and non-spatial relational statements according to their visualizability. The statements were accessible online via a link sent by email. They were generated and the data collected, using LimeSurvey, Version 1.92+ software. Example statements are: "Asparagus is thinner than cucumber", "Cucumber is thinner than cabbage"; "Whisper is quieter than speech"; "Speech is quieter than scream".

Participants rated the subjectively perceived visualizability of each statement on a scale with the points: "very easy to visualize"; "easy to visualize"; "easy to visualize and spatially represent"; "easy to spatially represent"; very easy to spatially represent"; and "neither easy to visualize nor to spatially represent". The four most clear-cut rated statements from the three categories, "very easy to visualize", "neither easy to visualize nor to spatially represent", and "easy to spatially represent" were chosen as experimental material. In accordance with these ratings, the relations were allocated to one of three experimental conditions: "visual"; "neutral", "spatial". Table 1 shows example statements.

Table 1: Examples of statements used in the experiment
Visual
The cucumber is thinner than the pumpkin. The asparagus is
thinner than the cucumber.
Neutral
The bird is weaker than the dog. The dog is weaker than the polar
bear.
Spatial
Russia is further east than Poland. Poland is further east than
Germany.

\section*{Discussion of the Pilot Study}

It is clear that many people experience their thinking as inspection of visual images. However, our pilot study indicates that some relations are more "visual" than others. The results show that, on the one hand, the categories "visual", "neutral", and "spatial" have no clear-cut borders. On the other hand, however, the results also clearly show that some relations are experienced as more visual than others while some relations are experienced as more spatial than others. So, we do not have relations that are purely visual or spatial. However, for our main experiment we could identify relations which are more visual or more spatial than other relations.

\section*{Experiment: Plausibility and Visualizability}

For the main experiment, the visualizabilty of the problems and the plausibility of revisions, were manipulated. Regarding plausibility, we relied on common knowledge. We assumed that a statement such as "the father is younger than the grandfather" is regarded as plausible, while the invers relation, "the grandfather is younger than the father" as implausible.

\section*{Method}

Participants A new group of 20 volunteers ( 8 male ; age range from \(20-35\); all native speakers of German) gave written informed consent to participation. They were tested individually in a quiet lab room.

Materials, Procedure, and Design The experiment is based on a \(3 \times 2\) (within-subject) design. We manipulated the factors visualizability (visual, neutral, spatial) and plausibility (plausible, implausible). The experiment consisted of 64 problems in the visual, neutral, and spatial condition, respectively. During the revision phase, participants chose between plausible and implausible revised models.

In the first phase, the description phase, the participant received two statements (premises, \(P\) ) describing the relations between three entities. In half of the problems, P1 was plausible and P2 implausible. In the other half, it was reversed. The premises were presented in a sequential manner, each at one time, by the participants' own speed. See an example problem of the "visual" condition below:

\section*{Description:}

P1: "Asparagus is thinner than cucumber"
P2: "Pumpkin is thinner than asparagus"
The task of the participants was to order the entities according to the description. Subsequently, two "models" were presented on the left and the right side of the monitor. One of the models was "correct", i.e. it was in agreement with P1 and P2, the other one was "incorrect".

Models constructed from the description:
Correct: Pumpkin Asparagus Cucumber
Incorrect: Cucumber Asparagus Pumpkin
Presentation locations of correct and incorrect models on the left and right side of the monitor were counterbalanced across the experiment. Participants were asked to indicate the correct model by pressing a left or right button. This step of the "correct model choice" was implemented in order to warrant that participants constructed the "correct model" before entering the next phase of a problem.

There is evidence that reasoners order objects spatially even when the relations are non-spatial. "Venus shines brighter than the moon but the sun shines even brighter", can easily be reflected by the order: Moon - Venus - Sun. Relations, also non-spatial ones, are thought to be closely linked to space. The argument of many researchers is that mental space is relational (rather than geometrical) space (e.g. Knauff, 1999; Knauff, 2013). This notion is corroborated by many findings, e.g. that spatial distance effects also occur with non-spatial relations (Prado, Van der Henst, \& Noveck, 2008; Prado, Chadha, \& Booth, 2011).

Indeed, participants' performance was very accurate. In more than \(90 \%\) of the cases ( \(M=92.90 \%\); SD=0.26), the correct models were selected. The few incorrect problems were excluded from further analysis.

In the second phase, the participants received a third premise which they were explicitly instructed to treat as an incontrovertible fact (while the instruction included the hint that the participant could not be entirely sure whether the description was true). The "fact" was always plausible. In half of the problems, it was consistent with P1 and P2; in the other half (see the example below) it was inconsistent.

\section*{Counterfact: "Cucumber is thinner than pumpkin"}

The participants decided - using "yes"- and "no"-buttons whether the fact was in agreement with the initial statements or not. Again, participants performed very accurate in this phase. In \(86.20 \%(S D=10.59)\) of the problems, the participants decided correctly. Incorrect problems were eliminated from further analysis, so were the consistent ones.

The third phase, the revision, was the most interesting part of the experiment. This part followed only if the participant recognized a fact as inconsistent with the initial description. Participants were then instructed to revise their
assumption about the objects' relations by taking into account the counterfact. Two alternative revised models, both variations of the initial model, taking into account the fact while preserving as much of the initial information as possible, were presented on the screen. The two revised models were presented on the left and the right side of the computer monitor. The task was to choose among the models the one which matched the participant's assumption about the revised object relations. Choices were indicated by left and right button presses. One of the revised models was plausible; the other one was implausible. The question was whether reasoners still apply the LO-principle or whether they prefer revisions based on the plausibility. The two alternative revised models for the example above were:
(1) Cucumber Pumpkin Asparagus
(2) Asparagus Cucumber Pumpkin

Note that model (1) results from the relocation of the LO of the fact (which is the cucumber) but leads to an implausible order of objects. Model (2), in contrast, results from the relocation of the RO of the fact (which is the pumpkin) but leads to a plausible order of the objects. Over the entire set of problems, in half of the problems the LO-principle led to implausible and the RO-principle into plausible relations of the entities (as in the example above), in the other half of the problems it was reversed.

Revision choices and duration were recorded. The problems were presented in a random order. They were preceded by eight practice trials (not analyzed). All stimuli were generated, presented, and recorded with Superlab 4.0 (Cedrus Corporation, San Pedro, CA, 1999) with an RB-530 response box running on a standard personal computer connected to a 19 '' -monitor.

\section*{Results and Discussion}

In the first analyses, we examined whether revision preferences were based on plausibility. Subsequently, we looked at the effects of visualizability. We also looked at the interactions between plausibility and visualizability. However, none of them reached the level of statistical significance ( \(p \mathrm{~s}>.05\) ).
Plausibility: ANOVAs were calculated, with the factors Plausibility (plausible, implausible) \(\times\) Relocated Object (LO, RO), separately for the frequency (in percent) of the respective revision choices and revision duration (in seconds). Both ANOVAs revealed a main effect of Relocated Object (choices: \(\left[F(1,19)=71.91 ; p<.001 ; \eta_{\text {part }}^{2}\right.\) \(=.79]\); duration: \(\left[F(1,19)=6.53 ; p=.019 ; \eta_{\text {part }}^{2}=.26\right]\); all other \(p \mathrm{~s}>.20)\). LOs were relocated more often and faster compared to ROs. Choices LO vs. RO: \(M=78.77 \% ; S D=\) 14.99 vs. \(M=21.23 \% ; S D=14.99 ; t(19)=8.59 ; p<.001\); duration LO vs. RO: \(M=2.69 \mathrm{~s} ; S D=1.71\) vs. \(M=3.46 \mathrm{~s}\); \(S D=1.74: t(19)=-2.35 ; p=.03)\).

Figure 1. Revisions [\%] and revision durations [s; error bars indicate standard errors] of "located" (LO) and "reference" objects (RO) showed an LO-effect. The preference was not modulated by plausibility

Figure 1 provides a graphically overview of the data. The result suggests that reasoners were guided by the distinction of LO and RO provided by the counterfactual relation. They followed the asymmetry of the objects and relied on the LOprinciple. Plausibility did not overwrite this preference. Next, we examined the impact of the visualizability of the statements. The question was: does the easiness to construct a visual mental image or a spatial representation of the problems affect reasoning and belief revision?

Visualizability: in order to compare the revision duration of visual, neutral and spatial problems, an ANOVA with the within-subject factor Visualizability (visual, neutral, spatial) was calculated. It indicated a significant main effect \(\left[F(2,18)=4.80 ; p=.014 ; \eta_{\text {part }}^{2}=2.02\right]\). When the statements were easy to visualize, the revision duration was significantly higher ( \(M=3.00 \mathrm{~s} ; S D=1.3\) ) compared to neutral and spatial problems (neutral: \(t(19)=-2.70 ; p=\) .014; spatial: \(t(19)=-2.73 ; p=.013\) ). Revision duration for neutral ( \(M=2.60 \mathrm{~s} ; S D=1.60\) ) and spatial problems ( \(M=\) 2.6 s ; \(\mathrm{SD}=1.3\) ) were comparable ( \(p>.85\) ).

Figure 2 provides a graphical overview. The result clearly suggests an impeding effect of statements that are easy to visualize. We also looked at the interaction between visualizability and relocated object, which was nonsignificant ( \(p>.35\) ).

Figure 2. Mean revision durations of different relation types [ s ; error bars indicate standard errors] indicate a visual impedance effect

\section*{General Discussion}

Belief revision is performed in order to re-establish consistency within belief sets (Gärdenfors, 1988). Frequently, there exists ambiguity because there are multiple solutions for revision. The present experiment on relational belief revision agrees with recent work suggesting that reasoners solve this ambiguity with strong preferences. Recent experiments used objects (e.g. fruits) which are "neutral" regarding their position within object arrangements. These objects were also not related to the individuals' prior knowledge or pre-existing beliefs. (e.g. Knauff et al., 2013). The current experiment, in contrast, addressed two novel aspects in reasoning with spatial and non-spatial relations: the plausibility of a relation and the visualizability of the reasoning problems. Both aspects have been shown to affect reasoning in general (e.g. Evans, 2008; e.g. Knauff, 2009).

A powerful theory in cognitive science puts forward that reasoners represent situations and states of the world in "mental models"; and that these models provide the basis for reasoning (Johnson-Laird \& Byrne, 1991; Goodwin \& Johnson-Laird, 2005; Krumnack, Bucher, Nejasmic, Knauff, 2010; Krumnack, Bucher, Nejasmic; Nebel, \& Knauff, 2011). Indeed, the mental model theory is corroborated by many phenomena. Moreover, model-based reasoning rather than the application of formal rules (e.g. Rips, 1994) nicely explains why reasoners often ignore the logical form of an argument. In fact, reasoners often base their problem solutions on the plausibility of the content or on prior experiences within a certain field, rather than on the validity of a conclusion (Newstead et al., 1992; Klauer et al., 2000; Evans, 2008, DeNeys, 2006; Knauff et al., 2010). These content effects show that reasoners have a strong tendency to take into account what is meaningful or plausible to them, even when this entails a trade-off with logic.
Recent findings on spatial belief revision suggest that reasoners vary spatial mental models and that they prefer certain variations above others. The variation of simple
spatial models of "neutral" objects was found to be based on a principle which we call the LO-preference. The first aim of the current experiment was to test whether reasoners hold on to that preference, even when it leads to implausible models. Our data suggest that they do. The LO-preference remained the guiding revision principle even when the resulting model was implausible.

Are there alternative interpretations of this result? One alternative account is that the effect is due to the specific layout of our experiment. In fact, during the construction phase, reasoners were forced to partially "ignore" plausibility of relations in order to construct the correct initial model from plausible and implausible statements. This might have triggered them to do the same in the revision process. Thus, they also ignored the plausibility of the revised model. We think that this might be a possible explanation for the finding that the LO-preference was stronger than the plausibility of the revised model. However, we think that the robustness of the LOpreferences is still an important result. In our future research, we will explore whether the plausibility effect is more powerful in more complex revision tasks. We assume that with more complex problems, the LO-effect on model variation would disappear and "plausibility" would play a more important role.

An important finding in the area of relational reasoning is that the visualizablity of a relation can modulate reasoning performance. Relations which are easy to visualize as mental images impede reasoning (e.g. Knauff \& JohnsonLaird, 2002). Reasoning with relations is best described by the construction and the manipulation of spatial mental models (e.g. Johnson-Laird \& Byrne, 1991; Schaecken, Johnson-Laird, P. N., \& d'Ydewalle, 1996; Goodwin \& Johnson-Laird, 2005; Jahn, Knauff, \& Johnson-Laird, 2007; Nejasmic, Krumnack, Bucher, \& Knauff, 2011). It is likely that problems that are easy to spatially represent accommodate reasoning because of their shared nature with (spatial) mental models. Image-like representations, in contrast, impede reasoning because they hold additional but irrelevant information (Knauff, 2009; 2013). Our results corroborate these assumptions. With the present experiment, we found an influence of the visualizability on revision. Problems that were easy to visualize appeared to impede the revision process. Indeed, visual problems seem to provide an additional effort which slows down the revision process. In contrast, relations that were rated as easy to represent spatially were manipulated faster during the revision phase. This is in line with the assumption that those relations accommodate revision because they share their spatial structure with the spatial model that is varied. In our experiment, spatial and neutral relations were both processed faster than visual relations. This result supports the assumption that spatial and non-spatial relations are both easily integrated into spatial models. Pursuing this thought could possibly reveal more interesting aspects of the mental space as relational space (Knauff, 1999; Prado et al., 2008; Prado et al., 2011).

\title{
Mechanistic Diagrams as Search Organizers
}

\begin{abstract}
Many in cognitive science have noted the importance of external visualizations for reasoning and learning, and have suggested that such visualizations play a role in complex reasoning contexts such as scientific investigation. However, what cognitive role diagrams play in scientific reasoning is unclear. I suggest that mechanistic diagrams function as search organizers in active research projects. Diagrams aid in scientific reasoning by being uniquely positioned to coordinate cognitive search through multiple search spaces, both within an individual and within a field. I examine this role using a number of published diagrams from mammalian chronobiology.
\end{abstract}

Keywords: scientific diagrams; cognitive search; chronobiology.

\section*{Introduction}

Diagrams are nearly ubiquitous in biological practice, in which the goal is often to construct an explanation of the mechanisms responsible for complicated phenomena. In journal articles, conference presentations, and whiteboard discussions, research scientists continually engage in the process of constructing, analyzing, and modifying diagrammatic representations. This ubiquity suggests that diagrams play an important role in reasoning about phenomena in biology. However, the specific role that diagrams play in reasoning is not established. Part of the difficulty is the sheer complexity of the reasoning processes involved. Scientists must coordinate a variety of representational resources in constructing mechanistic explanations, and diagrams are often involved in characterizing the phenomena of interest, organizing and presenting obtained data, and conveying the parts, operations, and organization of a proposed mechanism (Gooding, 2010; Sheredos, Burnston, Abrahamsen, \& Bechtel, forthcoming).

The current literature on diagrams has focused largely on the meaning of diagrammatic elements and how they relate (Tversky, 2011), as well as on how diagrams might encode complete explanations (Perini, 2005), or function as learning tools for novices (Cheng, 2011). While these are important analyses, they leave a gap in understanding how diagrams might play a role, even for experts, in constructing explanations of complex phenomena. Pioneering historical studies of episodes of scientific discovery (Cheng, 1992; Nersessian, 2008) have focused on the use of visualizations in the efforts of individual scientists to explain mathematical or physical phenomena. The use of diagrams in an active field of contemporary science presents new challenges, as
diagrams are used, discussed, and appropriated by numerous different researchers, each with different backgrounds, interests, and experimental skills.

In this paper I propose an account of how diagrams aid scientific reasoning in an active research field. The proposal draws upon several approaches in cognitive science, which construe reasoning as involving "cognitive search"-a process of selecting the right representations out of a space of possibilities in order to meet a cognitive goal. The search perspective on diagrams contends that diagrams facilitate scientists' cognitive search through the complex realm of possibilities that are relevant in explaining natural phenomena. Specifically, I contend that diagrams provide an external search space that allows for the coordination of both conceptual and experimental resources, both by individuals and by entire scientific communities.

I focus on diagrams of proposed mechanisms in biology. This type of diagram generally consists of proposed entities or events depicted by shapes and/or linguistic labels, organized in visual space, and related via arrows, lines, and enclosures to convey the structural, causal, functional, and/or conceptual (e.g., categorical) relations between them. Often, these diagrams occur at the beginning or end of a research article as a way of organizing the findings into a model of how physical components might interact to produce phenomena of interest. Moreover, these diagrams are often changed and expanded over a series of publications in order to incorporate new results.

While receiving relatively little attention in analyses of scientific practice, diagrams of this type can be extremely important, as even minor changes to diagrammatic form can have large effects on how the organization of a mechanism is interpreted. Sheredos et al. (forthcoming) have argued that these differences both constrain thought in particular ways and afford particular inferences that are useful for hypothesis construction. The search perspective expands on this viewpoint to further elucidate the use of mechanistic diagrams in a research field.

I will develop this perspective by analyzing the use of mechanistic diagrams in mammalian chronobiology. Chronobiologists study phenomena of circadian rhythmsdaily, roughly 24 hour cycles in biological activity-in a variety of different organisms, at each of the behavioral, physiological, and molecular levels. Many biological processes exhibit circadian rhythms, including gene transcription, cell division, metabolism, and overt sleep and feeding behavior. Over the last 25 years, much progress has been made in understanding how these rhythms are
regulated by internal, molecular clocks that both keep time and entrain the organism to environmental timing cues such as light and temperature.

Due to its extensive use of diagrams in identifying and explaining complex phenomena, chronobiology is a fertile ground for inquiries about diagrammatic reasoning in active science. My aim is to offer a theoretical perspective that can guide further empirical research on scientific reasoning, diagrams, and cognitive search. I begin by discussing how the notion of search has been employed in understanding reasoning in cognitive science, and how it can be applied to diagrams, before turning to discuss particular examples from chronobiology.

\section*{Diagrams and Cognitive Search}

One of the major challenges in science is the complexity of the reasoning processes that are required to grapple with natural phenomena. The notion of "search spaces" has been useful in trying to understand this challenge and how scientists proceed in meeting it. A "space," in this context, is simply a set of possibilities that are relevant to a reasoning task.

In a classic study, Klahr and Dunbar (Klahr \& Dunbar, 1988) asked subjects to discover the function of a particular command in a robot's programming language. There were two relevant spaces in the task: the "hypothesis" space of possible functions for the command, and the "experimental" space of possible manipulations to test given hypotheses. In the study, these spaces were artificially constrained via the experimenters-they chose what to tell subjects about the command, thus limiting the hypothesis space, and they set up the language of the robot, thus limiting what manipulations could be performed. They used this limited space to analyze subjects' reasoning, which allowed them to characterize the difficulty of the task and the (sometimes different) reasoning strategies that individuals used to solve it.

The search perspective has been used in a variety of other investigations into scientific reasoning (Schunn \& Klahr, 1996; Thagard, 1998), and experimental work in nonscientific contexts has begun to elucidate the cognitive and neural mechanisms that underlie search through the space of semantic memory (Hills, Todd, \& Goldstone, 2008). I here apply the search perspective as a way of understanding contributions of diagrams to reasoning in active scientific research.

While different numbers of search spaces have been proposed, for simplicity's sake I begin with two spaces, a conceptual space and an experimental space. The conceptual space consists of a scientist's or group of scientists' knowledge or beliefs about a system-including the particular entities that produce phenomena, their properties, and the kinds of interactions in which they can be involved. So, when a scientist approaches a phenomenon, they do so with an understanding of the
entities involved in producing that phenomenon. This knowledge provides a set of resources for reasoning about the system in question, which is continually modified and updated as investigation proceeds. In constructing and testing explanatory hypotheses, scientists consider this realm of possibilities in a flexible way-coming up with a good hypothesis involves "finding" the right system knowledge to account for the phenomenon of interest.

Experimental space consists of the possible manipulations that can be performed on the system in question given the practical strategies and limitations available to a field at a given time. This knowledge is often "embodied" in the sense that it involves practical know-how about successful manipulations, but it also can involve a theory of the instrument that licenses inferences to be drawn from particular results. To these I add a third, diagrammatic space, which plays the role of flexibly indexing and guiding search through the other two spaces. In employing the notion of search space, I make no claims about the format of the internal representations involved, or about the nature of the search algorithm. So long as such conceptual and experimental knowledge exists, my claim is that diagrams provide a way of indexing those bodies of knowledge.

One of the differences between reasoning tasks posed in psychology experiments and those undertaken by scientists "in the wild" is that in science the search task is often illdefined. That is, there are not clearly constrained solution options for a given reasoning task. Search through diagrammatic space, I propose, allows for flexible constraints on conceptual and experimental search, which allows both for productive investigation within specific models and continual questioning and reconceptualization of those models. Diagrams contain elements which provide directions of search through the diagram-arrows, enclosures, etc. This external search can then serve as a guide to the difficult work of employing one's conceptual space in reasoning about the system, and in using one's experimental space to devise tests of that reasoning. This external search space can be manipulated with relatively little cognitive demand. Moreover, diagrammatic space can be shared in common amongst individuals whose conceptual and experimental spaces differ, thus guiding a field's investigations into phenomena and mechanisms. I will discuss each of these points, with examples from mammalian chronobiology. My discussion will be illustrative. Importantly, I do not claim that all such reasoning must occur through diagrams. I only attempt to characterize the resources that diagrams can provide in active research, and I contend that this can help account for their importance and ubiquity in biology.

\section*{Mechanistic Diagrams in Biological Research}

As Klahr and Dunbar (1998) pointed out, one of the ways to constrain a space is to convey an abstract structure. Diagrams, given their particular elements and arrangements, do this exceedingly well. Consider Figure 1, a diagram
from a relatively early period in the history of mammalian circadian research. The diagram depicts a series of events

Figure 1: Three-stage model of the relationship between the endogenous clock and activity onset; from Welsh, Engle, Richardson, and Dement (1986).
that occurs at the beginning of an organism's "subjective day" (the part of the day during which the animal is active-dawn for diurnal organisms, dusk for nocturnal ones). The organism's internal clock functions to anticipate the external light schedule, and sends a signal to the mechanisms in the organism that govern waking and activity onset.

The diagrammatic space in the figure consists of the enclosed shapes and the arrows connecting them. Importantly, there are two distinct shapes, providing a visible, categorical distinction between the referent of the circle and those of the rectangles. The arrows imply an ordering of some sort between these referents, where this ordering has a directionality (i.e., it goes from the circle to the squares and not vice-versa) and is sensitive to the variables \(w\) and \(a\). This exhausts the purely visual set of constraints present in the diagram, which provide suggested patterns of search through the diagram. However, even these very minimal constraints manage to convey a great deal of abstract structure. It is abstract in that any entities and relations referred to must fit this pattern, if the diagram is taken as correct.

The connections to conceptual and experimental space are provided by the linguistic labels, as well as the instructions for how to interpret the figure. The denotation of the circle as a 'clock signal' indexes researchers' conceptual space regarding the nature of the clock and its relation to observable behavior. At this point, behavioral studies addressing rhythmicity had already established that the clock was endogenous-i.e., that it is an internal mechanism that can run without external input. Lesion studies had also suggested that the central clock in mammals has a particular brain locus in the suprachiasmatic nucleus (which was later conclusively confirmed), but little to nothing was known about the detailed mechanisms. Thus, the abstract model encoded in the diagram suggested that the 'clock signal', presumed to be coming from this central mechanism (whatever its detailed nature), must be related by an unknown process to the observable behavioral events under its control-in this case, waking and activity onset. The distinction between the circle and the rectangles denotes this categorical difference between the presumed mechanism and observable states. The caption, in addition, instructs that \(w\) and \(a\) should be interpreted as the time lag involved
in the transmission of the signal that cues wake processes, and the time lag between waking and activity onset, respectively.

Thus, the abstract structure conveyed in the diagram, along with its indexing of conceptual space and interpretational instructions, expresses a three-stage model of activity onset rhythms, in which a clock signal precedes waking, which precedes activity onset. As Welsh et al. stress, there is also an implied causal order in the diagramthat is, since the timing of activity onset is dependent on both the timing of the clock signal and that of the waking onset, it is suggested that the causal process leading to activity runs through these events.

In addition, the model's structure indexes the experimental space available to researchers. Two important experimental procedures in chronobiology are (i) the statistical analysis of variation in the phase of particular circadian events and (ii) external manipulation of the environmental factors involved in generating rhythms. Welsh et al. kept mice on a constant light schedule (ii), and analyzed the resulting phases of each stage (i) to test the model above. They discovered that there were no significant differences in phase between activity onsets over a period of days, while there were significant differences in wake onset.

Welsh et al. explicitly interpret this result with reference to the diagram in Figure 1. This result, initially, seems to be incompatible with the model, since variation across multiple time lags should produce greater variation at the end of the signaling chain. However, Welsh et al. argue that it is not incompatible, so long as the two signals are anti-correlated, with one becoming longer whenever the other is shorter. They then consider a number of possible mechanisms. The first proposes that a longer lag in \(w\) allows the organism to be better prepared to begin activity, and thus leads to shorter \(a\). The second, more radical proposal, argues that the timing of these events depends on a direct relationship between activity and the clock signal, with waking being indirectly regulated.

Interpreting these possibilities in light of the model further provides suggestions for experimental manipulation via method (ii)-namely, manipulating the availability of activity by controlling access to the running wheel. Several of the authors performed a separate study in which limiting wheel-running to specific times of day was shown to shift the phase of the central clock signal (Edgar, Martin, \& Dement, 1991). This in turn prompted the idea that there is a feedback signal from mechanisms controlling activity to the central clock, which was subsequently widely adopted. The picture that emerges is one in which continual consultation and interpretation of the figure allows for iterative episodes of indexing conceptual and experimental spaces, where the constraints present in the model guide subsequent investigation. Even if the model is eventually expanded (e.g., through the incorporation of a feedback
arrow running from the box on the right to the circle on the left) or overturned, this in no way lessens the potential importance of the figure for reasoning about the system in question. This analysis is at least broadly in tension with views of diagrams as conveyors or communicators of explanations-diagrams can aid cognitive search even if they are not taken as correct or complete explanations of phenomena. If this analysis is right, even extremely simple diagrams can be important reasoning tools. I now go on to discuss how this kind of analysis can be applied to more complex diagrams, which aid search in the construction of explanations involving complex mechanisms with many interacting parts.

\section*{Discovering Parts and Operations: The Function of CRY Proteins}

The central clock mechanism, in many organisms, consists of a "core" molecular clock, which operates via the interaction of multiple feedback processes. In this mechanism, the expression of a "positive" element causes, via DNA binding, the expression of a "negative" element, which in turn inhibits both its own transcription and that of the positive element. After the negative element is degraded, inhibition on the positive element is released and the cycle begins again-the period of the cycle is determined by the time course of the interactions between the relevant components. In the 1990s, several of the key genes involved in these feedback processes were discovered through research on fruit flies and rodents. Figure 2, from Dunlap (1999), represents the state of understanding of the mammalian core clock at the end of the decade.

Figure 2: Diagram of a model of the mammalian core clock, circa the late 1990s; from Dunlap (1999).

The positive elements of the core clock are the protein products of the genes Clock and Bmal, and the negative elements are transcripts of the various paralogs of the Period (Per) gene. The diagram depicts the positive element proteins binding to the promoter region (E-box) of the Per genes, whose transcribed mRNAs move outside of the nucleus and are translated into proteins. The proteins then form complexes of an unknown kind, and then inhibit
their own transcription by binding to the CLOCK::BMAL complex. External light, denoted with yellow arrows, is presumed to affect the clock by interacting with the negative loop.

Dunlap's diagram also included a question mark in the red box at the upper left, to indicate that there were likely other dimeric partners involved in the negative loop. At the same time, it was known that mammalian cells contained the gene Cryptochrome (Cry), a homolog of the Cry gene in drosophila, which serves as a photoreceptor for the light signaling pathway in flies. However, the function of Cry in the mammalian clock was unclear, as manipulation did not have any effect on entrainment to external light. Thus, it was left out of Dunlap's diagram. Further evidence against Cry as part of the entrainment mechanism appeared in the same year; Van der Horst et al. (1999) showed that individual knockouts of the Cryl and Cry2 paralogs had effects on circadian period, and that double knockouts eliminated rhythmicity completely. Kume et al. (1999), while citing Dunlap at several places, immediately proposed that CRY proteins might fit into the model at the point where, in the red box in the upper left, Dunlap had left a question mark-it might replace TIM as the proposed dimeric partner for PER. They performed a variety of manipulations on CRY, showing: (i) that CRY protein quantities are dependent on the functioning of Clock, (ii) that CRY can stop activation due to CLOCK::BMAL, and (iii) that CRY and PER dimerize and are transmitted to the nucleus together. It seems clear that Kume et al. were working from the model encoded in Dunlap's figure.

In this case, a change in conceptual space-the idea that Cry might be involved in the core clock-interacts with the model represented in the diagrammatic space to suggest experiments that can establish whether this new role is correct. Constraints for these experiments are present in the diagram-e.g., by guiding search for interactions with the proposed PER dimer-and its further indexing of the other elements of conceptual space. Once again we can see the potential cognitive benefits of encoding a model in diagrammatic space, and how this further relates to the interaction of conceptual and experimental space.

\section*{Diagrams for a Field: Coordinating Multiple Conceptual and Experimental Spaces}

In my final example, I show how diagrams can be shared search spaces for researchers with different theoretical and experimental backgrounds. The results of Kume et al., among others, are expressed in Figure 3, from Lowrey and Takahashi (2004). The basic organization from the Dunlap diagram is still present (although flipped left to right), and a few further elements have been added, including the additional support loop formed by the Rev-erb gene, which acts as a positive regulator of Bmal transcription. Ye, Selby, Ozturk, Annayev, and Sancar (2011) decided to test a core assumption of this model-that the PER::CRY dimer

Figure 3: Diagram of a model of the mammalian core clock, circa the mid-2000s; from Lowrey and Takahashi (2004).
inhibits transcription of Per and Cry by binding to the CLOCK::BMAL complex while it is on the E-box-via sophisticated biochemical analysis. They employed chromatin immunoprecipitation (ChIP), a technique that allows for the isolating of particular DNA/protein complexes in the nucleus, and the determination of what proteins bind to particular sections of DNA. Importantly, this technique allows for a different trajectory through experimental space than the techniques used to develop the core model, which did not allow for precise localization and analysis of binding within the nucleus. While ChIP had existed in other fields of biology, it began to be used frequently in chronobiology only in the mid-2000s.

Ye et al. found, contrary to the standard model, that only CRY, and not the PER::CRY dimer, bind to the CLOCK::BMAL dimer while it is on the E-box. Moreover, the presence of PER actually inhibits this process of binding. If correct, this forces a relatively major revision of the model. Ye et al. represent a possible revision in Figure 4. This re-coding has significant conceptual ramifications for anyone familiar with the core clock, as it forces revision of the standard assumption about the causal process in the negative loop.

As the diagram suggests, and Ye et al. elucidate, new functional posits are needed to understand the role of PER in the clock mechanism. What does the diagram contribute? First, it emphasizes the difference between the previous model and the current results. Second it provides a functional posit for PER, as being potentially involved inmodulating the Rev-erb loop. This diagram suggests a new course through experimental space-inquiry into the potential binding of PER to the elements of this loop at different times during the circadian day. Moreover, those familiar with the standard model must now adjust their representation of the place of PER in the core loop (this suggests "replacing the top part of Figure 3 with the type of representation given in Figure 4). Despite revisions such as this, the standard diagrams still provide structural and

Figure 4: Diagram of the results of Ye et al. (2011), suggesting a revised role for the PER protein in the core mammalian clock; from Ye et al. (2011).
functional indices that constrain conceptual search for new roles of PER, as we saw in the discussion of Figure 2. We can expect that, should these results gain widespread acceptance, future review articles will incorporate these changes to the standard model.

This example shows a broader role for diagrams than in the reasoning of individuals. The standard model is explicitly targeted by Ye et al. as the source of their analysis-and they cite the Lowrey and Takahashi paper, among others. This suggests that diagrams play the role of organizing different methodological approaches around the same phenomenon and proposed mechanism. As Ye et al. mention, a variety of methods were used in constructing the standard model; however, emerging methods of analyzing protein interactions using biochemistry have the potential to fill in gaps or question particular aspects of models that are standard in the field. Crucially, not all scientists studying a phenomenon possess the same methodological expertisethat is, their experimental spaces differ. Equally important, once the results regarding the PER::CRY dimer have been obtained, they are re-encoded into a diagrammatic form that is common to those across different experimental backgrounds.

Based on these analyses, I propose that a primary function of mechanistic diagrams is to provide an external search space that coordinates search in conceptual and experimental spaces, across both personal and interpersonal contexts.

\section*{Conclusion}

The ubiquity of diagrams, and their seemingly important resources for aiding reasoning about complex systems, resist the interpretation that they are eliminable-i.e., that all of the actual thinking done by scientists is purely internal. To treat diagrams as themselves sufficient to convey scientific theories or explanations, however, seems equally unrealistic, as it fails to account for the vast amounts of detailed conceptual knowledge and experimental expertise that individual scientists, as well as research fields, bring to understanding any particular diagram.

I have argued that a search perspective on diagrams can make sense of their role in active research, and used this perspective to construct a sense-making narrative of important epochs of research in mammalian chronobiology. While the success of the narrative is not proof of the theory, the view I have proposed has a number of potential benefits for experimental studies of scientific reasoning. First, it can relate the search for scientific solutions to the more general literature on cognitive search. Much progress has already been made in understanding how subjects search through a visible space in relation to a task. Do these principles carry over to search in scientific diagrams? Stieff, Hegarty, and Deslongchamps (2011) have conducted an eye tracking study showing that individuals' eye movement patterns while using multiple visualizations (a mechanism diagram, a graph, and an equation) in a problem solving task are related to their particular educational experience. Mechanistic diagrams, on the search perspective, are ripe for this kind of study.

Finally, the search perspective can aid discussions and experimentation on both scientific reasoning and diagrams in general. Diagrammatic form can be used in a variety of tasks, and can help model discovery situations when individuals' conceptual and experimental spaces are shaped by the experimental setup. As shown by Sheredos et al. (forthcoming), changes in diagrammatic form affect interpretation, and thus the experimental manipulation of diagrams across reasoning tasks can shed light on the nature of individuals' search strategies. Taking the search perspective on mechanistic diagrams, then, has promise for helping to overcome the difficult methodological gap between standard psychology experiments and creative scientific reasoning.

\begin{abstract}
Participants estimated allocentric headings using pictures of familiar buildings around a college campus, in an allocentricheading recall task. A weak relationship between sense-ofdirection and accuracy, an alignment effect, and a novel relationship between strategy and accuracy were found. These results demonstrate that sense-of-direction and strategy use differentially affect accuracy across heading disparities. Our findings suggest that individual differences and strategy differences need to be incorporated into current hypotheses regarding allocentric-heading - specifically, into the animalmodel hypothesis.
\end{abstract}

Keywords: allocentric heading; sense of direction; headingrecall; strategy; egocentric and allocentric reference frames.

\section*{Introduction}

People characterize their ability to move effectively through environmental-scale spaces, such as neighborhoods or cities, by referring to their 'sense-of-direction'. Kozlowski and Bryant (1977) found that people's ratings of their sense-ofdirection (or SOD) correlated with accuracy in distance, direction, and time estimation tasks. Since then, research has either focused on how to assess SOD or how SOD correlates with performance in environmental-scale spatial tasks (e.g., Hegarty et al., 2002). However, the field is lacking insights into the underlying causes of the vast individual differences found in environmental-scale spatial cognition.

Research on SOD has typically focused on strategy differences in navigation or on individual differences in learning novel environments. In terms of strategy differences, individuals with a poor SOD tend to prefer route strategies and those with a good SOD tend to prefer survey strategies (Prestopnik \& Roskos-Ewoldsen, 2000). In terms of individual differences, there are large individual differences in the rates and accuracy with which individuals can learn novel environments and these differences are related to self-reported SOD (Ishikawa \& Montello, 2006).

To date, little research has focused on strategy and individual differences in manipulating one's knowledge of familiar environments; however, manipulating one's spatial knowledge is essential for wayfinding and route planning. Research that has used familiar environments tends to focus on two tasks: egocentric pointing (pointing from one's current location towards a landmark) and judgments of relative direction (pointing from an imagined location and orientation towards another landmark) (e.g. Kozlowski \&

Bryant, 1977; Hegarty et al., 2002). These studies found significant correlations between SOD and task performance, but have not investigated strategy differences.

The strategies identified during navigation, namely route and survey strategies, are not necessarily relevant in all spatial knowledge manipulation tasks (such as egocentric pointing and judgments of relative direction tasks). Therefore, research is needed to uncover the strategies used in spatial knowledge manipulation tasks - specifically, in environmental-scale spaces. In contrast, research on strategy differences has tended to utilize small-scale tasks. Kozhevnikov and Hegarty (2001) found that when people complete judgments of relative direction tasks, while viewing a map, they use either perspective-taking or mental rotation strategies. They found individual differences in performance, which were related to SOD, and they identified two strategies, which were separable abilities.

The goal of this paper is to investigate the individual and strategy differences that exist within manipulating one's environmental-scale spatial knowledge. To do so, we will focus on one task, the allocentric-heading recall task (Sholl, Kenny, \& DellaPorta, 2006), which requires participants to manipulate their spatial knowledge of a familiar place.

Sholl et al. (2006) developed the allocentric-heading recall task to reveal the architecture of a proposed human head-direction system. They argued that SOD is a singlefaceted construct related to the performance of a headdirection system in humans, and they assumed that this system operated similarly to the head-direction system found in rats (Ranck, 1984). In rats, each head-direction cell fires maximally to one angle of difference between the rat's facing direction and a reference direction grounded in the environment. In other words, head-direction cells respond to allocentric headings and not directions based on the axis of the body (or egocentric headings). Sholl et al. proposed that the human head-direction system operates similarly to that of rats and that the human head-direction system is the neural mechanism underlying self-reported SOD. We will refer to this the animal-model hypothesis.

In the allocentric-heading recall task, participants view photographs of a familiar environment, identify the direction from which the photographs were taken, and then rotate in their chair to reproduce the direction. Initial studies (Sholl et al., 2006) revealed an alignment effect. Specifically, when a participant is facing the same direction as that from which the photograph was taken, participants
were more accurate (a facilitation effect). However, when participants were \(180^{\circ}\) misaligned from the direction of the photograph (for example, they faced north but the photograph was taken from a south-facing direction), participants were the least accurate (a detrimental effect). The alignment effect was explained as interference between one's current head-direction signals and the retrieval of the head-direction signals, which were activated when the individual viewed the photograph location in the real world. Strong correlations (. 7 or higher) between performance on the allocentric-heading task and self-assessed ratings of SOD supported Sholl et al.'s proposal that SOD solely reflects the operation of the human head-direction system.

The allocentric-heading recall task assesses people's ability to manipulate their spatial knowledge of environmental-scale spaces. According to Sholl et al., when viewing a building, the allocentric-heading of that view is stored in memory and is linked to signals of body-direction. Upon seeing a picture of that building, a person recognizes the building, and then recalls the allocentric-heading from spatial memory. Therefore, Sholl et al. proposed that only one strategy exists, and individual differences reflect differences in the fidelity of head-direction signals, and consequently, the ability to carry out this strategy.

In contrast to this view, Burte and Hegarty (2012) found preliminary evidence for possible strategy differences. During informal debriefing interviews, participants reported a range of strategies, including imaging a walk to the photograph location, and relating the photograph heading to the direction of a local mountain range. However, strategy differences have yet to be systematically investigated in this task.

There is also a possibility that familiarity with the tested environment drives individual differences in performance. Sholl et al. did not investigate familiarity differences, as pretesting had revealed that all their pictures were highly familiar to participants. However, Burte and Hegarty (2012) found significant correlations between familiarity and SOD, as well as between familiarity and accuracy, despite pretesting photos for high familiarity. This suggests that individual differences in this task might be partially due to differences in familiarity with the environment.

The main purpose of this study is to investigate individual and strategy differences within the allocentric-heading recall task. First we will describe the allocentric-heading task in more detail and then consider strategy differences found within a similar task.

\section*{Allocentric-Heading Recall Task}

The allocentric-heading recall task is a four-alternative, forced-choice task, using campus pictures as stimuli. Pictures were taken from magnetic north, east, south or west (to match the intrinsic structure of the environment). However, while cardinal directions will be used for simplicity in writing this article, it should be noted that cardinal directions were never used in written or verbal instructions, as they are not required to complete the task.

First, we will define key terminology used: picture heading is the photographer's orientation when taking the picture; default heading is the orientation of participant before each trial; response heading is the orientation the participant responded with; and heading disparity is the angular disparity between default heading and picture heading. The animal-model hypothesis makes predictions about the relationship between heading disparities and performance - specifically, about the alignment effect; therefore, heading disparity is the main independent measure of interest.

Turning in one's chair (to replicate the picture heading) was used as the response mode in previous studies. Sholl et al. (2006) argued that turning to represent an angle was a natural response for this task, because turning allows for one's current head-direction cells to find a match to the memory of one's head-direction cell firing. A secondary goal of this study was to investigate whether participants could perform this task without rotating in a chair, but only by using a button-press as the response mode. Therefore, we attempted to replicate Sholl et al.'s results with an alternative, less body-based response mode.

\section*{Strategy Differences}

In studies using a judgments of relative direction task (JRDs), a dissociation has been made between two strategies: (1) a perspective-taking strategy whereby participants imagined moving themselves to assume a new orientation, or used directions related to their bodies to assume a new orientation; and (2) a mental rotation strategy whereby participants imagined moving the entire scene around themselves, or imagined rotating angles between locations (Kozhevnikov \& Hegarty, 2001). This suggests that participants can think in terms of a body-based reference frame (egocentric), or a reference frame grounded in the environment (allocentric) while completing the task.

Kozhevnikov, Motes, Rasch, and Blajenkova (2006) found that the perspective-taking strategy resulted in decreased accuracy with increasing heading disparities, a similar pattern to that found by Sholl et al. (2006). However, use of a mental rotation strategy resulted in a significantly weaker alignment effect. Therefore, another goal of this study is to investigate if these strategy differences exist within the allocentric-heading recall task.

In sum, our goals are (1) to investigate if the predictions of the animal-model hypothesis are robust to a new context and to a button-press response mode; (2) to investigate our prediction that individual differences in familiarity are related to task performance; (3) to determine if egocentric and allocentric strategy use exist within this task; (4) to investigate if individual differences in SOD and strategy are related to task performance; and (5) to investigate whether strategy differences are related to SOD.

\section*{Method}

Participants Seventy-four students (39 males and 35 females) participated as part of a research requirement. Two
participants, both males, were excluded from analysis because their mean familiarity with the picture stimuli was 2 \(S D\) s below that of all participants. Participants had spent at least two quarters on campus before participating.

Design The methodology of the study was both experimental and correlational. The experimental factors were picture heading (within subjects) and default heading (between subjects). The correlational factors are familiarity, SOD, and strategy use. Participants were randomly assigned to one of the four default headings (19 participants faced north, 18 east, 17 south, and 18 west) and completed fortyfive trials, one for each picture.

Materials The experiment took place in a room that was aligned with the main axes of the campus (and the cardinal directions). The experimental room had one east-facing window that was open during the experiment. The view directly out that window was of a major pathway and a large (eight storey) building. However, if one stood next to the window, one could see the mountains and ocean (major orientation markers for the campus), and a few major buildings. Therefore, the window afforded excellent views for initial orientation to the campus (when standing near the window), but only basic information while participants completed the experiment.

Experimenters arranged a chair and laptop facing the assigned default heading before each participant arrived. The large table at which participants were seated (but in different orientations) was aligned with the room, the room was aligned with campus, and campus is aligned with the cardinal directions. Therefore, the space was aligned with respect to the default headings and response headings. This alignment was never mentioned to participants.

The photographic stimuli were sourced from the 36 most familiar photographs from a previous experiment (Burte \& Hegarty, 2012), and nine new photographs (two north and seven east), for a total of 45 pictures. A global positioning device (GPS) was used to ensure that photographs were taken facing the cardinal directions. Photographs were taken of highly recognizable building facades and were cropped to exclude surrounding buildings or large-scale landmarks.

A typical trial started with viewing a photograph of campus on a computer, and participants responded by using a keypad with four arrows (front, right, back, and left). The participant determined the direction (with respect to the campus environment) in which the photographer stood to take the photograph (i.e., picture heading) and pressed a button to reproduce that direction. For example, if the photograph was taken facing south, and the participant was facing north, then the participant should press the downward arrow to indicate the direction behind him/her.

Procedure Participants were briefly introduced to the experiment, completed a demographics questionnaire, and then completed the Santa Barbara Sense of Direction (or SBSOD) scale (Hegarty et al., 2002). Next, participants
were asked to orient to the layout of campus while looking out the window. The experimenter asked the participant to point towards six major campus landmarks, to ensure that \(\mathrm{s} / \mathrm{he}\) was oriented to the global layout of the campus. The experimenter provided feedback, if needed, but most participants oriented and pointed correctly.

Participants were then introduced to the allocentricheading recall task and presented with 12 practice trials in a fixed order. Participants were given feedback by being presented with the correct answer after each practice trial, and then completed 45 experimental trials without feedback.

After the allocentric-heading recall task, participants rated their familiarity with each photograph location on a 7-point Likert scale, with 1 being "Very familiar" and 7 being "Not at all familiar". As an objective measure of familiarity, participants were required to place an arrow on an unlabelled map of campus, to indicate the location and direction from which each photograph was taken. This map task and the familiarity task were used to ensure high familiarity with each photograph.

Finally, participants completed a strategy questionnaire that consisted of a free-response question, in which they entered the strategies they used, and then selected the strategies they used from a list of potential strategies. The list was created based on pre-testing and consisted of strategies such as "Using cardinal directions", "Using largescale landmarks to determine orientation (mountains, ocean, Isla Vista, etc.)", and "Imagining travelling to the location".

\section*{Results}

Photograph Familiarity To ensure that participants were sufficiently familiar with the pictures, pictures needed to pass three criteria to be included in the analysis: (1) mean familiarity for each picture could not be \(2 S D\) s lower than grand mean familiarity, (2) less than \(25 \%\) of participants needed to rate their familiarity as " 6 " or " 7 - Not at all familiar" for each picture; and, (3) at least \(25 \%\) of participants needed to correctly identify the orientation and location of the picture, on the map task. Given these criteria, seven photographs were dropped from analysis, resulting in 9 north-facing, 9 east-facing, 10 south-facing, and 10 westfacing pictures. The familiarity grand mean for the 38 photographs was 2.2. Familiarity ranged from 1.0 to 3.7 across participants and from 1.2 to 3.9 across pictures.

Accuracy Heading disparity (angular difference between default and picture heading) served as the main independent measure. For example, if the picture heading was aligned with the default heading for a particular participant and trial, then this trial would be labeled as having a \(0^{\circ}\) heading disparity. A 4 (Heading disparity: \(0^{\circ}, 90^{\circ}, 180^{\circ}, 270^{\circ}\) ) by 2 (Gender) ANOVA comparing mean accuracy indicated a main effect of heading disparity, \(F(3,216)=6.79, M S E=\) \(.13, p<.001\). The mean accuracy by heading disparity is shown in Figure 1. Post hoc tests revealed that the \(180^{\circ}\) condition was less accurate ( \(M=54 \%\) ) than all other conditions, which had similar accuracies ( \(0^{\circ} M=61 \%\); \(90^{\circ}\)
\(M=64 \% ; 270^{\circ} M=63 \%\) ). This can be interpreted as a detrimental effect on performance when one's body is positioned \(180^{\circ}\) away from the memory trace from one's head-direction cells when the location was last viewed. This detrimental effect is predicted by the animal-model hypothesis; however, we failed to replicate the predicted facilitation effect.

The main effect of gender was also significant, \(F(1,70)=\) 6.58, \(M S E=1.32, p<.05\), with males being more accurate ( \(M=67 \%\) ) than females ( \(M=54 \%\) ). The interaction of heading disparity and gender was not significant, \(F(3,210)\) \(=1.07, M S E=.02, p=.36\).

Figure 1: Mean accuracy rate as a function of heading disparity. Error bars are the standard errors of the mean.

Self-Reported Sense-of-Direction The correlation between SBSOD scores and overall accuracy was statistically significant, \(r(70)=.31, p<.01\), indicating that people who rated themselves as having a good SOD were more accurate on the task. This correlation is similar to that found by Burte and Hegarty (2012); but substantially lower than those reported by Sholl et al. (2006). In addition, we failed to find a significant correlation between familiarity and SBSOD scores, \(r(70)=.03, p=.81\), indicating that good SOD participants were not more accurate simply due to being more familiar with the photographs.

To further investigate individual differences in task performance, we compared the performance of good SOD (or GSOD) participants from the top \(25 \%\) of the SBSOD distribution ( \(N=18\) ), and poor SOD (or PSOD) from the bottom \(25 \%(N=19)\). A 2 (GSOD, PSOD) X 4 (Heading disparity: \(0^{\circ}, 90^{\circ}, 180^{\circ}, 270^{\circ}\) ) ANOVA comparing mean accuracy indicated significant main effects and a significant interaction. There was a main effect of heading disparity, \(F(3,105)=3.60, M S E=.08, p<.05\), such that a heading disparity of \(180^{\circ}\) resulted in lower accuracy ( \(M=54 \%\) ) compared to \(90^{\circ}(M=63 \%)\) and \(270^{\circ}(M=64 \%)\). The heading disparity of \(0^{\circ}\) ( \(M=60 \%\) ) was not significantly different from other headings.

As shown in Figure 2, GSOD participants were significantly more accurate ( \(M=71 \%\) ) than PSOD
participants \((M=49 \%), F(1,35)=7.82, M S E=1.78, p<\) .01, and there was a significant interaction of SOD with heading disparity, \(F(3,105)=2.60, M S E=.05, p<.05\). Importantly, the simple effect of heading disparity for GSOD participants was not significant, \(F(3,33)=1.13, p=\) .35, indicating that GSOD participants were equally accurate across all heading disparities. This is a novel finding and has not been found in previous studies (Sholl et al., 2006; Burte \& Hegarty, 2012).

In contrast, the simple effect for PSOD participants indicated a significant difference across heading disparities, \(F(3,33)=4.11, p<.05\). Not only are PSOD individuals less accurate on this task than GSOD participants, but they are significantly less accurate with \(180^{\circ}\) heading disparities compared to other disparities. This indicates that the detrimental effect of having one's body \(180^{\circ}\) misaligned with the picture, primarily affects PSOD individuals.

Figure 2: Mean accuracy rate as a function of heading disparity and SOD. Error bars are the standard errors of the mean.

Strategy Use To examine reported strategy differences, items in the strategy questionnaire were classified as egocentric or allocentric strategies (cf. Kozhevnikov \& Hegarty, 2001). Example items from the egocentric strategy were "imagining myself standing at the photograph location", "imagining traveling to the photograph location using campus walkways", "comparing my current facing direction to the photographer's facing direction at the photograph location", etc. These strategies were labeled as 'egocentric' due to their reliance on thinking about directions in relationship to the participant's body. Strategies that focused on thinking about directions in relationship to external frames of reference were labeled as 'allocentric'. Examples of these items are "using a mental map or imaging a campus map", "using cardinal directions", "using large-scale landmarks", etc.

Participants were classified into strategy groups by calculating z-scores to reflect each participant's tendency to use each strategy compared to that of the entire group. For each participant, the egocentric and allocentric z-scores
were compared and if the two scores differed by more than . 75 SDs, the participant was deemed to have used one strategy more than the other. If the z-scores did not differ by . 75 SDs, the participant was classified as using a mixed strategy. This resulted in 33 participants who used a mixed strategy, 15 who used an egocentric strategy, and 24 who used an allocentric strategy.

Strategy Use and Sense-of-Direction To test the relationship between SOD and strategy, we compared the SBSOD scores of those classified as using egocentric and allocentric strategies. Egocentric strategy use corresponded with lower (or poorer) SBSOD scores ( \(M=3.7, S E M=.2\) ) and allocentric strategy use corresponded with higher (or better) SBSOD scores \((M=4.5, S E M=.2)\), and this difference was statistically significant, \(t(37)=-2.24, p<.05\).

Looking at strategy use across PSOD and GSOD individuals, we see that PSOD individuals used egocentric ( \(N=8\) ), allocentric ( \(N=6\) ), and mixed strategies \((N=5\) ). However, GSOD individuals only reported using allocentric strategies \((N=8)\) and mixed strategies \((N=10)\). A chisquared test revealed a significant relationship between SOD and strategy, \(X^{2}(2, N=37)=9.93, p<.01\) GSOD individuals were less likely to use egocentric strategies than predicted by chance.

Figure 3: Mean accuracy rate as a function of heading disparity and strategy. Error bars are the standard errors of the mean.

Strategy Use and Accuracy A 2 (Strategy: egocentric or allocentric) X 4 (Heading disparity: \(0^{\circ}, 90^{\circ}, 180^{\circ}, 270^{\circ}\) ) ANOVA indicated a significant main effect of heading disparity, \(F(3,111)=6.07, M S E=.12, p<.001\), a significant main effect of strategy, \(F(1,37)=9.50, M S E=\) 1.72, \(p<.01\), and a non-significant interaction, \(F(3,111)=\) \(1.27, M S E=.03, p=.29\). Figure 3 shows the mean accuracy by heading disparity. Participants who tended to use allocentric strategies were significantly more accurate ( \(M=\) \(72 \%\) ) than those who tended to use egocentric strategies ( \(M\) \(=50 \%\) ). While Figure 3 shows a trend for allocentric strategy users to show a weaker alignment effect, this trend
was not statistically significant. The finding that strategy use impacts the accuracy with which participants respond to the allocentric-heading task is a novel finding and is not predicted by the animal-model hypothesis.

Photograph Familiarity and Accuracy Correlations between participants' mean familiarity rating (averaged over the 38 pictures) and their mean accuracy on the headingrecall task were not significant, \(r(70)=.03, p=.81\). This indicates that participants, who rated their familiarity as high, were not more accurate than participants with lower familiarity. One interpretation is that all participants had a level of familiarity high enough, as to not hinder their task performance. However, correlating mean familiarity per picture (averaged over individuals) with mean accuracy per picture resulted in a significant correlation, \(r(36)=-.49, p<\) .01. This suggests that despite pretesting for familiarity, some familiarity differences remained between the pictures. Importantly, as default heading is manipulated between participants, differences in picture familiarity cannot account for the effects of heading disparity on performance.

\section*{Discussion}

We replicated findings that individuals can recall allocentric-directional information from pictures, and that individual performance in the allocentric-heading recall task is related to SOD (Sholl et al., 2006; Burte \& Hegarty, 2012). We also showed that these results replicate with a button-press response rather than the more body-based response of turning in one's chair. Importantly, we provided evidence for the use two strategies in this task, and showed that strategy use was related to self-reported SOD. GSOD participants reported using allocentric or mixed strategies, compared to PSOD participants were equally divided across strategy groups. Furthermore these groups had very different patterns of performance; PSOD individuals showed an alignment effect while GSOD did not. This pattern suggests that allocentric strategy use resulted in better performance, in general, and the alignment effect primarily affects PSOD individuals.

Changing the response mode, from turning in a chair to pressing a button, led to a weakened relationship between heading disparity and accuracy relative to previous studies. Specifically, the facilitation effect at \(0^{\circ}\) was not found. Another weakened relationship was the correlation of SOD with accuracy. Our correlations were noticeably lower than those found by Sholl et al (2006); therefore, this experiment adds doubt to the conclusion that that SOD solely reflects the operation of the human head-direction system. Instead, self-reported SOD might also relate to strategy differences.

Egocentric strategy use resulted in decreased accuracy in general and decreased accuracy for larger heading disparities (an alignment effect). Allocentric strategy use resulted in somewhat more equivalent accuracy across heading disparities. Although the interaction of strategy and heading disparity was not significant in the present study, the trends are notable in that they are similar to trends found
by Kozhevnikov et al. (2006) using JRD tasks.
Although we found both strategy differences and performance differences between those with good and poor sense-of-direction, the relationship between SOD, strategy, and performance remains ambiguous. Participants who used the egocentric strategy were more likely to have a lower (or poor) SOD, and those who used the allocentric strategy were more likely to have a higher (or good) SOD. Good SOD participants were also less likely to use egocentric strategies, than would be predicted by chance. But the causal relationships between strategy differences, individual differences and performance are currently unclear, as having a good SOD could cause people to use the allocentric strategy or repeated use of the allocentric strategy could contribute to having a good SOD. We are investigating the causal relationship between strategy use, SOD, and performance in a current study.

The newly discovered strategy differences between good SOD participants and poor SOD participants might have been due to the replacement of the body-based response with the button-press response. It is possible that the response of turning in one's chair in previous studies forced participants to use an egocentric strategy, which resulted in the alignment effect for participants of all ability levels. Perhaps, pressing a button did not force participants into using an egocentric strategy, so good SOD participants were freed from this restriction to think in terms of their body. This allowed good SOD participants to demonstrate similar performance across differing default headings. While our findings cannot provide support for these ideas, our findings do suggest that individual and strategy differences need to be incorporated into accounts of the performance within the allocentric-heading task. Research is also needed to determine if the response mode change was responsible for the identification of strategy differences.
We found a more nuanced relationship between familiarity and performance than in our earlier study (Burte \& Hegarty, 2012). Specifically, familiarity was correlated with performance, but only when compared across pictures, and overall familiarity with the pictures was unrelated to SOD. It seems that our goal to use only familiar photographs was achieved, as accuracy was not correlated with mean familiarity for all pictures; however, the familiarity rating of individual photographs still impacted accuracy. Since recognition of a location is likely the first step in completing the allocentric-heading task, it follows that familiarity on a picture-by-picture basis would affect accuracy.

Another novel finding of this study is that we found gender differences in task performance. It is possible that females are more tied to their bodies than males, which leads to a greater gender difference with a button-press response than a more body-based response (i.e., turning). Future experiments should continue to monitor gender differences in this task.
In conclusion, we found novel evidence for strategy differences in the allocentric-heading recall task and these
differences are related to level of performance and selfreported sense-of-direction. Given similar findings in navigational tasks, we propose that choice of strategy is a critical element to the understanding of individual differences within spatial tasks. Specifically, this study demonstrates that individual and strategy differences can be found within tasks that are often conceptualized as universal or invariant cognitive processes. Neuroscientific research using animals has provided the foundation for understanding the functional architecture of human spatial abilities. Now, there is a need to incorporate the unique aspects of human cognition - like strategy and individual differences - into the functional architecture.

\title{
Explicit awareness supports conditional visual search in the retrieval guidance paradigm
}

\begin{abstract}
In two experiments we explored whether participants would be able to use probabilistic cues to simplify perceptually demanding visual search in a task we call the retrieval guidance paradigm. On each trial a background cue appeared prior to (and during) the search task and the diagnosticity of the background cue(s) was manipulated to provide complete, partial, or non-diagnostic information regarding the target's color on each trial. Only when participants were made aware of the possible relationship between the background cues and target features were they able to utilize the cue information for search. When participants were not made aware of the possible connection, they were only able to use target base rates. In the General Discussion we address how a recent computational model of hypothesis generation (HyGene, Thomas, et al., 2008), provides a useful framework for understanding how long-term memory, working memory, and attention coordinate in visual search.
\end{abstract}

Keywords: attention, memory, visual search, hypothesis generation.

In the present research we examined whether participants would be able to use experience in order to reduce the perceptual demands of visual search. More specifically, we ask whether participants would be able to use cues to retrieve associated target features in service of visual search. We argue that much of our day to day visual search relies on such long-term memory (LTM) retrieval to define an attentional set to support search. To investigate the processes unfolding in such circumstances we have developed a novel visual search paradigm in which participants are provided with cues that probabilistically predict a target feature (its color) in a forthcoming search array. We refer to this procedure as the retrieval guidance paradigm as retrieval of likely target colors given a cue will drastically improve search.

The usefulness of the paradigm lies partly in the ecologically relevant variables it affords control over. Importantly, it allows us to assess people's sensitivity to the probabilistic relationships between cues and targets through 1) the global base rate of a target (raw frequency of occurrence) and an individual cue's diagnosticity (i.e., its predictive ability). Both of these characteristics influence the posterior probability and thus should influence retrieval
from LTM.
Related research examining how people use systematic cue-target associations to support visual search has largely focused on the contextual cueing paradigm. The general trend in these experiments is that targets within repeated visual scenes (having the same target to distracter spatial configurations) are found faster than non-repeated scenes (Chun \& Jiang, 1998). One of the most intriguing aspects of the results emanating from this paradigm is that the facilitation of repeated scenes operates at an implicit level of awareness as participants are unable to distinguish between repeated scenes versus novel scenes in a recognition task. Much of this research has focused on comparing conditions where cues perfectly predict the location of the target and conditions in which cues are non-diagnostic. However, many of the environments that we encounter are probabilistic such that cues have varying degrees of diagnosticity regarding possible target characteristics. Moreover, recent research has suggested that there is minimal attentional guidance in contextual cueing (Kunar, Flusberg, Horowitz, \& Wolfe, 2007), suggesting that the paradigm may be lacking in allowing for the examination of how LTM, working memory (WM) and attention coordinate in a visual search task. In the present study we offer a new paradigm that allows for the promise of: 1) investigation into whether probabilistic relationships can be learned and exploited in a visual search task (c.f. contextual cueing, Zellin, Conci, Muhlenen, \& Muller, 2011), and 2) an examination of how LTM, WM, and attention coordinate in a visual search task. We accomplish this by manipulating both target base rates and cue diagnosticities within the same experimental paradigm (and within subject) by pairing background cues (preceding the onset of a search array) with critical target features (i.e., colors). Thus, the background cues provide complete, partial, or nondiagnostic information regarding the color of the target in the upcoming search array.

To foreshadow the findings of the present study, in Experiment 1 we find that participants are able to find a target faster when its color is associated with a more diagnostic cue. However, Experiment 2 reveals that when participants are explicitly aware of the associations between the cues and the color of the target, their visual search
performance is significantly improved (over the participants of Experiment 1). This difference is explained by participants reliance solely on target base rate or retrieval from LTM to guide search processes.

\section*{Experiment 1}

Experiment 1 was conducted to assess the degree to which participants would use cue information to simplify a difficult visual search task. Participants were asked to respond to a specific orientation of a "T" (rotated 90 degree clockwise or 90 degrees counterclockwise), while ignoring modified "L" letters in a visual array. Each visual array contained 14 different items (13 distracters and 1 target), with each item being unique in color. Note that there was always a target present in each search array and the search array was presented until participants responded (i.e., there was no time limit).

On each trial, a background cue appeared prior to (and during) the search array. The background cues consisted either of circles, squares, or triangles and were positioned randomly on the screen (i.e., one cue consisted of only circles, another only squares, and the last only triangles). The statistical relationship between the background cues and the identity of the upcoming target was manipulated in order to provide complete, partial, or non-diagnostic information regarding the color of the forthcoming target. Table 1 provides the contingency table describing how the backgrounds were paired with the different colors (see Figure 1 for an example background). For example, background 2 was paired with colors 2 and 3 (C2 and C3) such that when background 2 was presented the target's color was C2 on \(60 \%\) of trials and C3 on \(40 \%\) of trials (note that although C1 and C4-C14 were always present in the array when background 2 was presented, they were always "L"s in the search array). Each participant was exposed to each of the different background cues throughout the entire experiment (i.e., a within-subjects design was used). Participants went through 360 trials (i.e., 6 Epochs of 60 trials each. Within each epoch the 3 backgrounds were presented 20 times each and were randomly selected for each trial. For each Epoch C1 was the target 20 times given background 1, C2 was the target 12 times given background 2, C3 was the target 8 times given background 2, and each of the fourteen colors (C1-C14) appeared as the target roughly 1.43 times given background 3 . Thus, the base rate (raw frequency) of each color appearing as the target per epoch was approximately 21.43 for C1, 13.43 for C2, 9.43 for C3, and 1.43 for C4-C14.

Participants were not informed at the beginning of the experiment that a statistical relationship existed between particular backgrounds cues and the color of the target. Because of this, at the conclusion of the experiment they were asked whether they noticed a statistical relationship between particular backgrounds and the target colors. After providing an answer, participants performed a recognition task. For each trial during the recognition task, participants were provided with a search array that contained a target of
a particular color. The color of the target was either valid (the target was paired with that background in the experiment) or invalid. Participants performed the recognition task for the three different backgrounds. The participant's recognition performance was used as a measure of their explicit knowledge concerning the cuehypothesis contingencies.
Table 1: Contingency table, showing how the backgrounds were paired with the different colors (C1-C14) for
Experiments 1 and 2. Note that the last column indicates the contingencies for each of the eleven colors (C4-C14).
\begin{tabular}{|l|cccc|}
\hline & C1 & C2 & C3 & C4-C14 \\
\hline Background 1: 100 & 1.0 & 0 & 0 & 0 \\
Background 2: 60/40 & 0 & 0.6 & 0.4 & 0 \\
Background 3: Random & 0.07 & 0.07 & 0.07 & 0.07 \\
\hline
\end{tabular}

\section*{Method}

Participants Twenty-two participants (10 females; \(M_{\text {age }}=\) 19) from the University of Oklahoma participated in Experiment 1 for course credit. All participants reported normal or corrected-to-normal vision. Four participants were excluded from the analysis due to high error rates (error rates \(\geq 15 \%\) ) during the visual search task, leaving 18 participants for the analysis.
Stimuli and Apparatus Stimuli were presented on a 17 " monitor, controlled by a Dell computer with a 3 GHz Pentium 4 processor. Distance to the monitor was approximately 60 cm . Stimulus presentation and data recording were controlled via E-Prime 2 by PST, Inc. The following 14 colors were used in all of the experiments presented black, blue, brown, cyan, green, lime, magenta, maroon, orange, pink, red, tan, white, and yellow. All the stimuli (the T's and L's) in the visual search array were 22 \(\mathrm{mm} \times 22 \mathrm{~mm}\). For each visual array each of the 14 items were placed randomly at one of 35 possible locations based on 3 ellipses of varying sizes.

Procedure. Each trial started with a fixation followed by a background cue ( 2004 ms ). The search array then followed. Participants were told to find the rotated " T " as quickly as possible and press the F-key when the "T" was rotated 90 degrees counterclockwise and the J-key when it was rotated 90 degrees clockwise. After responding a brief mask was presented ( 68 ms ) followed by a feedback screen ( 500 ms ) that indicated whether the response to the visual search array was correct. Figure 1 provides a schematic of the main components of each trial (i.e., the background cue and visual search array). Following the completion of all 360 visual search trials the participants then performed the recognition task as described above.

Figure 1: Schematic illustration of the main components of each trial of Experiments 1 and 2. The background cue was presented for 2004 ms , while the search array was presented until response.

\section*{Results}

For our main analysis, we examined RTs for each of the cue validity conditions. Trials in which the orientation of the target was mis-reported ( \(4.19 \%\) ), as well as trials with RTs faster than 200 ms or slower than \(10,000 \mathrm{~ms}\) ( \(2.66 \%\) ) were removed prior to analysis. We report the differences in the cue validity conditions collapsed across the last 3 epochs (although see Figure 2 for RT performance throughout the entire experiment). Specifically, the means of the median values (for each cue validity condition at Epochs 3-6) were calculated for each participant for each cue validity condition.

A within subjects repeated measures ANOVA revealed a significant main effect of cue validity on visual search RTs, \(F(2,34)=30.31, p<.01, \eta_{p}^{2}=641\). Pairwise comparisons revealed a significant difference between all three conditions such that the 100 ( \(M=1942.1 \mathrm{~ms}\) ) cue validity condition was significantly different from the 60/40 ( \(M=\) 2667.1 ms ) cue validity condition ( \(p<.001\) ) and the random cue validity condition ( \(p<.001\) ). The 60/40 cue validity condition was significantly different from the random ( \(M=\) 3033.8 ms ) cue validity condition ( \(p=.003\) ).

Figure 2: Reaction time performance as a function of epoch and cue validity in Experiment 1.

Seven out of the 18 participants (38.88\%) indicated that they had noticed a relationship between the background and
the likelihood of the target being of a particular color \({ }^{1}\). To examine participant's accuracy in the recognition task we only considered the 100 and 60/40 cue-validity conditions. The overall accuracy rate for the recognition task was at chance level (50.93\%). Accuracy rates for the different cue validity conditions were \(55.56 \%\), and \(48.61 \%\) for the 100 and \(60 / 40\) cue validity conditions. Participants who indicated that they recognized a relationship between the background and the likelihood of the target being a particular color were no better at the recognition task, with accuracy rates of \(50 \%\) for both the 100 and 60/40 conditions. Note that when the participants that indicated that they noticed a relationship were excluded from the analysis, a similar pattern of RT results as described above was obtained. Additionally, a between-subjects analysis of RTs did not reveal a significant difference between the group that indicated that they noticed a relationship from those that did not, \(F(1,16)=1.355, p=.262\).

\section*{Discussion}

In Experiment 1 we found improved search performance in accordance with the diagnosticity of the background cue. This RT result, coupled with the poor recognition performance suggests that participants may have been using the background cues at an implicit level of awareness, which is common in the contextual cueing literature.

One of the striking aspects concerning the results from many contextual cueing studies is its implicit nature (e.g., Chun \& Jiang, 1998; 1999). That is, although participants are able to find a target faster when aspects of a scene are repeated (as opposed to when they are changed), this occurs at an implicit level as participants are not able to discriminate the visual scenes they have viewed previously from those they have not (at the end of the training). Therefore, it could be an implicit utilization of contextual cues that explains the observed discrepancy between search and recognition performance in the present data. However, it should be pointed out that there is another possible explanation of the results for Experiment 1, which is explored below.

The second possible interpretation of the results holds that participants were essentially ignoring the background cues (and by extension the cue target associations), but were noting the likelihood of the target colors across all trials (i.e., the target color base rates). That is, participants' expectations regarding the color of the target may have been based on the unconditionalized base rate of the target color across all background conditions. For instance, let's assume that the color of the target is red in the 100 cue validity condition. After enough trials participants adopt an

\footnotetext{
\({ }^{1}\) During debriefing some of the 7 participants that answered affirmatively to the question "Did you notice any relationship between the background and the target colors?" were confusing the probability of target color given background with the probability of the target being a particular color (i.e., the base rate of the target colors). Thus, it is likely that even fewer than 7 participants truly noticed the association between target color and background.
}
attentional set for red and begin searching for the red item across all background conditions, even though red is not valid for the other cue validity conditions. Likewise the higher likelihood of the targets in the 60/40 condition makes them suitable targets across all background conditions as well. This explanation is supported by a study by Kunar, Flusberg, \& Wolfe (2006) that demonstrated improved search efficiency for consistently mapped search arrays when the delay between cue and array onset was sufficiently increased and participants were explicitly told about the relationship between cues and the critical aspect of the target. In Experiment 2 we investigate the two possibilities discussed above, by explicitly informing participants about the possible relationships between the background cues and the colors of the target.

\section*{Experiment 2}

Experiment 2 assessed whether participants in Experiment 1 were merely using base rate information to inform search or if they were using the background cues to improve search performance by developing a conditional attentional set. The experiment was nearly identical to Experiment 1 except there was a knowledge test at the end of each epoch, as opposed to the recognition test administered at the end of Exp. 1. The intention of this manipulation was to provide a hint to the participants that the background cues and the color of the targets were systematically associated.

\section*{Method}

Participants Twenty-Seven participants (23 females; \(M_{\text {age }}=\) 20.6) from the University of Oklahoma participated in Experiment 2 for course credit (26 participants) or \(\$ 10\). All participants reported normal or corrected-to-normal vision. Two participants were excluded from the analysis due to a high error rate (error rate \(\geq 15 \%\) ) and one was excluded for having exceptionally long RTs as determined by having a mean RT value more than 3 standard deviations higher than the average for the mean of the collapsed \(100,60 / 40\), and random conditions.

Procedure The same procedure used in Experiment 1 was used in Experiment 2 with the following exception. At the end of each epoch, participants were asked to indicate the most likely colors of the target (up to 4) given the cue.

\section*{Results}

Error trials were excluded from analysis (2.3 \%) as well as trials with RTs faster than 200 ms and slower than 10,000 ms (5.1\%). Errors were not analyzed in any manner.

As in Experiment 1 we collapsed across the last 3 epochs (see Figure 3 for RT performance across all epochs). A within subjects ANOVA revealed a main effect of cue validity, \(F(2,32)=133.302, p<.001, \eta_{p}^{2}=.847\) on search

RTs. Pairwise comparisons revealed a significant difference between the 100 ( \(M=1053.5 \mathrm{~ms}\) ) cue validity condition to the \(60 / 40\) ( \(M=1885.3 \mathrm{~ms}\) ) cue validity condition ( \(p<.001\) ) and the Random ( \(M=3243.3 \mathrm{~ms}\) ) cue validity condition ( \(p<\) .001). The \(60 / 40\) cue validity condition was also significantly different from the Random cue validity condition ( \(p<.001\) ).

Figure 3: Reaction time performance as a function of epoch and cue validity in Experiment 2.

We next performed a between subjects analysis comparing the respective cue validity conditions of Experiment 2 to Experiment 1 (the mean values obtained whilst collapsing across the last epochs) with cue validity (100, 60/40, Random) as a within subjects variable and Experiment as a between subjects variable.

Figure 4: Reaction time performance comparing the participants of Experiment 2 with the participants of Experiment 1. Error bars represent standard errors. Note that the bars represent the means for Epochs 4-6.

A main effect of cue validity was found \((F(2,82)\) \(=134.183, p<.001, \eta_{p}^{2}=.766\) ) as well as a main effect for Experiment such that participants were faster in Experiment 2 than in Experiment 1, \(\left(F(1,33)=15.533, p<.001, \eta_{\mathrm{p}}^{2}=\right.\) .275). An interaction between Experiment and cue validity was observed, \(\left(F(2,82)=18.26, p<.001, \eta_{p}^{2}=.308\right)\). A Post-hoc analysis revealed a significant difference when comparing the 100 cue validity condition in Experiment 2 to the 100 cue validity condition in Experiment 1 ( \(p<.001\) ) and also the 60/40 cue validity condition was significantly different across experiments ( \(p=.012\) ), but the Random cue validity condition was not significantly different across Experiments ( \(p=1.0\) ). Thus, participants were significantly faster to find the target when they were informed of the possible connection between the cues and the color of the
target, suggesting that the participants in Experiment 1 were merely relying on base rate information to guide search \({ }^{2}\). There were also quite large differences in memory performance as well in Experiment 2. To examine whether this had an influence on the visual search process we split the participants into two groups based on their performance in the memory task. If a participant named the 100 color first for background 1 and the 60/40 colors first or second (in any order) for background 2 at one time during testing (out of the 6 times to do so), and only those colors, they were placed into the good memory performance group (17 participants) and the others were placed into the poor memory performance group (8 participants). Figure 5 plots the good and poor memory performers in the knowledge test.

Figure 5: Performance in the knowledge test as a function of epoch, cue diagnosticity, and memory performance classification for Experiment 2. Poor memory performers are plotted in gray and good memory performers are plotted in black. Those that performed well increased dramatically over the course of the experiment whereas the poor memory participants did not.

We performed a between subjects analysis on the visual search RTs to compare the good memory performers from the poor memory performers, with cue validity (100, 60/40, Random) as a within subjects variable and memory performance (good, poor) as a between subjects variable. This analysis revealed a significant main effect of cue validity \(\left(F(2,46)=123.781, p<.001, \eta_{\mathrm{p}}^{2}=.843\right)\) as well as memory performance on search RTs \((F(1,23)=12.881, p\) \(\left.=.002, \eta_{p}^{2}=.359\right)\) such that participants were faster as cue validity increased and participants who performed well in the memory task were faster overall in the visual search task. An interaction between cue validity and memory performance type was also revealed \(F(2,46)=5.007, p=\)

\footnotetext{
\({ }^{2}\) Although this statement is conjecture, we have additional empirical evidence that the participants' performance in Experiment 1 is entirely compatible with the notion that they were only using base rate information. In an additional follow up experiment we eliminated the diagnosticity of the background cue(s) by presenting only one background throughout the entire experiment (i.e., on each trial they saw the same background cue). We found remarkably similar performance in this experiment as compared to Experiment 1. Post hoc analysis revealed no differences between the 100 and 60/40 cue validity conditions across experiments (both \(p\) ' \(=1.0\) ).
}
\(.011, \eta_{\mathrm{p}}^{2}=.179\). Although a between subjects analysis using a post-hoc Bonferonni test did not reveal a significant difference when comparing the 100 cue validity condition of the good memory performers \((M=893)\) to the poor memory performers ( \(M=1394.7\) ) of Experiment 2 ( \(p=.59\) ), a significant difference was observed when comparing the respective \(60 / 40\) cue validity conditions ( \(p=.012\) ). The good memory performers were faster in the 60/40 condition ( \(M=1601.1\) ) relative to the poor memory performers ( \(M\) =2489.2).

Because there seemed to be a qualitative difference in search RTs for the poor memory performers to the good memory performers, we next compared the poor memory performers of Experiment 2 to the participants of Experiment 1 to examine whether these two sets of participants were qualitatively similar. A main effect of cue validity was found \(\left(F(1,48)=51.985, p<.001, \eta_{p}^{2}=.684\right)\). There was no effect for Experiment, \((F(1,24)=1.028, p=\) .321, \(\left.\eta_{p}^{2}=.041\right)\). An interaction was observed, \((F(2,48)=\) 3.568, \(p=.036, \eta_{p}^{2}=.129\) ), however, a post-hoc analysis revealed that the 100 cue validity condition was not significantly different across groups ( \(p=.91\) ) nor was the 60/40 cue validity condition ( \(p=1.0\) ), nor the Random cue validity condition ( \(p=1.0\) ). Thus, it appears that the poor memory performers: 1) were qualitatively different than the good memory performers of Experiment 2, particularly for the 60/40 cue validity condition and 2 ) were qualitatively similar to the participants of Experiment 1 for the 100 and 60/40 cue validity conditions.

\section*{Discussion}

Experiment 2 revealed that the participants who learned the associations between the cues and the critical features of the target were able to leverage that information in the visual search task. Although participants were unable to pick up on the cue-target associations without a suggestion from the experimenter that such a relationship may exist (see Footnote 2 and General Discussion), most participants were able to do so once this relationship was suggested in Experiment 2. We also found that performance of the poor memory performers was similar to that of the participants in Experiment 1. In the General Discussion we posit that an important cognitive mechanism (i.e., attentional selection) was not operating over the cues for the participants of Experiment 1 and the poor memory performers in Experiment 2, thus disabling them from using the cues to improve their search.

\section*{General Discussion}

In two experiments we explored whether participants would be able to use cues to simplify a perceptually demanding visual search task. We found that although participants were sensitive to base rate information in Experiment 1, Experiment 2 revealed that the participants in Experiment 1 were likely not utilizing the background cues. Although this conclusion may be un-warranted given that a cue validity effect was found in Experiment 1, we ran an additional
experiment where the diagnosticity of the background cues was eliminated by using the same background cue for the different cue validity conditions. We found remarkably similar performance to Experiment 1 such that there were no differences for the 100 and 60/40 cue validity conditions (see Footnote 2).

In Experiment 2 we also found a qualitative difference between participants who performed well on the knowledge tests versus those that did not. The good memory performers were faster overall and were particularly faster when the background cue suggested two features (i.e., the 60/40 condition). Thus, it appears that suggestion of the possible cue to target color connection and explicit knowledge of the cue-target associations (as evidenced by good performance in the memory task) are important factors in contributing to the use of cues from the environment to support conditional visual search in the retrieval guidance paradigm (c.f. contextual cueing; Chun \& Jiang, 1998; 1999). The results suggest that the paradigm used allows for an examination of how LTM memory, WM, and attention coordinate in a visual search task.

We argue that the difference between these two sets of participants is due to attentional selection (see TurkBrowne, Jungé, \& Scholl, 2005). We suggest that the poor memory performers of Experiment 2 and the participants of Experiment 1 were not attending to the background cue on each trial and thus were not able to exploit the cues later in the experiment (i.e., Epochs 3-6). The good memory performers, on the other hand, were attending to the cues, thereby allowing them to encode the cue-target color associations into LTM, and exploit their memories as the task progressed. We now turn to a discussion of how a recent model of hypothesis generation called HyGene (short for Hypothesis Generation; Dougherty, Thomas, \& Lange, 2010; Thomas, Dougherty, Sprenger, \& Harbison, 2008) provides a useful framework for theorizing about interactions between visual search and memory within the retrieval guidance paradigm and beyond.

Although HyGene was originally developed to bridge research concerning LTM, WM, and judgment \& decision making, we argue that it provides a useful framework for understanding how WM and LTM interact to support visual search. In this framework, an individual receives information from the environment, such as the background cue in the present experiment, which prompts the generation of hypotheses previously associated with the observed information. In the case of the retrieval guidance paradigm, the hypotheses being retrieved are the likely colors of the forthcoming target on each trial. The retrieved hypotheses are placed into WM and are then available to drive search processes in a top-down manner (e.g., Desimone \& Duncan, 1995), affording the filtering out of perceptual information that is discordant with WM content.

Although we believe that HyGene provides a useful framework for understanding ecological visual search, it currently does not have direct access to the outside world (i.e., visual input). Because of this, the model cannot yet
make specific predictions which are likely important to visual search researchers (e.g., RTs, fixations). Thus, it would be fruitful to integrate HyGene with models of visual search, such as the guided search model (Wolfe, 1994) or the more recent target acquisition model (Zelinsky, 2008). Not only would such models be able to perform visual search, but they would also would generate predictions concerning information foraging (e.g., Hypothesis testing; Dougherty, Thomas, \& Lange, 2010).

\begin{abstract}
People judge that harmful side effects are intentional, e.g., a CEO who introduces a new program to increase profits that results in harm to the environment is judged to have intentionally harmed the environment. They judge helpful side effects are unintentional, e.g., a CEO who introduces a new program to increase profits that results in helping the environment is not judged to have intentionally helped the environment. We report two experiments that suggest the effect arises because people believe individuals can make alternative choices in bad situations and not in good ones.
\end{abstract}

Keywords: Intentions, choices, side-effects, inactions.

\section*{Intentionality}
"Nothing hinders one act from having two effects, only one of which is intended, while the other is beside the intention. Now moral acts take their species according to what is intended, and not according to what is beside the intention, since this is accidental." Aquinas (1265-1274)

Intentionality is a core category of mental life, along with space, time and cause (Miller \& Johnson-Laird 1976). Philosophers, psychologists and legal scholars have identified that the accurate assessment of other people's intentions is vital to moral and legal judgment, and to how we understand and explain other people's behavior (e.g., Knobe 2010). Logicians and artificial intelligence researchers have modeled intentions using dynamic doxastic logic and related systems as an important aspect of simulating revisions to beliefs (e.g., Gardenfors 1988). Neuroscientists and psychiatrists have established that the loss of the ability to reason about intentions is catastrophic after prefrontal cortex damage (e.g., Young, Bechara, Tranel, Damasio, Hauser, \& Damasio 2010) and in disorders such as schizophrenia (e.g., Roese, Park, Smallman \& Gibson 2008), just as it is essential to children's proper development of a theory of mind (e,g., Leslie, Knobe \& Cohen 2006). Not surprisingly then, it is of concern that recent evidence indicates that people may make systematic errors in their assessments of other people's intentions, at least in relation to the intentionality of side effects (e.g., Knobe 2010). Consider the following story:

The vice-president of a company went to the chairman of the board and said, 'We are thinking of starting a new program. It will help us increase profits, but it will also harm the environment.' The chairman of the
board answered, 'I don't care at all about harming the environment. I just want to make as much profit as I can. Let's start the new program.' They started the new program. Sure enough, the environment was harmed.

Participants judged that the chairman intentionally harmed the environment (Knobe, 2003a). The judgment is puzzling because intentionality implies that the protagonist desires the outcome, has the belief or knowledge that the action will bring it about, and intends to carry it out, as well as that the protagonist is aware of carrying it out and has the skill to do so (Malle \& Knobe, 1997).
The puzzle deepens when participants are told that the program will help rather than harm the environment:

The vice-president of a company went to the chairman of the board and said, 'We are thinking of starting a new program. It will help us increase profits, and it will also help the environment.' The chairman of the board answered, 'I don't care at all about helping the environment. I just want to make as much profit as I can. Let's start the new program.' They started the new program. Sure enough, the environment was helped.

Participants judged the chairman did not intentionally help the environment (Knobe 2003a).
The asymmetry between harmful and helpful side-effects occurs in many different sorts of situations. It occurs for different contents, ranging from serious violations such as when an army commander's decision to capture a region in battle has the side effect of affecting the numbers of soldiers killed (Knobe 2003a), to more trivial ones such as when a protagonist's decision to mow the lawn early in the morning affects their neighbor's sleep (Sverdlik 2004). It is observed in languages other than English such as Hindi (Knobe \& Burra 2006) and for an array of linguistic expressions such as 'advocated' and 'decided' (McCann 2005; Pettit \& Knobe 2009). It emerges early in young children (Leslie, et al 2006) and occurs even in people with deficits such as Asperger's (Zalla \& Leboyer 2011).
Why do people judge that others bring about harmful side-effects intentionally but helpful side-effects unintentionally? The issue is hotly debated and several alternative explanations have been proposed to account for it.

\section*{Intentionality and morality}

One influential explanation for the asymmetry in judgments of the intentionality of harmful and helpful side-effects is that people first assess the morality of the side-effect. Their judgment of the side effect as morally good or morally bad infuses their judgment of its intentionality (e.g., Knobe 2006). Against this proposal however, it has been observed that people judge that a protagonist brought about a harmful side-effect intentionally even for non-moral side-effects. For example, when the CEO of a movie company decides to introduce a new program that will increase profits and have the side effect of making movies worse from an artistic standpoint, participants judged that he intentionally brought about the side-effect of harming movies from an artistic standpoint (Knobe 2004). When the story substituted 'help' for 'harm', they judged that he didn't intentionally bring about the side effect of helping movies from an artistic standpoint. Likewise, the effect occurs for non-moral norms, e.g., it occurs for a decision to change a manufacturing process that will have the side effect of creating a product that deviates from an industry standard of 'darker than blue' (Uttich \& Lombrozo 2010).
Most tellingly, badness and intentionality can be 'doubly dissociated'. On the one hand, some harmful side effects are judged intentional even when they are not judged to be bad e.g., a chairman who decides to increase profits in one branch of the company with the side effect of decreasing profits in another branch, is judged to have intentionally harmed the other branch's profits even though harming the other branch's profits is not judged to be bad (e.g., Knobe 2006; Knobe \& Mendlow 2007). On the other hand, some side effects are judged unintentional even though they are judged bad, e.g., a town-planner who introduces a program to clean toxic waste with the side effect of increasing joblessness is judged to have affected joblessness unintentionally even though joblessness is judged to be bad (e.g., Phelan \& Sarkissian 2008; Sverdlik 2004).
A related explanation is that people judge individuals to be blameworthy when their decisions lead to harm. The motivation to express blame leads participants to conclude that the harmful side effect is intentional (e.g., Adams \& Steadman 2004; Alicke 2008; Mele 2003; Nadelhoffer 2004). Against this proposal however, it has been observed that a harmful side-effect is judged intentional even when participants have the opportunity to blame the protagonist, or otherwise to assign responsibility to the protagonist separately (e.g., Knobe 2003b; Pellizzoni, Girotto \& Surian 2010). Again, most tellingly, blame and intentionality can be 'doubly dissociated'. On the one hand, some harmful side-effects are judged unintentional even when the protagonist is blamed, e.g., a driver who goes out of control while drunk and injures a family is judged to be blameworthy, but not to have harmed the family intentionally (Knobe 2003b). On the other hand, some harmful side-effects are judged intentional even when the protagonist is not blamed, e.g., a dentist who
carries out necessary dental surgery and inflicts pain on the patient is judged to have inflicted the pain intentionally but is not blamed for doing so (Sverdlik 2004).
Hence, moral assessments of goodness and badness, or judgments of blameworthiness, do not appear to be the reason why people tend to judge harmful side-effects to be intentional and helpful side-effects to be unintentional. However, one further possibility from this perspective is that the difference in intentionality judgments for harmful and helpful side-effects arises because of the moral disparity between the primary goal (increasing profits) and the side-effect (affecting the environment): the primary goal itself may be perceived to be morally bad in the context of the side effect. The first experiment tests this moral disparity explanation.

\section*{Experiment 1}

We gave participants an 'Aid' story in which the primary goal was elevated to be of equivalent moral status to the side-effect of affecting the environment:

The vice-president of an international aid charity went to the chairman of the board and said, 'We are thinking of starting a new program. It will help us save more people from starvation in Africa, but it will also harm the environment.' The chairman of the board answered, 'I don't care at all about harming the environment. I just want to save as many people as I can. Let's start the new program.' They started the new program. Sure enough, the environment was harmed.

If moral assessments are central to intentionality judgments, then harming the environment should be judged unintentional because its immorality is ameliorated by the morality of saving starving people. We also gave participants a 'Rival' story in which the side-effect was diminished to be of equivalent moral status to the primary goal of increasing profits:

The vice-president of a company went to the chairman of the board and said, 'We are thinking of starting a new program. It will help us increase profits, but it will also harm our rival's profits.' The chairman of the board answered, 'I don't care at all about harming our rival's profits. I just want to make as much profit as I can.' Let's start the new program.' They started the new program. Sure enough, the rival's profits were harmed.

\section*{Method}

The participants were 60 students from Trinity College Dublin who took part voluntarily. They were 17 men and 43 women, aged 16 to 58 years, with an average age of 24 years.

Participants were assigned to the Aid or Rival groups ( \(\mathrm{n}=30\) in each). They were each given a harm and help
version of the story. Half received the harm version first and half the help version first (and no effects of order were observed). They completed several tasks, such as a praiseblame assignment task, as well as the key side-effect intentionality judgment task, in response to the question, 'Do you think the chairman intentionally affected the <side-effect>?'. They circled their answer on a 7 point likert-type scale with 6 anchored as 'intentional' and 0 as 'unintentional' and the mid-point anchored as 'neither'.

They were instructed that they would be given two short stories and they were asked to read them carefully, to answer the questions in the order they were given, not to change any of their answers, and to complete all of the questions on one story before moving on to the next.

\section*{Results and Discussion}

Participants judged that the protagonist intentionally affected the side-effect more for the harmful side-effect than the helpful one in the Aid condition, Wilcoxon's \(\mathrm{z}=\) \(-2.828, \mathrm{p}=.005, \mathrm{r}=.365\) as Figure 1 shows. (For clarity, responses were graphed using scores translated from 0 to 6 to -3 to +3 ). The result shows that even when the protagonist's primary goal was elevated to be morally compelling (saving people from starving) participants tended to judge that he brought about the harmful side effect (harming the environment) more intentionally than the helpful side effect (helping the environment).

Figure 1: Judgments of intentionality for harmful and helpful side-effects in the Aid and Rival conditions. Error bars are standard error of the mean.

Participants also judged that the protagonist intentionally affected the side-effect more for the harmful outcome than the helpful one in the Rival condition, Wilcoxon's \(z=\) 2.481, \(p=.013, r=.3203\), as Figure 1 also shows. Even when the side-effect (affecting a rival's profits) was diminished to be as morally unenlightening as the primary
goal (increasing one's own profits), participants judged that the protagonist brought about the harmful side effect (harming the rival's profits) more intentionally than the helpful side effect (helping the rival's profits).
The results suggest that the moral disparity between the primary goal, of increasing profits, and the side-effect, of harming or helping the environment, does not underlie the asymmetry in judgments of intentionality. An alternative explanation is based on the availability of choice.

\section*{Intentionality and choice}

A new explanation for why people judge harmful side effects to be intentional and helpful side effects to be unintentional is that the protagonist is perceived to have a choice when faced with the harmful dilemma but not when faced with the helpful one. We propose that a harmful side-effect poses a genuine dilemma: the goal is positive whereas the side-effect is negative, and in a dilemma a protagonist makes choices between priorities.
This availability of choice explanation proposes that people think about whether the protagonist has other options. They can think about an alternative to the harmful side-effect: the protagonist could have decided not to introduce the program to increase profits, and so not harmed the environment. Because they can think of alternatives, they perceive that the protagonist had a choice and they judge the side-effect to be intentional. In contrast, a helpful side-effect poses no dilemma: the goal and side-effect are positive and the protagonist need not make choices between them: his action will increase profits and help the environment. Participants do not tend to think of an alternative to the helpful side-effect and so they perceive that the protagonist had little choice and they judge the side-effect to be unintentional. This suggestion is consistent with earlier acknowledgments that choice has a potential role in intentionality judgments (e.g., Alicke 2008; Cushman \& Young 2011; Machery 2008; Malle \& Knobe 1997; Phillips \& Knobe 2009; Royzman \& Baron 2002). For example, when the protagonist does not have sufficient knowledge of the outcome, the effect is eliminated (e.g., Nichols \& Ulatowski 2007; Pellizzoni et al 2010).
At the heart of the availability of choice explanation is the idea that thinking about choices requires people to imagine alternatives: they think about the protagonist's choice of pursuing the goal and its harmful side-effect, and they imagine a counterfactual alternative of not pursuing the goal and no harmful side-effect. Evidence to support this suggestion comes from the observation that when participants are required to create 'if only' counterfactual thoughts about how things could have turned out differently prior to making their judgments of intentionality, the side-effect asymmetry is amplified (Byrne 2012). They judged the harmful side effect to have been brought about intentionally more often when they were required to create counterfactuals compared to when they were not, presumably because they could think of
alternative choices the protagonist could have made; they judged the helpful side effect to have been brought about unintentionally more often when they were required to create counterfactuals compared to when they were not, presumably because they could not think of alternative choices the protagonist could have made. The suggestion is consistent with the idea that intentionality judgments may potentially be affected by counterfactual generation (e.g., Adams \& Steadman 2004; Knobe, 2010; McCloy \& Byrne 2000; Pellizzoni et al 2010; Young \& Phillips 2011). Our second experiment tests the availability of choice proposal, by examining intentionality judgments for side-effects that are brought about by actions or inactions.

\section*{Experiment 2}

Outcomes that result from a protagonist's actions may appear to be the result of deliberate choices, more so than outcomes that result from a protagonist's inactions. If so, the asymmetry in judging harmful side-effects to be intentional and helpful side-effects to be unintentional may be diminished when the side-effects result from the protagonist's inaction, rather than from the protagonist's action.
People tend to regret bad outcomes that arise from their actions more than bad outcomes that arise from their inactions. Consider the following scenario:

Mr. Paul owns shares in company A. During the past year he considered switching to stock in company B, but he decided against it. He now finds out that he would have been better off by \(\$ 1,200\) if he had switched to the stock of company B. Mr. George owned shares in company B. During the past year he switched to stock in company A. He now finds out that he would have been better off by \(\$ 1,200\) if he had kept his stock in company B . Who feels greater regret?

Most people judge that the actor, Mr. George, will regret his action more than the individual who did not act, Mr. Paul (Kahneman \& Tversky 1982). Even when their task is to judge the regret that a person experienced without making a comparison to the regret experienced by another person, their estimates of regret for an actor are higher than their estimates of regret for a non-actor (Feeney \& Handley 2006; N'gbala \& Branscombe, 1997). They also judge that actors will feel better about good outcomes that arise from their actions compared to individuals whose inaction leads to a good outcome (Landman, 1987). This 'omission bias' may arise because actions appear to change the status quo more than inactions (Byrne \& McEleney 2000; Ritov \& Baron 1999). Of course, when there are compelling reasons to act, inactions can be seem inexcusable (Gilovich \& Medvec 1995; Zeelenberg, Van den Bos, Van Dijk, \& Pieters 2002).

We gave participants a version of the company scenario which emphasized the protagonist action in switching to a new program:

The vice-president of a company UMT Ltd went to the chairman of the board, Mr. Smith, and said 'We are thinking of switching to a new program, instead of staying with our old one. If we switch to the new program it will help us increase profits, but it will also harm the environment'. The chairman of the board, Mr. Smith answered, 'I have no desire to affect the environment. I just want to make as much profit as I can'. Mr. Smith considered staying with their old program but in the end he said 'Let's switch to the new program.' They switched to the new program and sure enough, the environment was harmed.

We compared this 'Action' version to an 'Inaction' version which indicated instead that the protagonist had not acted:

The vice-president of another company in a different region, OZF Inc went to the chairman of the board, Mr. Jones, and said 'We are thinking of staying with our old program, instead of switching to a new one. If we stay with the old program it will help us increase profits, but it will also harm the environment'. The chairman of the board, Mr. Jones, answered, 'I have no desire to affect the environment. I just want to make as much profit as I can'. Mr. Jones considered switching to the new program but in the end he said 'Let's stay with the old program.' They stayed with the old program and sure enough, the environment was harmed.

We used the phrase 'I have no desire to affect the environment' rather than 'I don't care at all about harming the environment' to obviate any inference that the protagonist was maliciously negligent (Cushman \& Mele 2008; Guglielmo \& Malle 2010).

\section*{Method}

The participants were 40 students from Trinity College Dublin who participated voluntarily. They were 7 men and 33 women, aged 18 to 43 years, with an average age of 25 years.

Participants were assigned to the harm or help groups ( n \(=20\) in each). They each received an action and an inaction version of the story (in that order, see Feeney \& Handley 2006). They received the action and inaction versions for two vignettes, the company scenario and also a parenting scenario in which a county council chairwoman pursued a primary goal of funding basic community services such as maintenance of roads and parks, with the side-effect of harming (or helping) funding for a 'better parenting' program designed to provide skills to vulnerable adults in at-risk families.

Half the participants received the company scenario first and half the parenting one, and order had an effect (participants tended to give different responses to the company scenario when it appeared first rather than second). Hence we report the results for participants' responses to the first scenario they received only. There were no differences in responses to the two contents, company versus parenting when they were received first. Participants completed several tasks, such as a praiseblame assignment task, as well as the key side-effect intentionality judgment task. We eliminated four participants because their response to a final question on 'protected values' (absolute values that people protect from trade-offs) indicated they did not value the environment or parenting programs highly (Ritov \& Baron, 1999; Tanner \& Medin 2004). The procedure was similar to the previous experiment.

\section*{Results and Discussion}

Participants in the Action condition judged that the actor brought about the side-effect intentionally for the harmful side-effect more than the helpful one, Mann Whitney U, z \(=-2.111, \mathrm{p}=.035, \mathrm{r}=.3518\). The difference was eliminated in the Inaction condition, \(z=-1.203, p=.229\), as Figure 2 shows. The result is consistent with the suggestion that the asymmetry in judgments of intentionality for harmful and helpful side-effects arises from the perceived differential availability of choice for harmful and helpful side-effects that result from actions. Side-effects that result from a protagonist's inaction may appear not to be the result of deliberate choice as much as those that result from a protagonist's actions.

Figure 2: Judgments of intentionality for harmful and helpful side-effects in the Action and Inaction conditions. Error bars are standard error of the mean.

However, it is important to note that participants judged the protagonist had brought about a harmful side effect intentionally as often for an inaction as for an action,

Wilcoxon's \(z=-.680, p=.479\); in contrast, they judged the protagonist had brought about a helpful side effect marginally more unintentionally for an action than for an inaction, \(\mathrm{z}=-1.792, \mathrm{p}=.073, \mathrm{r}=.299\). The result indicates that people judge the unintentionality of side-effects differently when they arise from inaction rather than action.

\section*{Conclusions}

Participants tend to judge that an individual brought about a harmful side-effect intentionally, but a helpful side-effect unintentionally (Knobe 2003a). We suggest the phenomenon arises because a harmful side-effect poses a genuine dilemma in which the actor must make choices, whereas a helpful side-effect poses no dilemma and the actor does not need to make choices. People imagine a counterfactual alternative in which the actor made a different choice for a harmful side-effect and the readily available imagined alternatives for a harmful side-effect lead them to infer it was intentional.
The tendency to judge that an individual brought about a harmful side-effect intentionally but a helpful side-effect unintentionally persists even when the goal is of equal moral worth to the side effect, such as saving people from starvation, as the first experiment showed, ruling out an explanation based on moral disparity. The effect is eliminated when the side effects arise from inactions rather than actions, as the second experiment showed, consistent with an explanation based on the availability of choice. The availability of choice explanation is consistent with the view that common mechanisms underlie reasoning about intentionality in moral and non-moral domains (e.g., Byrne 2005; Rai \& Holyoak 2010; Royzman \& Baron 2002; Shenhav \& Greene 2010; Uttich \& Lombrezo 2011).

}

\begin{abstract}
We report two visual-world eye-tracking experiments that investigated how and with which time course emotional information from a speaker's face affects younger ( \(N=32\), Mean age \(=23\) ) and older \((N=32\), Mean age \(=64)\) listeners' visual attention and language comprehension as they processed emotional sentences in a visual context. The age manipulation was aimed at testing predictions by socioemotional selectivity theory of a positivity effect in older adults. After viewing the emotional face of a speaker (happy or sad) on a computer display, participants were presented simultaneously with two pictures depicting opposite-valence events (positive and negative; IAPS database) while they listened to a sentence referring to one of the events. Participants' eye fixations on the pictures while processing the sentence were enhanced when the speaker's face was emotionally congruent with the sentence/picture compared to when it was not. The enhancement occurred from the early stages of sentence-reference disambiguation; importantly, it was modulated by age, in that for the older adults it was more pronounced with positive faces, and for the younger ones with negative faces. These findings demonstrate for the first time that emotional facial expressions, similarly to previously studied speaker cues such as eye gaze and gestures, are rapidly integrated into sentence processing. They also provide new evidence for positivity effects in older adults in online incremental situated sentence processing.
\end{abstract}

Keywords: sentence processing; visual-world paradigm; emotional processing; speaker cues; positivity effect; facial expressions

\section*{Visual Context Effects on Language Processing}

The study of context effects on language processing has been a major topic of investigation in psycholinguistic research, and since the development of the visual world paradigm in the mid-nineties, psycholinguists have had at their disposal a powerful tool to investigate a potentially rich source of context effects on language processing, that of the visual context. Among other things, findings from this research have demonstrated how information such as an object's size, color, or shape, depicted clipart events, realworld action events, action affordances, and the spatial location of objects are all rapidly integrated during sentence comprehension and can affect a listener's visual attention
while processing sentences (for a recent review, see Huettig, Rommers, \& Meyer, 2011).
In recent years the scope of research on the languagevision interaction has been extended to more complex and subtle aspects of naturalistic, visually-situated language events, such as dialogue interactions. One topic has been how visually-perceivable speaker-based cues, for example, speaker gaze and gestures, affect language processing. Results suggest that a speaker's gaze is incrementally integrated into language processing by listeners (e.g., Hanna \& Brennan, 2007).

Another potentially powerful cue that could be used by a listener is a speaker's emotional facial expression. The question of how such a cue is used in language processing is particularly relevant to current psychological research, especially in light of the recent surge in interest in embodied and situated cognition, and the increasingly available evidence supporting a close interaction between emotions and language (e.g., Havas, Glenberg, \& Rinck, 2007). However, to the best of our knowledge there is todate no study that has examined effects of a speaker's facial expression on spoken sentence comprehension. Additionally, evidence for visual context effects in sentence processing comes almost exclusively from studies with young adults (ca. 19-31 years). By contrast, the extent to which visual context affects sentence comprehension in older adults is less clear. The present research addresses these two open issues in two eye-tracking experiments that examined (a) the time course with which a speaker's emotional facial expressions can influence a comprehender's visual attention to target pictures during spoken sentence comprehension; and (b) the nature of this influence in young versus older adults.

\section*{Emotion Processing and Emotional Priming}

Ekman's (1972) proposal of a set of six basic universal emotions associated with distinct facial emotional expression configurations (happiness, sadness, fear, anger, disgust, and surprise) has been widely tested over the years and assumed by many scholars in the field of emotion research (e.g., Lundqvist, Flykt, \& Öhman, 1998). Within this view, the basic facial expressions are associated with a
distinctive meaning, so they could, in principle, be used by a speaker to strengthen the meaning of her utterances. There is evidence that emotional faces such as happy or angry ones, are attended to faster and are processed more deeply than neutral ones (Palermo \& Rhodes, 2007). Generally, the same attention advantage enjoyed by emotional faces (compared to nonemotional, neutral ones) is found for emotional stimuli in different modalities, for example, emotional words, pictures and sounds (e.g., Hermans, De Houwer, \& Eelen, 2001).

Not only do emotional stimuli attract more attention and are remembered better than corresponding neutral ones, they can also influence how other stimuli (e.g., words, pictures) are processed. This influence has been demonstrated in emotional priming studies (Fazio, 2001), where responses to a target stimulus are facilitated (i.e., faster) when prime and target have the same emotional valence (e.g., positivepositive, negative-negative), compared to when they have opposite valence. Interestingly, priming occurs not only when prime and target belong to same modality and category (e.g., when they are both faces, pictures or words) but also across modalities. e.g., from a picture to a face (Carroll \& Young, 2005, Expt 2), or from a picture or facial expression to a word (Carroll \& Young 2005, Expt 1 and 4).

\section*{Emotional Priming of Sentences: Current Study}

With regard to the issue of whether a speaker's emotional facial expression can influence not just lexical but also sentence processing, the just-mentioned findings on emotional priming from faces to words suggest that it should: Just as the perception of a happy face (the prime) produces a faster response to a positive (vs. negative) target word, so a smile on a speaker's face might facilitate a listener's processing of a positive (vs. negative) sentence. To our knowledge, no research has so far investigated the emotional priming of whole sentences (as opposed to isolated words) using emotional facial expressions. In the current study, we used the visual world paradigm to examine the time course of emotional priming in sentence processing. We employed a design typical of many visualworld experiments on sentence comprehension: Participants listened to sentences relating to visual material displayed on a computer screen (see Fig.1, for the sequence of events in an experimental trial). Before hearing the sentences, our participants saw either a smiling or a sad face (see Fig. 1, Display 1). They were told that this was the face of the speaker of the ensuing sentence (thus simulating a speakerhearer scenario). Then two emotional pictures from the International Affective Picture System database (IAPS, Lang, Bradley, \& Cuthbert, 1999), one positive and one negative, were displayed side by side on the screen. After 1500 ms the sentence was played and referenced either one or the other picture; accordingly, the sentence also had a positive or negative emotional content (see Fig. 1, Display 2). Thus, the speaker's facial expression could be emotionally congruent or incongruent with the sentence. Participants' eye movements to the display on the monitor
while they listened to the sentence were recorded. In line with the usual findings from the visual world paradigm, when participants begin processing the sentence, we expect them to look at the target (the IAPS picture described in the sentence) from the time it becomes clear which picture the sentence is about (i.e., a sentence effect).

Figure 1: Sequence of events in an experimental trial
However, for us the more interesting question is whether and how the facial prime affects (i.e., primes) the processing of the sentence, in other words, the face x sentence interaction. In line with findings from emotional priming research, we expect facilitation when the prime (i.e., the face) is emotionally congruent with the target (i.e., the sentence/picture) compared to when prime and target are incongruent. In our experiment the dependent variable is fixations on the pictures while incrementally processing the sentence; so we expect that looks to the target picture should be facilitated when the emotional face is valencecongruent (vs. incongruent) with the sentence. This facilitation should be reflected in more and longer fixations to the target picture in congruent than in incongruent conditions (cf. Arai, Van Gompel, \& Scheepers, 2007).

Furthermore, the timing of this facilitation is of particular interest to us, as it would reveal details about the time course of integrating emotion information into language processing. Earlier findings (see above) suggest that emotional information enjoys privileged attention, so this would predict that facilitation effects should occur from the early stages of processing the sentence. Alternatively, considering the specifics of our experimental task, facilitatory effects may not surface until later or not occur at all during the processing of the sentence. This is because for facilitation to take place perceivers need to integrate cues from the visual, linguistic and emotional modalities and this may be a complex task to perform on the fly. In addition to facilitating the processing of the sentence itself (face \(x\) sentence interaction), the face may affect the fixations that listeners make on the pictures independently of the sentence
valence. This would be reflected in a preference to look at the picture which is emotionally congruent with the face, i.e., a face-picture congruence effect. To be triggered, this face-picture congruence effect does not require linguistic input from the sentence (but only information from the face and the pictures), so it could occur earlier, before sentence disambiguation, as well as later, after disambiguation. Note that a face \(x\) sentence interaction, which is the effect of primary interest to us, cannot be reduced to a face-picture congruence effect, as it requires the additional input from the sentence to occur.

\section*{Emotion Processing in Younger and Older Adults}

The age group manipulation in our study was inspired by research showing that emotion processing changes across the life span (for a review, see Ruffman et al., 2008). According to socio-emotional selectivity theory (Mather \& Carstensen, 2003), as people grow older, they realize that their time is limited and focus more on emotionallysatisfying experiences in the present moment. This change arguably leads to the so-called 'positivity effect', observed in studies where young and older adults were compared on emotional processing. For example, when presented with pairs of pictures (a neutral face, and a positive or negative face), older people spent less time inspecting the negative than positive face; i.e., they displayed an attentional bias away from the negative and towards the happy expression. Younger people, by contrast, showed no preference (Mather \& Carstensen, 2003), or preferred negative faces (Isaacowitz et al., 2006). Positivity effects have also been found in the recall of pictures and facial expressions (e.g., Mather \& Carstensen, 2003), or of long-term life events (Kennedy, Mather, \& Carstensen, 2004). In recent years, researchers have discussed the proper characterization of the positivity effect and the experimental conditions under which it can be observed. This has led to a broadening of the definition of the effect, which now includes, not only an increased focus on positive compared to negative information in older versus younger adults, but also a reduced focus on negative information in older adults (see especially Langeslad \& van Strien, 2009; Scheibe \& Carstensen, 2010).

In light of this, given that our study involves the processing of emotional faces and emotional pictures and sentences, we should see differences in the way younger and older adults integrate the information from a negative or positive face with the processing of a negative or positive target sentence and corresponding picture (i.e., a face \(x\) sentence x age interaction). A prediction is that older people should find it easier to integrate a positive face with a positive sentence than a negative face with a negative sentence (i.e., facilitation only for positive sentences, or greater facilitation for positive than negative sentences). For younger people, on the other hand, one may expect equal facilitation for positive and negative sentences, only facilitation for negative, or greater facilitation for negative than positive sentences. Similar modulations by age are predicted for the face-picture congruence effect.

\section*{Methods}

\section*{Participants}

Thirty-two older ( \(60-72\) years, \(M=64.37, S D=3.57\) ) and 32 younger ( \(19-29\) years, \(M=22.90, S D=2.73\) ) adults took part in the experiment in return for a monetary reward; all gave informed consent.

\section*{Materials}

Materials consisted of photographs of emotional facial expressions, emotional pictures and auditorily presented sentences. There were 28 experimental and 56 filler items. Each experimental item consisted of a facial expression (happy/sad), a display showing a positive and a negative picture taken from the IAPS database (Lang et al., 1999) and a sentence describing either the positive or negative picture. The emotional faces were selected from 15 sets of Bielefeld-University student portraits, each set depicting a neutral, a sad and a happy expression. From these sets we selected the 4 best sets ( 2 male, 2 female) based on the results of a valence-rating study ( \(N=18\) ).

The positive and negative images were selected on the basis of the valence ratings in Lang et al., 2008, (negative images: range \(2.42-5.07, M=3.46, S D=1.69\); positive images: range \(5.51-8.22, M=7.19, S D=1.55\) ). Arousal scores of negative and positive images were similar (paired t-test \(t(27)=-.84, p=.41)\).

The sentences for each of the two images of the 28 experimental item-picture pairs fulfilled constraints specific to length, structure and content. All started with an introductory main clause containing a verb of opinion in the first person singular (e.g., I think/believe/am of the opinion that...). This was followed by a subordinate clause about the event depicted in one of the two IAPS images of an item. The subordinate clause contained a subject noun phrase (N1), followed by an object noun phrase (N2), an adverb (Adv) and a final finite verb (Verb). Examples of the positive and negative sentence for an item are given in Figure 1. Care was also taken to match the sentences, so far as possible, by lemma frequency of nouns and adverbs, using frequency counts from the CELEX database (Baayen, Piepenbrock, \& Gulikers, 1995).

The sentences were recorded by 4 native speakers of German, two female and two male, and the speakers assigned to the faces, with 1 male being used for half of the experimental items (14) and 1 female for the other half (14). The sound files of the two experimental sentences associated with an experimental picture pair were edited using professional sound editing software, to ensure that the onsets of the critical words ( \(\mathrm{N} 1, \mathrm{~N} 2\), Adverb) occurred exactly at the same point in time from sentence start in the positive and corresponding negative sentence (to achieve this, pauses were shortened or between-word breaks were lengthened slightly as necessary). The combination of the experimental faces, pictures and sentences yielded a 2 (Face: positive vs. negative) x 2 (Picture: positive vs. negative) x 2 (Sentence: positive vs. negative) design.

For the 56 distractor item picture-pairs, we constructed a sentence that matched one of the two IAPS pictures. The content of half of the distractor sentences (28) was neutral, while 14 contained at least one positive word (e.g., The talented artist is drawing the nice portrait) and the remaining half one negative word (e.g., It is obvious that today the weather will be unbearable). The 56 filler items further differed from the experimental items as follows: the facial expression was either neutral ( 28 items), positive ( 14 items) or negative ( 14 items); both IAPS images had mid-range valence (3.5-6.5); there was only 1 sentence per filler item.

\section*{Procedure}

The experimental session started with the collection of demographic details from the participants, and with the administration of some cognitive tests and of a mood questionnaire. Eye movements were recorded using an SR Research Eyelink 1000 Desktop head-stabilised eye tracker (SR Research, Mississauga, Ontario, Canada). Participants were told that the study investigated language comprehension in relation to a visual display: They would first see the face of a person who was thinking about something and was about to speak, and after that they would hear him/her utter a sentence which described one of the two pictures shown on the screen. The task was to look, listen and understand the sentence, and decide whether the valence of the face matched the valence of the sentence ("Does the face match the sentence?") by pressing one of two buttons. The sequence of events in an experimental trial is illustrated in Fig. 1.

\section*{Analyses and Results}

The data of interest were the participants' fixations on the pictures during sentence processing, i.e., during the time listeners inspect Display 2 (see Fig. 1). Because the initial part of the sentence (cf. Fig. 1, "Ich meine dass") was neutral between the negative and positive sentence, disambiguation towards the positive or negative picture occurred from the initial NP (N1) of the embedded sentence onwards (cf. Fig. 1, "die Mechaniker/die Vorstadtkinder"). Therefore any possible facilitation in the processing of the sentence (face \(x\) sentence interaction) due to having seen a congruent face can only be expected to occur after N1 onset.

By contrast, a face-picture congruence effect (i.e., looks to the pictures as a function of prime face) can occur both before and after sentence disambiguation. We thus defined two time periods: the Post-N1 (onset) region (from the onset of N1 until sentence end (average duration \(4016 \mathrm{~ms}, S D=\) 456) and the Pre-N1 (onset) region (including, in addition to the initial, neutral part of the sentence, the last 1200 ms of the \(1500-\mathrm{ms}\) picture preview period, for a total duration of 3000 ms ). Because our main focus is the face x sentence interaction (and its possible modulation by age), we will first present the findings for the post-N1 onset region.

The measure we used to analyze fixations on the pictures is the mean \(\log\) gaze probability ratio, i.e., the \(\log\) of the ratio of the probability of looking at the negative picture
divided by the probability of looking at the positive picture ( \(\ln (p\) (neg picture) \(/ p\) (pos picture)). This measure expresses the strength of the visual bias towards the negative versus positive picture. It is particularly suited for eye tracking data analyses with parametric tests (such as ANOVAs) because it violates neither independence nor homogeneity of variance assumptions (cf. Arai et al., 2007). The log ratio is symmetrical around zero: A positive log ratio indicates more looks to the negative than the positive picture; a negative \(\log\) ratio indicates more looks to the positive than the negative picture; and a value of zero means the two pictures get an equal number of looks.

Fig. 2 (a)-(b) plots the time course of fixations for the Post-N1 onset region for the two age groups. These graphs are based on log gaze probability ratios (henceforth 'log ratios') computed on successive \(20-\mathrm{ms}\) time slices.

Figure 2: Mean log gaze probability ratios for young and older participants in the Post-N1 onset region, from the onset of N 1 .

In Fig. 2 the sentence effect can clearly be seen in the two sets of lines moving apart from about 500 ms after the onset of N1: The red lines (for the two negative sentence conditions) rise steadily above zero, indicating an increasing preference for the negative picture, while the black lines (for the positive sentence conditions) go in the opposite direction, indicating an increasing preference for the positive picture in these conditions.

A face-priming effect on the processing of the sentence (i.e., the facilitatory effect occurring from having seen a sentence-congruent emotional face) emerges in the relative distance between the solid and the dotted line of each sentence condition: If having seen a face of the same valence as the sentence facilitates sentence processing, the congruent condition (solid line) should be associated with a greater absolute value than the incongruent condition (dotted line).

The log-ratio means for the post-N1 region were submitted to \(2 \times 2 \times 2\) (Face x Sentence x Age) repeatedmeasures ANOVAs with participants and items as random effects. The ANOVAs revealed a significant effect of facepicture congruence ( \(\mathrm{s} \ll .001\) ), with a negative picture preference when the face was negative ( \(M=.15\) ) and a positive picture preference when the face was positive ( \(M=\) -.11 ). This effect was not modulated by age (both \(F\) 's \(<1\) ).

As expected, there was a highly significant sentence effect ( \(p \mathrm{~s}<.001\) ): When the sentence was negative, there was a preference for looking at the negative picture and the opposite was true when the sentence was positive ( \(M \mathrm{~s}=\) 1.65 vs. - 1.61). Importantly, the sentence effect was significantly modulated by age ( \(p \mathrm{~s}<.002\) ). This Sentence x Age interaction is due to the fact that older adults, when hearing a negative sentence, look less at the negative picture (vs. the positive one) than the younger adults; in other words, they are less "responsive" to the negative sentence than the younger group.

Crucially for our experimental hypotheses, the 3-way Face x Sentence x Age interaction was fully significant by participants ( \(p 1=.025, p 2=.13\) ). For our hypotheses, this interaction reflects the facilitating effect of the face on the processing of the sentence and the modulation of this effect by age. Post-hoc pairwise comparisons on participants and items means of the individual groups (i.e., for each age group) compared the two negative sentence conditions and the two positive sentence conditions (Bonferroni correction for 4 comparisons, \(p=05 / 4=.0125\) ). These comparisons can tell us if younger and older participants show different sensitivities to the negative or positive prime face during the processing of the sentence. In the comparisons for the younger participants, only the difference between the two negative sentence conditions was significant ( \(p \mathrm{~s}<.02\) ), while the corresponding comparisons for the older adults yielded only a significant difference between the two positive sentence conditions ( \(p \mathrm{~s}<.02\) ).

Thus, for younger participants a negative prime face (vs. a positive one) significantly enhanced looks to the negative picture during the processing of a negative sentence. By contrast, a positive face had no enhancing effect on younger adults' processing of a positive sentence. For the older group however, the opposite pattern emerged: A negative face had no effect on the processing of a negative sentence, but a positive (vs. negative) face elicited more looks to the positive picture when the positive sentence was processed.

To assess the time course of this facilitation, we performed pairwise comparisons (similar to the ones
reported above for the whole Post-N1 region) on mean log ratios for the individual word regions, i.e., N1, N2, Adverb and Verb (see Fig. 2). For the N1 region, these comparisons yielded a similar pattern of results as in the previous analyses, i.e., older participants showed a facilitation from the positive prime face in the positive sentence conditions ( \(p s<.01\) ), but not in the negative sentence conditions. By contrast, young participants showed significant facilitation in the negative sentence condition ( \(p s<.002\) ), while in the positive sentence condition facilitation was fully significant only in the item analysis ( \(p 1=.06 ; p 2=.02\) ). The only other (nearly) significant comparison occurred for the positive sentences in the adverb region ( \(p \mathrm{~s}<.05\) ): For older adults a positive (vs. negative) face, facilitated the processing of a positive sentence, but a negative face was of no advantage in processing a negative sentence. The fact that results were significant in the early, N1 region for both age groups suggests that the integration of the visual context with facial and linguistic information occurs early and that the time course of this integration does not substantially differ between the two age groups.

In the pre-N1 onset region, the ANOVA analyses on the \(\log\) ratios revealed a face-picture congruence effect ( \(p \mathrm{~s}>\) .02), not modulated by age: The negative picture was fixated longer when the face was negative and the positive picture, when the face was positive. There was also a significant picture effect, with the negative picture attracting overall more looks than the positive one ( \(p s<.02\) ). However, this general bias for the negative picture was weaker for the older participants (the interaction with age was marginally significant in the participants' analysis ( \(p 1=.069 ; p 2=.18\) ).

\section*{Discussion and Conclusion}

These eye-tracking results are important for the following reasons. First, they demonstrate for the first time that priming from an emotional face occurs during sentence comprehension in a visually-situated task (i.e., when language is about objects and actions in the visual context). Moreover, priming effects were found from the early stages of sentence-reference and valence disambiguation (i.e., N1), showing that the seemingly complex integration of visual information from an emotional face, a picture and a sentence happens rapidly and without particular effort. Previous research in visually-situated comprehension tasks has demonstrated that speaker-based information such as gaze is rapidly integrated into sentence processing (e.g., Hanna \& Brennan, 2007; Knoeferle \& Kreysa, 2012). Importantly, our results provide evidence that a speaker's emotional facial expression also has a rapid influence on sentence interpretation.

Crucially also, our results provide new evidence for age differences in the processing of emotional information. All of the age-based modulations that we observed are compatible with a positivity effect, i.e., either an increased focus on positive compared to negative information by older versus younger adults, or a reduced focus on negative information by older adults (Langeslad \& van Strien, 2009;

Scheibe \& Carstensen, 2010). The fact that positivity effects were found in the early stages of sentence processing using a highly time-sensitive methodology such as eye tracking has also implications for the question of the mechanisms underlying the positivity effect, and the level(s) of processing at which these mechanisms operate.

A central tenet of socioemotional selectivity theory is that emotion regulation improves with age and that the positivity effect occurs because older people are capable (consciously or unconsciously) to selectively regulate their emotions in order to enhance positivity and well-being. According to this view, the positivity effect should be strongest in tasks and situations that require controlled processing with associated exertion of cognitive effort, and less so in tasks that measure automatic or initial processing (Scheibe \& Carstensen 2010). Although evidence from several studies suggests that positivity effects require deliberate use of mood regulation strategies to occur (e.g., Isaacowitz, Toner, \& Neupert, 2009), recent evidence has shown that controlled processing and cognitive effort are not necessary to trigger positivity effects in older adults (e.g., Allard, Wadlinger \& Isaacowitz, 2010). We suggest that the positivity effects found in early processing in the eye tracking measures of our experiment are also more likely to be a result of an early and non-strategic emotion processing mechanism.

\begin{abstract}
Research on how information should be presented during inductive category learning has identified both interleaving of categories and blocking by category as beneficial for learning. Previous work suggests that this mixed evidence can be reconciled by taking into account within- and betweencategory similarity relations. In this paper we present a new moderating factor. One group of participants studied categories actively, either interleaved or blocked. Another group studied the same categories passively. Results from a subsequent generalization task show that active learning benefits from interleaved presentation while passive learning benefits from blocked presentation.
\end{abstract}

Keywords: interleaving; blocking; learning; comparison

\section*{Introduction}

Can the method with which information is presented substantially affect learning? The answer seems to be "yes." Changing the way with which information is presented not only changes what is learned (Schyns, Goldstone, \& Thibaut, 1998) but also how well it is learned (Goldstone, 1996). One example is the order in which instances are presented in a study session and the effect this has for inductive learning. Kornell and Bjork (2008) demonstrated that if participants are given study examples of paintings from several artists' interleaved, participants' later memory and generalization is substantially improved when compared to presenting each artist in a separate block.

The advantage of interleaving over blocking for inductive learning has been repeatedly shown in recent years. Interleaving of categories has been shown to improve learning of naturalistic materials for both young and older adults (Kornell, Castel, Eich, \& Bjork, 2010; Wahlheim, Dunlosky, \& Jacoby, 2011), as well as flashcard learning (Kornell, 2009). It has also been demonstrated in children (Vlach, Sandhofer, \& Kornell, 2008; Vlach \& Sandhofer, 2012).

Notwithstanding the clear benefit of interleaving in some situations, there have also been demonstrations of the advantage of blocking for category learning. For example, Goldstone (1996) presented participants with complex images consisting of 20 line segments. There were two conditions: frequent alternation of categories (interleaving) and infrequent alternation (blocking). The results showed that participants were better at learning the categories in the
infrequent alternation condition. The author associates this advantage with the relative difficulty in finding the common features shared by members of each category (for further evidence of blocking advantages using different kinds of tasks and stimuli see Kurtz \& Hovland, 1956; Whitman \& Garner, 1963).

Given this mixed evidence about the best way to sequentially present information for optimal learning, an important question is: what conditions yield an advantage for interleaving compared to blocking?

This question has received some attention in recent years. For instance, Carvalho and Goldstone (2012) showed that when studying low similarity categories, blocked presentation resulted in improved subsequent generalization performance. This pattern was reversed for high similarity categories (for similar results with category discriminability, see Zulkiply \& Burt, 2013).

Carvalho and Goldstone (2012; see also Goldstone, 1996) have proposed that interleaving categories allows participants to identify the features that distinguish between the categories, while blocked presentation promotes the identification of features that are characteristic among stimuli within a single category. This dichotomy is the result of the same principle: the selective emphasis of categorization-relevant features during comparison of sequentially presented objects.

In the case of interleaved presentation, differences between objects belonging to different categories will be emphasized while for blocked presentation, similarities among objects belong to the same category will be emphasized. This same process will result in improved or hindered learning depending on whether similarities or differences need to be learned. One possible way in which category learning could move from an emphasis on differences towards an emphasis on similarities is by changing the similarity relations within and between categories (Carvalho \& Goldstone, 2012; Zulkiply and Burt, 2013).

However, the characteristics of the categories being studied are not the only factors that can have an influence on how sequential comparison impacts learning. In theory, any property of the learning situation that changes attentional constraints could have similar impact by changing the task
demands from an emphasis on similarities to an emphasis on differences.

Inductive learning can take place in several ways. One such way is active category learning. In this kind of learning task, participants actively try to categorize never-beforeseen stimuli into one of the categories provided. Participants are then given feedback on the accuracy of their responses. Learning takes place via feedback-informed update of perceptual, attentional and decisional processes.

Another kind of inductive learning task can be referred to as passive learning. In this kind of situation, participants study category exemplars along with their correct category assignment. This task can be considered 'passive' in the sense that participants do not actively make responses during learning, and no feedback is provided via which a participant could adjust their judgments.

These two tasks differ in a number of educationally relevant aspects (e.g., motivation, engagement, etc.) but also in their cognitive aspects. It could be argued that if participants actively study the categories, emphasis will be placed on finding the differences between the categories. This is perhaps the most obvious way one can learn to discriminate As from Bs and achieve good performance. By contrast, in passive learning, participants are not tasked with learning how to discriminate between the categories. They are explicitly given the category assignments for the stimuli. Instead participants may search for features that characterize each category or the similarity amongst objects in each category.

Put another way, if participants passively study the stimuli along with their correct category assignments, their self-imposed task may be to identify the features that characterize that category (e.g., that all the 'Zups' have a similar nose shape). By contrast, if participants are not given the category assignment but instead have to try to categorize the stimulus and only then receive feedback, they may focus on finding differences between objects of different categories (e.g., that 'Zups' are round and 'Rikes' are squares; see Markman \& Ross, 2003; Yamauchi \& Markman, 2000).

Following Carvalho and Goldstone's (2012) proposal, combining interleaved study with active study will be beneficial for category learning because they are both compatible with focusing on features that differentiate between the categories being acquired. Likewise, combining blocked study with passive learning should be beneficial because they are consistent in leading participants to find similarities that are useful for successfully learning each category in isolation.

In this paper we aim to extend previous evidence for a comparison and attentional mechanism as the unifying processes behind both blocked and interleaved study, by manipulating the properties of the study session that affect attention allocation. One group of participants completed a passive study session associated with both interleaved and blocked presentations. The other group of participants
completed an active study session, while keeping all other aspects of the task constant between the two groups.

\section*{An Experiment}

In this experiment, participants studied a set of six categories, three presented interleaved and the remaining three presented blocked. Critically, for one group of participants, the study session was set up as a passive learning task. Participants studied each object for a short period of time during which the correct category assignment was also presented on the screen. For the other group of participants, the categories were studied in an active learning task. Both groups completed the same generalization task afterwards.

\section*{Method}

Participants Eighty-one undergraduate students at Indiana University volunteered to participate in return for partial course credit. Data from seven participants in the passive learning group were excluded from analyses due to failure to repeat the label of the object just presented on more than half of the total number of study trials (see bellow for details). All participants in the active learning group reached the criterion of \(34 \%\) correct responses during study and their data were kept for analyses.

Figure 1: Examples of one exemplar of each of the 6 categories used. The top row constitutes one group of categories and the bottom row another group.

Apparatus and Stimuli In this experiment, stimuli were "Fribble" objects (Williams, 1998). Three of the categories were composed of very similar objects differing diagnostically only in one of their parts (see top panel in Figure 1). The other three categories were also very similar and differed diagnostically from each other only in one of their parts, however, they were substantially different from the other three categories (see bottom panel in Figure 1). Random variation existed in each of the categories but was the same across the three categories in each group.

Each category was given a unique label that perfectly predicted the presence of the unique feature that defined that category. At the start of the experiment, one label was
randomly picked for each category from the pool: beme, kipe, vune, coge, zade, and tyfe (Hendrickson, et al., 2012).

Design and procedure This experiment had two conditions manipulated within-subjects (schedule of presentation: blocked category learning and interleaved category learning), and two conditions manipulated between-subjects (study type: active vs. passive). Each of these four conditions was composed of a study and test phase.

Study phase For the passive study group, during this study phase, participants were presented with a stimulus in the center of the screen along with the correct category assignment above the object for 2.5 s . Immediately after the presentation of the stimulus, three buttons were shown on the screen corresponding to the three possible category names for that study session. The participants' task was to press the button corresponding to the category of the object they just saw. This task was introduced to ensure participants' attention to the task and to equate the active and passive learning situations for the presence of a motor response. However, note that in this condition, participants simply needed to repeat the category they had just seen. There was no need for participants to learn a categorization rule. The mapping between the position of the buttons on the screen and the label was randomly shifted each trial.

For the active learning group, participants were presented with a stimulus for 500 ms . without its label. After the stimulus was removed, three buttons were shown on the screen and the participant had to choose the category assignment for that stimulus. After the participant's response, the stimulus along with the correct category assignment was shown on the screen for 2 s . The mapping between the position of the buttons on the screen and the label was also randomly shifted each trial.

For both groups, a 1000 ms inter-trial interval followed the trial and then the next trial began. In the blocked condition, the categories presented alternated \(25 \%\) of the time while in the interleaved condition they alternated \(75 \%\) of the time. That is, in the interleaved condition, the probability of an object being followed by an object of the same category was low, whereas for the blocked condition this probability was high. We used this probabilistic approach rather than creating purely interleaved or blocked conditions in order to diminish the possibility that participants noticed the pattern of alternation in responses, which would affect categorization accuracy. Furthermore, if a purely blocked condition had been used there would be no way to guarantee participants' attention to the task, as there would be no uncertainty as to the correct categorization. This approach has been used before in similar tasks with successful results (Carvalho \& Goldstone, 2012; Goldstone, 1996).

Each study phase was composed of 4 blocks for both groups of participants and the entire study phase took approximately the same amount of time for each group. Each block had 24 trials (4 exemplars of each category
repeated 2 times each). After the 4th block of study a new set of instructions was presented on the screen and the second phase began. Each participant completed two sets of study and test phases (one for each schedule of presentation).

The two schedule conditions (blocked vs. interleaved) differed only in the frequency of category change during study and the species labels. Which condition was presented first was counterbalanced across participants and the allocation of the stimuli to each category and condition was randomized across participants.

Test Phase This second phase was a generalization task during which 36 stimuli were shown in random order - the 12 blobs participants studied during the learning task and 24 new stimuli. The new stimuli were similar to the studied stimuli, with new instantiations of the unique features. Each stimulus was presented in the center of the screen for 500 ms , after which participants were asked to classify it into one of the species just learned, by pressing a key on the screen. After a 1000 ms inter-trial interval, a new trial would begin. No feedback was provided during this phase. Each test phase followed the respective study phase.

\section*{Results}

We started by analyzing participants' performance during the study phase in the active learning group. As can be seen from Figure 2, participants' performance improves across the task for both the interleaved and blocked conditions.

\section*{Study Phase - Active Learning}

Figure 2: Results from the Study Phase for the Active Learning group. Error bars indicate standard errors of the mean.

A within-subjects ANOVA with Block (1 vs. 2 vs. 3 vs. 4) and schedule of presentation (interleaved vs. blocked) as factors confirmed this interpretation. There is a main effect of Block, \(F(3,111)=139.93, p<.0001, \eta_{G}^{2}=0.36\). No
main effect of schedule of presentation, \(F(1,37)<1\) was found but the interaction between the two variables was also significant, \(F(3,111)=4.15, p=0.008, \eta_{G}^{2}=0.03\), indicating a larger improvement for the interleaved condition compared to the blocked condition.

However, the result of greater interest is how well participants are able to generalize this learning to new stimuli. These analyses will not only allow us to test the effect of interleaving vs. blocking and of passive vs. active learning but, more importantly, the interaction between the two.

\section*{Test Phase}

Figure 3: Main results of the Test Phase for both the Active and Passive groups and for each of the schedule of presentation conditions. Error bars indicate standard errors of the mean

The graph depicted in Figure 3 shows performance in the generalization task for participants in the active and passive study conditions and for each study presentation format. Given the overall high level of performance we began by analyzing possible differences in response time. No main effect or interaction between any of the variables was found for RT.

We then proceeded to analyze performance differences. The most obvious result is an interaction between the study condition and the presentation format. While for participants studying the stimuli actively, interleaving presentation of the objects results in better generalization performance, blocking is better for participants in the passive learning condition.

A mixed ANOVA with presentation schedule (blocked vs. interleaved) as a within-subject factor and study type (passive vs. active) as a between-subjects factor confirms this analysis. There is no main effect of presentation schedule, \(F(1,73)<1\) or study type, \(F(1,73)<1\).

However, the interaction between the two variables was reliable, \(F(1,73)=7.30, p=.04, \eta_{G}^{2}=0.03\).

Performance results for each group and schedule of presentation, sub-divided by studied and novel stimulus, are presented in Table 1. As can be seen, no differences in performance between novel and studied stimuli were found. We repeated the ANOVA analyses with stimulus type (studied vs. novel) as another within-subject factor. These analyses revealed the same critical interaction between schedule of presentation and study type, but no differences in performance for novel and studied stimuli or interaction with any of the other variables.

Table 1: Categorization accuracy in the test phase for both groups and schedule conditions, broken down by type of item (novel vs. studied). Standard deviations are presented in parentheses.

\section*{Discussion}

Determining how to order information so that learners can achieve the best learning outcomes is crucial for effective training. In this work we present further evidence that the way information is ordered impacts learning and that this influence is modulated by whether learning is active or passive.

The results of the experiment presented here show that whether interleaving examples of several concepts or blocking examples by category is beneficial is a function of the training task's implicit demands. More specifically, in a task involving discrimination of the concepts being studied by identifying their differences (the active learning situation), interleaved study results in better performance in a subsequent generalization task. However, if the learning situation involves creating a positive, stand-alone representation of the concepts by identifying the similarities among the instances within each category (the passive learning situation), blocked study benefits performance in the generalization task.

Interestingly, both study conditions result in similar performance during the learning task in the active learning condition. This eliminates the possibility that one study condition is more difficult and results in greater cognitive effort, which is a known important factor contributing to improved learning (Bjork, 1994).

In the generalization task, the interaction between the type of study situation and the schedule of presentation of the
exemplars had an effect for both studied stimuli and novel ones. This is an interesting result, suggesting that study benefits go beyond memorization of the whole exemplars. Very likely, participants succeeded at the categorization task by identifying the single defining parts for each category. These defining parts were instantiated identically for studied and novel objects, explaining why novel objects were not more difficult to categorize. Future research will be needed to assure that the interaction between learning activity and presentation schedule generalizes to other category structures.

Overall these results are consistent with the framework proposed by Carvalho and Goldstone (2012; see also Goldstone, 1996) hypothesizing that participants compare successive objects and update attention to stimulus features as a result of these comparisons.

The role of allocating one's attention during category learning has been highlighted before in different models (Kruschke, 1992; Love, Medin, \& Gureckis, 2004; Minda \& Smith, 2002; Nosofsky, 1986) and the use of eye tracking technology has made it possible to study the patterns of overt trial-by-trial, or even within-trial, attention. For example, Blair, Watson, Walshe, and Maj (2009) have demonstrated that in a categorization task, different stimuli can elicit different patterns of attention allocation to their features. Additionally, previous research has also demonstrated that during category learning, participants often take into account information from only the previous few trials to decide whether a stimulus belongs in one category or another (Jones, Love, \& Maddox, 2006; Jones \& Sieck, 2003; Stewart, Brown, \& Chater, 2002; Stewart \& Brown, 2004; Stewart \& Chater, 2002).

Carvalho and Goldstone (2012) propose that when studying a new exemplar in an inductive learning task, participants compare the properties of that object with the properties they recall from the previous ones. However, learners do not remember all the features from all the objects presented. Instead, when studying a new exemplar, learners weight more heavily the information presented in the immediately preceding instances. If the previous trial consisted of an object in one category and the current trial consists of another object in a different category, participants' attention will be directed towards the differences between the two objects. Conversely, if the two objects come from the same category, learners will attend to similarities between the objects.

This framework can aptly account for the results presented here: passive learning requires attending to similarities, while active learning requires attending to differences. When the presentation order also emphasizes those factors, learning will be facilitated.

Finally, although our results do not directly speak to the importance of active vs. passive learning, it is worth noting that this interaction should be taken into account when deciding whether learners should be given worked examples to study or not.

Indeed, we think one of the most important contributions of the present work is the proposal that when deciding how to structure learning, one needs to take into account the entire learning situation and possible interactions between situational factors. So far, we have demonstrated this for interleaving/blocking benefits relative to the training activity (passive vs. active) and the similarity structure of the categories being studied (similar vs. dissimilar; Carvalho \& Goldstone, 2012).

\title{
An eyetracking study of children's relational thinking: The role of labels and sustained attention
}

\author{
Paulo F. Carvalho, Catarina Vales, Caitlin M. Fausey \& Linda B. Smith \\ (\{pcarvalh, cvales, cfausey, smith4\} @indiana.edu) \\ Department of Psychological and Brain Sciences, Indiana University, 1101 E. Tenth St., Bloomington, IN 47405 USA
}

\begin{abstract}
Relational match-to-sample is a difficult task for young children. However, it has been shown that either presenting two examples of the relation or adding a label to a single presentation can improve children's performance. The role of labels has been seen as increasing the likelihood of comparing the instances available. In this paper, we present sustained attention as an alternative to this view. Children completed a relational match-to-sample task in different conditions while an eyetracker registered their eye movements. When only one instance was available, children benefited from the addition of a label. This benefit was associated with an overall decrease in switching behavior, indicating greater sustained attention. Moreover, in the absence of a label, children who showed greater sustained attention were able to achieve good performance by the end of the task.
\end{abstract}

Keywords: relational matching; comparison; sustained attention; labels; language and cognition; eyetracking.

\section*{Introduction}

Relational thinking is a fundamental activity of human cognition and everyday experience and might be uniquely human (Gentner, 2003). For example, knowing why both "left shoe goes with right shoe" and "left glove goes with right glove" entail a sameness relation transcends the properties of individual shoes and gloves. This kind of thinking involves going beyond superficial properties of stimuli and noticing the underlying commonalities and differences (Gentner, Rattermann, Markman, \& Kotovsky, 1995). Relational thinking, however, is a developmental feat: early in life, children appear to categorize based primarily on perceptual features, and only begin to attend to the relational properties of the objects after four years of age (Gentner \& Namy, 1999; Loewenstein \& Gentner, 2005).

One typical task used to study relational thinking in children is the relational match-to-sample task (see Figure 1 for an example). In this kind of task, children are presented with an object that instantiates a relational property (the sample) and are then presented with two choices where only one matches the relational property instantiated by the sample. The youngest children in this task do not reliably pick the object that matches the relation depicted in the sample. The research reported here concerns two task manipulations that have been shown to increase relational matching in young children.

\section*{How to promote relational thinking: Compare instances}

Multiple instances If given the right amount of support, children can succeed at the initially difficult task of relational match-to-sample. One way this can be achieved is by presenting multiple examples in the same trial (comparison). For instance, Christie and Gentner (2010) showed 3- and 4 -year old children cards depicting the relation of sameness. Children saw either only one card (solo condition), or two cards simultaneously (comparison condition) or two cards sequentially (sequential condition). Only children who saw two sample cards simultaneously reliably picked the relational match between two choice cards. Multiple instances have been proposed to benefit relational reasoning by encouraging comparison of the instances.

The benefits of multiple instances have been shown many times in children in a variety of tasks (Gentner \& Namy, 1999; Loewenstein \& Gentner, 2001; Namy \& Gentner, 2002; Oakes \& Ribar, 2005; Pruden, Hirsh-Pasek, Shallcross, Golinkoff, 2008; Wang \& Baillargeon, 2008) and also in adults (Gentner, Loewenstein, \& Thompson, 2003; Gick \& Holyoak, 1983). In the context of relational matching, "comparison" has two meanings: (1) the name of the task manipulation of the simultaneous presentation of another object that, although perceptually different, instantiates the same relation and (2) the presumed psychological mechanism that leads to better performance, that is, joint (or temporally close) inspection of the instances which fosters the discovery of deep relational similarities.
Label a single instance Another way to improve children's performance in the relational match-to-sample task is by labeling an original instance.

For example, Christie and Gentner (2007) presented 4and 8 -year old children as well as adults with only one sample instantiating the relation of 'sameness' and then asked participants to pick which of two options matched the sample. When the sample was not labeled, only the adults reliably picked another card instantiating sameness in this condition. However, when a label was added during the presentation of the original sample (e.g., "Look, this is a truffet!'"), children reliably picked the relational match and even adults' performance improved. It has been proposed that labeling benefits performance through comparison, this is, that a label prompts people to compare the original
sample to each choice, and through this comparison they discover relations (Christie \& Gentner, 2007; Gentner \& Namy, 1999; Namy \& Gentner, 2002).

In sum, presenting multiple instances, or labeling an instance, is hypothesized to invite comparison at some point during the relational match-to-sample task and this comparison supports successful relational matching.

\section*{A role for sustained attention?}

The fact that two rather different manipulations - adding another instance and labeling one single instance - help children to discover matching relations should provide insight into a more precise specification of the processes (i.e., of comparison) that limit children's relational comparisons. Our working hypothesis is that each of these manipulations change how children visually inspect instances, perhaps when initially presented or during the difficult step of figuring out what choice to make. One possibility is that when multiple instances are available, children may establish links between the two samples by looking back and forth between them. They may also switch between these samples and the choice options, as they try to make their decision, which may also link the instances and choices and thus reveal the common relations (see Vurpillot, 1968). The process of switching among instances could be the critical behavior that highlights relational similarities between the objects and foster relational choices.

But why would a label encourage switching? The addition of a label to a single sample has been interpreted as inviting just this comparison process and more back-and-forth examination of the sample and choices, resulting in more links between the sample and the options and thus the discovery of the underlying common relation (Christie \& Gentner, 2007; Gentner \& Namy, 1999; Namy \& Gentner, 2002). By fostering this sort of sampling, relational similarities can be discovered and children can successfully choose the relational match. Note that this hypothesized mechanism requires two steps: using a label leads to comparison, which then highlights relational features. The power of labels works only through comparison.

However this is not the only way that labels might work to promote relational matching. Using labels has been shown to improve performance across a great number of tasks other than making relational matches in both adults and children (Lupyan, Rakison, \& McClelland, 2007; Waxman \& Leddon, 2011; Vales \& Smith, 2012). One leading possibility on why labels help is that labeling an object increases sustained attention (see Baldwin \& Markman, 1989; McDuffie, Yoder \& Stone, 2006). Sustained attention is generally good for learning in young children (Smith \& Yu, 2013; Yu \& Smith, 2012) and so may be critical to success in challenging tasks. That is, whenever children face challenges, if they can sustain attention to the relevant stimulus information they may be able to move beyond superficial or salient properties to the underlying structure. The power of labels could come, not
from comparisons in the sense of back-and-forth looking, but from more sustained looking to individual stimuli.

A third issue important to understanding how comparison works concerns how performance changes across trials in the task. The two presented hypotheses concern what happens in a single trial. But relational-matching experiments present children with a series of trials that present, successively, instances of the same relation. By definition, successive presentation does not involve direct comparison, but if children remember what they have seen in previous trials, then comparison to items in memory becomes a factor that may affect either back-and-forth comparison or sustained attention. Critically, past research has shown that there can be accrued effects across trials that influence children's relational matching (Gentner, Loewenstein, \& Hung, 2007; Kotovsky \& Gentner, 1996).

The main goal of the current experiment was to test the competing hypotheses about the power of labels to promote relational matching: Either they increase (switch) or decrease (sustain) the rate that children visually sample available information.

If labels work through sustained attention, then we might also see improved performance when sustained attention is present in other ways. In order to detect this, the experiment includes both Multiple and Single instance conditions. The Single No Label instance condition is critical to our analysis as to the best of our knowledge, no research has reported that young children can successfully match relations when they see only one unlabeled instance on each trial. However, labeling this single instance has been shown to dramatically improve performance.

In the case of unlabeled single instances, children might need to accumulate enough evidence to allow them to understand the relation being instantiated across trials. They might only do so if they show sustained attention. Do children who show sustained attention over several trials reach the same level of success as children who got a single labeled sample?

To answer these questions, we designed a novel eyetracking relational match-to-sample task. To examine how labels and sustained attention matter for relational matching over time, we analyzed children's performance across eight trials. To capture how children sample visual information in different conditions, we used eye-tracking technology. We included a full set of four conditions: multiple or single sample, with or without label. As in previous studies, conditions with multiple exemplars (both labeled and unlabeled) should support relational matching. We included these conditions to show that our novel paradigm replicates well-known effects.

By considering learning over time as well as finer-grained measures of visual sampling, this study offers novel insight into the role of labels in children's relational thinking.

\section*{An Experiment}

\section*{Method}

Participants Fifty-eight children ( \(\mathrm{M}=54\) months, range \(=\) 42-68 months) were randomly assigned to one of four conditions: Multiple presentation without label, Multiple presentation with label, Single presentation without label, Single presentation with label. Twenty additional children were recruited but not included in the final sample due to inappropriate calibration, missing video data, refusal to complete the task or eye tracking data missing for more than half of the total number of samples. Children had no known developmental disorders and were reported to have normal (or corrected to normal) visual acuity. Parental consent was obtained for all participants in compliance with the IRB of Indiana University.
Apparatus and procedure Children were seated approximately 211 cm from a 55 '" LED screen. A freestanding Tobii X120 eye tracker (Tobii Technology BA, Stockholm, Sweden) was used to capture children's eye movements at 60 Hz sampling rate. E-Prime software (PST, Pittsburg, PA) was used to control stimuli presentation and to record eye gaze data. Before starting the main experiment, children completed a 9-point eyetracking calibration that was followed by a familiarization to the structure of the task. The main experiment included 8 trials, and each trial consisted of an Exposure phase followed by a Choice phase (see Figure 1). During the Exposure phase, children saw either one exemplar of a same-relation (Single Conditions) or two different exemplars of a same-relation (Multiple Conditions) on the top half of the screen. A prerecorded voice oriented children to the exemplar(s). In the Single No Label condition this prompt was "See this one?" or "This is one". In the Multiple No Label condition we added to the prompts of the Single condition the following prompts: "See this one too? See how they are the same kind of thing?" or "This is one too. They are both the same kind of thing!".

In the Label conditions, on each trial the pre-recorded voice said the name of the Target during the Exposure (e.g. "See this dax?" / "See this dax too? See how they are both daxes?" and "This is a dax" / "This is a dax too. They are both daxes!'"). A different label was used on each trial (dax, ryke, fode, pabe, zup, kiv, mell or cheem), with target-word assignment randomized across participants.

After the original instance(s) were presented, two new exemplars appeared on the bottom half of the screen for the Choice phase: one same-relation (Target) and one different relation (Foil). Children were asked to point to the choice that was "the same kind of thing" (no label conditions) or "another \(\{\) dax \}" (label conditions). Across trials, the Target appeared equally often on the left and right side of the screen. There was no time limit for children's response. The prompts used throughout the experiment were recorded by a female native English speaker at a sample rate of 44.1 KHz .

Figure 1: Schematic representation of the structure of a trial in the multiple and single conditions without label. In the label conditions prompts had a unique label for each trial. The top row represents the Exposure Phase and the bottom row the Choice Phase. Example prompts are presented in the picture for illustration purposes only and were not presented to children.

\section*{Results}

Accuracy Did children successfully find the relational match? In the first four trials, the pattern of responses is consistent with prior findings (see Figure 2). Specifically, children performed above chance when given multiple instances (No Label: \(M=.65, t(14)=3.16, p=.007\); Label: \(M=.62, t(15)=1.94, p=.07)\) and also when a single instance was labeled \((M=.63, t(15)=2.18, p=.04)\). Children who got a single unlabeled instance did not reliably choose the relational match ( \(M=.51, p>.05\) ). Thus as in previous research, both multiple samples and labels support relational matching.

We then analyzed performance during the last four trials of the task to examine if children are able to establish relational matching over several trials. In the second half of the task, only one group of children performed above chance. Children who got single unlabeled instances throughout the task learned over the course of the task and successfully found relations \((M=.63, t(14)=3.16, p=\) .007). Thus, performance did not get better over trials but declined in the multiple samples conditions and improved in the condition usually associated with the poorest relational matching in young children. On the last of the experiment, the single unlabeled condition yielded the highest performance.

Figure 2: Proportion of relational choices for each condition across the task. The dotted line represents chance performance in the task.

Sampling of information How did children sample the visual information that was available to them when making a relational match-to-sample decision? One of the hypotheses for the benefit of labeling in the Single condition is that labels encourage children to compare the sample with each of the choices. An alternative hypothesis is that labels increase sustained attention to each instance. Critically, these two hypotheses make opposite predictions about the number of switches between the sample and choice options: the label either increases switching (more comparing) or the label decreases switching (more sustained attention).

Figure 3: Median number of switches back to the original instances during the choice phase for each condition.

Accordingly, we analyzed how often children switched back to the original sample(s) while they made a decision in each condition (Multiple or Single) in the presence and absence of labels. The results are clear: Children switched less when instance(s) were labeled (see Figure 3).

Adding a label reduced considerably the number of switches for both presentation conditions. An ANOVA looking at the mean number of switches with label condition (Label vs. No Label) and condition (Multiple vs. Single) as between-subject factors revealed a main effect of label, \(F\) \((1,54)=4.74, p=.03\), and no main effect of condition, \(F\) \((1,54)=1.86, p=.18\) or interaction between the two, \(F\) \((1,54)=1.31, p=.26\).

These results are consistent with the sustained attention hypothesis: Less switching would be associated with greater sustained attention on each object. Could sustained attention also be critical for learning over time, as children in the unlabeled Single condition did?

To answer this question we divided children in the Single No Label condition into two groups based on how much children switched from the options back to the sample during the first half of the task. Children who switched back more than the median for the sample were considered "High Switchers" while the remainder was considered "Low Switchers". If the benefit of time in the Single No Label condition were associated with sustained attention during the initial part of the task, Low Switchers would show better performance in the second half compared to High Switchers. Indeed, children who showed sustained attention during the initial learning trials were the children who learned over the task (see Figure 4).

\section*{Switching back to samples - Single Condition}

Figure 4: Proportion of relational choices for the Single No Label conditions across the task as a function of the amount of switching back to the original instances while making the choice. The dotted line represents chance performance in the task.

Although less switching in this condition during the initial part of the task does not result in better performance during
that part of the task it does seem to be associated with improved relational matching performance by the second half of the task. Indeed, only performance of Low Switchers on the second half of the task was significantly above chance levels, \(M=.68, t(7)=3, p=.02\). Moreover, this group's improvement from performance in the first half ( \(M\) \(=.57)\) to the second half is also significant, \(t(7)=2.78, p=\) . 03 .

\section*{Discussion}

Can sustained attention play a role in relational thinking? In answering this question, we need to take into consideration how children sample the information presented and what are the dynamics between sampling and sustained attention.

In the present work we aimed to investigate this question in the context of children's relational thinking - an important cognitive tool in human development. We asked children to match one of two options to a sample relation by visually inspecting the objects. The inclusion of labels, which have been shown to enhance relational matching, did so in the present study on early trials (but not later ones) and also led to more sustained looking and less switching.

Performance in the one-instance condition was particularly informative. This condition has been shown to be particularly challenging to children. Furthermore, to measure children's sampling and attentional behavior we used eyetracking technology. This method allowed us to gain initial knowledge on the dynamics of single presentation of evidence, labeling and relational matching. The evidence from the present work shows that relational match-to-sample performance is related to accumulation of evidence, effective sampling of information and sustained attention.

Behaviorally, the results presented here replicate previous evidence that single presentation of an instance of the relation does not provide enough support for children's relational thinking without the addition of a label. However, if we analyze the progress of children's performance across the task, we see that even in the absence of a label, children in the single condition can achieve above chance performance.
Accumulation of evidence Children who are presented with multiple initial instances of the target relation are more likely to choose the relational match from the beginning. Conversely, children who are only presented with one instance of the target relation in each trial require more trials to achieve this level of performance. Thus, learning the relational structure of objects requires children to relate several instances of the target relation. This can be more easily done when two instances are presented in each trial (Multiple condition).

Our results show that children in the Single No Label condition were able to achieve above change relational match behavior by the end of the task. However, only children who switched less from the choices back to the sample were able to achieve higher levels of performance by the second half of the task. This indicates a role for both
accumulation of evidence and sustained attention on performance in a relational match-to-sample task.
Focal attention and effective sampling Overall, adding a label to the presentation of the original instances decreases the mean number of times children check back to the original instances. This result is in line with previous evidence that labels increase sustained attention to objects (Balaban \& Waxman, 1997; Baldwin \& Markman, 1989; Fulkerson \& Waxman, 2007, McDuffie, Yoder \& Stone, 2006). This increased attention to each object is essential for a better identification of the target relation, particularly when the support from multiple samples is not readily available (the Single conditions).

In sum, the present work demonstrates the important role of sustained attention in learning how to make a relational choice when only one sample is presented. When a label is present in this condition it will increase sustained attention and result in better, faster, learning. In the absence of learning, sustained attention is important in the accumulation of evidence across several individual trials.

The importance of sustained attention is evidently dependent on some switching between the objects to establish relevant links among them. However, it does show an alternative to the hypothesis that comparison involves greater amounts of switching between samples and that labeling improves performance by promoting comparison.

At present, the specific mechanisms that underlie the usual positive effects of simultaneously presented multiple instances, labeling, and accrued effects of repeated trials have all been explained under the rubric of "comparison". The present approach - seeking micro-level behavioral evidence of direct comparison - suggests that all these phenomena are not the same. By pulling these factors that benefit children's relational matching apart, we may get a better handle on the processes that limit relational matching and on just what "comparison" is.

Accordingly, we believe the biggest contributions of the work presented here is the use of a new analysis paradigm to the investigation of comparison benefits to learning across development and the introduction of sustained attention as an important player in relational thinking.

\title{
Investing Amid Uncertainty: A Test of the Domain Specific Anchoring Hypothesis
}

\begin{abstract}
The current study examined reactions to the precision of earnings' forecasts in hypothetical investment decisions. In a forced choice task, participants were found to be indifferent between point (e.g., \$2) or range (e.g., \$1.70-\$2.30) forecast formats when both outcomes were favorable (i.e., above market expectation). When the outcomes were unfavorable (below expectation), participants' preferences were significantly biased towards range estimates. When faced with options which mixed forecast formats and favorability, participants almost always opted for forecasts with a favorable outlook regardless of format. These results are inconsistent with domain specific ambiguity reactions found previously (Du, 2009) and also offer no support for the domain specific anchoring hypothesis (e.g. Du, 2009; Du \& Budescu, 2005). These findings raise some doubts about the generality of domain specific reactions to uncertainty and suggest that such effects might be dependent, in part, on the (financial) sophistication of participants.
\end{abstract}

Keywords: Point; Range; Uncertainty; Ambiguity; Communication; Precision format; Domain specific

Investors often rely on management earnings forecasts when making their investment decisions. However, these forecasts are rarely precise. For example, there is uncertainty surrounding the reliability and credibility of the forecasts, the forecasters might be unsure about the current economic outlook, the market might be too volatile for an accurate forecast to be made and so on. This growing uncertainty that the investors, inevitably, have to face has generated a heated discussion on how best to communicate uncertainty to financial decision makers (Christensen, Glover, Omer, \& Shelley, 2012).

Extant literature has found that managers often communicate uncertainty by incorporating imprecision into their management earnings forecasts (Christensen et al., 2012; Du, 2009; Du \& Budescu, 2005; Du, Budescu, Shelley, \& Omer, 2011). Instead of providing a precise point forecast (e.g. \$1.00), managers issue earnings forecasts in the form of a range estimate (e.g. \$0.60-\$1.40).

These findings are further evidenced in the National Investor Relations Institute survey results (NIRI, 2003). They found that the majority (78\%) of corporate members provided earnings forecasts information regularly and among them, \(75 \%\) use range estimates, whereas only \(11 \%\) choose the precise point formats. In addition, the authors found that, by the end of 2001 , \(55 \%\) of the firms reported their earnings in a range format while only \(23 \%\) issued the earnings forecasts in the form of point estimate (Cotter, Tuna, \& Wysocki, 2006).

\section*{Reactions to Range Forecasts}

Despite the fact that range forecasts are widely used in earnings forecasts, investors' reactions to this format are rather mixed. On one hand, some literature has found that being open about uncertainty by choosing a range disclosure format could not only increase perceived credibility, trustworthiness (Hirst, Koonce, \& Venkataraman, 2008), and investors' confidence in the company (Habicht, 1992) but also reduce the company's legal liability (Hirst et al., 2008).

On the other hand, evidence of range formats not being well-received has also been obtained. Prior research has shown that using the range format has led to reduced investors’ confidence (Hirst, Koonce, \& Miller, 1999), heightened risk perception (Han et al., 2009; Kuhn \& Budescu, 1996), negative affective reactions such as worry or distress related to choice outcomes and avoidance of decision making in choice situations (Camerer \& Weber, 1992; Han, Moser, \& Klein, 2006).

Mixed reactions towards range forecasts were also highlighted in participants' comments that, although they felt that range forecasts were more trustworthy and informative than precise point format, the range format has led them to question the company's competence and ability in estimating the uncertainty and risk involved (Dieckmann, Mauro, \& Slovic, 2010; Johnson \& Slovic, 1995).

In terms of people's understanding of the information conveyed in the range format, past studies reported that participants felt that range forecasts were more complicated and harder to understand (Han et al., 2009; Johnson \& Slovic, 1995), even for highly educated and professional participants (Sheridan \& Pignone, 2002).

\section*{Domain Specific Ambiguity Reactions}

Driven by the mixed findings between the reactions to point and range earnings forecasts, Du (2009) conducted a study to clarify how investors react to forecasts in different presentation formats and with different outcome favorability. In Du's study, MBA students were asked to evaluate four different investment options based on the brief company background information provided and also their respective CEO's forecasts of next year's earnings presented either in a point or a range form. Specifically, the participants were given prediction of the Earnings Per Share (EPS) for next year.

Furthermore, participants received information about the performance of the company relative to a benchmark.

Participants were told whether the forecasts were higher (indicating positive/favorable performance) or lower (negative/unfavorable performance) than market expectation. Having read the descriptions and forecasts information, the participants made a series of judgments, including earnings prediction, confidence, investment, risk and likelihood of investment decisions.

Drawing evidence from the literature on decision making under ambiguity (e.g. Camerer \& Weber, 1992; Du \& Budescu, 2005; Ellsberg, 1961), Du predicted that investors would display ambiguity attitudes which were domain specific. In other words, in the domain of favorable outcomes, participants would seek ambiguity and react positively to range forecasts whereas in the domain of unfavorable outcomes, participants would avoid ambiguity and react negatively to range forecasts.

Du (2009) found that precision format had no effect on investors' earnings predictions, confidence and risk judgments. However, partial support for the domain specific hypothesis was found in that when the outcomes were favorable (i.e. the forecasts were higher than market expectation), participants preferred ambiguity and invested more when the forecasts were presented in a range rather than in a point format. However, no such finding was found when the outcomes presented were unfavorable (investment was equally low in both range and point formats).

Du's (2009) findings are consistent with Viscusi and Chesson's (1999) findings that participants' reactions to ambiguity was driven by the "hope and fear" effects. Viscusi and Chesson found that when the situation generates a 'fear' effect (or a small possibility of loss), people are more averse to ambiguity whereas when the situation generates a 'hope' effect, people are more inclined to seek ambiguity. Du's favorable forecasts could have generated a 'hope' effect, and hence, driven participants to seek ambiguity and invest more in companies with range forecasts.

\section*{Domain Specific Anchoring Hypothesis}

Du (2009) suggested that her findings are consistent with the argument that participants selectively draw information from different focal end points of range estimates when the decision context changes ( Du \& Budescu, 2005). In particular, the domain specific argument posits that participants are more likely to focus on the upper bound of the range and seek ambiguity (or imprecision) when there is a potential for gains, but they are more likely to focus on the lower bound of the range and avoid ambiguity when there is a potential for losses (hereafter referred to as the domain specific anchoring hypothesis). Du's finding that people invested more in companies with range forecasts when the outcomes were favorable could be the result of a preference for the higher earnings values when participants compared the upper end of the range forecasts with the point forecasts.

Furthermore, this domain specific anchoring hypothesis has been linked to goal framing theory. Budescu, Kuhn and colleagues (2002) argue that investors are motivated by the
goals to maximize gains and to minimize losses in the financial market, and thus, anchor their judgments on different focal end points in different contexts. In the domain of gains, participants anchor their judgment on the upper end of the range estimates so as to maximize the potential gains and vice versa in the domain of losses in order to minimize their potential losses.

\section*{Aim and Hypotheses}

Whilst evidence shows that the domain specific argument is well-established, thus far, no research has tested this hypothesis directly in the context of investor decisions. Therefore, the current study examined the prevalence of domain specific ambiguity reactions and tested the extent to which these findings could be explained by the domain specific anchoring hypothesis. The current study adapted a method used by Du et al. (2011) and presented participants with eight forced choice options differing in the forecast format, predicted outcome favorability and forecasts values. After they read the brief descriptions of the two forecasts, participants evaluated the informativeness, accuracy and credibility of each form of presentation.

Prior to indicating their preference of investment in the two options, they were required to predict where the actual earnings would fall. That is, for the point forecasts (e.g., \(\$ 2.00\) ), they estimated the probability of the actual earnings being lower than, exactly at, and higher than the point estimate. For the range forecasts (e.g., \$1.70-\$2.30), participants indicated the probability of the actual earnings to be lower than the lower end, exactly at the lower end, between the range, exactly at the higher end, and higher than the higher end of the range forecasts (hereafter referred to as the anchoring task). Their responses served as an indication of where they anchored their judgments when making the investment decision under different domains.

In accordance with Du (2009), it was predicted that participants would show domain specific ambiguity reactions, that is, participants would show ambiguityseeking behavior when the forecasts were favorable (i.e., prefer range over point estimates) and ambiguity-averse behavior when the forecasts were unfavorable (i.e., prefer point over range).

Furthermore, it was expected that these patterns of responses could be explained by the domain specific anchoring hypothesis. We predicted that the participants' estimates of the actual earnings to be more likely to occur at the higher end of the range estimates when forecasts were favorable and given that this upper end estimate was higher as compared to the point estimate, they would be more inclined to choose range forecasts when they saw favorable outcomes. In a similar vein, we predicted participants would anchor more on the lower end of the range estimates when the forecasts were unfavorable and since this lower bound estimate was lower than the comparative point estimate, participants would prefer point estimates more when the outcomes were unfavorable.

In terms of informativeness, accuracy and credibility, it was predicted that point estimates would be rated as more accurate than range ones ( \(\mathrm{Du}, 2009\) ), and that as the imprecision increased, the perceived informativeness (Kim \& Verrecchia, 1991) as well as its credibility (Longman, Turner, King, \& McCaffery, 2012) would decrease.

\section*{Method}

\section*{Participants}

Thirty Psychology undergraduate students from the University of New South Wales participated (70\% male, \(M_{\text {age }}=19.5\) year-old, \(S D_{\text {age }}=2.2\) ) in return for course credit.

\section*{Experimental Design and Measures}

This study employed a 2 (forecasts format: point vs. range) X 2 (forecasts favorability: favorable vs. unfavorable) X 2 (forecasts values: high vs. low) withinsubject design. Participants were asked to assume the role of an investor and to assess a number of investment options that varied in three dimensions: (1) earnings forecasts format, (2) forecasts favorability, and (3) forecasts values.

Forecasts Format The earnings forecasts (i.e. EPS) were presented either in a point (e.g. \$2.00) or a range (e.g. \(\$ 1.70-\$ 2.30\) ) format. These two formats were considered to be informationally equivalent because the midpoint of the range estimate always matched the point estimate. The width of the range estimates was fixed at \(\$ 0.60\).

Forecasts Favorability Similar to Du (2009), benchmark information for each forecast was provided to indicate the overall performance of the company. Participants were asked to assume that an earnings forecast that was higher than market expectation indicated good performance whereas one that was lower than market expectation indicated poor performance.

Forecasts values Prior research has shown that investors' decisions were affected by the expected earnings values ( Du \& Budescu, 2005). Thus, the absolute values of the current earnings forecasts were also manipulated. Half of the estimates were high in values (with a midpoint of \(\$ 5.00\) or \(\$ 6.00\) ) while the remaining half was low in their absolute amount (with a midpoint of \(\$ 1.00\) or \(\$ 2.00\) ).

\section*{Procedures}

Subsequent to providing informed consent, participants were given earnings forecasts of two companies and asked to indicate which company they would invest in. They could also express indifference between the two options. However, prior to making their investment decision, they were required to evaluate the informativeness, accuracy and credibility of each of the formats on a 6-point scale (1: Not at all, 6: Very). Then, they were instructed to complete the anchoring task for each form of presentation. After
completing the rating and anchoring judgments, the respondents made their investment decision.

The two forecasts formats and two favorability outcomes yielded four possible combinations of the two dimensions:
1. Range favorable vs. Point favorable
2. Range unfavorable vs. Point unfavorable
3. Point favorable vs. Range unfavorable
4. Point unfavorable vs. Range favorable

For example, participants comparing statements in the first combination would evaluate "Company PA with a predicted EPS of \(\$ 2.00\), which is higher than market expectation" (point favorable statement) and "Company QC with a predicted EPS in the range of "\$1.70-\$2.30, which is higher than market expectation (range favorable statement). Altogether, participants completed eight forced choice options, two versions (a high and a low absolute value version) for each combination.

\section*{Results}

Table 1 displays the distribution of investor's preferences of forecasts format and outcome favorability across high and low earnings values. Contrary to prediction, the pattern of responses did not show that participants favored range (point) forecasts when the outcomes were favorable (unfavorable). Instead, Table 1 shows that when the outcomes were favorable (comparison 1), participants were about equally likely to choose the company with point or range forecasts. When the forecasts were unfavorable (comparison 2), participants were biased towards choosing range estimates. However, in situations where there was a mix between forecast format and outcome favorability (comparisons 3 and 4), participants almost always opted for the ones with favorable outlook, regardless of format.

A statistical analysis was conducted to examine if these differences were statistically significant. Participants’ choices were coded into an index of preference for precision. As in Du et al. (2011), a preference for point forecast was given a value of 0 whereas a preference for range forecast was given a value of 1 . Indifferent (or "Either") option was assigned a value of \(0.5^{1}\). A mean preference score was calculated with a mean of less than 0.5 indicating a preference for point estimates and a mean score of more than 0.5 indicating a preference for range forecasts. A one-sample t-test, with a test-value of 0.5 , was conducted and support for the patterns of responses aforementioned was found (see Table 2).

In short, no evidence of domain specific ambiguity reactions was found. As can be seen in Table 2, participants seemed to prefer range estimates more especially when the forecasts were unfavorable, and when they were faced with a choice with mixed forecast format and outcome favorability, their decisions were almost always swayed by the favorability of the outcomes.

\footnotetext{
\({ }^{1}\) A further analysis showed that excluded indifferent responses did not alter the statistical pattern of effects.
}

\section*{Domain Specific Anchoring Hypothesis}

The distributions of participants' predictions about the range and point forecasts are summarized in Figure 1. Figure 1 shows, overall, participants estimated that the actual earnings were more likely to be in between the range estimates and exactly at the point estimate. The participants also appeared to believe that the actual earnings were roughly equally likely to occur at the different focal end points, regardless of decision context.

Recall that the domain specific anchoring hypothesis predicted that participants’ allocation of the probability judgments at the different end points would differ as a function of favorability of the outcomes. Specifically, the hypothesis predicts that participants will anchor their judgments at the lower end of the range forecasts when the outcomes were unfavorable, but at the upper end when the outcomes were favorable. The data plotted in Figure 1a seem to show no support for this anchoring hypothesis.

In order to test this prediction statistically, an average of participants' responses at the lower ends (i.e. both 'exactly at lower bound' and 'lower than lower bound') and the upper ends (i.e. both 'exactly at upper bound’ and 'higher than upper bound') of the range estimates were calculated. T-tests were then carried out to examine if participants’ prediction of the occurrence of the actual earnings at the lower and upper ends would differ as a function of outcome favorability. No significant differences were found. The results indicated that participants believed that the actual earnings were equally likely to occur at the lower and upper ends regardless of outcome favorability, \(t(29)_{\text {lower }}=-.408\), \(p_{\text {lower }}=.686\) and \(t(29)_{\text {higher }}=1.378, p_{\text {higher }}=.179\) respectively.

Similar analyses were also conducted on point forecasts. In accordance with the domain specific anchoring hypothesis, it was predicted that participants would be more optimistic and believe that the actual earnings were more likely to be higher than the forecast when the forecast was favorable, but they would be more pessimistic and consider the actual earnings to be lower than the estimate when the forecast was unfavorable. T-tests revealed that none of the effects were significant, both \(p \mathrm{~s}>.05\).

Collectively, findings from both the point and range analyses showed no support for the domain specific anchoring hypothesis. Participants did not focus on the different end points when the favorability of the outcomes differed.

\section*{Informativeness, Accuracy and Credibility Ratings}

A 2 X \(2 \times 2\) repeated measure ANOVA was carried out on participants' informativeness, accuracy and credibility ratings. Consistent with prior research (Du, 2009), point estimates ( \(M=4.07, S D=1.18\) ) were rated as more accurate than the range forecasts \((M=3.32, S D=0.87), F(1,29)=\)
11.242, \(p=.002\). In terms of credibility ratings, favorable forecasts (or forecasts that were higher than market expectation; \(M=3.26, S D=1.14\) ) were rated as slightly less credible than unfavorable ones (or those that were lower than market expectation; \(M=3.46, S D=1.13), F(1,29)=\) 6.849, \(p=.014\). No other significant effects of forecast formats and favorability on how participants rated informativeness, accuracy and credibility judgments were found.

Table 1. Distribution of preferences of forecast format and outcome favorability across different earnings conditions.
\begin{tabular}{llccc}
\hline & DMs prefer & \begin{tabular}{c} 
Low \\
EPS
\end{tabular} & \begin{tabular}{c} 
High \\
EPS
\end{tabular} & Average \\
\hline 1. Point Fav vs. & Point Fav & 11 & 9 & 10 \\
Range Fav & Range Fav & 15 & 18 & 16.5 \\
& Either & 4 & 3 & 3.5 \\
2. Point Unfav vs. Point Unfav & 5 & 8 & 6.5 \\
Range Unfav & Range Unfav & 17 & 14 & 15.5 \\
& Either & 8 & 8 & 8 \\
3. Point Fav vs. & Point Fav & 17 & 22 & 19.5 \\
Range Unfav & Range Unfav & 8 & 6 & 7 \\
& Either & 5 & 2 & 3.5 \\
4. Point Unfav vs. Point Unfav & 6 & 3 & 4.5 \\
Range Fav & Range Fav & 21 & 23 & 22 \\
& Either & 3 & 4 & 3.5 \\
\hline
\end{tabular}

Note: DM = Decision Makers; EPS = Earnings per share; Low EPS = EPS with low values (with a midpoint of \(\$ 1.00\) or \$2.00); High EPS = EPS with high values (with a midpoint of \(\$ 5.00\) or \(\$ 6.00\) ); Fav = Favorable; Unfav = unfavorable, Either = indifferent between the two options.

Table 2. Comparison of point and range forecasts differing in favorability.
\begin{tabular}{|c|c|c|c|}
\hline & Mean Preference & \(t(29)\) & Sig. (2tailed) \\
\hline 1. Point Fav vs. Range Fav & 0.61 & 1.383 & 0.177 \\
\hline 2. Point Unfav vs. Range Unfav & 0.65 & 2.473 & .019* \\
\hline 3. Point Fav vs. Range Unfav & 0.29 & -3.117 & .004** \\
\hline 4. Point Unfav vs. Range Fav & 0.79 & 4.592 & .000** \\
\hline
\end{tabular}

Note: Ms > 0.5 indicates a preference for range forecasts; \(\mathrm{Ms}<\mathbf{0 . 5}\) indicates a preference for point forecasts
*indicates significance at the .05 level
** indicates significance at the .01 level

\section*{Discussion}

The current study aimed to test the domain specific anchoring hypothesis directly in the context of financial decision making. An examination of investors' preferences for point or range presentation format in favorable and unfavorable contexts revealed no evidence for domain specific ambiguity reactions. Participants did not show ambiguity seeking or avoidance behavior when the favorability of the outcomes changed. A further investigation of participants' anchoring judgments on where the actual earnings would fall also failed to support the domain specific anchoring hypothesis. Somewhat surprisingly, we found that even though participants believed that point forecasts were more accurate than range forecasts, they still seemed to prefer forecasts in range format more than those in point format, particularly when the forecasts were unfavorable. This finding was not affected by the perceived informativeness and credibility judgments on the presentation format.

Interestingly, favorable forecasts were rated as less credible than unfavorable estimates. Given the growing uncertainty in the current economy, participants may be more cautious and skeptical about the forecasts provided. They may feel that favorable forecasts have not sufficiently incorporated the uncertainty in the current economic conditions, and hence, rated them as less credible than unfavorable ones.

Another interesting finding of the present study is that financial decisions are largely dominated by the favorability of the outcomes. In the third and fourth comparisons where forecast format and outcome favorability were mixed, participants almost always selected the ones with favorable outcomes. Given that participants were told to regard 'higher (lower) than market expectation' as an indication of good (poor) performance, it is perhaps unsurprising that the effects of favorability may overshadow the concern for
forecast format when both dimensions are mixed. It would be interesting in follow up work to see if participants' preferences' differ when favorability of the outcomes is manipulated between subjects.

One possibility for why we did not find domain specific ambiguity reactions could be that the current participant pool was psychology undergraduates rather than the MBA students used in Du (2009). Moreover, we did not take into account participants' prior investment experience or knowledge about the stock market. Limited exposure to the financial settings may have affected participants’ understanding of the earnings prediction presented to them making them less susceptible to the influence of the different forecast formats. Future work could examine this role of 'expertise' in reactions to imprecision.

Another difference between the current research and Du's (2009) is that Du employed range forecasts with variable width whereas we used range forecasts with fixed width. The largest range width used in Du's study (i.e. \$1.80) was three times the value of the current width (i.e. \(\$ 0.60\) ). It could be that the domain differences in ambiguity reactions are only found in forecasts with larger range width.

This assertion is further supported by examination of the range width used in Du and Budescu's (2005) study which also found support for domain specific ambiguity reactions. The size of the range width chosen by the authors ranged from \(\$ 2.00\) to \(\$ 32.00\). Although participants in the current study rated range forecasts as different (in terms of accuracy) from point forecasts, the \(\$ 0.60\) range width may still be too narrow, and hence, too subtle to influence their preferences between the two formats.

On the other hand, previous evidence of domain specific ambiguity reactions (e.g. Du \& Budescu, 2005) is not as direct as Du’s (2009). For example, Du and Budescu (2005) found that domain specific ambiguity reactions was task specific. They only found the reversal of ambiguity attitudes in a certainty equivalent task but not in a pairwise
comparison task. Thus it seems that reactions to ambiguity might be dependent on the particular task used to elicit preferences.

Furthermore, in their study, the authors manipulated the sources of uncertainty - whether it is uncertainty in the estimates or in the outcomes (Du \& Budescu, 2005). It could be that the effect of domain specific ambiguity reactions would be stronger when another source of uncertainty is included. Future research specifically focusing on these issues will help to clarify the exact nature of domain specific ambiguity reactions.

In conclusion, we found no evidence for domain specific ambiguity reactions or for the anchoring hypothesis in the context of investment decisions. However, our results revealed that favorability of the outcomes dominates judgments and its effect may have masked the concern for presentation format when both dimensions were mixed. Future research, controlling for the issues discussed, is required to unpack the domain specific observations more thoroughly.

\title{
Producing gestures facilitates encoding of spatial relation
}

\begin{abstract}
This paper examines whether producing gestures would facilitate encoding of spatial relation in a navigation task. In this experiment, we focused on gestures produced without accompanying speech. Adult participants were asked to study spatial sequence of routes shown in four diagrams, one at a time. Participants rehearsed the routes with gestures, actual hand movements (actually drew the routes on papers), or mental simulation. They then were asked to reconstruct the routes with sticks. Participants who moved their hands (either in the form of gestures or actual drawing) recalled better than those who mentally simulated the routes and those who did not rehearse, suggesting that hand movements produced during rehearsal facilitate encoding of spatial relation. Interestingly, participants who gestured the routes in the air recalled better than those who drew them on papers, suggesting that gesture, as a kind of representational action, exerts more powerful influence on spatial relation encoding.
\end{abstract}

\section*{Introduction}

Spatial knowledge consists of three major skills, including spatial visualization, spatial relation, and spatial orientation (Lohman, 1979). The present study focuses on spatial relation. Understanding relational information enables us to form a spatial representation regarding relation between locations, objects, and paths. Such understanding is particularly useful when we are processing spatial information of how starting points and destinations are considered in relation to one another. Therefore, developing techniques to facilitate encoding of spatial relation has received increasing attention from cognitive and educational psychologists all over the world.

In the present study, we examine whether embodied movements like gestures might be effective in encoding spatial relation. Previous research has shown that producing gestures is directly involved in encoding new information but those studies focused on mathematics domain. Children who were told to gesture when explaining their solutions to a math problem benefited more from the subsequent math lesson, compared to children who were told not to gesture (Broaders, Cook, Mitchell, \& Goldin-Meadow, 2007). Children who were instructed to reproduce teacher's gestures while acquiring new mathematics concepts learnt and memorized mathematics knowledge better than did those who were instructed to reproduce teacher's verbal instructions only (Cook, Mitchell, \& Goldin-Meadow, 2008). However, no experimental work has examined whether gestures strengthen spatial relation encoding. Gestures are spontaneous hand movements. They are produced in space, and thus are inherently spatial (McNeill, 1992; 2005). Therefore, learners can exploit the spatial properties of gestures to encode spatial relation between the starting point and destination. For example, when encoding spatial sequence of a route, learners may trace the steps with an index finger in the air by moving it to the right, upwards, and to the right again.

In fact, gestures and spatial relation are tightly linked. Previous studies have shown that speakers produce cospeech gestures (gestures that are co-occurring with speech) when they convey spatial relation to listeners in speech. For example, they use co-speech gestures to depict spatial layout of an area (Emmorey, Tversky \& Taylor, 2000) and spatial arrangement of objects (Sauter, Uttal, Alman, GoldinMeadow, \& Levine, 2012). In addition, previous studies have reported that speakers produce co-speech gestures frequently when they are identifying spatial relation between two characters in narratives (So, Coppola, Liccidarello, \& Goldin-Meadow, 2005; So, Kita, \& GoldinMeadow, 2009). They also increase gesture production
when encountering difficulty in describing complex spatial patterns (Hostetter, Alibali, \& Kita, 2007; Melinger \& Kita, 2007).

The present study asks whether asking participants to produce gestures while encoding spatial relation information would enhance subsequent spatial recall. We here focus on gestures produced while thinking silently (i.e., co-thought gestures, see Chu \& Kita, 2011). If co-thought gestures merely depict spatial relation, then participants who are told to gesture when rehearsing spatial sequence silently should recall comparable number of steps than those who are told not to gesture. However, if co-thought gestures do more than simply conveying spatial relation, i.e., they are involved in encoding and constructing spatial relation, then participants who are told to gesture during rehearsal should recall more steps than those who are told not to gesture.

In order to test the above hypotheses, adult participants were told to study various routes and to rehearse the routes by producing co-thought gestures (e.g., index finger moves up and then to the right). We then compared their recall performance to another three groups of learners who were instructed, respectively, to rehearse the routes by actually drawing them out on papers, to mentally rehearse the routes while having their hand movements prohibited, and to read letters that prevented rehearsal.

\section*{Method}

\section*{Participants}

One hundred and twelve Chinese-speaking undergraduates (53 men, age range: 19-21 years) were recruited and each of them was paid for HKD \(\$ 30\) for their participation. All of them had correct or correct-to-normal vision. All but one participant were right-handed. They were undergraduates at the Chinese University of Hong Kong. The participants were randomly assigned to one of the four experimental conditions: 1) co-thought gesture; 2) actual drawing; 3) hand movement prohibited; and 4) no rehearsal, with 28 participants in each condition.

\section*{Stimuli}

We designed the stimuli that purposefully examined spatial relation. Four diagrams were created by the software "Edraw Max". In each diagram, there were seven vertical lines and ten strokes that were horizontal, diagonal, or curly connecting or not connecting with the vertical lines. The strokes that were connected to vertical lines formed a route navigating from the starting point to the destination. See Figure 1 for one of the diagrams (top) and its route highlighted in red (bottom). For the sequence of this route, one should move down, then move diagonally downwards, move up, move to the right, move down, move to the right, move down, cross the curly road, move up, move diagonally upwards, move down, cross the bridge, and finally move to the destination. There were thirteen steps in each route.

Figure 1. The top figure shows one of the maps tested in this experiment. The bottom figure shows the route navigating from the starting point to the destination.

\section*{Procedure}

Participants were tested individually. They were asked to study four routes, one at a time, and later on describe the routes to an experimenter. Each time they were presented with a diagram that showed a complete route on an A4-sized paper (see the bottom figure in Figure 1). In order to help them to get familiar with the steps, participants were told to trace the complete route twice with a highlighter. They should trace every step and not to pause at any junctions of the route. Then we removed the diagram.

Participants then received different instructions for rehearsal in different conditions. In the co-thought gesture condition, participants were told to rehearse the route from the starting point to the destination with their hands. In the actual drawing condition, participants were instructed to draw the route from the starting point to the destination once on a piece of blank A4-sized paper. Participants were told that they were not required to draw the route in the same scale as that shown in the previous diagram. They were also told that neatness of their drawing would not be evaluated. In the hand movement prohibited condition, participants were told to visualize or mentally simulate the route sequence from the starting point to the destination once while holding a softball in both hands. Then they informed the experimenter when they finished visualizing a complete route. In the no rehearsal condition, participants were given an A4-sized paper with different alphabets randomly printed on it. They were told to read the alphabets aloud for 20 seconds in order to prevent them from mentally rehearsing
the route. Before this experiment, we conducted a pilot study and found that on average participants spent 20 seconds on rehearsing a complete route in the hand movement prohibited condition. Therefore, we asked participants to read letters aloud for 20 seconds. We also expected that reading letters aloud would not interfere with participants' spatial representations because the letters were randomly printed on an A4-sized paper such that they did not form any clear spatial pattern.

Then all participants recalled the route they had just rehearsed. They were given thirteen sticks with the same length and told to reconstruct the route sequence from the starting point to the destination on a table. They were told that they were not required to reconstruct the route in the same scale as that shown in the diagrams.

Before they studied the second route, participants were required to work on a set of mathematics problems for two minutes in order to prevent proactive interference of the directions from the previous route. Then the second diagram was presented and the aforementioned procedures were repeated. The experiment was complete after all four routes were studied. The order of diagrams was randomized across participants. The whole experiment was videotaped.

\section*{Coding}

We measured the average amount of time (in seconds) each participant spent on rehearsing a complete route (including pauses and self-corrections, if any) across four diagrams in different conditions (except the no rehearsal condition). We also examined the mean number of steps participants rehearsed in the co-thought gesture and actual drawing conditions.

We then assessed the accuracy of recall by considering how many steps (out of thirteen) were correctly reconstructed by sticks for each diagram. A step was considered recalled correctly if the direction and sequence of the corresponding stick matched those in the diagram. The mean proportion of steps correctly recalled in each diagram was calculated for each participant, which was the number of steps correctly recalled, divided by thirteen (i.e., the total number of steps in the diagram). We also measured the average amount of time (in seconds) each participant spent on reconstructing each route (including all pauses and hesitations)

Reliability was assessed by having a second coder coded a subset (20\%) of the data. Inter-rater agreement was \(98 \%\) (Cohen's Kappa \(=.95\) ) for measuring the time spent on rehearsal; \(91 \%\) (Cohen’s Kappa \(=.88\) ) for identifying the number of steps rehearsed in the co-thought gesture in the air, and actual drawing conditions; 95\% for determining the accuracy of steps reconstructed (Cohen's Kappa = .92); and \(100 \%\) for determining the duration of reconstruction (Cohen's Kappa = 1).

\section*{Results}

All participants in the co-thought gesture condition gestured when they were rehearsing the routes and most of them used their index fingers. All but one participant gestured with their right hands. On average, participants in the co-thought gesture condition spent 17.86 seconds ( \(S D=2.32\) ) to rehearse a route. Participants in the actual drawing and hand movement prohibited conditions spent 24.81 seconds ( \(S D\) \(=3.14\) ) and 19.18 seconds ( \(S D=1.19\) ) respectively. Oneway ANOVA showed that there was a significant difference in the rehearsal duration among different conditions, \(F\) (2, 82) \(=12.19, p<.001\). Tukey posthoc tests showed that the time spent on rehearsing a complete route in the actual drawing condition was significantly longer than that in the co-thought gesture, \(\mathrm{p}<.001\), and hand movements prohibited condition, \(\mathrm{p}<.002\). There was no difference between co-thought gesture and hand movement prohibited conditions, \(p s=n s\).

The mean number of steps participants rehearsed in the co-thought gesture was \(11.83(S D=3.54)\) and that in the actual drawing condition was \(11.91(S D=5.43), t(54)=.88\), ns. Thus, participants in both conditions rehearsed comparable number of steps.

We then examined the proportion of steps accurately reconstructed, which was our main interest. Figure 2 shows the mean proportion of steps correctly reconstructed in the four conditions. We conducted ANOVA with condition (cothought gesture, actual drawing, hand movement prohibited, no rehearsal) as the between-subject independent variable and the proportion of steps correctly reconstructed as the dependent variable.

Figure 2. The mean proportion of steps correctly recalled in the co-thought gesture, actual drawing, hand movement prohibited and no rehearsal conditions.

There was a significant effect of condition, \(F(3,107)=\) 12.81, \(p<.001, \eta^{2}=.35\). Planned contrasts using Bonferroni correction showed the proportion of steps correctly reconstructed in the co-thought gesture condition was higher than that in the actual drawing condition, p \(<.001\), that in the hand movement prohibited condition, \(p\) \(<.001\), and that in the no rehearsal condition, \(p<.001\). The proportion of steps correctly reconstructed in the actual
drawing condition was also higher than that in the hand movement prohibited condition, \(\mathrm{p}<.04\), and that in the no rehearsal condition, \(\mathrm{p}<.001\). Participants in the hand movement prohibited condition reconstructed more steps than those in the no rehearsal condition, \(\mathrm{p}<.02\).

On average, participants spent comparable amount of time (in seconds) in reconstructing a route in all conditions: 28.32 seconds \((S D=3.51)\) in the co-thought gesture in the air condition; 29.48 seconds ( \(S D=3.19\) ) in the actual drawing condition; 28.38 seconds ( \(S D=3.29\) ) in the hand movement prohibited condition; and 30.26 seconds ( \(S D=\) \(3.41)\) in the no rehearsal condition, \(F(3,107)=.89\), ns. Therefore, the greater reconstruction accuracy in the cothought gesture conditions was not attributed to the time spent on recall.

\section*{Discussion}

To summarize, participants who were instructed to gesture reconstructed more steps than those who were told to mentally rehearse the routes and those who did not rehearse the routes at all, suggesting that producing co-thought gestures during rehearsal facilitates encoding of spatial relation. Besides gesturing, drawing the routes on a paper also yielded better spatial recall than mentally rehearsing the routes. Therefore, hand movements produced during rehearsal, either in the forms of gestures or actual drawing, enhance spatial relation encoding, which in turn promote subsequent recall.

There are very few studies to date that show the role of gesture in encoding spatial relation or spatial learning in general, despite the fact that gesture itself is spatial in nature (McNeill, 1992) and it often represents visuo-spatial information (e.g., Alibali, 2005; Lavergne \& Kimura, 1987; McNeill, 1992; Kita \& Özyürek, 2003; So, Coppola, Liccardello, Goldin-Meadow, 2005). Of a few studies, Chu and Kita (2011) found beneficial roles of co-thought gestures in mental rotation task; Ehrlich, Levine, and Goldin-Meadow (2006) reported that frequency of cospeech gestures is positively associated with children's performance in the mental rotation task. The findings in the present study contribute to the field of gesture research in a way that producing co-thought gestures while encoding spatial information of route sequence increases recall accuracy.
Our findings converge with the embodied viewpoint of cognition. According to the theories of embodied cognition, our bodily actions are interconnected with mental representation of objects and events (e.g., Barsalou, 1999; Glenberg, 1997; Wilson, 2002). However, most of the previous studies that supported the theories of embodied cognition focused on actions on real objects. For example, Beilock, Lyons, Mattarella-Micke, Nausbaum, \& Small (2008) found that expert ice-hockey players understood hockey-language scenarios better than did hockey novices, suggesting that previous action experience facilitates the comprehension of action-related language. Casasanto and Dijkstra (2010) also reported that participants who were told
to move marbles upward retrieved positive memories more often and faster than did those who moved marbles downward, suggesting a causal link between bodily action and cognition. Previous research has also shown that actual movements improved spatial skills. For example, Weidenbauer, Schmid, and Jansen-Osmann (2007) found that participants who were trained to use a joystick to rotate two-dimensional figures had better performance in the mental rotation task than did those who were not trained. Similarly, Wexler, Kosslyn, and Berthoz (1998) showed that participants who were required to turn a joystick while solving the mental rotation task had faster response rate and higher accuracy when the direction of hand movements was congruent with the direction of mental rotation than when it was not congruent. Our findings provide additional support to the theories of embodied cognition by demonstrating that actual movements like drawing routes on papers facilitate encoding of spatial relation. However, we here take a step further and find that representational actions, i.e., gestures, produced during rehearsal also exert significant influence on encoding and retention of spatial information. Hence, embodied movements, both real and representational, would influence our spatial cognition.

In addition, although it was not part of our prediction, our findings showed that participants in the co-thought gesture condition had better recall than those in the actual drawing condition. Participants who gestured the routes recalled more steps than did those who drew them on paper. As a result, co-thought gestures seem to bring a greater impact on encoding and retaining spatial relation than actually drawing on paper. The better performance in the co-thought gesture condition, as compared to the actual drawing condition, might indicate that less concrete actions provided a greater cognitive benefit in reinforcing the spatial representation. It is possibly because producing co-thought gestures might solidify the spatial information better than drawing on paper. In the actual drawing condition, participants could see the route sequences drawn on paper and they might rely on those sequences for the rehearsal of the subsequent steps. As such, it was not necessary for them to maintain the steps actively in their memory. In contrast, participants in the cothought gesture condition did not leave visible trails. Hence, they might have to keep rehearsing the previous steps in order to proceed to the subsequent ones. As a result, producing co-thought gestures would help participants to maintain and create a richer mental representation of the path than drawing on paper. The findings might advance our understanding about the effects of different kinds of embodied movements on spatial learning. While embodied movements in general enhance spatial relation encoding, representational movements (i.e., gestures) seem to be more effective than actual movements in improving encoding and retrieval of the path information.

However, one might contend that drawing was also involved in facilitating encoding of spatial relation in the cothought gesture condition. This is because participants in this condition traced the complete paths twice while
studying the routes before they produced co-thought gestures during rehearsal. Hence, their recall performance might be attributed to dual encoding of spatial relation by drawing and gesturing (Paivio, 1971). In contrast, participants in the actual drawing condition seemed to repeat what they were doing (i.e., drawing on papers) when they were learning and rehearsing the routes. However, participants did see the complete routes on papers while they were tracing the routes on papers whereas they did not see those routes during rehearsal. As a result, although participants drew on papers when learning and rehearsing the routes, they might use different mental processes to encode spatial relation.

While our results provide strong evidence that cothought gestures play a causal role in encoding spatial relation, they do not tell us how gesture is involved in the encoding process. We propose that co-thought gestures can facilitate encoding of spatial sequence in various ways. First, they provide participants with rich sensori-motor representation of the sequence of steps (Hegarty, Mayer, Kriz, \& Keehner, 2005; Hostetter \& Alibali, 2008). In addition, they help participants to maintain the representation active in memory (de Ruiter, 1998; Wesp, Hesse, Keutmann, \& Wheaton, 2001). They also help participants to offload intermediate representations of the spatial sequence to their hands in order to reduce the chance of forgetting those representations (Chu \& Kita, 2011; Goldin-Meadow, Nasbaum, Kelly, \& Wagner, 2001).

To our knowledge, this study is the first one to test the hypothesis that co-thought gesture is more powerful than actual movement in facilitating spatial relation encoding. Producing co-thought gestures allows us to construct the spatial information and retain it in our memory with relatively little effort. Further research should also address whether gestural encoding can be applied to other spatial tasks and how long its mnemonic effect lasts for. Based on the findings in this study, however, we could start practicing moving our fingers in the air when we are learning a direction in a new environment.

\title{
Aspectual Coercion in Non-native Speakers of English
}

\author{

}

\begin{abstract}
This study examined the processing correlates of aspectual coercion among native and non-native speakers of English. For native English speakers, results suggested that the processing delay associated with aspectual coercion is minimal. Aspectual coercion was perhaps cognitively easy to perform. By contrast, non-native speakers of English from unlike first language (L1) backgrounds differed in their reading performance. The differences varied systematically as a function of aspectual contrasts in L1 after controlling for second language (L2) English proficiency. Korean participants showed trends of aspectual coercion despite the absence of significant effects; German participants exhibited indifference across experimental conditions; Chinese participants showed aspectual coercion effects opposite to the predictions specified by the English grammar. A coupling of these data with evidence from the semelfactive progressive (e.g. coughing) in English suggests that the socalled online aspectual coercion effects may arise from a prototype organization of aspectual categories that is prone to L1 influence.
\end{abstract}

Keywords: Aspectual coercion; semelfactive progressive; prototype; L1 transfer

\section*{Introduction}

The study of aspectual coercion in non-native speakers provides an unusual opportunity to understand how aspectual conflicts are recognized and resolved in the course of language processing. Presumably, the challenge for nonnative speakers to process subtle semantic nuances on the fly is far greater than that of native speakers. If aspectual coercion incurs an extra processing cost, it will be more likely to find evidence of that in non-native speakers than in native speakers. This may in turn shed light on aspectual coercion research conducted on native speakers that have reported mixed findings in the literature.

\section*{Aspectual Coercion}

Verbs denote events that take place in time. A semelfactive verb (e.g. cough) denotes a single-stage, atelic situation (Smith, 1991; 1997). When the semelfactive verb cough combines with an adverbial modifier of duration or durative adverbial for an hour in the sentence Sam coughed for an hour, the combination becomes problematic. The semelfactive verb and durative adverbial are aspectually incompatible with each other. However, the sentence is neither ill-formed nor ungrammatical. Often an iterative interpretation is derived, namely Sam coughed repeatedly for an hour. Researchers have hypothesized that a computational process is invoked to resolve the incompatibility and construe a more coherent interpretation.

Such a process is commonly known as aspectual coercion. The discussion of coercion phenomena first appeared in Moens and Steedman (1988).
Empirical studies to date have yet to provide conclusive evidence about the processing consequence of aspectual coercion. Also, it remains unexplored that semelfactive progressive (e.g. coughing) in English derives an iterative interpretation even in the absence of durative adverbials. Whether a construction such as Sam was coughing for an hour incurs an extra processing cost or not, and how nonnative speakers respond to aspectual coercion relative to native speakers, become the twin goals of this study. It is hypothesized that a greater processing cost can be found in non-native speakers than in native speakers if aspectual coercion is computationally costly. Another prediction is that a construction like Sam was coughing for an hour will not incur an extra processing cost, because there is not any aspectual mismatch between the verbal predicate and the adverbial in the first place.

\section*{Psycholinguistic Evidence}

A small number of empirical studies have examined the psycholinguistic evidence of aspectual coercion using behavioral and brain-imaging techniques. The reported findings were mixed. Some studies found longer decision times and/or higher reading latencies in cases of aspectual coercion, while others reported null results.
Task differences may be responsible for these dissimilar findings. Piñango, Zurif, and Jackendoff (1999) first examined the processing load associated with aspectual coercion using a cross-modal lexical decision task. They found longer decision times at the probe positions of coercion sentences. Todorova, Strab, Bedecker, and Frank (2000) employed a self-paced, makes-sense judgment task, and found higher reading latencies in coercion sentences. Piñango, Winnick, Ullah, and Zurif (2006) later reported that online effects of aspectual coercion could only be found when a secondary lexical decision task was administered at a delayed interval of 250 ms . Unlike previous paradigms, Pickering, McElree, Frisson, Chen, and Traxler (2006) employed the self-paced reading and eye-tracking techniques to foster more naturalistic reading in experimental settings. Nonetheless, Pickering et al. found no behavioral differences in terms of reading times and other eye-tracking estimates across conditions. The researchers attributed the null results to an underspecification account, which claimed that native English speakers did not commit to the telicity of situations immediately during normal sentence comprehension.

Another challenge stems from lexical aspect. Lexical aspect (or Aktionsart) refers to the temporal meanings
inherent in verbal predicates. A semelfactive verb (e.g. cough) is, by definition, semelfactive because it conveys a single-stage, atelic situation (Smith, 1991; 1997). The classification of lexical aspect can be tricky. Brennan and Pylkkänen (2008) addressed this by first norming a selection of verbs for punctuality with native English speakers. Only a set of strongly punctual verbs (all semelfactives indeed) was then chosen for their self-paced reading and MEG (i.e. magnetoencephalography) experiments. As illustrated in (1), the critical sentences varied in adverbial type (either a durative adverbial or a punctual adverbial), followed by a genuine semelfactive verb:
(1) a. Throughout the day the student sneezed in the back of the classroom.
b. After twenty minutes the student sneezed in the back of the classroom.

Crucially, Brennan and Pylkkänen reported significantly longer reading times at the inflected verb in 1a than in 1 b in native English speakers from the self-paced reading experiment.

In addition to tasks and experimental control, previous empirical studies have only narrowly examined aspectual coercion in which a punctual situation is interpreted as iterative by means of an interaction with a specific type of temporal modifier, namely durative adverbial. Little is known about how other factors such as grammatical aspect could affect aspectual coercion. Comrie (1976) stated that grammatical aspect encodes different ways of viewing the internal temporal constituency of a situation. One can therefore distinguish what happened from what was happening owing to grammatical aspect, which is often marked via verbal morphology. In this light, semelfactive progressive in English (e.g. coughing) provides an exceptional window to elucidate this issue, precisely because it denotes iterative action-in-progress (Smith, 1991; 1997) without any temporal adverbials. A psycholinguistic investigation along this line shall cast some light on the study of aspectual coercion phenomena at large.

\section*{Experiment}

This study examined the influence of grammatical aspect and temporal adverbials on aspectual coercion in the course of language processing. The two research questions were:
1. Does aspectual coercion incur an extra processing cost in native and non-native speakers of English?
2. Does grammatical aspect mediate the online effects of aspectual coercion? In other words, is there a trade-off between grammatical aspect and temporal adverbial?

\section*{Method}

Participants Participants consisted of native English speakers and non-native speakers of English from Korean, Mandarin Chinese, and German L1 backgrounds. The
profiles of the participants were summarized as follows: native English speakers ( 15 women, 9 men, \(M_{\text {age }}=20.2\) years, age range: 18-25 years); Korean ( 14 women, 1 man, \(M_{\text {age }}=21.7\) years, age range: 18-29 years); Chinese (16 women, 5 men, \(M_{\text {age }}=23.8\) years, age range: 21-30 years). These participants enrolled at the University of Pittsburgh and Carnegie Mellon University in the US. The German participants ( 21 women, 4 men, \(M_{\text {age }}=25.5\) years, age range: 20-41 years) were recruited from the Ruprecht-KarlsUniversität Heidelberg, Germany. All participants took part in the experiment for compensation.

Also, all non-native speakers completed a standardized English proficiency test - the Michigan Test of English Language Proficiency (MTELP) of the Michigan Test Battery (Corrigan, Dobson, Kellman, Spaan, Strowe, \& Tyma, 1979). The maximum score was 100 . At the time of testing, both Korean ( \(M=81.13, S E=3.67\) ) and German ( \(M\) \(=79.88, S E=2.85\) ) participants were more proficient in English than their Chinese \((M=63, S E=3.11)\) counterparts, \(p \mathrm{~s}=.001\).

Stimuli Twenty-four sentences were constructed from seventeen semelfactive verbs. These verbs were selected based on the norming results of punctuality (Brennan \& Pylkkänen, 2008) as well as ratings for telicity (Wulff, Ellis, Römer, Bardovi-Harlig, \& Leblanc, 2009). Participants’ knowledge of English was also taken into consideration. The experiment implemented a \(2 \times 2\) design crossing Grammatical Aspect (SIMPLE, PROG) and Adverbial (Punctual, Durative). Here, SIMPLE means the grammatical aspect is unspecified, whereas PROG denotes the progressive aspect. All critical items were distributed into 4 lists such that each list contained one token of each of the 24 critical items and six items from each of the four conditions. The 4 sets of experimental stimuli were each embedded into a list of 120 filler sentences, plus an additional 84 items from two other experiments (Chan, 2012). Presentation orders were completely randomized. Table 1 summarizes the quadruple design crossing grammatical aspect and adverbial.

Table 1: Conditions and sample stimuli
\begin{tabular}{|c|c|c|}
\hline & Punctual adverbial & Durative adverbial \\
\hline SIMPLE & At noon the kid jumped into the swimming pool. & All day the kid jumped into the swimming pool. \\
\hline PROG & At noon the kid was jumping into the swimming pool. & All day the kid was jumping into the swimming pool. \\
\hline
\end{tabular}

Condition A is a control condition. It serves as a baseline for condition B , in which there is an aspectual mismatch between the durative adverbial all day and the verb jumped. Condition B is an example of aspectual coercion. Previous studies described this as an instance of iterative coercion
(e.g., Brennan \& Pylkkänen, 2008). Because iteration is triggered by an adverbial, condition B is called Adverbial Coercion. This term is not new; it first appeared in Todorova et al (2000). Conditions C and D represent new manipulations, as they have never been tested before. As discussed earlier, Smith \((1991\); 1997) asserted that semelfactive verbs marked in English progressive denote iterative action-in-progress. The combination of the semelfactive progressive jumping with the punctual adverbial at noon therefore creates an aspectual conflict in condition C. Although conditions B and C both involve aspectual mismatch, the iteration in condition C arises via the progressive marking on the semelfactive verb, whereas that in condition B is enforced by a durative adverbial external to the verbal predicate. To differentiate between the two, condition C is therefore called Grammatical (Aspect) Coercion. Lastly, condition \(D\) serves as a baseline to Grammatical Coercion in condition C.

Two predictions are made for native English speakers. First, Adverbial Coercion sentences (Condition B) will incur longer reading times than respective control sentences (Condition A). This is based on previous findings that durative adverbials could trigger coercion (e.g. Todorova et al., 2000). Second, a new prediction for this study is that Grammatical Coercion sentences (Condition C) will take longer time to read than control sentences (Condition D) because of the aspectual mismatch. Therefore, the \(2 \times 2\) design predicts aspectual coercion effects as a trade-off between adverbial and grammatical aspect.
It is generally assumed that native and non-native speakers will have similar reading performance. Of course, one may predict some variations as a result of L1 differences. For example, Korean participants may perform similarly to native English speakers, considering the many meaning overlaps between aspectual systems of Korean and English. Because German lacks a grammatical aspectual system, a reasonable prediction is that German participants may not exhibit any differences between SIMPLE and PROG. The Chinese participants may as well perform similarly to native English speakers. It must be emphasized that Chinese has richer perfective and imperfective contrasts, in addition to the optional marking system. The progressive aspect is obligatory in English, however. Given these cross-linguistic differences in aspectual meaning and grammar, the above predictions are speculative at best.

Procedure The current study involved a computerized selfpaced reading experiment, which was administered individually to participants in a laboratory setting. Participants were instructed to read English sentences as quickly as possible and answer comprehension questions as accurately as possible. Six practice items were given before the actual experiment.

The self-paced reading task was implemented on Linger software (Rohde, 2001), following a word-by-word noncumulative moving window paradigm presentation technique (Just, Carpenter, \& Woolley, 1982). Each
sentence was masked by a series of dashes (-). These dashes were replaced by a word from left-to-right every time the participant pressed the space bar. Only one word was shown on the computer screen at a time.
An optional break was provided in between every 50 trials. To ensure meaningful comprehension, a yes/no comprehension question prompt was presented to each of the 120 filler sentences embedded throughout the experiment. Feedback on accuracy was also provided. The majority of participants finished the experiment in an hour.

\section*{Data Analysis}

The following procedures were employed. First, I ascertained that all participants scored \(90 \%\) or above for the comprehension questions. For native English speakers, the mean accuracy was \(94 \%\) ( \(S D=3.9 \%\) ). For non-native speakers, Korean participants achieved a mean accuracy of \(94.2 \% ~(S D=3.4 \%)\), German 94.6\% ( \(S D=2.9 \%\) ), and Chinese \(91 \%\) ( \(S D=4.8 \%\) ). The overall high accuracy confirms that all participants paid attention and read the sentences carefully.
Next, extreme reading times (RTs), including those shorter than 100 ms or longer than \(2,500 \mathrm{~ms}\) per word, were discarded. These criteria excluded \(0.59 \%, 1.36 \%, 1.26 \%\), and \(2.31 \%\) of data points among the English, Korean, German, and Chinese participants, respectively.
RTs were then transformed logarithmically. A linear regression was performed on the \(\log\) RT data to correct for word length differences across conditions, while taking into account each participant's individual reading speed. This procedure utilized all words from experimental items and fillers for each participant (e.g., Ferreira \& Clifton, 1986; Trueswell, Tanenhaus, \& Garnsey, 1994). The values predicted from the regressions were subtracted from the actual reading times to produce residual reading times for each participant. Thus, word-length adjusted residual \(\log\) RTs became the dependent variable for subsequent statistical tests.
Separate analyses were conducted on RTs at four target word regions: 1) the verb; 2) the first word following the verb \((\mathrm{V}+1)\) to capture spill-over effects; 3 ) the second word following the verb \((\mathrm{V}+2)\) to assess further downstream effects; and 4) the sentence-final (SF) word to investigate sentence wrap-up effects (Just \& Carpenter, 1980).
Furthermore, a number of problematic items were excluded from statistical analyses. All trials containing yesterday, last night, last week and the verb open that were intended to serve as punctual adverbials and semelfactives were excluded. This procedure reduced the entire data set by another \(36.98 \%\).

\section*{Results}

A three-way mixed-design ANCOVA was performed with Grammatical Aspect (SIMPLE, PROG) and Adverbial (Punctual, Durative) as within-participant variables, group (English, Korean, German, and Chinese) as a between-

Figure 1: ANCOVA reading time results. Error bars indicate \(\pm 1\) standard error.
participant variable, and English proficiency as a covariate. A default score of 100 was entered for native English speakers in the covariate for ANCOVA analyses. An \(\alpha\)-level of .05 was used. Figure 1 plots the ANCOVA RT results for each participant group.

Verb An ANCOVA controlling for English proficiency at the verb revealed a significant Adverbial \(\times\) Grammatical Aspect interaction by both participants and items, \(F_{I}(1,80)\) \(=5.773, p=.019 ; F_{2}(1,56)=4.607, p=.036\). The main effect of grammatical aspect was significant by participants, \(F_{l}(1,80)=7.265, p=.009 ; F_{2}<3.072\). No other effects approached significance by either participants or items: adverbial, \(F_{l}(1,80)=3.757, p=.056 ; F_{2}<.071\); language, \(F_{l}(3,80)=1.412, p=.245 ; F_{2}<.892\); all interactions, \(F \mathrm{~s}<\) 1.128.

To explore the Adverbial \(\times\) Grammatical Aspect interaction collapsed across language groups, a follow-up simple main effect of adverbial across levels of grammatical aspect was performed in this word region. However, none of the comparisons reached significance, \(p \mathrm{~s}>.113\).

V+1 An ANCOVA controlling for English proficiency at the first word after the verb revealed a significant Adverbial \(\times\) Grammatical Aspect interaction by participants, \(F_{l}(1,80)\) \(=5.036, p=.028 ; F_{2}<.002\). The main effect of language was significant by both participants and items, \(F_{l}(3,80)=\) 5.456, \(p=.002 ; F_{2}(3,56)=2.893, p=.043\). All other main effects and interactions were not significant by either participants or items: grammatical aspect, \(F_{l}(1,80)=.119\), \(p=.731 ; F_{2}<.559\); adverbial, \(F_{l}(1,80)=1.605, p=.209\); \(F_{2}<.818\); all interactions, \(F \mathrm{~s}<1.025\).

To explore the Adverbial \(\times\) Grammatical Aspect interaction, a follow-up simple main effect of adverbial across levels of grammatical aspect was conducted in this word region. No comparisons approached significance, \(p \mathrm{~s}>\) .492.

In order to understand how different language groups performed in this word region, posthoc pairwise comparisons with Bonferroni adjustment revealed that the reading speed of Chinese participants \((M=.041, S E=.011)\)
was significantly slower than that of native English participants \((M=-.03, S E=.01), p=.001\), as well as German participants \((M=.000, S E=.008), p=.014\), respectively. No other comparisons were significant, \(p \mathrm{~s}>\) . 107.
\(\mathbf{V + 2}\) An ANCOVA controlling for English proficiency at the second word after the verb revealed a significant Adverbial \(\times\) Grammatical Aspect interaction by participants, \(F_{I}(1,80)=11.736, p=.001 ; F_{2}<.39\), and a three-way Adverbial \(\times\) Grammatical Aspect \(\times\) Language interaction by participants, \(F_{l}(3,80)=3.251, p=.026 ; F_{2}<.169\), suggesting that the four language groups may behave differently across levels of adverbial and grammatical aspect. All other main effects and interactions were not significant by either participants or items: grammatical aspect, \(F_{l}(1,80)=.848, p=.36 ; F_{2}<.038 ;\) adverbial, \(F_{l}(1\), \(80)=.923, p=.34 ; F_{2}<.143\); language, \(F_{l}(3,80)=1.025\), \(p=.386 ; F_{2}<.149\); all interactions, \(F \mathrm{~s}<2.206\).

Because of a significant three-way interaction, a followup simple main effect of adverbial across levels of grammatical aspect was performed separately for each language group in this word region. Native English speakers slowed down at Adverbial Coercion sentences ( \(M=-.011\), \(S E=.017\) ) relative to corresponding control sentences \((M=\) \(-.061, S E=.019), p=.052\). Also, they read Grammatical Coercion sentences \((M=-.011, S E=.016)\) marginally slower than respective control sentences \((M=-.047, S E=\) .016 ), \(p=.096\). Although these results were only marginally significant, native speakers in this experiment behaved in accord with the prediction that sentences involving aspectual coercion generally took longer to read than noncoercion sentences. These results provided a reasonable baseline when evaluating non-native speakers' reading performance in the same experiment.
Unexpectedly, Chinese participants read Adverbial Coercion sentences ( \(M=-.071, S E=.018\) ) significantly faster than the respective control sentences \((M=.01, S E=\) .02 ), \(p=.003\), which is opposite to the prediction of adverbial coercion. All other comparisons were not significant in this word region, \(p \mathrm{~s}>.164\).

SF An ANCOVA controlling for English proficiency at the sentence final word revealed a significant main effect of language by both participants and items, \(F_{l}(3,80)=7.122\), \(p<.001 ; F_{2}(3,56)=11.948, p<.001\). All other main effects and interactions were not significant by either participants or items: grammatical aspect, \(F_{I}(1,80)=1.207\), \(p=.275 ; F_{2}<.952 ;\) adverbial, \(F_{l}(1,80)=.155, p=.695 ; F_{2}\) \(<.049\); all interactions, \(F \mathrm{~s}<1.549\).

To explore how different language groups performed in this word region, posthoc pairwise comparisons with Bonferroni adjustment revealed that the reading speed of German participants ( \(M=.162, S E=.016\) ) was significantly slower than that of native English speakers \((M=.066, S E=\) \(.021), p=.004\), and Chinese participants \((M=.077, S E=\) .022 ), \(p=.01\), respectively. German participants also appeared to be slower than Korean participants ( \(M=.098\), \(S E=.02\) ), \(p=.087\). All other comparisons were not significant, \(p \mathrm{~s}>.087\).

Taken together, the ANCOVA analyses revealed several interesting results. At the verb, there were no RT differences by condition collapsed across language groups. The same was generally true for \(\mathrm{V}+1\). At \(\mathrm{V}+2\), native English speakers exhibited marginally significant trends that Adverbial Coercion and Grammatical Coercion sentences took longer time to read. The Chinese participants, however, took significantly longer to read control sentences relative to Adverbial Coercion sentences \((p=.003)\). At the sentence final word, the German participants showed elevated RTs across all conditions when compared to Korean, Chinese, and native English participants.

\section*{General Discussion}

Overall, results provided partial support for the first research question that there is a processing cost for aspectual coercion. Native English speakers had the tendency to slow down at sentences involving Adverbial Coercion (All day the kid jumped...) and Grammatical Coercion (At noon the kid was jumping...), even though the reading time results were only marginally different from their control counterparts. These findings were consistent with the general prediction that aspectual coercion may incur a somewhat greater processing cost. However, it is noted that these results were delayed, and emerged only at the second word after the verb \((\mathrm{V}+2)\). It is unclear why no strong, immediate online effects emerge as other self-paced reading studies have shown. Brennan and Pylkkänen (2008), for example, presented evidence that iterative coercion can produce significant, immediate effects. The highly salient semelfactive verbs used in this experiment may have been responsible for the diminished online effects within native English speakers.

Despite these suggestive findings, one unambiguous result was that aspectual coercion is mediated by the interaction among grammatical aspect, lexical aspect, and adverbial. This is evident in the significant Adverbial \(\times\) Grammatical Aspect interaction effect collapsed across language groups
at three of the four word regions probed, \(p \mathrm{~s}<.028\). As predicted, not only adverbials but also grammatical aspect triggers aspectual coercion. This finding provides a new theoretical insight to aspectual coercion phenomena, as previous studies showed that a durative adverbial is responsible for iteration involved in a semelfactive predicate (e.g., Todorova et al., 2000). Here, results clearly show that there is no reason to believe that temporal adverbials independently cause processing slowdown. Instead, lexical aspect, grammatical aspect, and adverbial conspire to shape the aspectual interpretation of a sentence.
Moreover, the findings here were at odds with the underspecification account put forward by Pickering et al. (2006) to account for their null results. Pickering et al. asserted that readers routinely underspecify aspectual properties of an interpretation during comprehension. The underspecification account seemed to be untenable here because of the strong interaction between adverbial and grammatical aspect. In this light, the current study is more compatible with Brennan and Pylkkänen (2008), among others.
For the first time, this study extended the psycholinguistic investigation of aspectual coercion to non-native speakers. Although native English speakers behaved differently from non-native speakers in general, non-native speakers also differed systematically from one another after removing preexisting differences in L2 English proficiency. For example, the Chinese participants showed significantly shorter reading times in Adverbial Coercion (All day the kid jumped...) sentences than control sentences (At noon the kid jumped...), which was opposite to the prediction ( \(p=.003\) ). These results seemed puzzling at first glance. One potential explanation may rest on the differences in the aspectual systems of English and Chinese. According to Yang (1995), the perfective marker le strongly prefers telic and bounded situations in Chinese. This explains why the semelfactive predicate kesou 'cough' in (2) cannot felicitously co-occur with \(l e\), because semelfactives are by definition atelic (i.e., Activities). However, when a bounded temporal situation is introduced via a verbal classifier phrase yi-sheng 'once' as shown in (3), the utterance becomes felicitous.
(2) *Lisi kesou le

Lisi cough PERF
"Lisi coughed"
(3) Lisi kesou le yi-sheng Lisi cough PERF one-CL "Lisi coughed once"
(Yang, 1995; cited in Xiao \& McEnery, 2004, p. 103)
Xiao and McEnery (2004) adduced native Chinese corpus data to support the idea that the sensitivity of le to boundedness is relative rather than absolute. In their sample, an overwhelming \(89.4 \%\) of all 1138 tokens of le occur in bounded contexts, whereas a meager \(10.6 \%\) occurred in unbounded contexts. Of the 27 tokens of semelfactives taking \(l e\) in the same corpus, 16 are bounded by additional
adverbials that impose a spatially or temporally bounded situation. This distributional pattern suggests that the semelfactive plus durative adverbial combination is quantitatively more common in Chinese. Although Xiao and McEnery did not articulate the underlying reason for such a language-specific bias in Chinese, they maintained that semelfactive verbs taking perfective \(l e\) prefers to be bounded, particularly by means of a verbal classifier phrase, verb reduplication, or by a for-adverbial as shown in (4).
(4) Da-le ni ji-tian
beat-PERF you how-many-day
"For how many days did they beat you?"
(Xiao \& McEnery, 2004, p. 111)
The co-occurrence of a semelfactive verb taking \(l e\) in the presence of a durative adverbial in (4) is equivalent to the Adverbial Coercion construction in English. Accordingly, the processing advantage found in Chinese participants can be attributed to the skewed distribution of \(l e\) in bounded contexts for semelfactives. Although I consider such a possibility using Xiao and McEnery's Chinese corpus data, future Chinese sentence processing experiments will need to independently verify this claim. What is remarkable here is that Chinese participants exhibited a language-specific bias from their L1 Chinese aspectual system even when they were reading in English. If that's the case, results from Chinese participants provided crucial support for L1 transfer.
Korean participants did not show any within-subject differences in terms of their reading performance across experimental conditions. They exhibited trends of aspectual coercion, despite the absence of statistically significant results. The same can be said about the German participants in which the reading times performance were highly comparable across conditions. I reckon that the lack of grammatical aspect (and associated grammaticized meanings) is responsible for their indifference (e.g., Stutterheim \& Carroll, 2006).

\section*{Conclusion}

What is interesting about aspectual coercion is that it involves contextual re-interpretation of aspectual information, rendering it computationally more demanding for non-native speakers. Although this prediction has not been borne out in all non-native speaker groups, the current study revealed important L1-based variations that could not have been exposed otherwise. A psycholinguistic investigation comparing both the performance of native and non-native speakers can thus reveal rather than obscure aspectual coercion operations in the course of language processing. Importantly, I contend that the so-called online aspectual coercion effects arise from a prototype organization of aspectual categories, which is, not surprisingly, prone to L1 influence in a systematic way.

\begin{abstract}
We examined the role of spatial representations and word order on thematic role assignment in Greek. Previous studies suggest that spatial representations influence thematic role assignment; agent is typically depicted on the left, and patient on the right. Here, we address this issue using a language with flexible word order which allows us to manipulate sentence structure (SVO-OVS) orthogonally to thematic role. Greek speakers heard SVO/OVS sentences while viewing depictions of actions involving two characters and they judged whether sentence and picture matched in meaning. The agent's position in the picture was directly manipulated. The results support the effect of left bias on language processing. However, this bias may be better understood when its interaction with other sources of information and languagespecific constraints are taken into account. Theories of prediction may help us illuminate how spatial biases and linguistic factors interactively affect the way we process our world.
\end{abstract}

Keywords: spatial representation, language, thematic role assignment, word order, sentence comprehension, prediction, Greek.

\section*{Introduction}

The combinatory study of language and space aims to shed light on how an analog, geometric and continuous representation is encoded into a propositional algebraic and discrete representation (Jackendoff, 1992; Geminiani, Bisiach, Berti \& Rusconi, 1995; Hayward \& Tarr, 1995; Jackendoff, 1996; Chatterjee, Southwood \& Basilico, 1999; Levinson, 2003; Papafragou, Hulbert \& Trueswell, 2008, among others). Recent research has inaugurated a discussion on how language structures are constrained by spatial biases (Chatterjee, Maher, Gonzales-Rothi, \& Heilman, 1995; Chatterjee, Southwood, \& Basilico, 1999). Researchers (Chatterjee et., al, 1995; Chatterjee, Southwood, \& Basilico, 1999; Chatterjee, 2001; 2008) have entertained the claim that events are conceptualized spatially and prelinguistically proceeding from left towards the right. They assume that language development exploits systems meant for left-toright spatial attention in the left hemisphere. Therefore, the left-to-right directional bias indicates primitive spatial representations and reflects a prelinguistic neural encoding of events and actions.

Evidence for this claim comes from case studies in agrammatic speech (Caplan \& Futter, 1986; Caramazza \& Miceli, 1991). In these studies, the person with
agrammatism systematically assigned agency to the first noun heard or to the one located to the left of the verb. Chatterjee and colleagues (Chatterjee, et al. 1995; Chatterjee, Southwood, \& Basilico, 1999), based on the Jacksonian notion that primitive cognitive functions are overlaid with more complex functions, hypothesized that people with agrammatic aphasia tend to follow a temporal or spatial strategy based on those primitive spatial representations in order to interpret a sentence once their more complex linguistic abilities fail. To test for their assumption they conducted studies in typical population (Chatterjee et al., 1995; Chatterjee, Southwood, \& Basilico, 1999; Barrett \& Craver-Lemley, 2008). In these studies, participants were asked to depict sentences describing an action with two persons involved or to match sentences to pictures. Participants tended to draw the agent of an action closer to the left side of the picture. For example, in the sentence «The girl chased the boy», it was more probable for the participants to depict the girl on the left side of the picture and the boy on the right side. Also, participants responded faster when the agent was located on the left side in sentence-picture matching tasks.

According to an alternative explanation, the left-to-right directional bias is culturally determined by the directionality of the reading/writing system (Maass \& Russo, 2003; Chan \& Bergen, 2005; Dobel, Diesendruck, \& Bolte, 2007). Specifically, Maass and Russo (2003) investigated spatial biases in thematic role assignment in directionally opposite writing system, such as Italian (left-to-right) and Arabic (right-to-left). They found that Italian speakers tended to assign the agent on the left, while Arabic speakers had the reverse tendency. Furthermore, the more years Arabic speakers had spent abroad exposed to the opposite writing system, the more mitigated their right-to-left bias was.

Furthermore, Dobel, Diesendruck, and Bolte (2007) strengthened this argument by showing that the left or right bias in depicting agency is based not only on reading and writing practices, but also on the degree of exposure on those practices. Specifically, they tested spatial biases in German- and Hebrew-speaking adults and preschool children. They found that the writing system influenced thematic role assignment in adults, that is, German-speaking adults had a left-to-right spatial bias, while Hebrewspeaking adults had the opposite bias. However, this was not observed for preschool children who had no exposure to the reading and writing systems of their language.

The previous studies suggest that thematic role assignment is affected conceptually and spatially by the reading and writing systems. The present study extends the role of language on thematic role assignment bias by adding word order, that is, the within-sentence structure, as a possible variable. The methodological paradigm used in previous research (Chatterjee et al., 1995; Chatterjee, Southwood, \& Basilico, 1999) was based on English, a language with highly restrictive word order. To manipulate temporally or spatially the agent or the patient of an action, previous studies either used active and passive voice (Chatterjee et al., 1995), or verbs with different trajectories (e.g. "The circle pushes the square", in which the circle is the agent and the action moves away from the agent, "The circle pulls the square" in which the circle is the agent and the action goes forward to the agent) (Chatterjee, Southwood, \& Basilico, 1999).

A question arising from this manipulation is whether agency will be affected by the within-sentence structure, that is, the order that thematic roles are presented within the sentence. In Greek, which has a left-to right reading and writing system, grammatical information is conveyed through inflection, thus multiple word orders are allowed (SVO, OSV, VOS, VSO, OVS, OSV). The agent or the patient of an action can appear in any order within the sentence independently of whether the sentence is active or passive. For example, in active voice, structures such as "The cook \({ }_{\text {nom }}\) kicks the pirate acc" (the cook=agent) and "The pirate \({ }_{\text {acc }}\) kicks the \(c o o k_{\text {nom }}\) " are both grammatical. Therefore, highly inflectional languages, such as Greek, allow us to manipulate word order without necessarily using the passive voice which is of less frequency. In our study, we assume that spatial biases will be influenced by the within-structure sentence. We predict that participants will be faster in responding to sentences that not only match in terms of agency, but also in terms of characters' position in the sentence independently of thematic role assignment, that is, even in conditions that characters' share the same location spatially and temporally, independently of meaning.

\section*{Methods}

A sentence-picture verification task was used. Pairs of characters were presented in a \(2 \times 2 \times 2\) experimental design. Each picture involved two characters (character \({ }_{1}\) character \({ }_{2}\); e.g. "cook", "pirate") and each sentence contained two nouns corresponding to those characters ( noun \(_{1}-\) noun \(_{2}\) ), one in nominative (agent) and one in accusative (patient). The experimental stimuli were manipulated on three dimensions: 1 . characters' position in the picture (left - right), by flipping the image, 2. characters' position in the sentence (e.g. SVO - OVS) and 3. characters' thematic role (agent - patient) in the sentence by interchanging nominative and accusative case. Therefore, thematic role assignment was actually the variable that produced either matched- or mismatched-in-meaning sentence-picture pairs. Eight experimental conditions were
created (see Table 1). Every pair of characters was presented in each of eight conditions.

Table 1: Experimental design for sentence-verification task
\begin{tabular}{|c|c|c|c|c|}
\hline \multirow[t]{4}{*}{} & \multicolumn{4}{|c|}{Meaning} \\
\hline & \multicolumn{2}{|c|}{Match} & \multicolumn{2}{|c|}{Mismatch} \\
\hline & \multicolumn{4}{|c|}{Position in sentence} \\
\hline & Match & Mismatch & Match & Mismatch \\
\hline  & "The cook \(_{\text {nom }}\) kicks the pirate \(_{\text {acc }}\) " & "The pirate \({ }_{\text {acc }}\) kicks the \(\mathrm{cook}_{\text {nom }}\) " & "The cook \(_{\text {acc }}\) kicks the pirate \(_{\text {nom }}\) " & "The pirate \(_{\text {nom }}\) kicks the cook acc" \\
\hline  & "The pirate \({ }_{\text {acc }}\) kicks the cook \(_{\text {nom }}\) " & "The \(\mathrm{Cook}_{\text {nom }}\) kicks the pirate \(_{\text {acc }}\) " & "The pirate \({ }_{\text {nom }}\) kicks the cook \(_{\text {acc }}\) " & "The cook \(_{\text {acc }}\) kicks the pirate \({ }_{\text {nom }}\) " \\
\hline
\end{tabular}

In half of the experimental conditions thematic role assignment reflected the depicted action resulting in matched-in-meaning pairs, whereas in the other half, thematic roles mismatched the depicted action (mismatched-in-meaning pairs). Furthermore, in half of the matched-inmeaning pairs, nouns' location in sentence matched characters' position in picture, whereas in the other half, nouns' location in sentence mismatched characters' position in picture. The same was true for the mismatched-inmeaning conditions. Our dependent variable was response times and our independent variables were character's position in the picture (left, right), and word order (SVO OVS).

\section*{Participants}

Thirty-three adults, 18-30 year olds, participated in the present experiment. They were all Greek native speakers. They did not receive any compensation for their participation.

\section*{Materials}

Pictures The test stimuli consisted of 9 colored pictures. Each picture depicted two characters taking part in an action, and additional objects and people. The action presented in the picture was always the same, that is, character \({ }_{1}\) was always doing the action and character \({ }_{2}\) was receiving the action. However, there were two conditions. Half of the pictures depicted the agent on the left and half of them depicted the agent on the right. For each target picture, the agent of the action was either depicted on the left or on the right side of the screen by flipping the image. The filler items consisted of 60 colored pictures depicting objects and people. The order of experimental and filler items was pseudo-randomized, with the constraint that each experimental item was separated by a minimum of one filler item. All pictures were part of a larger set of pictures used in

Gennari, Mirkovic, and MacDonald (2012) and were appropriately adjusted for the purposes of this experiment.

Sentences For the test sentences, 9 verbs representing actions were used to construct quadruplets of active sentences, resulting in 36 Greek sentences as test items, ranging in length from 5 to 6 (mean \(=5.5\) ) words. These sentences had two possible word orders (SVO or OVS) and half of them were matching in meaning with the experimental pictures, whereas the other half were not. Examples of sentences are presented in Table 1. Additionally, 120 Greek sentences were used as filler items ranging in length from 3 to 10 words (mean \(=4.9\) ). Half of them matched in meaning the filler pictures and half of them did not. All sentences were recorded by a female native Greek speaker whose instructions were to read each sentence aloud in a natural, clear manner, in normal intonation.

\section*{Procedure}

Each participant, after giving verbal consent to participate in the study was seated in a quiet room and given instructions about the experiment. DMDX (Forster \& Forster, 2003) was used for the presentation of the stimuli. Visual stimuli were presented at the center of a laptop screen. Auditory stimuli were delivered over high quality headphones. In each trial, participants saw a picture and simultaneously heard a sentence corresponding or not to the picture. Participants had to perform a 2AFC task to indicate whether the sentence they heard matched the picture by pressing one of two buttons. Participants were given three practice trials at the beginning of the experiment in order to make sure they had understood the task. There was no feedback. The experiment lasted approximately 30 minutes.

\section*{Results}

Data were analyzed with generalized linear mixed-effects modeling, with random effects for participants and items, employing function lmer of package lme4 (Bates, Maechler, \& Bolker, 2012) in R (R Development Core Team, 2012). Response times were log-transformed. Only accurate responses were included in the analysis ( \(2 \%\) excluded) and only those participants that had lower than \(8 \%\) error rate. None of the participants was excluded from the analysis. Outliers were removed, that is, items with response time values below 500 msec or above two standard deviations from the mean. This resulted in excluding \(4 \%\) of the total data.
We conducted separate analyses for matched- and mismatched-in-meaning stimuli. For the matched-inmeaning condition, a main effect of agents' position was found (t value \(=-5.19, p=0.0001\) ) (i.e. participants' responses were faster when the agent was depicted on the right) and a main effect of word order ( t value \(=-9.29, \mathrm{p}=\) 0.0001). However, agents' position interacted with word order ( t value \(=4.13, \mathrm{p}=0.0004\) ). Contrasts among SVO and OVS conditions revealed that participants' reaction
times did not differ in the SVO condition ( \(\mathrm{t}=0.65\); \(\mathrm{p}=\) 0.5306 ), that is, agent's position did not affect reaction times. However, in the OVS condition, participants were significantly faster in responding to pictures presenting the agent on the right compared to left ( \(\mathrm{t}=-5.56\); \(\mathrm{p}=0.0001\) ), i.e. when within-sentence structure matched in characters' position in the sentence (Figure 1).

Figure 1: Agents' position and word order interaction in reaction times in matched-in-meaning pairs. In all figures, untransformed RTs are presented for ease of interpretation.

Same effects were found for the mismatched-in-meaning condition. A main effect of agents' position, (-6.06, p = 0.0001 ), word order ( t value \(=-10.12, \mathrm{p}=0.0001\) ) and an interaction between agents' position and word order was found ( t value \(=4.13, \mathrm{p}=0.0001\) ). Contrasts among SVO and OVS conditions revealed that participants were slower in responding to pictures that depicted the agent on the right compared to left in the SVO condition (6.07; \(\mathrm{p}=0.0001\) ). However, in the OVS condition, people were faster when the agent was presented on the right compared to left ( \(\mathrm{t}=-\) \(6.24 ; \mathrm{p}=0.0001\) ). That is, participants were faster in rejecting a mismatched-in-meaning pair when characters’ position in the sentence and characters' position in the picture matched (Figure 2).

Figure 2: Agents' position and word order interaction in reaction times in mismatched-in-meaning pairs.

\section*{Discussion}

The interaction between spatial and linguistic representations was investigated in a sentence-picture
verification task. Stimuli were manipulated in order to explore the role of word order in spatial representation of agency in a language with flexibility in word order. Our experimental manipulation allowed us to disentangle sentence structure and thematic role, in that agents could appear in one of two positions in the sentence. We found that when word order matched agents' position latencies dropped. This effect was not only observed in matched-inmeaning pairs, i.e. pairs in which both structure and thematic role represented the depicted action, but also, in mismatched-in-meaning pairs, i.e. pairs that only matched in sentence structure independently of thematic role.

However, a robust finding in literature, that processing of spatial representations is influenced by the directionality of the reading and writing system, was not obtained in this study. Since Greek is a left-to-right language we expected that participants would be faster in responding to pictures representing the agent on the left. In our study, participants were faster responding to pictures presenting the agent on the left only when the paired sentence was presented in SVO structure. In the other conditions, left agency did not facilitate participants' responses. We suggest that this seemingly contradictory result could be explained by the interaction between agents' spatial position and word order.

Specifically, we suggest that when the agent was presented on the left it was consistent with the left-to-right bias. This led to the formation of a strong expectation about the upcoming sentence structure (i.e. SVO). When this expectation was violated (i.e. OVS), reaction times became longer. In contrast, when the expectation was fulfilled, processing was significantly faster and reaction times dropped. However, when the agent was presented on the right side, no strong expectations were formed because the two effects (agent's position and left-to-right bias) partly canceled each other out. Therefore, the differences in latency between SVO and OVS structures should be much smaller in this case. Moreover, since SVOs are more frequent (and therefore easier to process), the mismatching between the agent's position and the sentence structure, should affect to a greater extent the processing of the less frequent OVS structures. Indeed, our results are in accordance with this prediction. In sum, the seeming absence of a left-to-right effect may be due to the violation of a strong left expectation.

Our explanation seems compatible with recent theories of prediction in cognition (Clark, 2012) and in sentence processing (Kamide, Altmann, \& Haywood, 2003; Dikker \& Indefrey, 2007; Altman \& Mirkovic, 2009; Farmer, Brown, \& Tanenhaus, in press). Specifically, a way of explaining the rapid nature of language comprehension stems from the idea of prediction. Comprehenders exploit all available information, integrate contextual constraints rapidly and generate predictions about upcoming stimuli. In our study, stimuli pairs were presented simultaneously. However, auditory stimuli are inherently more dynamic than visual stimuli. Sentences take longer to be presented and thus are processed later than a static picture. Therefore, we assume
that participants had the opportunity to process the picture longer and faster than the sentence, arguably allowing them to formulate predictions about the sentence structure. To test for this hypothesis, a future experimental manipulation could involve pictures and sentences presented not simultaneously but in different time points so that expectations about upcoming stimuli could be enhanced. For example, a sentence presented first in SVO structure may formulate the expectation of left agency, whereas an OVS structure may formulate the reverse expectation. If this turns out to be correct, then language may impose strong constraints and guide the way we conceptualize spatially thematic roles.

To conclude, we found that sentence processing not only reflects generic language characteristics, such the directionality of the writing system, but is also sensitive to frequency-driven effects, such as the occurrence rate of specific syntactic structures (i.e. SVO versus OVS). In addition, online language processing seems to be affected by non-linguistic information, which is in line with other findings (Tanenhaus, Spivey-Knowlton, Eberhard, \& Sedivy, 1995). Crucially, our findings are consistent with the left-bias account according to which language-specific factors may constrain and affect our conceptual representations. In sum, our findings suggest that different sources of information (both linguistic and non-linguistic) are interactively used in forming expectations about upcoming material.

\section*{Acknowledgments}

We would like to thank Silvia Gennari (University of York) for providing the visual stimuli. We also thank Efthymia Kapnoula for useful comments on earlier versions of the manuscript.

\title{
Whether Chinese Speakers Think about Time More Vertically Depends on their Immediate and Lifetime Experience of Reading Horizontal or Vertical Texts: Evidence from Contextual Priming
}

\begin{abstract}
Do Chinese speakers think about time vertically because they use vertical spatial metaphors to express time? Inconsistent findings have been reported even when the same paradigms were used. The present study examined participants' performance on a temporal judgment task while holding language constant but varying their lifetime and immediate reading experience of horizontal and vertical texts. Chinese participants from Taiwan and China were randomly assigned to a reading task involving horizontally or vertically arranged texts (contextual primes). A temporal judgment task (spatial-temporal association of response codes or STARC) followed the reading task, asking the participants to judge if the event depicted in a second picture occurred earlier or later than that in a first picture. Responses were faster when the left keys represented the 'earlier' responses than when the right keys did, representing a STARC effect. Half of the participants responded with horizontally oriented keys while the rest with vertically oriented keys. For the Taiwan participants, the overall STARC effect was greater when the response keys were vertical than horizontal, but no difference was observed for the China participants. A questionnaire indicates that the two groups of participants had similar lifetime experiences of reading horizontal texts, but the Taiwan participants read vertical texts in their life far more frequently than the China participants. Immediate reading experiences interacted with lifetime experiences in modulating the vertical bias. For the Taiwan participants, the vertical bias was strong following the vertical prime, but disappeared following the horizontal prime. For the China participants, the horizontal prime led to no vertical bias whereas the vertical prime brought about a horizontal bias. We conclude that the directionality of orthography and speakers' immediate and lifetime reading experiences, rather than the use of vertical spatial metaphors, can better explain the vertical bias (or the lack of it) in the Chinese speakers.
\end{abstract}

Keywords: linguistic relativity; temporal reasoning; reading direction

\section*{Introduction}

Once denounced as scientifically unsound (Devitt and Sterelny, 1987; Pinker, 1994), the linguistic relativity hypothesis has regained much attention in the past two decades. The essence of the hypothesis is that the
particular linguistic form in a language can shape the habitual way of thinking by the speakers of the language (Whorf, 1956; Hunt \& Agnoli, 1991). For example, if language A does not distinguish two shades of blue whereas language B does, speakers of language A would not be able to tell apart the two shades of blue as easily as speakers of language B (Davidoff, Davies, \& Roberson, 1999; Gilbert, Regier, Kay, \& Ivry, 2006; Winawer et al., 2007). Similarly, if language \(A\) does not encode the biological gender lexically whereas language \(B\) does, the gender information would become less accessible to speakers of language \(A\) than speakers of language \(B\) (Chen \& Su, 2011). In the temporal domain, it has been observed that Chinese speakers seem to conceptualize time continuously and maintain an "extended present" view that encompasses recent past and near future, whereas English speakers tend to maintain a relatively discrete view of time with distinct present, past and future. This cross-linguistic difference has been attributed to the use of explicit tense and aspect markers in English and the lack of them in Chinese (Chen, Su, Lee, \& O'Seaghdha, 2012; Chen, Su, \& O'Seaghdha, 2013).

While much of recent empirical work has produced evidence consistent with the linguistic relativity hypothesis, there were controversies due to inconsistent findings as well. One particular controversy comes from the study of spatial metaphors of time. An early study employing a spatial priming paradigm found that the frequent use of vertical spatial metaphors to express time in Chinese led to a vertical bias in the Chinese speakers' conception of time whereas the rare use of such metaphors in English led to a horizontal bias in the English speakers (Boroditsky, 2001). However, subsequent studies were unable to confirm such a differential bias (Chen, 2007; January \& Kako, 2007; Tse \& Altarriba, 2008; Sanvido, de Rose, \& Chen, 2011).

More recently, a SNARC-like paradigm (spatial-numerical association of response codes, Dehaene, Bossini, \& Giraux, 1993) applied to temporal processing (spatial-temporal association of response codes or STARC) detected a similar vertical bias in the Chinese speakers relative to the English speakers (Boroditsky, Fuhrman, \& McCormick, 2011; Fuhrman et al., 2011; Miles, Tan, Noble, Lumsden, \& Macrae, 2011). In a STARC task, the participants saw two photographs of an event and had to determine if the second photograph
occurred earlier or later than the first one. In the canonical condition, they pressed a left key to indicate 'earlier' and a right key to indicate 'later' while in the non-canonical condition, the key assignment was reversed. Response times were typically slower in the non-canonical condition relative to the canonical condition, representing a STARC effect. For half of the participants, the keys were placed horizontally while for the other half, the keys were oriented vertically. It was found that Chinese and English speakers displayed similar horizontal STARC effects, but more importantly, the Chinese speakers demonstrated a greater vertical STARC effect than the English speakers. Unfortunately, inconsistent findings were observed with this paradigm as well. Chen and O'Seaghdha (2012 accepted) observed a vertical bias in the Chinese speakers from Taiwan, but no such bias in the Chinese speakers from China. Because horizontal printing of texts is a national policy in China, but not in Taiwan, where vertical texts are fairly common, it was suggested that reading experience of horizontal and vertical texts might have something to do with the participants' performance on the STARC task. The suggestion, however, was inferred from quasi-experimental evidence.
The present study was designed to test the effect of reading experience on Chinese speakers' performance on the STARC task by experimentally manipulating the layout of texts (horizontal or vertical) which participants read before the STARC task. The reading task, serving as a contextual prime, was expected to bias the Chinese participants towards displaying a greater or smaller horizontal or vertical STARC effect depending on the direction of reading. The modulation of immediate reading experience might interact with Chinese speakers’ lifetime reading experience, which was assessed by including participants from Taiwan and China. The participants from Taiwan would have more extensive experience of reading vertical texts than the participants from China.

\section*{Method}

\section*{Participants}

Fifty-six native Mandarin Chinese speakers from Taiwan and the same number from China participated in this study. The participants from Taiwan were graduate or undergraduate students from National Taiwan Normal University and nearby universities in Taipei, while those from China were similar students from Beijing Normal University and nearby universities in Beijing. The age range for the participants was from 18 to 26 . All the participants had normal or corrected-to-normal vision and they were paid 200 TWDs or 20 RMBs for participation.

\section*{Design and Materials}

The Reading Task Seven short essays with 11 comprehension questions were chosen from the Taiwan University Entrance Exams for the reading task. Two versions of the texts (the essays and the questions) were prepared as paper booklets, one arranged horizontally and the other vertically. Participants were randomly assigned to one version. There was no time pressure for taking the
task. On the average, it took approximately 15 to 20 minutes for the participants to complete this task. Upon completion, the participants proceeded immediately to the STARC task.
The STARC Task The design and procedure of the STARC task followed those of Chen \& O'Seaghdha (2013). The materials were 37 action events, each being photographed at three different phases of time (e.g., Time X : a man holding the handle and about to turn the key to open a door, Time Y: door being open with the man stepping half into the room, and Time Z: door being half closed with the man inside the room facing inward with his left hand holding against the closing door). On each trial, a Time Y picture was randomly chosen from the 37 events and shown to the participants. The Time Y picture was followed by a Time X or a Time Z picture. The participants were asked to determine whether the action depicted in the second picture occurred earlier or later than the action depicted in the first. In one condition (the canonical response), the number-4 key on the numeric keypad of a standard keyboard, marked with a blue sticker, was designated as the 'earlier' response, and the number-5 key, marked with a orange sticker, was designated as the 'later' response. In the other condition (the noncanonical response), the key assignment was reversed, i.e., the ' 5 ' key was the blue one designated as the 'earlier' response and the ' 4 ' key was the orange one designated as the 'later' response. Canonicity was a within-subjects factor. The same set of 37 action events was used in the two canonicity conditions, with the Time X and the Time Z pictures appearing exactly once in each condition. The order of the two conditions was counterbalanced across the participants. A between-subjects factor was also included. Half of the participants, randomly determined, responded with the keyboard placed on the desk in a normal horizontal orientation, and the other half responded with the keyboard oriented vertically (propped up against a bookend).

The task was programmed in E-Prime and was run on a desktop (ASUS B53S with an Intel® Core \({ }^{\mathrm{TM}}\) i5 2520 M processor and a 15.6" 16:9 HD 1366x768-resolution LED screen) and a laptop computer (ASUS R500V with an Intel \({ }^{\circledR}\) Core \({ }^{\mathrm{TM}}\) i7 3610QM 2.3 GHz processor and a \(15.6^{\prime \prime}\) 16:9 HD 1366x768-resolution LED screen), both with a separate USB- connected numeric keypad (Kingyo). A trial began with a fixation cross which appeared at the center of the screen for 500 msec . and was followed by a blank screen for 500 ms . Then, the first picture in a pair appeared at the same location for 2000 ms followed by another blank screen for 500 ms . The second picture followed and stayed on until the participants responded. Upon a response, a last blank screen of 500 ms replaced the second picture and the next trial began. Both pictures measured 22.5 cm in width and 17 cm in height. The participants sat at a viewing distance of 70 cm in front of the computer screen. The participants were told to respond with the index finger of their preferred hand as quickly and accurately as soon as the second picture appeared. The index finger was parked at the gulf between the blue and orange keys at the beginning of a
trial. The participants received five practice trials before going on with the experimental trials.

The Reading Experience Questionnaire Upon completion of the reading task and the STARC task, the participants also filled out a questionnaire to indicate how frequently they encountered a vertical text, a horizontal text printed from left to right, and a horizontal text printed from right to left on a 8-point scale ranging from never (0) to very frequently (7). They also reported the sources of the texts (e.g., magazines, newspapers, textbooks, street signs, slogans, advertisements, etc.).

\section*{Results}

\section*{The Taiwan Sample}

For the Taiwan sample, the participants’ comprehension scores in the reading task were close to perfect. Their rated experience of vertical texts, horizontal left-to-right texts and horizontal right-to-left texts was 5.7 ( \(\mathrm{SD}=1.6\) ), 6.5 ( \(\mathrm{SD}=0.5\) ), and 1.4 ( \(\mathrm{SD}=1.6\) ), respectively. Their error rate in the STARC task was on the average \(3 \%\). The analysis of their log-transformed response times in the STARC task shows the pattern in Figure 1. The STARC effect on the Y-axis represents the averaged difference in log-transformed response time of the noncanonical condition minus the canonical condition. The overall STARC effect was significant by the linear mixed-effect analysis: \(F(1,7915)=59.18, p<.0001\). As the figure shows, the STARC effect was greater when the response keys were oriented vertically than when they were oriented horizontally: \(F(1,7915)=11.13, p=.0009\). This indicates an overall vertical bias in temporal judgment by our Taiwan participants. The figure also shows that whereas the vertical bias was fairly strong following the vertical prime (i.e., having read the vertical texts and questions), it was substantially reduced (in fact disappeared) following the horizontal prime. Statistically, the response orientation by canonicity interaction was highly significant under the vertical prime, \(F(1,3952)=\) 18.51, \(p<.0001\), but the same interaction was far from being significant under the horizontal prime, \(F(1,3927)\) \(=.35, p=.5564\).

\section*{The Beijing Sample}

For the Beijing sample, the participants' comprehension scores in the reading task were also close to perfect. Their rated experience of vertical texts, horizontal left-to-right texts and horizontal right-to-left texts was 2.7 ( \(\mathrm{SD}=1.6\) ), 6.9 ( \(\mathrm{SD}=0.7\) ), and 1.3 ( \(\mathrm{SD}=1.3\) ), respectively. Their averaged error rate in the STARC task was \(3 \%\). The analysis of their log-transformed response times in the STARC task shows the pattern in Figure 2. The overall STARC effect was significant by the linear mixed-effect analysis: \(F(1,7857)=50.07, p<.0001\). As the figure shows, the STARC effect interacted significantly with prime and response orientation: \(F(1,7857)=8.01, p\) \(=\).0047. Separate post-hoc analyses show that the response orientation by canonicity interaction was significant under the vertical prime, \(F(1,3895)=4.83, p\) \(=.0280\), showing a greater horizontal STARC effect than
the vertical one; under the horizontal prime, the vertical STARC effect was greater than the horizontal one, but the interaction fell short of the conventional level of significance, \(F(1,3926)=3.22, p=.0728\). Worth noting is no significant difference between the horizontal and vertical STARC effects ( \(p=.57\) ), indicating no overall vertical bias in the Beijing participants. None of the other effects were significant, \(p\) 's > .24.

Figure 1: The STARC effect (difference in log RT of the noncanonical condition minus the canonical condition) as a function of response key orientation and type of contextual prime (the Taipei sample).

Figure 2: The STARC effect (difference in log RT of the noncanonical condition minus the canonical condition) as a function of response key orientation and type of contextual prime (the Beijing sample).

\section*{Discussion}

The Chinese language employs both horizontal and vertical spatial metaphors for expressing time. It has been suggested that the common use of vertical spatial metaphors biases the Chinese speakers to conceptualize time vertically. We hypothesized that reading experience of horizontally and vertically arranged texts might be a potent variable contributing to such a bias. The hypothesis was tested by assigning Chinese participants from Taiwan and China to a reading task involving either horizontally or vertically arranged texts, followed by a STARC task. Although the vertical STARC effect was overall greater than the horizontal one among the Taiwan participants, such a vertical bias was absent among the China participants. These results can be accounted for by the significantly more frequent lifetime experience of encountering vertical texts among the Taiwan participants
than among the China participants: 5.7 vs. \(2.7, \mathrm{t}(110)=\) \(9.9, \mathrm{p}<.0001\). The rated experience of encountering horizontal left-to-right texts was similar between the two groups of participants: 6.5 vs 6.9.
Furthermore, the vertical bias, when present, was modulated by the immediate reading experience such that it disappeared when the Taiwan participants had just read horizontally arranged texts. For the China participants, the immediate reading experience also modulated the vertical bias, but in the opposite direction. The horizontal prime led to no significant vertical bias while the vertical prime brought about a horizontal bias. The different patterns of results between the Taiwan and the Beijing participants indicate that lifetime reading experience interacts with immediate reading experience in its effect on the participants' temporal judgment in the STARC task.
The finding of a causal role of directionality of orthography and reading experience in Chinese speakers’ temporal judgment is consistent with the findings of many studies in the literature showing a relationship between the directionality of orthography and the performance on a space-implicated task (Tversky, Kugelmass, and Winter, 1991; Dehaeneet al., 1993; Zebian, 2005; Chan \& Bergen, 2005; Fuhrman \& Boroditsky, 2010; Ouellet, Santiago, Israeli, \& Gabay, 2010). In conjunction with these findings as well as the facts that (1) horizontal spatial metaphors are used far more frequently than vertical ones in Mandarin Chinese (Chen, 2007) and (2) our Taiwan and China participants speak the same language, the results of the present study suggest that the directionality of orthography and speakers’ (immediate and lifetime) reading experience, rather than the use of spatial metaphors per se, can better explain the vertical bias (or the lack of it) in the Chinese speakers.

Chen and O'Seadhgha (2012 accepted) previously observed a vertical bias in the Chinese participants from Taipei (Taiwan), but a horizontal bias in the Chinese participants from Guangdong (China). The discrepancy was attributed to the fact that China has adopted the national policy of printing all texts horizontally whereas both horizontal and vertical directions are allowed and prevalent in Taiwan. The evidence, however, is indirect due to the quasi-experimental nature of the study. By directly manipulating the participants’ experience of reading horizontal and vertical texts, the present study offers the needed evidence for establishing the causal role of directionality of orthography and reading experience.

Reading experience can also account for the inconsistent findings across studies. Because the Chinese participants in the previous studies came from different regions, their experience of reading horizontal and vertical texts could vary greatly, which was attested to by the rating data in the present study, and thus could contribute to the inconsistency in findings.

Returning to the use of spatial metaphors for expressing time, Chen (2007) has previously reported that horizontal spatial metaphors were actually used far more frequently than vertical spatial metaphors in Chinese. He argued that the usage pattern did not lend the logical support for the hypothesis that Chinese speakers would think about time
more vertically. Boroditsky et al. (2011) countered Chen's argument by maintaining that it was the cross-language difference in the usage of vertical spatial metaphors that predicted the vertical bias in the Chinese speakers. However, without controlling for potent factors such as directionality of orthography and speakers’ reading experience, it is impossible to make certain that Chinese speakers do think about time differently than English speakers and that this is due to the differential usage of vertical spatial metaphors in the two languages.

The hypothesized conceptual link between spatial and temporal reasoning has also been questioned recently with respect to the use of frame of reference. It has been claimed that people reference time onto space, and because different linguistic communities prefer different spatial frames of reference, their temporal references vary as well. Beller, Rothe, Hüther and Bender (2012) examined existing data as well new data, concluding that there is not a close link between referencing preferences across spatial and temporal domains.

Although linguistic relativity has manifested itself in several domains of cognition, whether it extends to the conception of time in relation to the latter's metaphorically projected meaning requires further investigations at best.

\title{
Hemispheric Asymmetry in Nonconscious Processing
}

\begin{abstract}
Here we investigated whether hemispheric asymmetry effects can be observed in nonconscious processing with a basiclevel animal categorization (cat/dog) task. We found a significant nonconscious congruency priming effect when the prime was presented in the right visual field/left hemisphere but not when it was presented in the left visual field/right hemisphere when the prime duration was only 10 ms ; the leftlateralized congruency priming effect was consistent with the left hemisphere superiority in processing abstract category information reported in the literature (e.g., Marsolek, 1999). This result thus showed that nonconscious processing can go beyond the sensory level to influence hemispheric asymmetry in the processing of category information. In contrast, this hemispheric difference was not observed when the prime was presented for 50 ms (nonconscious) or 150 ms (conscious). This effect may be because 10 ms subliminal information was insufficient to allow inter-hemispheric transfer/processing, allowing the hemispheric difference to emerge. It also suggests that hemispheric asymmetry may be better observed at subliminal level.
\end{abstract}

Keywords: subliminal priming; hemispheric asymmetry; attention; nonconscious processing;

\section*{Introduction}

It has been well established in the literature that subliminal stimuli are able to elicit subsequent cognitive and behavioral influences (see Kouider \& Dehaene, 2007 for a review). It remains unclear, however, how a subliminally presented stimulus is processed. Here we aim to examine whether a subliminally presented stimulus can induce hemispheric asymmetry effects.

In the literature of hemispheric asymmetry in perception, hemispheric asymmetry effects typically did not emerge until a late perceptual stage (Fendrich \& Gazzaniga, 1990; Hsiao., Cipollini., \& Cottrell., accepted; Sergent, 1982). More specifically, hemispheric asymmetry effects were typically observed in tasks involving high-level perception such as face recognition (e.g., Keenan, Whitman, \& Pepe, 1989), but not in tasks more relevant to early perceptual processes such as grating detection (e.g., Fendrich \& Gazzaniga, 1990). Based on these findings, it has been argued that hemispheric asymmetry effects "must result from processing taking place beyond the sensory level" (Sergent, 1982). Thus, examining hemispheric asymmetry effects in subliminal priming can help us understand whether nonconscious processing can go beyond early
perceptual processes to induce hemispheric asymmetry effects.

Nevertheless, in the literature on subliminal priming, whether hemispheric asymmetry effects can be observed in the processing of subliminal stimuli was rarely studied. Marzouki, Grainger, and Theeuwes (2007) examined subliminal priming effects in a letter/pseudo-letter judgment task. In their experiment, the target stimulus always appeared at the center, while the preceding \(45-\mathrm{ms}\) prime (the same letter as the target) could be in the left visual field (LVF) or the right visual field (RVF). The results showed that in the trials with a letter target, a robust priming effect was found, however, only when the prime was presented in the RVF/left hemisphere (LH), but not when it was presented in the LVF/right hemisphere (RH). While Marzouki et al. (2009) interpreted the results as an attentional bias in favor of the RVF, their results may suggest a hemispheric asymmetry effect in subliminal letter processing as well. However, it is also possible that the RVF priming effect Marzouki et al. (2007) observed was due to perception-response compatibility, as participants always used their right hand to respond to the letter targets. Thus, it remains unclear whether hemispheric asymmetry effects can be observed in subliminal priming.

Using a supraliminal priming paradigm, Marsoleck (1999) found hemispheric asymmetry effects in processing category-related information. In Marsoleck (1999)'s study, participants were asked to name pictures of objects presented for 17 ms in either the LVF or the RVF. Before the target presentation, the same object or another object from the same basic category as the target object was presented centrally for 3 seconds as the prime. While a same-object priming effect was found for both LVF and RVF targets, the same-category different-object priming effect was only observed in the RVF/LH. This result suggested that the LH may be biased towards abstractcategory representations whereas the RH is biased towards exemplar-specific representations. This hemispheric asymmetry in the representation of category knowledge was further supported by several follow-up studies using various stimuli (Laeng, Zarrinpar, \& Kosslyn, 2003; Studer \& Hübner, 2008).

Thus, in the present study, we aimed to examine whether this hemispheric asymmetry in the representation of category knowledge can be induced with subliminal stimuli in a category judgment task (Marsolek, 1999), with perception-response compatibility controlled (cf. Marzouki
et al., 2007). The results of this examination can shed light on whether subliminal information can go beyond the sensory level to influence late perceptual processes.

In the representation of object category information, there are multiple levels of abstraction. A cat can be identified as "cat" (the basic level), or "animal" (the superordinate level), or "Sam" (a specific cat, the subordinate level). The current study focuses on the processing of basic-level category information (i.e., a cat/dog classification task). In a previous study (Finkbeiner \& Palermo, 2009), the authors investigated nonconscious congruency priming effects in an animal/tool classification task (experiment 1a; or an animal/vegetable classification task in experiment 2a), which was at the superordinate level. In their study, the prime was always at the top location and the target was always at the button location. And the top prime can be spatially cued or not. The results showed that a nonconscious congruency priming effect was found only in the condition when the prime was cued. This effect suggests that nonconscious processing of superordinate-level category information relies on the engagement of spatial attention.

Thus, the other aim of the current study was to examine whether nonconscious processing of basic-level category information also relied on spatial attention. Previous studies showed that, compared with superordinate-level category information, basic-level information was more accessible (e.g., Rosch, Mervis, Gray, Johnson, \& Boyes-Braem, 1976), basic-level terms were preferred in naming objects (e.g., Jolicoeur, Gluck, \& Kosslyn, 1984; Rosch et al., 1976) and recognizing objects at the basic level required less reaction time (e.g., Tanaka, 2001). Thus, it is possible that nonconscious processing of basic-level category information is more automatic than that of superordinate-level category information and does not require attention.

Therefore, in the current study, we aimed to 1) examine whether there is a hemispheric asymmetry in the subliminal priming effect by presenting the prime in either the LVF or the RVF, and 2) investigate whether nonconscious processing of basic-level category information relies on the engagement of spatial attention. In addition, we manipulated the duration of the prime ( \(150-\), 50 -, and \(10-\mathrm{ms}\) ) in order to compare hemispheric asymmetry and attentional modulation effects across conditions with different levels of consciousness.

\section*{Experiment 1}

In experiment 1, the prime ( \(150-\mathrm{ms}\) duration) was visible in order to: 1) examine whether the congruency priming effect can be found at the supraliminal level, and 2) investigate whether this congruency priming effect can be modulated by hemispheric asymmetry and spatial attention.

\section*{Method}

Participants 20 students ( 13 females, age mean \(=20.7\), range \(=18-24)\) at the University of Hong Kong participated
in exchange for course credits or payment. All were Asian, with normal or corrected-to-normal vision.

Stimuli Dog and cat images, all frontal-view or close to frontal-view, were selected from the Oxford-IIT Pet Dataset (Parkhi, Vedaldi, Zisserman, \& Jawahar, 2012), with cat images from the species of British Shorthair and dog images from that of Shiba Inu. Only the head parts of the animal images were used and were converted to grayscale, and were further cropped to fit within a black oval. They all had equal size, luminance, and contrast.

Two types of black and white noise images were used as masks. The random noise mask was generated by assigning a random value between 155 and 255 to each pixel, while the animal mask was created by, firstly, combining a cat and a dog image, and then scrambling the combined image. The animal mask was used as a backward mask for the prime as well as the target.

Each stimulus, including both animal images and masks, spanned \(4^{\circ}\) visual angle vertically and \(2.5^{\circ}\) horizontally with a \(60-\mathrm{cm}\) viewing distance.

Design and Procedure The experiment used a 2 (spatial attention: prime-cued vs. uncued) \(\times 2\) (congruence between the prime and target: congruent vs. incongruent) \(\times 2\) (visual field: LVF vs. RVF for the location of the prime) withinparticipant design. Participants were instructed to judge the category of the target pictures, i.e., a dog/cat judgment. They made the binary choice by pressing two buttons ("F" and "J") on a keyboard with their two index fingers simultaneously, or another two buttons ("D" and "K") with their middle fingers simultaneously. The response buttons were counterbalanced across participants.

Figure 1: Sequence of stimuli in a single trial
The basic trial structure was similar to Marzouki, Grainger and Theeuwes (2007)'s study (Figure 1). After a forward mask with a duration randomly selected among 400, 500, 600, and 700 ms , a yellow box cue was presented
either at the left or the right side for 150 ms , followed by the \(150-\mathrm{ms}\) prime image at either the same (Prime-cued) or the opposite (Prime-uncued) side of the cue. Then, the target image appeared for 200 ms at the center together with two animal backward masks at both the left and right sides. Following the target, another animal mask appeared at the center for 1500 ms (See Figure 1). Participants were instructed to make their judgment as quickly and as accurately as possible after they saw the target.

Before the main experiment, a practice section with 20 trials was performed. The procedure of the practice was the same as the main experiment. The images used in the practice never appeared in the main experiment. After the main experiment, in order to confirm that the prime images were visible, participants were instructed to do a primediscrimination task, i.e., to judge the category of the prime images. The procedure was identical to the main experiment except that participants were to make judgments on the prime instead of the target stimulus, and that the backward masks at the end of each trial stayed until participants made their response.

40 images ( 20 cat and 20 dog images) were used as the target as well as the prime stimuli in all four conditions (congruent with prime cued, congruent with prime uncued, incongruent with prime cued, incongruent with prime uncued), with the constraint that the prime and the target could not be the same image. In each condition, all 40 images appeared once as the target, resulting in 160 trials in total. Trials were presented in a random order, with the limits that the same target did not appear in succession, that no more than 3 trials in a row elicited the same response, and that no more than 3 trials in a row were in the same condition. In the prime-discrimination task, there were also 160 trials.

\section*{Results}

In analyzing the response times (RTs), null responses and incorrect responses (6.47\%) were excluded. And any RT outside 2.5 standard deviations from the mean, for each participant, was treated as outliers (2.78\%). In analyzing the accuracy data, only null responses ( \(0.75 \%\) ) were excluded.

The result of the prime-discrimination task confirmed that the \(150-\mathrm{ms}\) prime was visible. The mean accuracy reached \(77.7 \%\), significant higher than the \(50 \%\) chance level, t (19) \(=9.57, p<.001\).

A 2 (spatial attention) \(\times 2\) (congruency) \(\times 2\) (visual field) repeated measures ANOVA on the RTs revealed a significant main effect of congruency, \(\mathrm{F}(1,19)=4.90, p\) \(<.039\), with faster RTs for congruent trials (Mean \(=638 \mathrm{~ms}\) ) than incongruent trials (Mean \(=648 \mathrm{~ms}\) ). No significant main effects of spatial attention or visual field (both \(p>.10\) ) were found. There was no interaction between spatial attention and congruency ( \(p>.70\) ) or between visual field and congruency ( \(p>.29\) ), suggesting that spatial attention and visual field did not modulate the priming effect under this supraliminal condition.

The same \(2 \times 2 \times 2\) repeated measures ANOVA was conducted on the accuracy data; no reliable effects or interactions were observed (all p > .10).

\section*{Discussion}

The \(150-\mathrm{ms}\) prime was long enough for conscious processing of category information, as participants had well above-chance performance in the prime-discrimination task. At the conscious level, a robust congruency priming effect was observed, both when the prime was cued or uncued. This result was consistent with the results of Lachter, Forster and Ruthruff (2004)'s study (experiment 1). In a lexical decision task, Lachter et al. (2004) observed a significant repetition priming effect in conditions where a supraliminal prime ( 110 or 165 ms ) was at a task-relevant or task-irrelevant position. At supraliminal level with a long prime duration, participants were typically able to shift their attention to the prime even when the prime was at an irrelevant location (Lachter, Forster, \& Ruthruff, 2004) or uncued. Thus, no attentional modulation effect was observed.

\section*{Experiment 2}

In experiment 2, the prime duration was changed to 50 ms in order to be rendered invisible, as was in the previous studies (Finkbeiner \& Palermo, 2009; Harry, Davis, \& Kim, 2012). In contrast to the superordinate level recognition task (animal vs. tool; or animal vs. vegetable) used in Finkbeiner and Palermo (2009)'s study (the animal condition); participants in the current study were to categorize images at the basic level (cat vs. dog). Finkbeiner and Palermo (2009) found that nonconscious processing of superordinate-level category information relies on the engagement of spatial attention. Here we aimed to examine whether a similar effect can be found in the processing of basic-level category information.

\section*{Method}

Participants 16 students ( 9 females, age mean \(=21.8\), range \(=18-27)\) at the University of Hong Kong participated in exchange for course credits or payment. All were Asian, with normal or corrected-to-normal vision. None of them participated in experiment 1.

Stimuli, Design and Procedure All settings in experiment 2 were exactly the same as those in the experiment 1, except that the prime duration was changed from 150 ms to 50 ms .

\section*{Results}

In analyzing the RTs, null responses and incorrect responses (6.8\%) were excluded. And any RT outside 2.5 standard deviations from the mean, for each participant, was treated as outliers (3.7\%). In analyzing the accuracy data, only null responses (1.5\%) were excluded.

The result of the prime-discrimination task confirmed that the 50 -ms prime was invisible, with the mean accuracy of
51.6\% being not significantly different from the \(50 \%\) chance level, \(\mathrm{t}(15)=1.64, \mathrm{p}>.10\).

A 2 (spatial attention) \(\times 2\) (congruency) \(\times 2\) (visual field) repeated measures ANOVA on the RTs showed a significant main effect of congruency, \(\mathrm{F}(1,15)=4.88, p\) \(<.043\), with faster RTs for congruent trials ( 668 ms ) than incongruent trials ( 680 ms ). In contrast to the results of Finkbeiner and Palermo (2009), however, we did not find evidence of attentional modulation on the congruency priming effect, \(\mathrm{F}(1,15)=0.65, p=.43\). In addition, followup analysis revealed a significant priming effect when the prime was uncued, F \((1,15)=6.91, \mathrm{p}<.019\); but the priming effect when the prime was cued failed to reach significance, \(p>.50\). There was no main effect of visual field ( \(p>.40\) ) or interaction between visual field and congruency ( \(p>.60\) ).

The same \(2 \times 2 \times 2\) repeated measures ANOVA on the accuracy data revealed a main effect of congruency, \(\mathrm{F}(1,15)\) \(=6.74, p<.02\), with lower accuracy in congruent trials (93.5\%) than incongruent trials (95.7\%). No modulation effects of attention ( \(p>.70\) ) or visual field ( \(p>.50\) ) were found.

Table 1: Mean RTs (SE) in experiment 1 and 2
\begin{tabular}{lll}
\hline \multicolumn{1}{c}{ Condition } & \multicolumn{2}{c}{ RTs (ms) } \\
& Prime-cued & Prime-un-cued \\
\hline 150-ms prime & & \\
Congruent & \(635(14)\) & \(641(15)\) \\
Incongruent & \(647(14)\) & \(648(13)\) \\
Priming & 12 & 7 \\
& & \\
50-ms prime & & \\
Congruent & \(670(17)\) & \(666(18)\) \\
Incongruent & \(676(19)\) & \(685(18)\) \\
Priming & 6 & 19 \\
\hline
\end{tabular}

\section*{Discussion}

The results in experiment 2 showed no evidence suggesting attentional modulation on the nonconscious priming effect in the basic-level categorization task; in addition, a significant nonconscious priming effect was observed when the prime was not cued. This effect suggests that nonconscious processing of basic-level category information does not rely on spatial attention, in contrast to the finding that nonconscious processing of superordinate-level category information depends on spatial attention (Finkbeiner \& Palermo, 2009).

Results in some earlier studies examining nonconscious priming effects with visual word stimuli (Fuentes, Carmona, Agis, \& Catena, 1994; Kiefer \& Brendel, 2006) were consistent with this finding. In Fuentes et al. (1994)'s study, for instance, a lexical decision task was used. In experiment 2 , the two nonconscious prime words, one presented in the foveal and the other in the parafoveal vision, were presented at the same time, followed by masks. The center target
could be semantically related to the foveal prime or the parafoveal prime. The results showed that similar, reliable priming effects were found for both the foveal and parafoveal prime. It was argued that semantic representations stored in the long-term memory were ready to be activated even when no attention was drawn to the nonconscious prime word (Kiefer \& Brendel, 2006). Thus, similar to semantic information, basic-level category information may also be readily accessible even when no attention was drawn to the nonconscious prime picture.

\section*{Experiment 3}

In experiment 3, the prime duration was further changed to 10 ms . As no modulation from attention or VF was observed in experiment 1 and 2 , experiment 3 aimed to explore it further by testing the condition where the awareness of the prime was extremely low.

\section*{Method}

Participants 18 students ( 14 females, age mean \(=22.9\), range \(=18-29)\) at the University of Hong Kong participated in exchange for payment. All were Asian, with normal or corrected-to-normal vision. None of them participated in experiment 1 or 2.

Stimuli, Design and Procedures All settings were exactly the same as those in experiment 1, except that the prime duration was changed to 10 ms and that there was a \(40-\mathrm{ms}\) inter-mask between the prime and the target.

\section*{Results}

In analyzing the RTs, null responses and incorrect responses (4.8\%) were excluded. And any RT outside 2.5 standard deviations from the mean, for each participant, was treated as outliers (3.3\%). In analyzing the accuracy data, only null responses ( \(1.0 \%\) ) were excluded.

The results of the prime-discrimination task confirmed that the \(10-\mathrm{ms}\) prime was invisible, with the mean accuracy of \(50.5 \%\) being not significantly different from the \(50 \%\) chance level, \(\mathrm{t}(17)=0.69, p>.50\).

A 2 (spatial attention) \(\times 2\) (congruency) \(\times 2\) (visual field) repeated measures ANOVA on the RTs did not find any reliable effect or interaction (all \(p>.10\) ).

The same \(2 \times 2 \times 2\) repeated measures ANOVA on the accuracy data, however, showed a significant interaction between VF and congruency, F \((1,17)=5.64, p<.03\), but no main effect of congruency, \(p>.15\), or interaction between attention and congruency, \(p>.70\). Follow-up analysis revealed a significant congruency priming effect when the prime was presented in the RVF, \(\mathrm{F}(1,17)=9.19\), \(p<.01\), with a higher accuracy in the congruent trials (97.3\%) than that in the incongruent trials (95.2\%); in contrast, no congruency priming effect was observed in the LVF, \(p>.60\). This priming effect in the RVF did not interact with spatial attention, \(\mathrm{F}(1,17)=1.41, p>.25\). Also, there was no significant interaction between congruency and spatial attention overall, \(\mathrm{F}(1,17)=0.15, p>.70\).

\section*{Discussion}

With extremely low awareness of the prime (with only 10ms duration), a significant congruency priming effect was obtained on accuracy in the RVF/LH, but not when the prime was presented in the LVF/RH. Marzouki et al. (2007) found similar results using a \(45-\mathrm{ms}\) prime with letter/pseudo letter stimuli. One potential concern in Marzonki et al. (2007)'s study was that, participants always used their right hand to respond to letter targets. Thus it was possible that the RVF superiority effect was due to the compatibility between prime location and response hand. In the present study, the location-response compatibility was counterbalanced across participants, and a strong RVF (LH) advantage was still observed.

The finding of the RVF/LH superiority in congruency priming in the basic-level categorization task here is consistent with Marsolek’s (1999) results, which suggested that the LH was biased towards abstract-category representations whereas the RH was biased towards exemplar-specific representations (e.g., Laeng et al., 2003; Marsolek, 1995, 1999; Studer \& Hübner, 2008). Here our participants were required to make a basic-level category judgment on the target, with a prime presented in either the LVF or the RVF. The target and the prime were always different exemplars from the same category or from different categories. Since the prime was always different from the target, the abstract category representation in the LH activated by the prime was able to facilitate the categorization of the target. Thus, the priming effect was only observed with a RVF prime but not a LVF prime.

A critical difference between the present study and the earlier studies was that visual information projected to the LH and the RH was rendered nonconscious by masks and brief duration. Our findings suggested that the processing of nonconscious information could go beyond the sensory level to induce hemispheric asymmetry effects

\section*{General Discussion}

In the current study, we aimed to examine whether there is hemispheric asymmetry in the processing of nonconscious information. We observed a nonconscious congruency priming effect on accuracy when the prime was presented in the RVF/LH, but not when the prime was presented in the LVF/RH, with a \(10-\mathrm{ms}\) prime, in a basic-level object categorization task.

Previous studies have shown that hemispheric asymmetry effects typically do not emerge at an early visual processing stage, such as findings in grating detection tasks (e.g., Fendrich \& Gazzaniga, 1990). In contrast, hemispheric specialization can typically be observed in high-level perception tasks such as face recognition (e.g., Keenan et al., 1989). Our results of hemispheric asymmetry in subliminal priming suggest that the processing of subliminal information can go beyond the sensory level to influence high-level perceptual processes. It is consistent with previous findings that nonconscious information could
influence semantic processing (e.g., Yeh, He, \& Cavanagh, 2012).

The LH advantage in the present study was in accordance with the abstract-specific representation account of hemisphere asymmetry in the representation of category knowledge proposed by Marsolek (1999). However, surprisingly, this effect was not found under the \(50-\mathrm{ms}\) (nonconscious) and \(150-\mathrm{ms}\) (conscious) prime conditions. The effect that longer prime presentation duration diminished hemispheric asymmetry effects in subliminal priming may be due to interhemispheric communications. It is possible that for a prime appeared in the LVF/RH, 50 ms or longer was long enough for the information to reach the LH through the corpus callosum, and to consequently activate the abstract representation of the corresponding category, resulting in a similar level of priming as compared with a prime presented in the RVF/LH. 10 ms duration, however, might be insufficient for a LVF/RH subliminal prime to reach the LH. Without the activation of abstract representations stored in the LH (Marsolek, 1999), a prime in the LVF/RH failed to facilitate the processing of the target in the basic-level categorization task; consequently, a significant priming effect was observed only with a RVF prime. This effect also suggests that hemispheric asymmetry may be better observed at subliminal level.

Note that in the present study, the prime was followed by a mask. Previous studies have revealed that a backward mask is able to block brain processing of stimuli (BaconMacé, Macé, Fabre-Thorpe, \& Thorpe, 2005). In BaconMacé et al.'s (2005) study, an image (with 6.25 ms duration) was followed by a \(100-\mathrm{ms}\) mask. The SOA between the image and the mask was manipulated, raning from 6 ms to 106 ms . Participants were asked to judge whether there was an animal in the image. The behavirol accuracy decreased as the SOA became shorter, reaching the chance level when the SOA was 6 ms . In addition, brain activities trigerred by the image decreased rapidly with shorter SOAs, indicating that brain processing was impaired significantly by the backward mask. These findings further suggest that in our study the \(10-\mathrm{ms}\) LVF/RVF subliminal prime with a backward mask was too fragile to reach the other side of the brain, allowing hemispheric difference to emerge.

Another major finding in the current study was that no attentional modulation on the nonconscious congruency priming effect in the basic-level categorization task was observed across the 3 experiments with different prime durations; in particular, we observed a significant priming effect when attention was not drawn to the \(50-\mathrm{ms}\), invisible prime (experiment 2). This result was in contrast to the superordinate-level categorization task used in Finkbeiner and Palermo (2009)'s study, in which the nonconscious priming effect depended on attention. Our results provided evidence for the influence from levels of abstraction in a categorization task in nonconscious processing. This is consistent with previous findings that basic-level category information was accessed first in the perception of visual objects and named first by children (Rosch et al., 1976).

Why is basic level information special? It is possible that in the human evolution, people had to recognize "tiger" as a tiger (i.e., the basic level), rather than as an animal (i.e., the superordinate level), in order to detect and escape from potential dangers in the environment. The basic-level categorization was crucial for survival, and thus through evolution we developed the ability to process basic-level category information both nonconsciously and without attention.

\begin{abstract}
Bayesian Analogy with Relational Transformations (BART) is a discriminative model that can learn comparative relations from non-relational inputs (Lu, Chen \& Holyoak, 2012). Here we show that BART can be extended to solve inference problems that require generation (rather than classification) of relation instances. BART can use its generative capacity to perform hypothetical reasoning, enabling it to make quasideductive transitive inferences (e.g., "If \(A\) is larger than \(B\), and \(B\) is larger than \(C\), is \(A\) larger than \(C ? "\) ). The extended model can also generate human-like instantiations of a learned relation (e.g., answering the question, "What is an animal that is smaller than a dog?"). These modeling results suggest that discriminative models, which take a primarily bottom-up approach to relation learning, are potentially capable of using their learned representations to make generative inferences.
\end{abstract}

Keywords: Bayesian models; generative models; discriminative models; relation learning; transitive inference; deduction; induction; hypothetical reasoning

\section*{Introduction}

\section*{Generative and Discriminative Models}

Bayesian models of inductive learning can be designed to focus on learning either the probabilities of observable features given concepts (generative models) or the probabilities of concepts given features (discriminative models; Friston et al., 2008; Mackay, 2003). Generative models are especially powerful as they are capable of not only classifying novel instances of concepts (using Bayes’ rule to invert conditional probabilities), but also generating representations of possible instances. In contrast, discriminative models focus directly on classification tasks, but do not provide any obvious mechanism for making generative inferences.

In recent years, generative Bayesian models have been developed to learn complex concepts based on relational structures (e.g., Goodman, Ullman \& Tenenbaum, 2011; Kemp \& Jern, 2009; Kemp, Perfors \& Tenenbaum, 2007; Tenenbaum, Kemp, Griffiths \& Goodman, 2011). Representations of alternative relational structures are used to predict incoming data, and the data in turn are used to revise probability distributions over alternative structures. The highest level of the structure typically consists of a
formal grammar or a set of logical rules that generates alternative relational "theories", which are in turn used to predict the observed data. That is, the set of possible relational structures is provided to the system by specifying a grammar that generates them.

Despite their impressive successes, there are some reasons to doubt whether the generative approach provides an adequate basis for all psychological models of relation learning. Since the postulated grammar of relations is not itself learned, the generative approach implicitly makes rather strong nativist assumptions. Moreover, generative models of relation learning do not fit the intuitive causal direction. For example, it seems odd to claim that a binary relation such as larger than somehow acts to causally generate an ordered pair (e.g., <dog, cat>) that constitutes an instantiation of the relation. It seems more natural to consider how observable features of the objects in the ordered pair give rise to the truth of the relation, i.e., to apply a discriminative approach.

\section*{Discriminative Models of Relation Learning}

Recently, discriminative models have also been applied to relation learning. Silva, Heller, and Ghahramani (2007) developed a discriminative model for relational tasks such as identifying classes of hyperlinks between webpages and classifying relations based on protein interactions. Although their model was developed to address applications in machine learning, the general principles can potentially be incorporated into models of human relational learning. One key idea is that an \(n\)-ary relation can be represented as a function that takes ordered sets of \(n\) objects as its input and outputs the probability that these objects instantiate the relation. The model learns a representation of the relation from labeled examples, and then applies the learned representation to classify novel examples. A second key idea is that relation learning can be facilitated by incorporating empirical priors, which are derived using some simpler learning task that can serve as a precursor to the relation learning task.

These ideas were incorporated into Bayesian Analogy with Relational Transformations (BART), a discriminative model that can learn comparative relations from nonrelational inputs (Lu, Chen \& Holyoak, 2012). Given
independently-generated feature vectors representing pairs of animals that exemplify a relation, the model acquires representations of first-order comparative relations (e.g., larger, faster) as weight distributions over the features. Learning is guided by empirical priors for the weight distributions derived from initial learning of one-place predicates (e.g., large, fast). BART's learned relations support generalization to new animal pairs, allowing the model to discriminate between novel pairs that instantiate a relation and those that do not. Moreover, BART's learned weight distributions can be systematically transformed to solve analogies based on higher-order relations (e.g., opposite).

BART has thus demonstrated promise as a discriminative model of relation learning, which does not presuppose an innate grammar of relations. However, the challenge remains to extend the model to tasks requiring generative inferences. For example, people are able to construct actual instantiations of relations, answering questions such as, "What is an animal that is smaller than a dog?" (Although one might suppose that such questions could be answered by undirected trial-and-error, we shall see that people's answers are often systematically guided by their representations of the relation and of the animal provided as a cue.) Another challenging task is purely hypothetical reasoning, which requires making inferences about arbitrary instances of the relation. Comparative relations such as larger exhibit the logical properties of transitivity and asymmetry, supporting deductions such as "If \(A\) is larger than \(B\), and \(B\) is larger than \(C\), then \(A\) is larger than \(C\)." Children as young as five or six years can make such transitive inferences reliably (Halford, 1992; Goswami, 1995; Kotovsky \& Gentner, 1996). In the present paper we describe an extension of the BART model that addresses these challenges of making generative inferences.

\section*{BART Model of Relation Learning}

\section*{Domain and Inputs}

We focus on the same domain and inputs used in the initial BART project (Lu et al., 2012): the domain of comparative relations between animal concepts (e.g., a cow is larger than a sheep). To establish the "ground truth" of whether various pairs of animals instantiate different comparative relations, Lu et al. used a set of human ratings of animals on four different continua (size, speed, fierceness, and intelligence; Holyoak \& Mah, 1981). These ratings made it possible to test the model on learning eight different comparative relations: larger, smaller, faster, slower, fiercer, meeker, smarter, and dumber.

Each animal concept is represented by a real-valued feature vector. In order to avoid the perils of hand-coded inputs (i.e., the possibility that the model's successes may be partly attributable to the foresight and charity of the modelers), we use what we call "Leuven vectors." These representations are derived from norms of the frequencies with which participants at the University of Leuven
generated features characterizing 129 different animals (De Deyne et al., 2008; see Shafto, Kemp, Mansinghka, \& Tenenbaum, 2011). Each animal in the norms is associated with a set of frequencies across more than 750 features. We created vectors of length 50 based on the 50 features most highly associated with the subset of 44 animals that are also in the ratings dataset (Lu et al., 2012). Figure 1 provides a visualization (for 30 example animals and the first 15 of the 50 features) of these high-dimensional and distributed representations, which might be similar to the representations underlying people's everyday knowledge of various animals.

Figure 1: Illustration of Leuven vectors (reduced to 15 features to conserve space) for some example animals. The cell intensities represent feature values (light indicates high values and dark indicates low values).

\section*{Relations as Weight Distributions}

BART represents a relation using a joint distribution of weights, \(\mathbf{w}\), over object features. A relation is learned by estimating the probability distribution \(P\left(\mathbf{w} \mid \mathbf{X}_{\mathbf{s}}, \mathbf{R}_{\mathbf{s}}\right)\), where \(\mathbf{X}_{\mathbf{s}}\) represents the feature vectors for object pairs in the training set, the subscript \(\mathbf{S}\) indicates the set of training examples, and \(\mathbf{R}_{\mathrm{s}}\) is a set of binary indicators, each of which (denoted by \(R\) ) indicates whether a particular object (or pair of objects) instantiates the relation or not. The vector \(\mathbf{w}\) constitutes the learned relational representation, which can be interpreted as weights reflecting the influence of the corresponding feature dimensions in \(\mathbf{X}\) on judging whether the relation applies. The weight distribution can be updated based on examples of ordered pairs that instantiate the relation. Formally, the posterior distribution of weights can be computed by applying Bayes' rule using the likelihood of the training data and the prior distribution for \(\mathbf{w}\) :
\[
\begin{equation*}
P\left(\mathbf{w} \mid \mathbf{X}_{\mathbf{s}}, \mathbf{R}_{\mathbf{s}}\right)=\frac{P\left(\mathbf{R}_{\mathbf{s}} \mid \mathbf{w}, \mathbf{X}_{\mathbf{s}}\right) P(\mathbf{w})}{\int_{\mathbf{w}} P\left(\mathbf{R}_{\mathbf{s}} \mid \mathbf{w}, \mathbf{X}_{\mathbf{s}}\right) P(\mathbf{w})} \tag{1}
\end{equation*}
\]

The likelihood is defined as a logistic function for computing the probability that a pair of objects instantiates the relation, given the weights and feature vector:
\[
\begin{equation*}
P(R=1 \mid \mathbf{w}, \mathbf{x})=\frac{1}{1+e^{-\mathbf{w}^{\mathrm{T}} \mathbf{x}}} \tag{2}
\end{equation*}
\]

The prior, \(P(\mathbf{w})\), is a Gaussian distribution and is constructed using a bottom-up approach in which initial learning of simple concepts provides empirical priors that guide subsequent learning of more complex concepts. Specifically, BART extracts empirical priors from weight distributions for one-place predicates such as large to guide the acquisition of two-place relations such as larger. Lu et al. (2012) trained BART on the eight one-place predicates (e.g., large, small, fierce, meek) that can be formed using the extreme animals at each end of the four relevant continua (size, speed, ferocity, and intelligence).

After learning the joint weight distribution that represents a relation, BART discriminates between pairs that instantiate the relation and those that do not by calculating the probability that a target pair \(\mathbf{x}_{T}\) instantiates the relation \(R\) :
\[
\begin{align*}
& P\left(R_{T}=1 \mid \mathbf{x}_{T}, \mathbf{X}_{\mathbf{s}}, \mathbf{R}_{\mathbf{s}}\right)= \\
& \int_{\mathbf{w}} P\left(R_{T}=1 \mid \mathbf{x}_{T}, \mathbf{w}\right) P\left(\mathbf{w} \mid \mathbf{X}_{\mathbf{s}}, \mathbf{R}_{\mathbf{s}}\right) . \tag{3}
\end{align*}
\]

Although the general framework of the relation learning model is straightforward, the calculations of the normalization term in Eq. (1) and the integral in Eq. (3) are intractable, lacking analytic solutions. As in Silva, Heller, and Gharamani (2007), we employed the variational method developed by Jaakkola and Jordan (2000) for Bayesian logistic regression to obtain closed-form approximations to the posterior weight distribution \(P\left(\mathbf{w} \mid \mathbf{X}_{\mathrm{s}}, \mathbf{R}_{\mathrm{S}}\right)\) and the predictive probability \(P\left(R_{T}=1 \mid \mathbf{x}_{T}, \mathbf{X}_{\mathrm{S}}, \mathbf{R}_{\mathrm{S}}\right)\).

\section*{Extension to Generative Inference}

The goal of the present paper is to endow BART with generative abilities, allowing it (for example) to complete a partially-instantiated relation, answering questions such as, "What is an animal that is smaller than a dog?" We use the weight representation for a relation learned by BART to construct a new generative model for the completion task. When presented with a cue relation (e.g., smaller) and a cue object (e.g., dog), the model produces possible responses for the remaining object (e.g., cat) so that the ordered object pair satisfies the relation. More specifically, given the features of an object \(B, \mathbf{x}_{B}\), and the knowledge that relation \(R\) holds for the object pair \((A, B)\), the model generates a probability distribution for the features of object \(A, \mathbf{x}_{A}\), by making the following inference:
\[
\begin{equation*}
P\left(\mathbf{x}_{A} \mid \mathbf{x}_{B}, R=1\right) \propto P\left(R=1 \mid \mathbf{x}_{A}, \mathbf{x}_{B}\right) P\left(\mathbf{x}_{A} \mid \mathbf{x}_{B}\right) . \tag{4}
\end{equation*}
\]

The likelihood term, \(P\left(R=1 \mid \mathbf{x}_{A}, \mathbf{x}_{B}\right)\), is the probability that relation \(R\) holds for a particular hypothesized object \(A\), \(\mathbf{x}_{A}\), and the known object \(B, \mathbf{x}_{B}\). It is defined using a logistic function, just as in Eq. (2):
\[
\begin{equation*}
P\left(R=1 \mid \mathbf{x}_{A}, \mathbf{x}_{B}\right)=\frac{1}{1+e^{-\boldsymbol{w}_{1}^{T} \mathbf{x}_{A}-w_{2}^{T} x_{B}}} . \tag{5}
\end{equation*}
\]

Relative to Eq. (2), we have only introduced small differences in the notation. The learned relational weights, \(\mathbf{w}\), are written as two separate halves: weights associated

Figure 2: Illustration of the generative model for inferring an animal that is larger than a sheep. Colors annotate probability densities (red indicates high values and blue indicates low values). The top panel shows the prior and posterior distributions with \(\sigma^{2}=7\) (favoring similaritybased completions such as cow), and the bottom panel shows the prior and posterior with \(\sigma^{2}=25\) (favoring "landmark" completions such as elephant). Various animals are represented in the two-dimensional space based on their size and speed ratings. The posterior was generated using the relational weights that BART learned from the full ratings input (i.e., all four dimensions).
with the first relational role ( \(\mathbf{w}_{1}\) ) and weights associated with the second relational role ( \(\mathbf{w}_{2}\) ). Similarly, the feature vector \(\mathbf{x}\) for a pair of objects is separated into the feature vector for object \(A\left(\mathbf{x}_{A}\right)\) and the feature vector for object \(B\) ( \(\mathrm{x}_{B}\) ).
The prior for the features of object \(A, P\left(\mathbf{x}_{A} \mid \mathbf{x}_{B}\right)\), is the conditional distribution given the features of object \(B\). It is defined as the following:
\[
\begin{equation*}
P\left(\mathbf{x}_{A} \mid \mathbf{x}_{B}\right)=N\left(\mathbf{x}_{B}, \sigma^{2} \mathbf{I}\right) . \tag{6}
\end{equation*}
\]

We assume that object \(B\) (the referent) serves a starting point for generating object \(A\), so the means of \(P\left(\mathbf{x}_{A} \mid \mathbf{x}_{B}\right)\) are taken to be the feature values of object \(B\), reflecting a certain degree of semantic dependency between the two objects (i.e., people's tendency to think of \(A\) objects that are similar to \(B\) ). The prior also encodes the assumptions that the features of \(A\) are uncorrelated and have the same variance \(\sigma^{2}\), the value of which is a free parameter reflecting the strength of the model's preference for generating \(A\) objects that are similar to \(B\).
Our generative model infers a feature distribution for object \(A\) that reflects a compromise between (1) maximizing
the semantic similarity of \(A\) and \(B\), which is reflected in the prior term; and (2) maximizing the probability that the relation holds, which is reflected in the likelihood term. We adapted the variational method to estimate the posterior distribution, using the following update rules for the mean \(\boldsymbol{\mu}\) and covariance matrix \(\mathbf{V}\) of the feature distribution, as well as the variational parameter \(\xi\) :
\[
\begin{gather*}
\mathbf{V}^{-1}=\frac{\mathbf{I}}{\sigma^{2}}+2 \lambda(\xi) \mathbf{w}_{1} \mathbf{w}_{1}^{\mathbf{T}} \\
\boldsymbol{\mu}=\mathbf{V}\left(\frac{\mathbf{I}}{\sigma^{2}} \mathbf{x}_{B}+\frac{\mathbf{w}_{1}}{2}-2 k \lambda(\xi) \mathbf{w}_{1}\right),  \tag{7}\\
\xi^{2}=\mathbf{w}_{1}^{\mathbf{T}}\left(\mathbf{V}+\boldsymbol{\mu} \boldsymbol{\mu}^{\mathbf{T}}\right) \mathbf{w}_{1},
\end{gather*}
\]
where \(\lambda(\xi)=\frac{\tanh \left(\frac{1}{2}(\xi+k)\right)}{4(\xi+k)}\) and \(k=\mathbf{w}_{2}^{\mathrm{T}} \mathbf{x}_{B}\).
Figure 2 illustrates the operation of the model in generating an animal \((A)\) that is larger than a sheep \((B)\). The feature distribution for \(A\) is updated from a prior favoring some degree of similarity between the two animals (left panel; top: high similarity, bottom: low similarity) to a posterior distribution after taking into consideration the relation (i.e., larger) instantiated by the animals (right panel). These distributions are shown in a simplified twodimensional feature space (the size and speed ratings for animals; Holyoak \& Mah, 1981).

\section*{Modeling Transitive Inference}

Comparative relations such as larger exhibit the logical properties of transitivity and asymmetry, supporting deductions such as, "If \(A\) is larger than \(B\) and \(B\) is larger than \(C\), then \(A\) is larger than \(C\)." Such hypothetical reasoning seems to depend on the ability to generate arbitrary instantiations of the relation without any guidance from object features (as the object representations are semantically empty). Our first test evaluated whether the generative extension of BART enables transitive inferences on comparative relations using arbitrary hypothetical instances.

\section*{Operation of the Model}

The basic approach to transitive inference is straightforward: The model "imagines" objects \(A, B\), and \(C\) that instantiate the two given premises, as in the example above, and then tests the unstated relationship for the pair \(<A, C>\). If the larger relation that BART has learned is indeed transitive, then any such instantiation will satisfy the conclusion, " \(A\) is larger than \(C\)." This test is done repeatedly, in essence searching for a counterexample. If no counterexample is ever found, the transitive inference is accepted.

Specifically, for each of the eight comparative relations that BART learned, we first let the model "imagine" an animal \(B\) (because the statement " \(A\) is larger than \(B\) " implies that \(B\) is the referent against which \(A\) is being compared) by sampling a feature vector from a distribution representing
the animal category. This is a Gaussian distribution with a mean vector and covariance matrix that were directly estimated from the feature vectors of the 44 animals in the Leuven dataset that are included in the ratings dataset.

Given the sampled animal \(B\), the generative model constructs a distribution for animal \(A\) (e.g., to satisfy the premise that " \(A\) is larger than \(B\) ") by letting \(B\) fill the second role of the relevant relation. Similarly, the model constructs a distribution for animal \(C\) (e.g., to satisfy the premise that " \(B\) is larger than \(C\) ") by letting \(B\) fill the first role of the same relation. Next, the model creates feature representations for specific animals \(A\) and \(C\) by setting their feature vectors, \(\mathbf{x}_{A}\) and \(\mathbf{x}_{C}\), to be the means of the inferred feature distributions for \(A\) and \(C\), respectively. Note that these "imagined" animals are hypothetical: although their features are sampled from the distribution of animal features, the results will seldom correspond to actual animals. To ensure that the premises have actually been satisfied, the model accepts the imagined animal \(A\) only if \(P\left(R=1 \mid \mathbf{x}_{A}, \mathbf{x}_{B}\right)>0.5\) and \(P\left(R=1 \mid \mathbf{x}_{B}, \mathbf{x}_{A}\right)<0.5\), and the imagined animal \(C\) only if \(P\left(R=1 \mid \mathbf{x}_{B}, \mathbf{x}_{C}\right)>0.5\) and \(P\left(R=1 \mid \mathbf{x}_{C}, \mathbf{x}_{B}\right)<0.5\).
Finally, if \(\mathbf{x}_{A}\) and \(\mathbf{x}_{C}\) have been accepted as satisfying the premises, the model calculates both \(P\left(R=1 \mid \mathbf{x}_{A}, \mathbf{x}_{C}\right)\), denoting the probability that \(A\) is larger than \(C\), and \(P\left(R=1 \mid \mathbf{x}_{C}, \mathbf{x}_{A}\right)\), denoting the probability that \(C\) is larger than \(A\). The model concludes that the relation holds for the pair \(\left\langle A, C>\right.\) (and not for \(\left\langle C, A>\right.\) ) if \(P\left(R=1 \mid \mathbf{x}_{A}, \mathbf{x}_{C}\right)>0.5\) and \(P\left(R=1 \mid \mathbf{x}_{C}, \mathbf{x}_{A}\right)<0.5\), implying that a counterexample has not yet been found to refute the transitive inference.

We conducted tests of transitive inference using the relational representations that BART learned based on 100 randomly-chosen training pairs. For comparison, we also tested a baseline model that substituted an uninformative prior for the empirical prior that guides BART's relation learning (see Lu et al., 2012). For each of the eight comparative relations, the relation learning model was run ten times, each time with a different set of training pairs and resulting in a different learned weight distribution. For each of these learned weight distributions, we let the model generate \(100 A-B-C\) triads satisfying the premises, testing the relevant relationship between \(A\) and \(C\) for each triad. To assess the influence of the free parameter in model predictions, the tests were conducted multiple times with different values of \(\sigma^{2}\) ranging from 1 to 1000 . The strongest tests are those in which \(\sigma^{2}\) is set at low values, creating a strong prior preference that \(A, B\), and \(C\) are similar to one another. When the similarity constraint is strong, the model is forced to generate animals that are similar on the relevant dimension, and hence more likely to yield a counterexample. When the value of \(\sigma^{2}\) was reduced below 1, the models produced many instantiations that did not satisfy the required premises (i.e., \(A>B, B>C\), and not vice versa). We therefore treated the value of 1 as the
minimal value of \(\sigma^{2}\) that yields triplets of animals with discriminable values on the relevant dimension.

\section*{Results and Discussion}

Figure 3 shows the mean proportion correct (i.e., the mean proportion of triads that satisfy the conclusion based on transitive inference) for BART and the baseline model as a function of \(\sigma^{2}\). These results are averaged over the eight comparative relations. The critical result is that the BART's accuracy remains constant at \(100 \%\) as \(\sigma^{2}\) is reduced to the effective minimal value of 1 . Thus, BART demonstrates what may be considered an inductive approximation to deduction: despite exhaustive search for a counterexample to the transitive inference, no counterexample is ever found. In contrast, the baseline model often fails to infer that \(A>C\) (and not vice versa) even when the value of \(\sigma^{2}\) is as large as 100 .

Figure 3: Mean proportion correct on the transitive inference task for BART and baseline model, as a function of the variance parameter. These results are averaged across the eight comparative relations.

\section*{Animal Generation Task}

A second evaluation of the model involves predicting the distribution of human responses in an animal generation study conducted using Amazon Mechanical Turk. In this free-generation study, participants typed responses to queries of the form, "Name an animal that is larger than a dog." They were instructed to enter the first animal that came to mind. Four comparative relations (larger, smaller, faster, and slower) and nine cue animals (shark, ostrich, sheep, dog, fox, turkey, duck, dove, and sparrow) were used. At least 50 responses were collected for each of the 36 relation-animal pairs. To minimize learning across trials, we asked each participant to answer only two questions about a single animal: either larger and then slower, slower and then larger, faster and then smaller, or smaller and then faster.

The same relation-animal pairs were presented to the model after it had been trained on the relevant relations. For each question, the model produces a continuous posterior distribution for the feature vector of the missing animal using Eq. (4). This distribution was used to calculate the probability densities for the feature vectors of all animals among the human responses that had Leuven vectors. These probability densities were normalized to produce a discrete

Figure 4: Observed human response proportions and BART's predictions for the queries, "Name an animal that is smaller than a dog" (top), and "Name an animal that is slower than a dog" (bottom).
probability distribution over the animals included in the human responses. The model's predicted probabilities were averaged across the ten runs.

The human results were complex, and here we report only a partial and preliminary attempt to make a comparison with model predictions. Qualitatively, human responses were dominated by two trends: (1) reporting an animal similar to the cue animal and fitting the cue relation (e.g., cat for "smaller than a dog"), or (2) reporting a "landmark" animal at an extreme of the continuum (e.g., turtle for "slower than a dog"). The landmark animal coupled with the cue animal provides an ideal example of the cue relation. This tradeoff between reporting animals that are similar to the cue animal and reporting animals that are landmarks for the cue relation (and usually more dissimilar to the cue animal) is captured by the single free parameter in the generative module, \(\sigma^{2}\). As explained earlier (see Figure 2), a low \(\sigma^{2}\) results in a response distribution that favors animals similar to the cue animal, whereas a high \(\sigma^{2}\) leads to a preference for response animals that are more likely to satisfy the cue relation with respect to the cue animal (i.e., landmark animals for the cue relation).

To reflect the unique pattern of human responses to each question, the variance parameter in the generative model was chosen separately for each question (from the values, 1 , \(5,10,50\), and 100) to maximize the average of Pearson's \(r\) and Spearman's \(\rho\) (rank-order) correlations between the model's predicted probabilities and the observed response proportions for that question. Here we present results for two illustrative questions. The top panel of Figure 4 shows the model's predicted response distribution and the human response distribution for the request, "Name an animal that is smaller than a dog." The human response pattern reveals a strong influence of semantic similarity between the cue
animal and generated animal. The most common human response was cat, followed by mouse (the landmark animal for the smaller relation). With \(\sigma^{2}=10\), the correlation between the model predictions and the human response pattern was \(r=.76\).

The bottom panel of Figure 4 depicts the model predictions and human response pattern for the request, "Name an animal that is slower than a dog." For this question, the most common response was the landmark animal turtle. With \(\sigma^{2}=50\), the correlation between the model predictions and the human response pattern was \(r=\) .72. The higher variance assumed for this question (relative to that for the smaller question) reflects the dominance of the landmark response for the slower question.

Note that even though the two questions use the same cue animal (dog), different sets of animals were generated depending on the cue relation, revealing that humans do take relations into consideration in this free generation task. The model showed a similar pattern of results.

\section*{Conclusions}

These results provide initial evidence that a discriminative model of relation learning, BART (Lu et al., 2012), can be extended to yield generative inferences. These inferences can involve relations between either hypothetical (in the case of transitive inference) or actual (in the case of the animal generation task) objects. In the latter free generation task, preliminary analyses indicate that BART achieves some success in modeling human response patterns.

The model's ability to make transitive inferences based on relations it has learned in a bottom-up fashion from examples illustrates the potential power of the discriminative approach to relation learning. Importantly, BART is not endowed with any notion of what a "transitive and asymmetric" relation is (though like a 6 -year-old child, it is endowed with sufficient working memory to integrate two relations as premises). Rather, it simply uses its learned comparative relations to imagine possible object triads, and without exception concludes that the inference warranted by transitivity holds in each such triad. The model thus approximates "logical" reasoning by a systematic search for counterexamples (and failing to find any), akin to a basic mechanism postulated by the theory of mental models (Johnson-Laird, 2008). The fact that BART achieves errorfree performance in the tests of transitive inference is especially impressive given that its inductively-acquired relational representations are most certainly fallible (e.g., the model makes errors in judging which of two animals close in size is the larger; see Lu et al., 2012). It turns out that imperfect representations of comparative relations, acquired by bottom-up induction, can be sufficiently robust as to yield reliable quasi-deductive transitive inferences.

\begin{abstract}
Logical consistency and objectivity are cornerstones of science that distinguish it from cult and dogma. Scientists' concern with objectivity has led to the dominance of associative statistics, which define the basic concept of independence on observations. The same concern with avoiding subjective beliefs has led many scientific journals to favor frequentist over Bayesian statistics. Our analysis here reveals that to infer causes of a binary outcome, (1) the associative definition of independence results in a logical inconsistency -- even for data from an ideal experiment -- for both frequentist and Bayesian statistics, and (2) removing the logical error requires defining independence on counterfactual causal events. The logically coherent causal definition is the one intuitively adopted by humans. Our findings have direct implications for more consistent and generalizable causal discoveries in medicine and other sciences.
\end{abstract}

Keywords: Causal inference, rationality, cognition, statistics.

\section*{Introduction}

Whenever we humans or other animals apply causal knowledge to achieve a desired outcome, we implicitly assume that the future resembles the past. Without the assumption that the course of nature remains invariant, all experience becomes useless (Hume, 1739). But what is the course of nature if not change (e.g., seeds sprout, species evolve, oceans warm, stars implode)? What we assume to remain invariant in nature are -- instead of events -- the forces of change, namely, causation (Kant, 1781; Kitcher, 1995). The fact that we routinely base actions on our causal knowledge (e.g., I strike this match because I expect it to ignite) is indubitable evidence that we hold the causal invariance assumption across the learning and application contexts. The present paper examines a previously unsuspected role that this assumption should play in scientific causal inference, leading to implications for more rational evaluations of hypotheses regarding causes of a binary outcome (e.g., a student graduating or not, an organism being dead or alive).

To test causal hypotheses based on data from experiments or quasi-experiments, the statistics in typical scientific use define invariance (often termed "independence" or "no interaction") on observations (Fienberg, 1980/2007; Jaynes, 2003; Wickens, 1989). Objectivity would seem to dictate this definition, given that the input necessarily consists of
observations only. Because causal relations are inferred and inherently unobservable (Hume, 1739), defining invariance on causal relations seems objectionable.

Thus, for the respective purposes of scientific causal discovery and of justifying the application of causal knowledge, there are two distinct definitions of invariance: the associative and the causal. The associative conception defined on observable events traces its inspiration to the philosophical works of Hume (1739), who questioned the grounds for our compelling belief that causation exists in the world. The causal conception defined on causal influences rests on Kant's (1781) argument that an ontological commitment to causation is essential for a coherent interpretation of the world. We use "causal influence" here in the sense of capacity or power, which when realized explains the occurrence of the outcome.

There is a discrepancy between the two conceptions, but the discrepancy has not seemed problematic: The unspoken consensus is that while causal invariance justifies generalization, it plays no role in causal discovery. Accordingly, using associative statistics to test experimental data is standard practice, and is viewed as appropriate as long as the experimental manipulation, which disambiguates causal direction, succeeds in eliminating confounding.

The consensus opinion, however, is mistaken. Here we show that even in the ideal case in which there are no confounding variables, the definition of invariance incorporated in a measure can affect the statistical output. Moreover, with regard to causes of a binary outcome, a type of outcome prevalent in medical and business research (e.g., a tumor cell being malignant or not, a consumer buying an item or not), only the definition based on counterfactual causal events, the Kantian causal power definition, is logically consistent. Notably, the coherent definition is the seemingly less objective one.

To explain the inferential problem, we step back and examine the nature and definitions of causal invariance from a cognitive-science perspective, in particular, within the broader issue of how an intelligent agent with access to inherently limited information can construct a representation of the world that best enables desired outcomes. From this perspective we examine the implications of conceptions of causal invariance for the experimental sciences and everyday causal inference.

\section*{Causal Invariance and its Implications}

Under the premise that all changes are caused, one way of stating causal invariance is: a cause \(c\) of an effect \(e\) retains the same capacity to affect \(e\) regardless of the temporal or spatial context, in which alternative (often unobserved) causes of \(e\) may occur with different probabilities. That is, the causal power of \(c\) is independent of the occurrence of alternative causes of \(e\), as if those alternative causes were not there. A change in the capacity of a cause to produce its effect is an indication of the causal mechanism operating differently. As we show later, this interpretation of causal invariance applying the concept of independence (i.e., "no interaction") to causal powers enables logical implications of the assumption to emerge, by enabling a mathematical definition of causal invariance (Eq. 4). (Causal invariance is the simpler of two conceptions that are equivalent with respect to our conclusions; the other conception is that although \(c\) interacts with enabling conditions in the background, the enabling conditions occur just as frequently in the learning and application contexts [Cheng, 2000].)

The concept of causal invariance serves two distinct functions. First, as a working hypothesis, a defeasible default assumption, it justifies causal generalization and prediction. By rendering inference compositional, it enables the generation of logically consistent answers to an unlimited variety of questions regarding an outcome's occurrence in an unlimited range of application contexts (Cheng et al., 2007). Second, as a definition of what it means for the nature of a cause to remain the same (rather than as a description of a particular causal mechanism), causal invariance serves as a criterion for hypothesis revision. Thus, if a generalization proves wrong, as would often happen in the dynamic mental construction of our complex causal world, the deviation from expectation signals a need to better capture invariance. In this second role, causal invariance is a navigation device that orients hypothesis testing towards its goal of formulating the simplest explanation of a phenomenon that allows invariance to obtain (Carroll \& Cheng, 2010).

Consider the alternative, the non-uniformity of nature, as the default. Not only would predictions and applications be impossible, so would hypothesis revision -- given no expectation, there is no deviation from expectation to guide revision towards causal invariance. Thus, the choice is a) inapplicable and stagnant causal knowledge or b) risky causal inference with the potential for effective generalization and hypothesis revision. In its two roles, as a default and a criterion for revision, causal invariance embodies the conviction that the world is knowable, that one can tease things apart, comprehend them, and mentally recompose them at will.

\section*{Defining Causal Invariance: Hume versus Kant}

Assuming causal invariance requires two leaps of faith. The first is apparent: faith that the future resembles the past. The second is subtler: faith in the existence of causation, a faith Hume (1739) resisted. Here we show why the second
leap plays a central role in rational causal discovery, in particular, why an associative definition of invariance, omitting this leap, is irrational for causal discovery.

We classify models as causal or associative depending on whether or not they have a definition of independence on causal influences. Whereas the ontological commitment to the existence of causation under the causal view enables this view to define independence on causal influences (e.g., Cartwright, 1989; Cheng, 1997; Lu, Yuille, Liljeholm, Cheng \& Holyoak, 2008; Pearl, 2000; Sheps, 1958; Sloman, 2005; Yuille \& Lu, 2008), the lack of this a priori assumption confines the associative view to defining independence on observations only (e.g., the cross product ratio; Fienberg, 1980/2007; Wickens, 1989). These two views differ most clearly for causes and effects that are represented by binary variables with a "present" value and an "absent" value; our argument therefore uses this variable type. For this variable type, observable events consist of the values of candidate cause \(c\) and of effect \(e\). We denote the "present" and "absent" values by " 1 " and " 0 " respectively.

The Associative View The associative view defines independence on observations of \(c\) and \(e\) (we use \(c\) and \(e\) as variables or values depending on context): if \(c\) occurs independently of \(e\), then
\[
\mathrm{P}(c=1, e=1)=\mathrm{P}(c=1) \cdot \mathrm{P}(e=1)
\]
where \(\mathrm{P}(c=1, e=1)\) is the probability of the joint occurrence of \(c\) and \(e\). This view computes associations, and leaves causal inference to a separate and subsequent interpretation of the associative output, for example, according to scientists' principles of experimental design or as Hume's "habit of mind". To enable predictions, this view typically amends Eq. 1 with additional assumptions, often variations of linearity or additivity. This amendment implicitly extends the definition of independence; deviation from linearity is what signals the need for interaction terms.

We illustrate the linear combination of associative strengths with the \(\Delta P\) model (Jenkins \& Ward, 1965; Salmon, 1965),
\[
\Delta \mathrm{P}=\mathrm{P}(e=1 \mid c=1)-\mathrm{P}(e=1 \mid c=0) \quad \text { (Eq. 2) }
\]
where \(\mathrm{P}(e=1 \mid c=1)\) and \(\mathrm{P}(e=1 \mid c=0)\), respectively, denote the probability that \(e\) occurs given that \(c\) occurs and given that \(c\) does not occur. Eq. 1 is a special case of Eq. 2, the case in which \(\Delta \mathrm{P}=0\). To tease apart the influence of \(c\) from all other influences on \(e\), our analysis partitions all direct causes of \(e\) into \(c\) and \(a\), where \(a\) represents a composite of alternative causes of \(e\) in the context. When \(c\) is absent, the occurrence of \(e\) is explained by \(a\). Let \(w_{\mathrm{c}}\) represent the weight (i.e., strength) of the association between \(c\) and \(e\), and \(w_{\mathrm{a}}\) represent that between \(a\) and \(e . \Delta \mathrm{P}\) has been shown to be a maximum-likelihood estimator of \(w_{c}\) in the Bayesian framework (Griffiths \& Tenenbaum, 2009; Tenenbaum \& Griffiths, 2001).

When there is no confounding (i.e., \(a\) occurs just as often whether or not \(c\) occurs), \(\Delta \mathrm{P}\) estimates \(w_{\mathrm{c}}\). Thus, replacing \(\Delta \mathrm{P}\) with \(w_{\mathrm{c}}\) and \(\mathrm{P}(e=1 \mid c=0)\) with \(w_{\mathrm{a}}\), Eq. 2 can be rewritten and rearranged to give the linear equation:
\[
\mathrm{P}(e=1 \mid c=1)=w_{\mathrm{c}}+w_{\mathrm{a}}
\]
(Eq. 3).
That is, when multiple causes are present, the occurrence of \(e\) according to this model is explained by a sum of the associative strengths of the causes. Bayesian structurelearning models can likewise adopt the linear definition ( Lu et al., 2008; Yuille \& Lu, 2008; Tenenbaum \& Griffiths, 2001).

Similarly, generalized linear models (GLMs [Fienberg, 2007; McCullagh \& Nelder, 1989]), some process models in psychology (e.g., Rescorla \& Wagner, 1972), and prominent causal models in epidemiology (Rothman et al., 2008) also adopt the definition in Eq. 1 amended with variants of linearity. For example, logistic regression, likely the most commonly used model for evaluating causal hypotheses in medical research and widely used in business research as well, amends Eq. 1 with a logistic scale transformation to better justify the linearity. A feature common across the generalizations in GLMs is "the presence in all the models of a linear predictor based on a linear combination of explanatory or stimulus variables" (McCullagh \& Nelder, 1989, p. xvi).

Now, consider a situation in which representation in terms of observable events alone cannot capture the constancy of a causal relation across contexts. When effect \(e\) is binary, a factor's capacity to influence \(e\) may have no observable manifestations, even when there is no confounding. Suppose \(c\) is a cause of \(e\) that does not interact with any other cause of \(e\). Yet, whenever \(e\) is already present (regardless of which other cause produced it), introducing \(c\) will yield no change in the state of \(e\), indistinguishable from introducing a noncausal factor. For example, suppose someone is already dead (the binary outcome in question) from being hit by a car. Being hit by another car will show no change in the outcome (the person is still dead), despite the sameness of the forces underlying car accidents (the second car would have killed the person too). In such occlusion events, unobservable causal capacities lose their mapping onto observable changes. Given the lack of constancy in this mapping, postulating capacities becomes crucial for representing a stable causal world; observable changes, as used in associative models, or even actual causation in an episode, as used in epidemiological causal models (Rothman, Greenland \& Lash, 2008), would be inadequate. Just as objects occluded in the 2-d visual input on our retinas are assumed to continue to exist in the world, so should occluded causal capacities.
The Causal View The causal view builds on Hume's insight - that causal knowledge is induced from noncausal data - but goes beyond it: Intervening between the observable input and the causal output is a causal explanation of the data. This explanation, under Kant's domain-general a priori causal framework, posits the existence of such things as causal relations: theoretical events that yield observed phenomena. We denote "causing" by " \(\rightarrow\) " (e.g., "c \(\rightarrow \mathrm{e}\) " denotes " \(c\) causing \(e\) "). Once causal events are assumed to exist, the definition of their independence analytically follows:
if \(c \rightarrow e\) is independent of \(a \rightarrow e\), then
\[
\mathrm{P}(c \rightarrow e, a \rightarrow e)=\mathrm{P}(c \rightarrow e) \bullet \mathrm{P}(a \rightarrow e)
\] \(\mathrm{P}(c \rightarrow e)\) is the probability of \(c\) causing \(e\); it corresponds to the theoretical probability that \(e\) would occur if \(c\) is present but no other (observed or unobserved, generative or preventive) cause of \(e\) were present. The probability is theoretical because it is impossible to know that a context has no unobserved causes. Note that \(\mathrm{P}(\mathrm{c} \rightarrow \mathrm{e})\) is not a conditional probability involving two random variables, but instead the probability associated with a single random variable. Likewise, \(\mathrm{P}(a \rightarrow e)\) is the probability of \(a\) causing \(e\), and \(\mathrm{P}(c \rightarrow e, a \rightarrow e)\) is the probability of one of the two causes, \(c\) or \(a\), producing \(e\) and the other cause also producing \(e\) if \(e\) had not been already produced. ("No interaction" between the occurrences of \(c\) and \(e\), as defined in Eq.1, is a special case of the independence of causal powers as defined in Eq. 4 when there is no confounding and \(\Delta \mathrm{P}=0\).)
Notice that the definition in Eq. 4 centers on conjunctive causation in an "occlusion" event. The conjunctive causal event (e.g., a dead car-accident victim being killed by a second car) can never occur (rather than happen to not have occurred). Our " \(\rightarrow\) " notation serves as a reminder that the causal events denoted are nonexistent and theoretical.

Although none of the events in Eq. 4 is observable, the intervening causal explanation of the data (e.g., when \(e\) occurred in the presence of \(c\), it occurred because \(c\) caused it or \(a\) caused it) maps observable event frequencies (e.g., how often \(e\) occurred when \(c\) was present) onto their theoretical causal probabilities [e.g., \(\mathrm{P}(c \rightarrow e\) OR \(a \rightarrow e)\) ]. Thus, \(\mathrm{P}(e=1 \mid c=1)\) estimates \(\mathrm{P}(c \rightarrow e\) OR \(a \rightarrow e)\). The latter in turn can be expressed in terms of the constituent events in Eq. 4:
\(\mathrm{P}(c \rightarrow e\) OR \(a \rightarrow e)=\mathrm{P}(c \rightarrow e)+\mathrm{P}(a \rightarrow e)-\mathrm{P}(c \rightarrow e, a \rightarrow e)\) (Eq. 5), where the final term equals the product, \(\mathrm{P}(c \rightarrow e) \cdot \mathrm{P}(a \rightarrow e)\), if \(c\) and \(a\) produce \(e\) independently (Eq. 4).

Under this view, causal interpretation is integral to the computation of the numerical output (e.g., Cheng, 1997; Griffiths \& Tenenbaum, 2009), rather than subsequent to it. Data analysis incorporates causal invariance.

The difference between the two views and its implications for rational scientific causal inference has not received attention. Like frequentist statistics for the experimental sciences, causal Bayes nets adopt the separation of statistics and causal inference. The "generic" parameterization most commonly adopted in causal Bayes nets uses neither the associative nor the causal definition, and the "noisy OR" parameterization in Eq. 5 is used for efficiency rather than rationality. In a similar vein, Bayesian causal models allow both the associative and causal definitions (Griffiths \& Tenenbaum, 2009; Lu et al., 2008; Yuille \& Lu, 2008).

The Rationality of the Two Views Is it rational to define causal invariance on unobservable, imaginary events, as the causal view does? Ceteris paribus, it is objectionable to use unobservable events. What is at stake, however, is logical consistency. What it means for the nature of a cause in our physical world to remain invariant across contexts is nonarbitrary. There is only one way for a causal mechanism in
a coherent world to operate the same way, without change. For binary causes and effects that are "present" or "absent," Eqs. 4 and 5 specify the only logically consistent definition of causal invariance (e.g., so that \(c\) causes \(e\) with indeed the same probability in one context as in another). In other words, systematic deviation from independence as specified in these equations indicates causal interaction. (Note that for other variable types and combinations of variable types, the singular meaning of causal invariance in the world is captured by other mathematical functions.)

We first explain the correlated influences inherent in associative amendments by illustrating how the linear model in Eq. 3 deviates from causal invariance. The additivity in Eq. 3 holds only if the capacities of \(c\) and of \(a\) to cause \(e\) are mutually exclusive [i.e., \(\mathrm{P}(c \rightarrow e, a \rightarrow e)=0\); there are no occlusion events]. But, to define independence as mutual exclusivity (i.e., to define "no correlation" as a negative correlation) is self-contradictory.

To see the self-contradiction without the abstraction of causal inference, consider a simple concrete example involving two events regarding a deck of playing cards: drawing a diamond and drawing a face card. (Assume that the deck has diamonds and face cards, among other cards.) Defining independence between the two events as mutual exclusivity of the events would entail asserting that the chance of drawing a face card is the same for diamonds as for other suits if and only if face cards and diamonds are mutually exclusive: when there are no face cards that are diamonds. The chance of drawing a face card then would be 0 for diamonds but not for other suits. The mutualexclusivity definition therefore implies a logical contradiction: "the chance of drawing a face card is the same across suits only if it is not the same across suits."

Our analysis so far may seem irrelevant to current frequentist statistics: nonlinear GLMs, which avoid a logical shortcoming of linear models for analyzing data with binary outcome variables, have long replaced linear models for that purpose (Fienberg, 1980/2007; Wickens, 1989). But, GLMs in fact do not sidestep the contradiction in other associative models. First, GLMs concur with the \(\Delta \mathrm{P}\) model in adopting the mutual-exclusivity definition for special cases involving data that have the feature of symmetry. We illustrate this agreement presently with a logistic-regression analysis of fictitious data in a story in an experiment designed for preschool children. Second, GLMs more generally carry the broader contradiction of defining independence as interaction. Because \(\mathrm{P}(e=1 \mid c=1)\) estimates \(\mathrm{P}(c \rightarrow e\) OR \(a \rightarrow e)\), Eqs. 3 and 5 can be directly compared. They differ by the final (negative) term in Eq. 5 being omitted in Eq. 3. A scale transformation that would avert the contradiction would therefore need to result in subtracting the product, \(w_{\mathrm{c}}{ }^{\bullet} w_{\mathrm{a}}\), from the right-hand-side of Eq. 3. But this is neither the intent nor the result of the transformations in GLMs. The logistic function, for example, is symmetric (see s-shaped curve in Figure 1), as is characteristic of associative models. In contrast, for every value of \(w_{\mathrm{a}}\), subtracting \(w_{\mathrm{c}} \bullet w_{\mathrm{a}}\) from the sum, \(w_{\mathrm{c}}+w_{\mathrm{a}}\), yields an asymmetric concave function of \(w_{\mathrm{c}}\) (as
\(w_{\mathrm{c}}\) increases, an increasing amount is subtracted from the linear sum).

Without the a priori postulate that causal relations exist, associative models cannot coherently define independence on the missing relations, hence cannot justify the application of causal knowledge. They cannot, even when ideal experiments are concerned, because the error is logical.
An Illustration of the Associative and Causal Views Arriving at Opposite Conclusions We return to the mutual-exclusivity definition of causal invariance in associative statistics. In a story presented to preschoolers in our experiment, two brothers -- a farmer and a zookeeper try to figure out what prevents red dots from appearing on the faces of animals at their farm and at zoo. The candidate preventive causes of red dots are two treats: a grain and a type of leaves. At the farm, the brothers gave the grain to all 10 animals there: 9 of them had red dots before eating the grain, and 6 did so afterwards. At the zoo, the brothers gave both treats -- grain and leaves -- to all 10 animals there: 4 of them had red dots before eating the two treats, and only one had red dots afterwards. The question is: which treat is one's best bet for removing red dots from the faces of farm and zoo animals?

Regardless of how "sameness" is defined, the rationale underlying the choice is: Assuming the grain operates "the same way" across contexts (i.e., farm and zoo), if the influence of the intervention (grain at farm vs. both treats at zoo) remains invariant across contexts, one's best guess would be that leaves had no effect - grain alone would already explain the outcome. But, if the influence of the intervention varies across contexts, one would attribute the difference to leaves.

According to the causal view, the grain operating with the same causal mechanism across contexts implies that for every animal (all 20), grain has the same causal power to remove red dots. We denote the two interventions by "farm_iv" and "zoo_iv" respectively and "red dots on the face" by "red" in the calculations below. The causal power of candidate cause \(c\) to prevent effect \(e, p_{c}\), is estimated according to (Cheng, 1997):
\[
\begin{equation*}
p_{c}=\frac{P(e=1 \mid c=0)-P(e=1 \mid c=1)}{P(e=1 \mid c=0)} \tag{Eq.6}
\end{equation*}
\]

Thus,
\[
\begin{equation*}
p_{\text {farm }-i v}=p_{\text {grain }}=\frac{9 / 10-6 / 10}{9 / 10}=1 / 3 \tag{Eq.7}
\end{equation*}
\]

Likewise,
\[
\begin{equation*}
p_{z o o_{i} i v}=\frac{4 / 10-1 / 10}{4 / 10}=3 / 4 \tag{Eq.8}
\end{equation*}
\]

But, according to causal invariance (Eqs. 4 and 5),
\[
\begin{equation*}
p_{\text {zoo_iv }}=p_{\text {grain }}+p_{\text {leaves }}-p_{\text {grain }} \cdot p_{\text {leaves }} \tag{Eq.9}
\end{equation*}
\]

It follows that
\(3 / 4=1 / 3+p_{\text {leaves }}-1 / 3 \cdot p_{\text {leaves }}\)
Therefore, \(p_{\text {leaves }}=5 / 8\). Because \(5 / 8\) is greater than \(1 / 3\) (i.e., the leaves treat is a stronger cure than grain), the causal view prescribes choosing leaves.

Associative models, whether Bayesian or frequentist, all reach the opposite conclusion, prescribing grain instead. The mutual-exclusivity definition implies that the set of animals with "no red dots" due to grain, 3 out of 10 animals, has no overlap with the set due to the contextual cause at each place: grain should therefore heal 3 animals both at the farm and at the zoo. Because 3 animals indeed had their red dots "go away" at each place, leaves must have no effect. The \(\Delta \mathrm{P}\) model therefore prescribes grain.

Logistic regression is a GLM used for predicting the probability of the occurrence of a dichotomous outcome (e.g., red_dots vs no red_dots) by fitting data to a logistic function of a linear combination of input variables (e.g., grain, leaves, background causes at the farm and at the zoo). For the farm-and-zoo scenario (see Figure 1), because the pattern of events is symmetrical around the probability of .5 , the same reduction in P (red_dots) occurs at the farm and at the zoo (see vertical dashed lines) at symmetrical segments of the logistic curve. Therefore, the grain (see heavy horizontal dashed lines) -- which explains the reduction in the probability of animals with red dots at the farm explains the entire reduction at the zoo as well. That is, logistic regression detects no influence at all from leaves, either by itself or in an interaction, concurring with the \(\Delta P\) model. Increasing sample size does not change this conclusion.

Figure 1. A schematic explanation of the probability of the outcome according to logistic regression: the probability of having red dots at the farm and at the zoo, before and after the respective interventions in the scenario, as a logistic function of the weighted sum of the four predictor variables.

Preschoolers in our experiment chose leaves, in accordance with the causal view. Recall that the causal view avoids the incoherence of the associative view by defining causal invariance on counterfactual causal events. Note that the causal explanations involve no prior domain-specific knowledge; the causal-invariance assumption is domaingeneral and the input consists of data alone. This view thereby achieves objectivity without sacrificing coherence.

If the world happens to be causal, then a leap of faith to assume unobservable causal capacities would be adaptive,
by enabling a coherent definition of causal invariance in our representation. Coherence is essential because there are infinitely many possible representations of the world based on available observations, only some of which support generalization to new contexts. Reasoners use logical consistency and, more generally, parsimony of the represented explanations to prune the vast search space and efficiently converge on truth, if truth exists (Kelly, 2007). Causal discovery should therefore require general-purpose Sherlock Holmeses, who make use of coherence to infer how things work.

\section*{Discussion}

In summary, noting a simple logical consequence of Kant's a priori assumption of causation for rational causal inference, we have shown that -- contrary to the unspoken consensus among scientists -- the causal invariance assumption critically affects causal discovery. To evaluate a causal relation involving a binary outcome variable that is "present" or "absent", only invariance defined on causal capacities is logically consistent and supports generalization to new contexts. Thus, associative statistics, for which invariance is only defined on observations, may arrive at a fallacious conclusion even when applied to data from a perfect experiment.

The potential for the associative and causal views to arrive at opposing recommendations has obvious implications. For example, a critical linear-regression analysis in the influential Seven Countries Study (Keys, 1980), a large longitudinal study on how diet affects coronary heart disease and other health outcomes, shows that controlling for saturated fat, consumption of sugar is unrelated to death (a binary outcome). Medical and publichealth dietary advice in the U.S. based on this and other analyses in the study (Keys et al., 1984; Menotti et al., 2003), using linear models as was common practice, has created a food industry that produces low-fat but high-sugar foods (e.g., fat-free salad dressings with added sugar to compensate for taste). More generally, these associative analyses formed the foundation for three decades of dietary advice to adhere to a low-fat diet, without special attention to sugar intake (as distinct from caloric content). There is currently no causal analogue of logistic regression, which allows predictor variables that are continuous (e.g., consumption of sugar) as well as discrete. As we have shown for binary outcome variables, coherent causal generalization requires a causal framework, and applying causal instead of associative statistics to evaluate the influences of fat and sugar intake could potentially reverse estimates of the magnitude of their harm or change their assessed causal status. The researchers could have found that consumption of sugar causes coronary heart disease, diabetes, cancer and other diseases constituting the metabolic syndrome, as recent evidence indeed suggests. A more rational statistical approach could have profoundly altered the course of the obesity epidemic in the U.S. and worldwide.

Note that one interpretation of associative models that would remove the incoherence we noted is to posit a mediating continuous variable and to assume that the causes operate independently on this continuous variable rather than on the observed binary outcome variable. The linear definition of causal invariance holds for continuous outcome variables, thereby removing the incoherence. Regardless of the plausibility of the revised hypothesis with the mediating variable, note that it is deviation from the criterion of causal invariance that signals the need to revise the simple hypothesis (Carroll \& Cheng, 2010), the tenacious goal being to achieve causal invariance.

\title{
Inferring One's Own Prosociality Through Choice: Giving Preschoolers Costly Prosocial Choices Increases Subsequent Sharing Behavior
}

\begin{abstract}
Prosociality emerges early in ontogeny, but the mechanisms driving its early-emergence are not well understood. We propose that the experience of choice is tied to the expression of children's prosocial behavior. In Experiment 1, preschoolers shared with a puppet by either making a Costly Choice (giving a resource they could have kept for themselves), Non-Costly Choice (giving a resource that would otherwise be thrown away), or No Choice. Subsequent prosociality was measured by allowing children to share with a new puppet. While most children shared initially, children who were given costly choices shared more with the new puppet. Experiment 2 replicated this result using a different manipulation for Costly vs. Non-Costly choices. Experiment 3 found that preschoolers were more likely to infer that actions are intentional when they are costly. Results suggest a prosocial construal hypothesis: that children rationally infer their prosociality through making difficult, autonomous choices.
\end{abstract}

Keywords: cognitive development; choice; altruism; preschoolers

\section*{Introduction}

People very rapidly acquire remarkable prosocial tendencies. By the second to third year of life, children help others complete their goals (Warneken \& Tomasello, 2006), share toys (Schmidt \& Sommerville, 2008; Svetlova, Nichols, \& Brownell, 2010), sympathize with those who are harmed (Vaish, Carpenter, \& Tomasello, 2009) or are in distress (Zahn-Waxler, Radke-Yarrow, \& Wagner, 1992), and punish those who harm others (Dunfield \& Kuhlmeier, 2010; Vaish, Carpenter, \& Tomasello, 2010; Vaish, Missana, \& Tomasello, 2011). But how children acquire such tendencies remains an understudied empirical question. Here, we explore the possibility that having and making choices encourages young children's prosocial behavior.

One potential mechanism for the expression of prosocial behavior is through past experience with prosocial action (Staub, 1971). Self-perception theory (see Beaman, Cole, Preston, Klenty, \& Steblay, 1983; Bem, 1967; Eisenberg, Cialdini, McCreath, \& Shell, 1987; Lepper, 1973) suggests that individuals are likely to act in congruence with their past actions because of a desire to stay self-consistent. Thus, through acting prosocially, children may be forming a cognitive representation of what "the self" is like, and acting in accordance with that representation (Freedman \& Fraser, 1966; Grusec, Kuczynski, Rushton, \& Simutis 1978; Grusec \& Redler, 1980).

Importantly, however, children evaluate their own actions not simply by their occurrence, but also by the contexts under which they occur (Warneken \& Tomasello, 2008). Here we explore one important context critical to evaluating prosocial behavior: that of choice. Choice differs from action in that it involves the contrast between actions performed and alternative actions not performed. For example, I evaluate Bob, who gave \(\$ 5\) to charity but could have kept it for himself (had an alternative) more positively than Jim, who accidentally dropped \(\$ 5\) into the hands of a homeless person (had no alternative). In fact, we often go beyond evaluating choice in absolute terms (having vs. not having choice) to also consider degree of costliness of the alternatives. To extend the above example, I would consider Bob more generous if his choice was to give away his last \(\$ 5\) than if his choice was to give away \(\$ 5\) out of his last \(\$ 100\). Thus, both the presence and the costliness of choice influence how we evaluate others.

No study to our knowledge has addressed whether choice plays a causal role in young children's own prosocial behavior. In this work, we asked whether making costly choices increases young children's prosociality. Specifically, we hypothesized that the contrast between actions chosen and alternative actions not chosen influences children's later prosocial behavior above and beyond the prosociality of the actions themselves.

We allowed preschool-aged children (3-4 year-olds) to perform a prosocial action: allocating a limited and desired resource to a puppet who was feeling sad. We systematically manipulated the presence and magnitude of alternative actions (non-prosocial actions) that children could also undertake. We were interested in how the presence and valence of these alternative actions affected children's subsequent prosociality. Subsequent prosociality was measured by allowing children to then make a new prosocial action towards a different puppet.

\section*{Experiment 1}

In Experiment 1, children were presented with an attractive and limited resource: 1 star sticker that they could give to a puppet ("Doggie") who was described as feeling sad. We manipulated children's experience of choice by allowing children to either make a Costly Choice (give the sticker to Doggie instead of keeping it for themselves), Non-Costly Choice (give the sticker to Doggie instead of having the experimenter put the sticker away), or No Choice (instructed to give the sticker to Doggie). As such, all children were given the option between (a) a positive
prosocial action \((+)\), and (b) either a selfish, negative action \((-)\), a neutral action (0), or no action. See table 1 for a summary. Children's actions towards Doggie were recorded. We were then interested in how the contrast between the action chosen (action a) and the action unchosen (the alternative action b) affected children's subsequent prosociality. To measure subsequent prosociality, children were introduced to a new puppet ("Ellie") who was also feeling sad, and given three stickers that they could either keep or share with Ellie.

\section*{Participants}

Seventy-two preschool-aged children (mean: 3.96 years; range: 2.85-4.98) participated. Conditions were fully balanced for age and gender. There were no age differences between conditions, \(F(2,71)=.96, p=.39\). One child was replaced due to parental interference. Participants were tested at a local school or children's museum.

\section*{Materials and Procedure}

Materials were two plush puppets ("Doggie" and "Ellie"), three small wooden boxes: Doggie's box, Ellie's box (which had pictures on the tops and insides of Doggie and Ellie, respectively), and the child's box (no pictures), and a set of small star and smiley face stickers. A schematic of the materials and procedure is shown in Figure 1.

Introduction All children sat at a table facing the experimenter. Children were first shown a plush animal named "Doggie" and told that Doggie was feeling "very sad today". Doggie was then put away. One of the toy boxes was placed on the table and introduced as "Doggie's box."

Choice Manipulation All children were induced to act prosocially. However, we varied the presence and magnitude of the alternative option across conditions. In the Costly Choice Condition, children were presented with the choice of either keeping the sticker for themselves or giving it to Doggie. In the Non-Costly Choice condition, children were presented with the choice of putting the sticker away or giving it to Doggie. Finally, in the No Choice Condition, children's actions were restricted by experimenter instruction ("This star sticker, you have to put in the box for Doggie so that he feels better"). Across all conditions, once
children made their choices, the experimenter said "good job!" and put the box away.

Dependent Measure A new puppet was then shown ("Ellie") who was also feeling sad. Ellie was then put away, Ellie's box was presented along with a second (plain) box on the table, and three smiley-faced stickers placed between the two boxes. The positioning of the two boxes was counterbalanced across participants. The experimenter then said that the three stickers were for the child, but that Ellie also really liked them. The number 3 was chosen to force children to create an uneven distribution (either to prioritize themselves, or to prioritize Ellie).

After counting the stickers, the experimenter then said that the child could either keep all of the stickers for him/herself (and pointed to the plain box) or share some with Ellie (and put them in Ellie's box). Re-prompts were used if children left any stickers on the table ("and what do you want to do with this/that one?"), until a box was chosen for each sticker.

\section*{Results and Discussion}

We first analyzed children's initial prosocial responses: the majority of children chose the prosocial action over the non-prosocial alternative: \(19 / 24\) in the Costly Choice condition, \(23 / 24\) in the Non-Costly Choice condition, and \(23 / 24\) in the No Choice condition (all Binomial \(p\) 's \(<.01\) ).

Next, we analyzed children's prosocial actions subsequent to the choice manipulation (Figure 2). Almost all children gave at least one sticker and shared at least one sticker, confirming that children both liked stickers and were motivated to share. Children were thus divided into two response groups based on whether they distributed unequally in favor of themselves or Ellie: other-prioritizing (giving majority, 2, or 3 , stickers to Ellie), and selfprioritizing (giving the minority, 1 , or 0 , stickers to Ellie). \({ }^{1}\) See Table 2 for details on number of stickers given per condition. A higher proportion (16/24; 67\%) of children in the Costly Choice condition made an other-prioritizing response than those in the No Choice ( \(8 / 24 ; 33 \%\) ) condition, Fisher's exact test \(p<.05\) (see Figure 2), suggesting that having choice influenced children's subsequent sharing. The cost of the choice also affected sharing: a higher proportion of children who made the initial Costly Choice were more likely to be other-prioritizing than those who made the NonCostly Choice (7/24; 29\%), Fisher's exact test \(p<.01\). Making a non-costly choice did not increase subsequent sharing over being instructed to share, \(p>.15\).

The results of Experiment 1 thus provide initial evidence that having made a costly choice to perform a prosocial action increased children's later prosocial behaviors. Why might this be the case? One possibility is that, by

\footnotetext{
\({ }^{1}\) Results remain nearly identical when analyzing only the subset of children who made the initial prosocial choice. For a conservative estimate, we thus include the full set of children across all experiments.
}

Figure 1: Schematic of materials and procedure used in all experiments.
Choices (a) and (b) were presented verbally in the order shown.

Contrasting their chosen actions with non-prosocial alternatives, children inferred their prosociality. The above explanation is consistent with traditional self-perception theories (e.g.,Bem, 1967) which predict that people learn about their own preferences from observing their past actions. There are, however, at least two alternative explanations, also consistent with self-perception theory, which consider the actions but do not take into account whether the action was contrasted with alternatives. One possibility is that the initial costly choice may have led children to believe they had exhibited their dislike for the object ("I gave away the sticker so I must not like stickers). Another possibility is that the initial Costly Choice caused children simply to repeat the initial outcome of distributing more to another than to themselves.

\section*{Experiment 2}

Experiment 2 was designed to rule out these possibilities. Procedures mirrored Experiment 1's Costly Choice condition, with the following modifications. Children were once again introduced to the first puppet, Doggie. This time, however, in the Costly Choice condition, children were given a colorful rubber toy frog, rather than a star sticker. In the Non-Costly Choice condition, children were given a
small white piece of torn paper. All children were told they could choose to keep the object for themselves or give it to Doggie. The dependent measure (and the new puppet, Ellie) remained the same.

It is important to note that unlike in Experiment 1, the objects used were different between the choice manipulation (which involved either a frog or piece of paper) and the dependent measure (which again involved smiley face stickers). Thus, any increased tendencies to share stickers during the dependent measure phase could not be attributed to children's inferences about their preference (or lack thereof) for stickers. Additionally, the choice manipulation of both the Costly And Non-Costly choice conditions required children to undertake the same prosocial action of giving the object to Doggie instead of keeping it for themselves, controlling for the possibility that initial practice with giving away objects causes children to repeat the outcome of giving more to others than to themselves.

\section*{Participants}

Forty-eight preschool-aged children (mean: 3.91 years; range: 2.81-4.96) participated. Conditions were fully balanced for age and gender. There were no age differences

Figure 2: Proportion of children who allocated the majority of their stickers in the dependent measure phase (to Ellie) in Experiments 1 and 2. \({ }^{*} p<05, * * p<.01\).
between conditions, \(t(46)=.41, p=.69\). Four children were replaced due to either experimental error or prior participation. Participants were tested at a local school or children's museum.

\section*{Materials and Procedure}

Materials were the same as those used in Experiment 1, except a set of colorful toy frogs and plain torn pieces of paper were used during the introduction instead of smiley face stickers (see Figure 1).

The procedure also largely followed that of Experiment 1, with the following modifications. In the Costly Choice Condition, children were given an attractive object (a colorful toy frog), and told they could either keep it or give it to Doggie. In the Non-Costly Choice condition, children were given a small torn piece of paper and also told they could either keep it or give it to Doggie. The dependent measures remained the same.

\section*{Results and Discussion}

First, to confirm that giving away the toy frog was in fact a more costly choice than giving away the piece of paper, we showed the two objects (side of object counterbalanced) to an independent sample of age-matched children, and asked them which object they preferred more. Nineteen (of 20) confirmed they preferred the frog (Binomial \(p<.001\) ). Once again, the majority of children in both the Costly Choice (frog) condition (21/24) and the Non-Costly Choice
(paper) condition (24/24) chose the prosocial action over the non-prosocial alternative (Binomial \(p\) 's \(<.01\) ).

Table 2: Number of Stickers Donated Across Conditions (modal responses bolded and underlined)
\begin{tabular}{lllll}
\hline Condition & \multicolumn{3}{c}{\begin{tabular}{c} 
Number of Children Who \\
Made Each Allocation
\end{tabular}} \\
& 0 & 1 & 2 & 3 \\
\hline Exp 1: Costly Choice & 2 & 6 & \(\underline{\mathbf{1 1}}\) & 5 \\
Exp 1: Non-Costly Choice & 3 & \(\underline{\mathbf{1 4}}\) & 3 & 4 \\
Exp 1: No Choice & 3 & \(\underline{\mathbf{1 3}}\) & 4 & 4 \\
Exp 2: Costly Choice & 2 & 6 & \(\underline{\mathbf{1 3}}\) & 3 \\
Exp 2: Non-Costly Choice & 3 & \(\underline{\mathbf{1 3}}\) & 5 & 3 \\
\hline
\end{tabular}

A higher proportion of children in the Costly Choice (16/24; 67\%) condition performed other-prioritizing prosocial behaviors than those in the Non-Costly Choice (8/24; 33\%) condition, Fisher's exact test \(p<.05\), demonstrating once again, that costly choices led to greater subsequent sharing behaviors. Once again, for details on number of stickers given per condition, see Table 2.

Moreover, we confirmed that children's prosociality could not be explained by the child making inferences about their own lack of preference for stickers: sharing rates across the two Costly Choice conditions of Experiments 1
and 2 were identical. Moreover, we ruled out the possibility that children in Experiment 1 simply repeated the outcome of having fewer objects than another agent - children in both conditions of Experiment 2 initially shared an object with Doggie instead of keeping it for themselves.

\section*{Experiment 3}

The results of Experiments 1 and 2 provide initial evidence that making costly prosocial choices plays an important role in children's subsequent prosocial behavior. We suggest that our findings are best explained by a prosocial construal hypothesis (see Cialdini, Eisenberg, Shell, \& McCreath, 1987; Grusec et al., 1978): In making costly prosocial choices, children construe their actions as a signal of their prosociality (e.g., "I shared so I must like to share").

How children perceive costly vs. non-costly situations, however, remains an important question. In Experiment 3, we wished to more closely investigate the differing perceptions that might occur during costly vs. non-costly choice situation. One possibility is that children perceive their own costly choices as intentions (i.e., that their actions were in fact, intentionally and freely chosen, rather than obligatory). On this account, children would encode costly choice situations as choices, and non-costly choices as obligatory acts (e.g., "I chose to give the sticker to Doggie instead of keeping it for myself" vs. "I had to give the sticker to Doggie instead of throwing it out").

In Experiment 3, we tested for this possibility, by once again giving children either a Costly or Non-Costly Choice, and then asking them whether they chose to or had to perform the target action.

\section*{Participants}

Fifty preschool-aged children (mean: 3.37 years; range: 2.84-4.84) participated. There were no age differences between conditions, \(t(48)=98, p=.34\). Five children were replaced due to either experimental error, or because they refused to answer the question. Participants were tested at a local school or children's museum.

\section*{Materials and Procedure}

Materials were the same as those used in Experiment 1, except there was no new puppet (Ellie). See Figure 1.

The Introduction and Choice Manipulation were nearly identical to that of Experiment 1, with the following modifications: a smiley-face sticker was used instead of a star sticker in the Introduction phase. Additionally, because we did not wish to bias children's answers with choice language, we avoided using the phrase "You get to choose", and instead simply presented the two options (e.g., "You can either give this sticker to Doggie or you can keep it for yourself").

Dependent Measure In the dependent measure, children were reminded of the choice they had made ("Do you remember when you put that sticker in Doggie's box?"). Children were then asked a Choice Question ("Did you
choose to do that, or did you have to do that?"). The question was re-asked if children did not initially answer.

\section*{Results and Discussion}

As in Experiments 1 and 2, the majority of children in both the Costly Choice condition (19/25) and the NonCostly Choice condition ( \(25 / 25\) ) chose the prosocial action over the non-prosocial alternative (Binomial \(p\) 's \(<.01\) ).

A greater proportion of children in the Costly Choice condition stated that they chose to perform the target action (18/25; 72\%) than those in the Non-Costly Choice condition (9/25; 36\%), Fisher's exact test \(p<.05\).

These results suggest that one of the inferences children may be making during Costly Choice situations is that their actions were intentional. These results are consistent with work that finds that young children learn about people's intent, both in the moral and non-moral domain, through evaluating the presence and amount of alternative actions available to them (e.g., Kushnir, Xu, \& Wellman, 2010; Zelazo, Helwig, \& Lao, 1996).

\section*{General Discussion}

We began this paper with the hypothesis that allowing children opportunities to make costly choices would influence their subsequent prosocial behavior. In fact, children were more prosocial after making costly than noncostly choices, and after making costly choices than making no choices at all. Moreover, children were sensitive to different types of evidence for what counts as a costly action: they shared more after making costly choices, and also after giving away costly objects. Finally, we found that children were more likely to construe their actions as intentional when making costly vs. non-costly choices.

Further work may examine the specific features of costly choice situations that enable children's subsequent prosocial behavior. One possibility is that children felt positive emotion by making a costly choice, and therefore were motivated to repeat the behavior at the next timepoint. The positive emotion may have occurred because children were subconsciously attuned to their own pride in making a choice that was costly, and were thus motivated to make themselves proud again by being prosocial. Yet another possibility is that in making a costly prosocial choice, children actively self-regulated their own physiological arousal elicited by hearing about a sad puppet (Hepach, Vaish, \& Tomasello, 2012). The coordination of setting goals and watching oneself effectively self-regulate in order to meet those goals may then have empowered children to repeat the self-regulatory prosocial behavior later on (Grolnick, 2009).

It is also important to examine the scope of influence that costly choices have on the development of prosocial behavior and on later-developing altruistic behaviors. Moral self-construction, as well as altruistic behavior, are likely to be the product of a rather complicated process involving emotional, behavioral, and cognitive components (Blasi, 1983; Hardy \& Carlo, 2011; Kochanska, 2002). Our
findings show that costly choices play a causal role in determining the short-term prosocial behavior of very young children. Though more research is needed to investigate how choice interacts with other components of moral development, demonstrating the short-term results underscores previous findings that choice may make a critical contribution to children's emerging understanding of themselves as moral beings through rational inference.

\begin{abstract}
Video-sharing websites have begun to provide easy access to user-generated video content. How do we find what we want to view among the huge video database? When people search for a video, they may want to know whether the video evokes a certain emotional sensation. The evoked emotion is one of the important factors we consider when we select a video. One of the key concepts of evoked emotions from videos: the evoked emotions are different for each scene and for each viewer. Considering these differences, we obtained humanevoked emotions from 33 videos. We used these emotions to estimate the multiple emotions evoked by each scene of the videos. Using a computational model of emotion estimation based on mid-level visual features, we found that, in individual videos, the same scene evoked multiple emotions. Our results show that a video evoked different emotions from different people. A computational model might deliver probabilistic multiple-evoked emotions from video analyses.
\end{abstract}

Keywords: evoked emotion; visual feature; video retrieval

\section*{Introduction}

Video-sharing websites provide easy access to a wide variety of user-generated video content, including movie clips, television clips, music videos, and amateur content. We can search a huge database of videos for a video that we want to see via the use of keywords or a search by genre. Unfortunately, these search strategies are not sufficient. If we do not have any prior knowledge of a video, how do we find what we want to see? The mood of movie is one of the most important factors we consider when we select a movie. When people search for a movie or TV series, they may want to know whether the video has a mood that is similar to that of a video they have viewed before. Sometimes, they may want to change their mood by watching a video.

Until now, most of the research efforts have focused on a content- or genre-based analysis of videos despite many users' needs for emotion-sensitive video retrieval. Fortunately, some have studied the emotions evoked by images (Wang \& He, 2008; Yanulevskaya et al., 2008; Li, Zhang \& Tan, 2010). Wang and He (2008) focused on emotional semantic image retrieval (ESIR) instead of content-based image retrieval (CBIR) to reduce the "semantic gap." Others studied emotional picture categorization using the International Affective Picture System (IAPS) according to the 10-emotion model (Yanulevskaya et al., 2008; Li, Zhang \& Tan, 2010). However, the application of these approaches to a video sequence may not be appropriate due to the lack of consideration of temporal variations. Various moods change sequentially within a given video. That is, within a given video, different emotions may be evoked across scenes.

Two different studies evaluated the emotions evoked by videos. Canini et al. (2009) evaluated the emotional identity of videos. The research used light source color, motion dynamics, and audio track energy as the temporal features of videos. It was a first attempt to evaluate the temporally changing emotional identity of movies. They used a 3 dimensional (3D) emotional identity space (warm/cold, dynamic/slow, and energetic/minimal) to show the trajectory of one video clip. Unfortunately, the emotional identity space was used to express movies' content changes rather than humans' various emotional changes. Bailenson et al. (2008) focused on a classification algorithm of emotions evoked by videos. Facial feature tracking was used and physiological responses were measured. The study tried to predict 2 emotions (amusement and sadness) and the intensity of each emotion. Unfortunately, this approach is not applicable to the study of video retrieval.

Winter and Kuiper (1997) reported that individual difference factors play an important role in the experience of emotion. In fact, individuals may respond differently depending on their current state of mind. However, most research of the emotion of videos has assumed that an emotion is unified at any given moment.

In the present paper, we propose a new temporally changed emotional analyzer that functions as a probabilistic estimator of multiple emotions evoked by videos. The goal of this study is to generate sequentially changing emotional responses from a video clip. This paper is organized as follows: First, a psychophysical experiment to investigate the evoked emotions by each scene is described. Second, the proposed system is introduced with mid-level visual features, an estimation model, and a performance test. Finally, the conclusions are summarized and future tasks are proposed.

\section*{Method}

\section*{Data Set}

To investigate the evoked emotion of each video clip, stimuli were taken from following movies and TV series: Amélie of Montmartre (2001), Artificial Intelligence: AI (2001), Curse of the Golden Flower (2006), The Amazing Spider-Man (2012), Wuthering Heights (2012), Friends Season8: The One Where Rachel Tells Ross (2001), and CSI: Miami Season8 Episode4: In Plane Sight (2009). The movies and TV series were selected non-intentionally. Each was decomposed to a set of video scenes, the emotional valence of which varied. Thirty-three video clips were selected in order to not exceed one hour per experiment per person. The average run time of the clips was 81 seconds. Each video clip had one main event that occurred in one location. We preferred that each video clip evoke one kind of emotion.

\section*{Evoked Emotions}

To examine the emotions evoked, we used emotional models instead of Canini's 3D emotional identity space (Canini et al., 2009). Ekman's model is defined by 6 basic facial emotional expressions: anger, surprise, disgust, sadness, happiness, and fear (Ekman \& Friesen, 1978). However, this model may not be applicable for videoevoked emotions because it contains more negative emotions than positive ones: it has 4 negative emotions (anger, disgust, sadness, and fear), one neutral emotion (surprise) and one positive emotion (happiness). Thus, the model needs to be balanced. Moreover, the model did not include some key emotions that viewers experience while watching videos. Gross and Levenson (1995) modified the 6 -emotion model to an 8 -emotion model. The 8 -emotion model comprises the following emotions: amusement, anger, contentment, disgust, fear, neutral, sadness and surprise. Unfortunately, this model is also not balanced.

We designed a 12-emotion model that includes Gross and Levenson's (1995) 8-emotion model with 4 emotions (humor, romance, tension, and suspicion). Our emotional space is balanced in that there are 4 positive emotions (humor, romance, contentment, and joy/pleasure), 4 blended emotions (suspicion, tension, surprise, and neutral), and 4 negative emotions (anger, disgust, sadness, and fear).

\section*{Procedure}

20 people participated in the experiment. At the beginning of the test, the 12 emotions were described (Fig. 1) to the participants. The video clips were shown to the participants on a TV monitor. The presenting order of videos was randomized to minimize potential error. After watching each video clip, the participants were asked to choose 1 of the 12 emotions that best represented the emotion evoked by the video clip.

Figure 1 : The names and illustrations of the 12 emotions used in this experiment.

Figure 2 : Emotions evoked by the 33 video clips.

\section*{Results}

\section*{Responses of Evoked Emotion}

The participants' responses are summarized by a 12emotion population for each video clip. The results of the evoked emotional responses for the 33 video clips are illustrated in Figure 2. The figure shows the frequency of the most commonly reported and the second most commonly reported emotion per video clip. Some emotions were not reported often; this may generate some noise in our model. Gross and Levenson (1995) reported that contentment, anger, and fear are more difficult to be evoked by movies than are other emotions. Notably, anger was not evoked by the video clips.

\section*{Statistical Analysis}

To determine whether the response data varied according to the video clip, we analyzed the data statistically using SPSS 1.9. First, we tested independence of the participants' responses for all of the test video clips, through a crosstabulation analysis using chi-square tests. The relationship between the evoked emotion and the video clip presented was significant ( \(\mathrm{p}<0.001\) ).

Second, the independence of participants' evoked emotions was evaluated in the several extracted video clips from the same movie or TV series. The video clips were composed of 3 clips of AI, 5 clips of CSI, 4 clips of Wuthering Heights, 4 clips of Amelie, 4 clips of Friends, and 12 clips of Spider-Man. The evoked emotion was significantly related to the video clip ( \(p<0.001\) ). The results provided in Tables 1 and 2 are examples of our statistical analysis applied to the data collected in response to the 3 clips of \(A I\). While the \(A I\) clips evoked all of the 12 emotions, the other clips evoked as 3 or 4 emotions.

Table 1 : The results of the cross-tabulation analysis for the \(A I\) video clips.

\section*{Estimation Model of Evoked Emotions}

Figure 3 : A block diagram of our proposed estimation system.

Do computers mimic human emotions such as the emotions evoked by the video clips? To answer this question, we proposed a movie-evoked emotion estimator by introducing mid-level visual features. The mid-level visual features were composed by referring to color emotional theory with a 3color combination and emotionally correlated general visual features: contrast by histogram distribution, relative brightness, and motion size. To create the evoked-emotion estimator, we examined the relationship between humans' psychophysical responses and the mid-level visual features extracted from the video clips. The emotion model was trained by supervised learning with humans' psychophysical responses and their features. The proposed approach generated multiple emotional states of the video contents sequentially and is illustrated in Figure 3.

\section*{Visual Feature Extraction}

Psychologists have investigated the emotion-eliciting properties of industrial media (Gross \& Levenson, 1995; Pos \& Armytage, 2007; Kobayashi, 1981). In particular, Gross and Levenson (1995) focused on eliciting the emotion of films. They determined that each film could evoke 8 different emotions from the viewers. The results show that video clips can be categorized by the different emotions that they evoke from the viewers. However, they did not attempt to draw relationships between the visual cues and the elicited emotions. The present study focused on some midlevel visual cues and evoked emotions from some video clips. The mid-level visual cues are reorganized by an analysis of low-level features. Moreover, the mid-level cues were differentiated from low-level cues. The mid-level cues were extracted by color, contrast, brightness, and motion.

Color Color is known to correlate strongly with psychological constructs. Many studies describe the relationships between these variables (Pos \& Armytage, 2007; Kobayashi, 1981; Solli \& Lenz, 2010), but to date, correlations in movie settings have not been studied. Pos and Armytage (2007) investigated the relationships between emotions, facial expressions, and colors. Kobayashi (1981) matched 1170 3-color combinations to 180 adjective words describing emotional appearance. Solli and Lenz (2010)
transformed and classified natural images on the basis of Kobayashi's list of emotional words. Kobayashi's color scale is useful for industrial design. Unfortunately, it is not appropriate to apply the 180 emotional words (i.e, warm, cold, luxury, etc.) to movies. Pos and Armytage (2007) studied the relationships between 3-color combinations and Ekman's 6-emotional facial expressions. The 3-color combination might connote simple feelings (e.g., warm, cold) and emotions (e.g., happy, sad).

We extracted the color distribution of a video clip to estimate evoked emotions. We transformed the colors of the input video clips into Kobayashi's 130 -color scale Hue and Tone System. The transformation helped to reduce the complexity of the analysis \(\left(2^{8 \times 3} \rightarrow 130\right)\) and to classify the input colors into emotionally meaningful representative colors. An input pixel color (RGB) is converted to the Hue and Tone value (HT) as shown in Equation 1.
\[
\begin{equation*}
R G B t o H T(x)=\underset{i}{\arg \min }\left\{R G B_{-} \operatorname{Dist}(x, H T[i])\right\} \tag{1}
\end{equation*}
\]
where \(x\) is 1 of the \(2^{8 \times 3}\) colors used as an input color, \(H T[\mathrm{i}]\) is 1 of the 130 Hue and Tone colors ( \(1 \leq i \leq 130\) ), and \(R G B \_\operatorname{Dist}(x, y)\) is a distance measuring method such as Euclidean distance on RGB space. The HT with the minimum distance was selected as the HT value of the pixel. Then, we extracted 3 colors used most frequently in the frame. The 3 dominant colors were accumulated for all of the frames of a video clip as a probability distribution of hue and tone colors. The entire process is illustrated in Figure 4.
(a)

Figure 4 : Our color extracting method: (a) a video stream; (b) RGB images of each of the frames; (c) converted HT images of each of the frames; (d) three dominant colors of each of the frames; and (e) a probability distribution of HT for all of the frames.

Figure 5 : Contrast classification method (Kim, Choe, \& Lee, 2006).

Contrast Except for the color feature, we can extract many features from visual information. Above all, a high-contrast scene may evoke a different emotion than a low- or mildcontrast scene. We used a contrast-categorization-method based histogram analysis of image intensity (Kim, Choe, \& Lee, 2006). The categorization performance of the method has already been proven by a previous human psychophysical experiment. The method assigns the histogram distribution of every image to 1 of 5 representative contrasts. We merged class \(\mathbf{D}\) and class \(\mathbf{E}\) (see Figure 5) into 1 category since they yield similar contrast.

Brightness Image brightness is 1 of the important cues serving as a connotative feature of videos. Low brightness may not be used by directors to express a hopeful scene. However, it would be inappropriate to use absolute brightness as an estimating tool for eliciting emotion, because the overall brightness of a video depends on the brightness characteristics of the video camera or the director's preference. Consequently, we extracted the relative brightness \((\widetilde{\boldsymbol{Y}})\) to the average brightness of the entire video as described in Equation 2. \(Y_{f}(i)\) is an average brightness of all of the pixels in the \(i\) th frame, \(n\) is the total number of frames for a scene, and \(m\) is the total number of frames for an entire video.
\[
\begin{equation*}
\tilde{Y}=\frac{\sum_{i=0}^{n} Y_{f}(i)}{n}-\frac{\sum_{j=0}^{m} Y_{f}(j)}{m} \tag{2}
\end{equation*}
\]

Motion Motion is an important factor in the evaluation of how dynamic scene is. We used a scale-invariant feature transform (SIFT, Lowe, 2004) to obtain motion information. SIFT features are extracted from the video frames and their trajectory is evaluated to estimate inter-frame motion (Lowe, 2004). In this study considers the distance of their trajectory was considered as the motion size. Then, the motion feature defined the largest motion size of each inter-frame.

\section*{Emotion Estimation}

To estimate emotions evoked in participants while watching videos, we used an evoked-emotion model. The psychophysical experiment was used to develop the emotion model and the multiple emotional responses were the
training data. Then, the emotion model was learned by a supervised learning method using the psychophysical responses.

Training Data As mentioned above, we extracted a motion feature from inter-frame data and 3 other features from intra-frame data. We needed some representative values of the features to train the emotion model. Thus, each feature was analyzed in every frame of a clip, and all feature data were summarized during 1 -second intervals. All video clips were standardized to the same pixel resolution and frame rate. Every clip was composed of 24 frames per a second. The color feature was encoded by using a 130 -variable combination. The variable was calculated by normalization (between 0 and 1) of the accumulated HT probability distribution for all of the frames. The contrast feature was encoded by using a 5 -variable combination and the variable was presented by the normalization of the accumulated probability distribution for contrast categories of all of the frames. Brightness and motion features were calculated by averaging them over all of the frames.

A training set of supervised learning consisted of an input feature vector and an output target vector. The target vector was designed as 6 probability values. The probability values were such that five emotions (contentment, surprise, anger, sadness, and fear) were filtered out to prevent mis-learning by null data (see Fig. 2). Moreover, "neutral" is a broad emotional term with diverse meanings and, therefore, it was also filtered out. Owing to the removal of the emotions, 6 clips in which one of the removed emotions predominated had to be excluded.

Estimation Model The emotions evoked in the participants were the target data used to train the model. Classification and Regression Trees (CART, Breiman, et al., 1984), a kind of decision tree learning, was selected as the learning method to classify the evoked emotion from a video. One advantage of CART is that it can consider misclassification costs in the tree induction, using handling numerical-valued attributes. The model learns a probabilistic response for each emotion and the extracted visual features. The participants' responses are set as the independent variables and mid-level visual features serve as the dependent variables of the model.

Estimation Performance Finally, we conducted supervised learning with CART. The model outputs probability values (between 0 and 1) for every 6 emotions for an input video. We evaluated the performance with a between-clip crossvalidation of 27 video clips.

A summary of our estimation performance is shown in Table 3. For the sake of convenience, the accuracy of performance was calculated by using an emotion with the estimated maximum probability for each clip. That is, each of the 27 videos had a predicted emotion with a majority probability. The predicted emotions were compared with the most common emotion of the target data; the correction rate
was \(56 \%\). In Table \(3,2^{\text {nd }}\) emotion accuracy refers to the percentage of times that either the most common or the second-most-common emotions was the predicted emotion.

Table 3: Details of the accuracy of the evoked emotion model.
\begin{tabular}{cccc}
\hline & \(1^{\text {st }}\) emotion & \(2^{\text {nd }}\) emotion & \(3^{\text {rd }}\) emotion \\
\hline \begin{tabular}{c} 
Prediction \\
accuracy
\end{tabular} & \(56 \%\) & \(63 \%\) & \(70 \%\) \\
\hline
\end{tabular}

Figure 6 shows a partial emotional profile of The Amazing Spider-Man using our model. The profile shows that the movie does not have 1 evoked emotion; instead, it has 3 or more evoked emotions at the same time. In addition, each emotional state is shown as a probability value. The emotional state exhibits variations that are similar to the original characteristics of the movie. For instance, the middle of the movie has many scenes with a heroine and a hero that induce a romantic mood, and the latter part has many episodes in which the hero challenges a powerful villain. Further, the dominant emotion of each second from Figure 6 is illustrated in Figure 7. The pie chart might help one to search a movie for some of the most important information.

Figure 6 : A partial emotional profile of The Amazing SpiderMan using the proposed method.

Figure 7 : The emotional composition of The Amazing Spider-Man.

\section*{Discussion}

Previous attempts to characterize the emotions of videos have used a single emotion, as a representative emotion for an entire video sequence (Gross \& Levenson, 1995; Bailenson et al., 2008; Canini et al., 2009). However, a person's emotions vary every moment (Winter \& Kuiper, 1997).

To take these individual differences into consideration, the present paper proposes a probabilistic model that can estimate multiple emotions evoked by a video over time. The proposed method involves the automatic labeling of videos with the emotions that were evoked and the duration of the evoked emotions. The present study attempted to characterize the evoked emotions by using mid-level features from the video frames, such as dominant colors, contrast, brightness levels, and motion quantification. The characterization was derived from a previous psychophysical experiment using human participants. A classical machine learning methodology was applied in order to build and test the model of the emotional categories targeted.

The present study provides 2 significant advances. First, it is the first to propose a new paradigm for video retrieval, using probabilistic multiple-evoked emotions. This approach may be used to construct an emotion-based video retrieval system, a video recommendation system, or an emotional treatment system using a video. It may also help a machine to generate a new video profile that automatically describes sequentially changing emotions. Second, this study provides a technically new approach. That is, we used emotionally meaningful mid-level visual features and we modeled them to estimate multiple-evoked emotional states from videos.

However, there are limitations to the present research. The experimental video clips were limited and participants made non-various responses (Figure. 2). Having participants choose only a single emotional response in the experiment might lead to inadequate data for generation of a probabilistic emotional estimator. One of the interesting findings was that there were no anger responses. Mikels, et al. (2005) reported the same result with still images. The authors concluded that anger is very difficult to elicit with the passive viewing conditions of static images. Our experiment used some video clips that were a few minutes long. One explanation for the finding of no anger responses is that the video clips were not long enough to evoke the emotion.

Thus, 3 tasks are left for future research to implement our approach in a real system. First, more video clips are required to teach the various emotions to the evoked emotion model. Second, a larger sample is required to get a robust trained model. Third, other machine learning methods should be tried to find an optimal solution.

\title{
How Working Memory Capacity Constrains the Learning of Relational Concepts
}

\begin{abstract}
We investigated the way in which working memory (WM) constrains the learning of relational concepts - categories defined by the way objects are assigned to roles in the structure of an underlying relation, and not by objects' intrinsic features. By applying to a large sample a novel test of concept learning as well as the battery of WM tasks, we found that WM is a strong predictor of the scores on the test, but the WMlearning correlation decreases as the relational complexity of the to-be-learned concepts increases. Such results support those theoretical models of relational learning, which assume that learning of relational concepts (and relations, in general) consumes more WM resources than just the processing of relations which have already been learned.
\end{abstract}

\section*{Introduction}

The issue of relational thinking - the humankind's ability to acquire, process, and effectively use mental representations of relations - has huge importance in cognitive science (Gentner \& Kurtz, 2005; Halford, Wilson, \& Phillips, 1998; Hummel \& Holyoak, 2003). A relation can be described as an ordered list (a structure, a predicate) of well-defined roles and objects that fulfill them. The key aspect of relations consists of the fact that understanding of them as well as inferring from them depends primarily on the way objects are assigned to roles in the relation's structure, and not necessarily on objects' intrinsic features. Relational representations constitute the core of human complex cognition, including abstraction, reasoning, analogy making, creativity, and language (Halford, Wilson, \& Phillips, 2010).

The extension of an \(n\)-ary relation (where \(n\) is a number of roles in a relation; its arity) is a subset of Cartesian product of \(n\) sets, which includes all lists of objects ( \(n\)-tuples) that can fulfill roles in that relation (i.e., an object from the first set in a tuple fulfills the first role, etc.; Halford et al., 1998). So, each relation can be treated as a relational category/ concept (Gentner \& Kurtz, 2005). Unlike so-called entity categories, that is, categories formed by objects due to their perceptual or/and internal (e.g., genetic) similarity (e.g., natural kinds), relational concepts in the first place organize entity categories (or lower level relational categories), and so their exemplars may drastically vary featurally. For example, the instances of the relational concept of barrier will include: a wall, a river, a person, but also an insult, and loss of support (ibidem). Relational concepts constitute the main part of culture, science, and technology.

A key goal of cognitive science is to understand what relational concepts are, how they are acquired in childhood and adulthood, and how they are used in relational thinking. Consequently, the present paper aims to deal with one specific problem in this domain: it investigates in what way the constraints of human cognitive architecture, particularly its working memory capacity (WMC), influence the learning of relational concepts (from here on, the process/ability referred to as relational learning).

\section*{Working memory and relational learning}

Computational models of relational thinking (e.g., Chuderski, Andrelczyk, \& Smolen, 2013; Doumas, Hummel, \& Sandhofer, 2008; Halford et al., 2010; Hummel \& Holyoak, 2003) as well as psychometric studies on reasoning and analogy making (e.g., Martinez et al., 2011) suggest that processing relations is grounded in working memory (WM). WM is a neurocognitive mechanism responsible for maintenance of a limited, but crucial for the current task/goal, amount of information, in an active and easily available state (Cowan, 2001). It thus allows for flexible manipulation of that information (Hummel \& Holyoak, 2003; Oberauer, Süß, Wilhelm, \& Sander, 2007), including binding of relational roles and corresponding objects, which is a necessary process for a relational representation to be constructed. People can hold in their WM up to, on average, as few as three or four chunks of information (Cowan, 2001; Luck \& Vogel, 1997) and, probably, the similar number of bindings (Chuderski et al., 2013; Oberauer et al., 2007), though these values vary among individuals (approx. from 1 to 6 ). This clearly corresponds to the fact that accuracy of processing relations sharply decreases with increasing arity of relations, and few participants can cope with relations more complex than quaternary ones (Halford et al., 2010).

An interesting research question pertains to a problem of whether similar influence of WMC, as in abovementioned case of processing relations (e.g., during analogical mapping or inference), also takes place in case of relational learning, when people have to discover an (abstract) relation between related objects and construct a mental representation of the relational concept referring to that category.

A widely used paradigm of relational concept learning was proposed by Shepard, Hovland, and Jenkins (1961). They presented to participants series of eight three-feature geometric figures, each of which could take one out of two values on each featural dimension (shape, size, color), and
needed to be classified as belonging or not to a category defined by an arbitrary rule of propositional logic (henceforth named a Boolean concept). Each decision was followed by a feedback information on whether an object was categorized correctly or not. Participants improved on that classification task, thus learning to some extent a hidden Boolean concept. The most important result suggested that the accuracy of categorization decreased as the number of features relevant for a concept increased from one to three. This observation was generalized beyond Boolean concepts domain by Halford et al. (1998), who defined relational complexity in terms of the number of entities (variables or dimensions of a relation, that is, its arity) that must be related in parallel, because their decomposition into a set of less complex relations would lead to the loss of the relation's meaning.

Moreover, accuracy of categorization decreased with increasing complexity (expressed by minimal description length, MDL; Feldman, 2000) of a logical rule associated with the three-feature concepts. However, as the MDL approach led to a problem of which logical operators should count as minimal (e.g., if we include exclusive disjunction, then MDL no longer predicts Shepard et al.'s data; see Goodwin \& Johnson-Laird, 2011), later this approach was disputed. For example, Feldman (2006) proposed an algebraic complexity metric of discrete-value concept learning difficulty, which depends on the sum of a number of constant values of variables and the number of implications which derive values of one variable from values of another variable, into which a given concept can be decomposed. Kemp, Goodman, and Tenenbaum (2008) adopted this approach to describe relational concepts beyond a Boolean domain. Those approaches nicely predicted observed data. Similarly good fit was obtained by a theory predicting that the number of all possible mental models (iconic-like representations precisely corresponding to the structure of themselves roughly represented - elements of a situation) which match a rule describing a concept (Goodwin \& Johnson-Laird, 2011).

In the present paper, we ask whether the effectiveness of relational learning can be predicted by WMC. Moreover, we test whether the link between those two variables, if any is found, depends on the abovementioned complexity of concepts which are learned. Such a test may be very informative regarding the validity of existing models of relational learning, because, as we will see, some of them seem to yield opposite patterns of predictions on the strength of WMC-relational-learning link in the function of complexity.

Although Halford et al. (1998) have not inferred such predictions directly from their theory (instantiated also in a computational model called STAR), closer inspection of this theory leads to the prediction that the critical value of relational complexity for learning relations should be four dimensions. For example, Halford, Baker, McCredden, \& Bain (2005) have shown that accuracy to understand statistical interactions is quite high for two- and three-way interactions, while it radically falls down in the case of fourway ones. As Halford et al. (2010) assume that the same constrains pertain to both processing and acquiring relations (both limits are grounded in the maximal size of a tensor that humans can mentally represent), learning bi- and ter-
nary relations should be relatively easy and not so much constrained by individual WMC, as the mean WMC is about four. In contrast, there should be substantial differences in learning quaternary relations, as people of WMC below four (i.e., one, two, or three) will not be able to learn them fully, while people of WM above that limit (i.e., of four, five or six slots) will have enough capacity to do that. So, the correlation between WMC and relational learning should be the strongest in case of the mean value of WMC.

In contrast, a neurosymbolic model of the discovery of relations proposed by Doumas et al. (2008) assumes that in order to learn a relation, a cognitive system has to represent each role-filler pair as two separate neuronal oscillations, asynchronic, but peaking close in time. This implicates that for learning each dimension of a relation, the system needs two WM chunks, and only after having learned it, both a role and a filler can be compressed into one synchronized oscillation. So, even learning binary relations will consume WMC (i.e., four chunks) of a large part of participants, and their performance on binary relations should be particularly sensitive to individual differences in WMC. Learning ternary (i.e., requiring six WM slots) or quaternary (i.e., occupying eight slots) relations should be difficult for almost everyone's WM, and - if nevertheless effective - will have to rely on mechanisms other than WM (e.g., relational knowledge accretion, compressing relations, etc.).

Interestingly, a recent study by Lewandowsky (2011), who examined correlations between each type of Shepard et al.'s concepts and WMC, has shown that the strength of such a correlation is basically the same in case of unary, binary and ternary concepts of such a kind. This study suggests that a third possibility regarding the pattern of correlations between relational learning and WMC is possible, specifically that WMC influences learning relations of any complexity. However, three disputable aspects of the Lewandowsky's study suggest that more data is needed before a decisive conclusion on WMC-relational learning link can be given.

Firstly, the criterion for a successful learning of Shepard et al.' concepts was that a certain number of correct classifications can be consecutively made by a participant. However, this does not guarantee that he or she really started to represent a relation underlying the concept, because due to a large number of classification trials a complex association, instead of a fully-blown relational representation, may be formed as well. So, in order to prevent such a case, participants should be able to explicitly report a relation to be found, as a necessary criterion for judging that a relational representation has indeed been learned.

Secondly, with the use of Shepard et al.'s concepts, at most ternary relations can be investigated, what does not allow to directly test predictions derived from Halford et al. (1998, 2005, 2010). More complex relations, above and beyond binary features and three dimensions, are needed (e.g., Kemp et al., 2008). Optimally, participants should be required to learn quaternary relations, in which each variable depends on the values of three other variables.

Finally, all existing studies (e.g., Goodwin \& JohnsonLaird, 2011; Halford et al., 2005; Kemp et al., 2008; Lewandowsky, 2011) have investigated relational learning defined
as the rate of success in acquisition of a to-be-learned concept/rule. However, learning is a dynamic process, and its most important indicator is the increase of knowledge one has gained, and not the total amount of knowledge (including the knowledge possessed before the study started) that one can display. So, the examination of the progress in the discovery of relations, and not only how one can discover them in general, as well as the testing of possible associations between the rate of that progress and WMC, can bring a vital insight about relational learning and its WM mechanisms. To our knowledge, no study so far addressed all aforementioned issues in parallel.

In the remaining part of the paper, we present a direct examination of possible predictions on the link between WMC and relational learning, by applying to a large sample of participants a test that requires discovery of relational concepts differing in complexity. Each discovered concept must aptly describe six presented associated exemplars, while excluding three accompanying counterexamples. We also measured participants' WMC with four versions of a well-established WM measure (a complex span task). We investigated the resulting correlations with the use of confirmatory factor analysis (CFA). Firstly, we correlated relational learning accuracy with WMC, in the function of the complexity of the former. Secondly, we tested the link between the latter and the improvement on learning, that is, when structurally identical relations must be discovered for the second time, but now governing new kind of stimuli. That is, we examined if the transfer of the effects of relational learning would be linked to WMC or not.

\section*{A study}

\section*{Participants}

A total of 243 participants ( 142 women, mean age \(=24.3\) years, \(S D\) age \(=5.0\), range \(18-45\) years) were recruited via publicly accessible social networking websites. Each person was paid 15 euro for their participation in the study. Data from six people were discarded because of theirs failure to provide even one elaborate description in the learning test.

\section*{A test of relational concepts discovery}

The DREL (Discovery of RELations) paper-and-pencil test consists of two, letter and digit, parts. Each part includes 15 items. Each item consists of six four-symbol strings, which are governed by a to-be-discovered relation, and another three strings, which form counterexamples for that relation, that is, the discovered relation must exclude all three counterexamples. A participant is required to write down a concise and abstract description of a relation that matches six positive exemplar strings. The counterexamples were introduced in order to prevent describing too general relations (e.g., all strings consist of four symbols). In each part of the test, there are five binary, five ternary, and five quaternary relations, and item positions for each complexity level with regard to the beginning of the test were balanced (the sequence of levels is: 324234342432423 ).

In the first part of the test, symbols in each string are two different letters, and a relation governs the place of each letter relative to some number of remaining letters in a string. We assumed that in binary-relation items, the proper relation can be discovered using only pairwise comparisons of letters, so in each step of analysis of a string, a participant needs to maintain in WM only two representations. One example of a binary-relation item requires to discover a relation the same letters in the middle are different from the same two letters on the extremes:

\section*{OEEO LSSL BVVB \\ ZKKZ NUUN YAAY \\ RRVV AKAK PPLL}

Counterexamples prevent people from proposing relations like there are always two exemplars of one letter and two of the other letter. There is only one mental model corresponding to binary relations (in case of this example: \(a b b a\) ).

In the ternary-relation items, the proper relation can be discovered using comparisons of three letters in parallel, so in each step of analysis three representations have to be maintained in WM. An instance of ternary relation is one and only letter different from three other identical letters is always placed in the middle (corresponding models are: \(a a b a\) and \(a b a a\) ). In the item presented below, a participant is expected to relate: a pair of two identical letters to another identical letter on the opposite, and both of them to one remaining different letter always placed in the middle:
\begin{tabular}{llc} 
ZEZZ & LLUL & NRNN \\
ASAA & JJWJ & PBPP \\
OLLL & KKKN & VVVB
\end{tabular}

In the most difficult, quaternary-relation items, we assumed that all four letters have to be related in one step. An example relation is the first letter is different from the second one or the third one or both, and the third letter is different from the fourth one (three corresponding models: \(a a b a, a b a b\), and \(a b b a\) ). The complexity of this relation is a result of introducing an inclusive disjunction \(x\) or \(y\) or both. A participant in this example is expected to simultaneously relate the first letter to the second, the first one to the third, and the third one to the fourth:

The only difference between the first and the second part of the test is that symbols are digits, and relations pertain to
their evenness or oddness. However, the abstract structure of relations of corresponding items in both tests is identical. For example, the digit version of aforementioned binary relation would be: two digits in the middle are both odd or both even, and in the former case two extreme digits are even, while in the latter case two extreme digits are odd. This part is more difficult, as the crucial feature (evenness/ oddness) is not linked to the appearance of a symbol, while the crucial feature of the letter part (identity/difference) is.

The scoring on the test depended on the abstractness on given descriptions. One point was scored if a described relation was correct and properly abstract (as in the examples), no matter what exact formulation were used by participants. Half point was scored if a description was correct, but it was not abstract enough, instead it was composed of particular subcategories of strings (usually corresponding to possible models), for example, in case of the ternary example, if a description was like there is either (a) one letter, then another is different, and then two last letters are the same as the first one, or (b) there are two same letters, then another is different, and then the last letter is the same as the two first ones. No score was given for incorrect descriptions, no matter if they excluded valid instances of strings or included counterexamples. Such a partial scoring resulted in much better reliability of the test (Cronbach's \(\alpha=.91\) ) than did binary (correct/incorrect) scoring ( \(\alpha=.78\) ). The dependent variables were total scores (in range 0 to 5 ) on each level of relational complexity, and the corresponding differences between scores on the second and first part of the test (i.e., indices of learning).

\section*{Working memory tasks}

Four complex span tasks were designed following Conway et al. (2005). In general, a complex span requires memorizing a sequence of a few stimuli, each of them followed by a simple decision task. In the present versions, each task required memorizing three to seven (set size) stimuli, presented for 1.2 s apiece, out of nine possible ones for that task. After two two-stimuli training trials, three trials for each set size (in increasing order) were presented in each complex span task. The letter span task (sometimes called an operation span task) required memorizing letters, while deciding with a mouse button if intermittent simple arithmetical equations (e.g., \(2 \times 3-1=5\) ? ) are correct or not. The digit span consisted of memorizing digits, while checking if letter strings begin and end with the same letter. The spatial span task required memorizing locations of a red square in the \(3 \times 3\) matrix, while deciding which of two presented bars is larger (the difference was always \(25 \%\) ). In the figural span task, participants were instructed to memorize simple geometric figures, while judging colors to be light (yellow or beige) or dark (brown or navy blue). The dual (decision) task in each WM test aimed to prevent the chunking of stimuli or the extensive use of phonological loop, which could obscure "real" WMC of individuals. The participants were instructed that they should recall as many stimuli as they can (in proper order), but that they should also try to be correct on the decision tasks.

The response procedure in each task consisted of a presentation of as many \(3 \times 3\) matrices as was a particular set size, in the center of the computer screen, from left to right. Each matrix contained the same set of all nine possible stimuli for a task. A participant was required to point with the mouse those stimuli that were presented in a sequence, in the correct order (from left to right). Only choices that matched both the identity and ordinal position of a stimulus were taken as correct answers. The dependent variable for each complex span task was the proportion of correct choices to all stimuli presented in the task. All complex span tasks displayed high reliability ( \(\alpha \mathrm{s}=.85\) to .89 ).

\section*{Procedure}

The presented study was a part of a larger project testing various cognitive abilities (WM, attention, reasoning), which included 17 computerized tasks applied in one fourhr session, and 5 tests of relational thinking applied in another four-hr session (sessions were administered in a random order), with a 1 -hr break between the sessions. Complex span tasks were the \(5^{\text {th }}, 9^{\text {th }}, 13^{\text {th }}\) and \(16^{\text {th }}\) tasks in a row applied in the former session, while the DREL test was the first task in the latter session. Half hour was allowed for each part of the DREL test.

\section*{Results}

Table 1 shows the descriptive statistics and correlations of all dependent variables. No variable deviated from the normal distribution. Correlations ranged from moderate \((r=\) \(.21)\) to strong \((r=.75)\).
\begin{tabular}{lcccccccccc}

Table 1: Correlation coefficients and descriptive statistics for all dependent variables in the study ( \(\mathrm{N}=237\) ). All correlations were significant at \(p=.001\) level. Note: D DREL test, L or D - its letter or digit version, 2, 3, or \(4-\) relational complexity level. SPAN - versions of complex span task, L - letter, N - number, S - spatial, F - figural.

Figure 1: The general structure of the CFA models linking the discovery of binary, ternary, and quaternary relations to WMC. Ovals represent latent variables (factors), while boxes stand for observed variables (measures). Arrows represent factor loadings, while a line stands for correlation.

The two (test versions) by three (levels of complexity) ANOVA of the DREL test's scores indicated that they were significantly higher in the letter version \((M=2.72)\) than in the digit version \((M=1.77), F(1,236)=316.93, p<.001\), \(\eta^{2}=.57\), and that they decreased with increasing relational complexity \(\left(M_{\mathrm{RC} 2}=3.75, M_{\mathrm{RC} 3}=1.74\right.\), and \(\left.M_{\mathrm{RC} 4}=1.20\right)\), \(F(2,472)=1523.80, p<.001, \eta^{2}=.87\). Also, both factors interacted, \(F(2,472)=43.18, p<.001, \eta^{2}=.15\), as the effect of complexity was more profound in the letter version than in the digit one. These data indicate that the DREL test seems to be a proper tool for measurement of how effectively people discover relations, and that participants were sensitive to the complexity of the test's items.

Then, we tested whether our participants improved at all in the digit version of the DREL test, by comparing their scores on that version to another 79 participants from a similar study, who only attempted the digit version (i.e., they did not "train" on the letter version). This control group scored \(M=1.34\) per condition (comparing to \(M=1.77\) in the experimental group), that is, there was a highly significant learning effect, \(t(314)=3.46, p<.001\).

Next, with CFA, we assessed the strengths of correlations between the latent variable reflecting WMC (loaded by four complex span tasks) and variables representing the effectiveness of the discovery of relational concepts, separately for each level of complexity. The structure common to three calculated models is shown in Fig. 1. Each model had a good fit, as estimated by Bentler's comparative fit index (CFI; its widely accepted criterion value \(=.92\) ) and the standardized root mean square residual (SRMSR; the criterion value \(=.05\) ). For all models, CFIs surpassed .965 , and SRMSRs were below .035. Complex span measures' loadings on WMC variable were high ( \(>.667, p<.001\) ), as well as loadings of DREL measures ( \(>.609, p<.001\) ). This data indicates that the structure of models reflected very well the structure of correlations among variables. The comparison of correlations between both latent variables showed that there was no significant difference between the correlations for binary ( \(r=.663, S E=.068, p<.001\) ) and ternary ( \(r=.631, S E=.065, p<.001\) ) relations ( \(\Delta r=-.028\), n.s.),
while discovery of quaternary ones was more weakly correlated with WMC \((r=.477, S E=.071, p<.001)\) than discovery of both binary \((\Delta r=-.186 ., t[235]=2.70 ; p=.004)\) and ternary relations ( \(\Delta r=-.154 ., t[235]=2.30 ; p=.009)\).

Finally, we tested another CFA model, which related the WMC variable to the index of learning that occurred from the letter to the digit version of the DREL test. Because the scores in quaternary conditions approached floor, and thus the difference between them might have poor psychometric parameters, we decided to aggregate indices of learning of ternary and quaternary relations. The model, presented in Fig. 2, had a very good fit (CFI \(=.979, \mathrm{SRMSR}=.035)\). Most importantly, it suggests that the performance of participants displaying more capacious WM deteriorated less on the more abstract version of the test in comparison to less capacious participants ( \(r=.207, p=.002\) ), most probably due to a more effective process of the transfer of the abstract pattern of relations, which had been introduced in the letter part of the test, to its digit version.

\section*{Discussion}

The newly designed DREL test appeared to be a very reliable tool, and scores on DREL responded well to experimental manipulations. The significant drop of the DREL-WMC correlation only for quaternary relations (in comparison to binary and ternary ones) seems to provide more support for Doumas et al.'s (2008) model than to Halford et al.'s (1998) model. Moreover, not only quaternary relations were very difficult to learn ( \(24.5 \%\) accuracy), as the latter model predicts, but also ternary relations were rarely found (34.8\%), though according to that model they should well fit in WMC of most of participants. In contrast, people displayed fair performance only in cases of binary relations (75.0\%), and that fact better corresponds to Doumas et al.'s (2008) assumption telling that during relational learning (but not when processing relations) even as few as two role-filler representations may occupy the whole available capacity. The study provided data convergent with Lewandowsky (2011) results, though moving beyond ternary relations to newly introduced quaternary condition suggests that relational learning is not uniformly linked to WMC with regard to the complexity of relations being learned.

Figure 2: The CFA model linking WMC to relational learning (a difference in scores between two parts of DREL). The same graphical symbols were used as in Fig. 1.

It must be acknowledged, however, that due to the floor effect in the quaternary condition, a possible alternative explanation of the drop in the value of the DREL-WMC correlation coefficients might appeal to a possible worse psychometric usefulness of scores on quaternary relations. However, this is an unlikely explanation, because of relatively low values of the \(95 \%\) confidence intervals [. 338 .616] for that correlation, comparable to the respective intervals regarding binary and ternary conditions, indicating that all three correlation coefficients have been estimated with a similar precision. Nevertheless, in order to be able to draw firm conclusions on the issue of which model best explains WM contribution to relational learning, the present results should be replicated with a similar method, but one yielding relatively higher scores in the quaternary condition.

Another new result brought by the present study pertains to the fact that not only some general ability to discover relational concepts correlated - though with a varied strength depending on the complexity of those concepts with WMC, but WMC predicted also the amount of transfer of relational knowledge from one task to another. Although whole our test was strongly dependent on WM resources, we accounted for this fact by subtracting the initial (i.e., general) performance on the task, from the final performance, thus measuring the sheer increase in effectiveness of relational thinking during the coping with the test. It appeared that more capacious WM allows for better learning of abstract relational structures and more effective application of them to new, but analogous, situations. This observation seems to be an interesting challenge for existing models of analogy-making and relational learning, and has potentially profound practical (e.g., educational) implications.

\section*{Summary}

This study provided another evidence for the thesis that mechanisms of WM impose substantial constraints on human complex cognition, especially its core component: relational thinking. Understanding those constraints by developing computational models of thinking within WM is one of the crucial current focuses in cognitive science. This study seems to contribute to those efforts by presenting data supporting those models (e.g., Doumas et al., 2008) which predict that WM resources may be exceptionally loaded during the acquisition of relations, in comparison to a lesser load predicted in situations requiring only transformations and manipulations of relational representations which have already been learned.

\begin{abstract}
The aim of the present study was to investigate whether face age and social status information associated with faces have different effects on gaze following behaviour as an index of joint attention. Participants were instructed to perform goaldirected saccades towards a peripheral stationary target, while a task-irrelevant face with averted gaze was presented. Faces of three different age groups (younger adults; middle-aged adults; and older adults) were associated with fictional résumés which could describe distracters as high or low social status people. Results showed that face age affected both saccade accuracy and latencies. Social status did not have an effect on accuracy and only affected correct saccades with higher latencies by modulating the face age effect. It is argued that the overt orienting of joint attention could be affected both by perceptual and higher order socio-cognitive factors, but at different stages of processing.
\end{abstract}

Keywords: Joint attention, Social Status, Face Age, Gaze Following, Social cognition, Automaticity.

\section*{Introduction}

Understanding what a co-specific sees is necessary for social cognition. The gaze of others allows the rapid extraction of socially relevant information such as their mental and attentional states (i.e. the focus of their attention; e.g. Baron-Cohen 1995), and allows us to understand and predict their future actions (e.g. Pierno et al. 2006; Innocenti et al., 2012). Several studies have shown that perceiving averted gaze leads the observer to automatically shift his/her attention in the same direction or towards the same object that the other person is looking at (Friesen and Kingstone, 1998; Driver et al., 1999; Frischen, Bayliss and Tipper, 2007). For example, an uninformative cue by a centrally-
presented face gazing to one-location reliably reduces reaction time to targets presented peripherally at the location consistent with the gaze (i.e. gaze cueing effect, e.g. Driver et al., 1999).

The automatic shift of attention in the direction of another person's gaze - known as joint or social attention, can be achieved both overtly, through eye movements (gazefollowing behaviour), and/or covertly without eye movements. Gaze following behaviour (i.e. overt orienting of joint attention), which is considered an early and a direct index of joint attention orienting, is present early in development (Morales et al., 1998; Mundy and Newell, 2007) in humans and studies have shown that many species, including non-human primates, orient gaze in the direction of a co-specific's gaze and use it for interaction (for a review see Shepherd, 2010).

In adults the automatic nature of gaze following behaviour has been shown by Ricciardelli and colleagues (2002) who by using an oculomotor task reported a significant increase in the number of erroneous saccades matching the direction of the distracting gaze (gaze following errors, GFE). This was taken as evidence that perceiving a gaze shift can interfere with the execution of an oculomotor task by affecting oculomotor programming.

However, recent studies have shown that attention orienting driven by gaze is likely to be a product of both stimulus-driven and top-down attentional mechanisms (e.g. Greene et al., 2009). Therefore, modulatory effects on joint attention should be possible. It is more likely, in fact, that some gaze shifts are more important than others depending on face features, environment relevance or current task.

Age is known to be one of the sources of information that is rapidly extracted from faces and is an important dimension that influences how face are attended to (e.g. Slessor et al., 2010), encoded and retrieved from memory (Wiese et al., 2008). Several studies, using different kinds of face processing-task, reported that young adults show an advantage for faces within their own age group compared to elderly faces (for a review see Anastasi \& Rhodes, 2012). In a recent study, Slessor and colleagues (2010) reported a greater gaze cueing effect in younger adults for own-age face distracters than for distracters with elderly faces.

Moreover, recent studies have shown that the automatic and reflexive nature of gaze-mediated attentional orienting can be modulated by a number of high-order cognitive variables, such as the task context (Ricciardelli et al., 2012), social identification (Cesario, 2006; Liuzza et al., 2011), social status (Dalmaso et al., 2012, Shepherd et al., 2006), emotional expression (Tipples, 2006; Bonifacci et al., 2006) and familiarity (Deaner et al., 2007). In particular, Dalmaso and colleagues (2012) showed a greater gaze cueing effect for faces associated with high-status information. Although these authors (2012) did not report differences related to face age (younger vs. older adults) on gaze mediated attention orienting, there is evidence of both differences in interference from emotional faces of different ages (Ebner and Johnson, 2010), and of face-age effects in overt orienting of attention (Ciardo et al., 2012).

A possibility that has not been investigated before is whether they affect overt orienting of joint attention differently when combined together. This stems from the different nature of face age and the information regarding social status associated with the face (perceptual vs. cognitive). In particular, it is reasonable to expect that their distracting/cueing effect may vary as a function of task accuracy and response speed. In other words, given that age is a perceptual feature that is extracted rapidly from the face, one may expect that it affects early stages of saccade programming and the execution of eye movements with lower latencies. By contrast, since the processing of social status information is a more complex and time-consuming higher-order cognitive process, it should play a role later on and its effect should be more evident, for example, in the execution of eye movements with higher latencies.

In the present study we tested this hypothesis by investigating in young human adults the impact of distracting face age and associated social status information on performance in a goal-directed oculomotor task.

\section*{Methods}

\section*{Participants}

Thirty-two right-handed undergraduates ( 23 female, 9 male, mean age \(=22.8\) years, \(\mathrm{SD}=2.0\) ) from the University of Milano-Bicocca participated, in exchange for course credits. All had normal or corrected to normal vision and were unaware of the experiment's purpose. The study was
conducted in accordance with the Declaration of Helsinki and approved by the local ethical committee.

\section*{Stimuli}

Grayscale photographs \((7.98 \times 15.76\) degrees of visual angle) of the faces of 4 younger adults ( 2 females and 2 males, age range: \(18-23\) years), 4 middle-aged adults ( 2 females and 2 males, age range: 34-40 years), and 4 older adults ( 2 females and 2 males, age range: 74-85 years), bearing a neutral expression and a straight gaze, were used. All the photos were taken from the Productive Aging Lab Face Database (Minear and Park, 2004). The gaze direction of each photo was manipulated using Adobe Photoshop, creating face pictures with gaze-averted 0.75 degrees of visual angle both to the left and to the right.

\section*{Procedure}

The experiment was carried out in a sound-attenuated room, dimly illuminated. Participants sat in front of a 19-inch LCD monitor (Samsung Syncmaster 943; \(1280 \times 1024\) pixels; 60 Hz ), with their head supported by a chin rest in order to maintain a stable eye-to-screen distance of 50 cm . At the beginning of the experimental session, participants were invited to read 12 fictional résumés associated with the photographs selected as stimuli. The résumés indicated either a relatively high social status or a relatively low social status. Social status was mainly related to educational/professional information (e.g., high status: She was recently admitted to the faculty of Medicine/ He is a Public Prosecutor of the Supreme Court of Palermo; low status: He did not complete Secondary school/She was dismissed as a worker for incompetence; for a similar manipulation see Dalmaso et al., 2012). The résumés could be considered as brief biographies (hereafter biography). Participants were randomly divided into two groups. For participants in the first group, 6 faces (a male and a female of each age range) were displayed along with biographies indicating a relatively high social status, and the remaining 6 faces to biographies indicating a relative low social status. For participants in the second group, the same faces were displayed along with biographies indicating the opposite social status to that used for the first group. The biography presentation order was randomized. After the biography presentation, the associations created by participants between social status information and faces were tested by means of a true/false questionnaire composed of 12 items (one for each biography). The items were randomly selected from one of two lists (one containing true items and the other containing false items). Item presentation order was randomized. If participants gave a wrong answer to an item, they were immediately presented again with the biography to which the item was related. At the completion of the questionnaire, the biography procedure was restarted for those participants whose accuracy was less than \(90 \%\). Biography presentation and response collection were controlled using the software package E-Prime2 (Psychology Software Tools, Inc.).

Having successfully completed the biography procedure, participants took part in an instructed saccadic eye movement task (Figure 1). Each trial started with the presentation of a black fixation circle (diameter: 0.51 degrees of visual angle) centrally presented on the betweeneyes point of a stimulus face, bearing a straight gaze, on a grey background. The face was flanked by two black target circles (diameter: 0.89 degrees of visual angle), one to the left and the other to the right of the horizontally aligned fixation circle (eccentricity: 10.66 degrees of visual angle). After a delay of 1500 ms , the color of the fixation turned either green or red. 100 ms before the fixation color change, the stimulus face bearing the straight gaze was replaced by the same face with the gaze averted either to the left or to the right. This face replacement created a dynamic gaze, shifting towards the left or the right target. Participants were required to perform a fast and accurate saccade towards the left or right target, depending on the change in color of the fixation. The correspondence between color instruction and saccade direction was inverted for half of the participants. The direction of the dynamic gaze could be congruent or incongruent with the instructed direction. Since it was task irrelevant participants were explicitly instructed to ignore the distracting face. The stimulus face, the fixation and the two targets remained on the screen until a response was given. Immediately after a response was given a new trial was presented.

Figure 1: Experimental procedure.
Participants performed a training block, comprising 12 trials, and a test block, comprising 240 trials, with each of the 12 faces being randomly presented 20 times. In 120 test trials ( 10 replications of the male and the female belonging to each age range and social status), the direction of the dynamic gaze was congruent with the instructed direction. In the remaining 120 test trials ( 10 replications of the male and the female belonging to each age range and social status), the direction of the dynamic gaze was incongruent with the instructed direction.

The participants' eye positions and movements were recorded monocularly in real-time by an infrared video gaze tracking system (EyeLink II, SR Research Ltd., Mississauga, Ontario, Canada). For all participants, we
recorded the movement of the dominant eye. Stimulus generation and presentation were controlled by the SR Research Experiment Builder software (version 1.10.56). Throughout the test block, participants took a break every 80 trials (a total of 3 breaks). During the second break, the biography procedure was repeated to maintain the association between stimulus faces and their fictional social status.

At the end of the experimental session, participants were asked to rate the age of each distracting face with a value between 1 and 99 , in order to verify that they perceived the faces as belonging to the 3 age groups of interest (age manipulation check). Participants were also asked to rate the social status associated during the biography procedure to each distracting face with a value between 1 and 5 (social status manipulation check).

The experiment used a \(3 \times 2 \times 2\) repeated measures factorial design with Distracter Age (younger adults, middle-aged adults, and older adults), Distracter Social Status (high and low), and Congruency between gaze direction and instructed direction (congruent and incongruent) as the within-subjects variables.

\section*{Results}

\section*{Age manipulation check}

Age rating scores were entered in a one-way repeated measures ANOVA with Distracter Face (DF1, DF2, DF3, DF4, DF5, DF6, DF7, DF8, DF9, DF10, DF11, and DF12) as the within-subjects factor. The analysis revealed that the effect of Distracter Face was significant \([F(11,341)=734.9\), \(M S=17215.9, p<.001]\). Post-hoc tests with Bonferroni correction showed significant differences (all \(p s<.05\) ) among distracter faces belonging to different age manipulation levels (i.e. younger adults, middle-aged adults, and older people). Furthermore, post-hoc tests revealed that the faces belonging to each age manipulation level did not differ from each other, confirming our manipulation.

\section*{Social status manipulation check}

A two-way mixed ANOVA, with Distracter Face (DF1, DF2, DF3, DF4, DF5, DF6, DF7, DF8, DF9, DF10, DF11, and DF12) as the within-subjects factor and Subject Group (Group 1 vs. Group 2) as the between-subject factor, was used to determine whether or not participants considered the distracter faces as having the same social status as in the biography procedure. The analysis revealed that the interaction between Distracter Face and Subject Group was significant \([F(11,330)=107.97, M S=68.126, p<.001\), Figure 2b]. Post-hoc tests, performed as before, showed significant differences between distracter faces associated with biographies emphasizing different social status levels (high vs. low). Furthermore, post-hoc tests revealed that the faces associated with biographies belonging to the same social status level did not differ from each other, confirming our manipulation.

\section*{Saccadic eye movement errors}

Practice trials were discarded from the analyses. Saccadic eye movements were defined as correct if landing within \(\pm 2\) degrees of visual angle of the instructed target along the horizontal dimension. Saccadic eye movements landing within \(\pm 2\) degrees of visual angle of the non-instructed target along the horizontal dimension were defined as Gaze Following Errors (GFE) in the incongruent trials (i.e. incongruency between distracter's gaze direction and instructed direction), or as Generic Errors (GE) in the congruent trials (i.e. congruency between distracter's gaze direction and instructed direction). Saccadic eye movements landing outside \(\pm 2\) degrees of visual angle of either the instructed or not-instructed target along the horizontal dimension were defined as Saccades to Nothing Errors (SNE, \(14.5 \%\) of total trials) and were excluded from the analysis.

The first focus of interest was the difference between GFE and GE since it provides a direct and early measure of the automatic tendency to follow the distracting gaze direction. Mean percentages of GFE and GE across subjects were computed for each combination of Distracter Age and Distracter Social Status. These data were entered in a threeway repeated measures ANOVA, with Error Type (GFE and GE), Distracter Age (younger adults, middle-aged adults, and older adults), and Distracter Social Status (high and low) as within-subjects factors. Post-hoc comparisons were performed using the Duncan's test with an alpha level of .05. The analysis revealed that the main effect of Error Type was significant \([F(1,31)=35.59, M S=10385.44, p<.001]\), indicating that participants made more GFE than GE (13.40 \(\%\) vs. \(2.99 \%\) ). This confirmed the automatic tendency of participants to follow the distracter's gaze (for similar results see e.g., Ricciardelli et al., 2002). The analysis also showed a significant main effect of Distracter Age [ \(F(2,62)\) \(=6.01, M S=244.37, p<.005]\) and a significant Error Type \(\times\) Distracter Age interaction \([F(2,62)=12.80, M S=833.07\), \(p<.001]\), indicating that the age of the distracter critically modulated GFE but not GE. Specifically, GFE measured for middle-aged distracters (17.25\%) were higher than GFE measured for both younger ( \(13.55 \%, p<.02\) ) and older distracters ( \(9.39 \%, p<.001\) ), which were also significantly different from each other \((p<.006)\). No other main effects or interactions were significant.

\section*{Saccadic eye movement latencies}

The second focus of interest was the reaction times (RTs) of correct saccadic eye movements, since they could provide an indirect measure of the interference/cueing effect of the distracting gaze. Indeed, although people may be able to suppress the automatic tendency to make saccades in the direction of the distracting gaze, one might expect a higher latency for saccades in the incongruent trials than in the congruent trials. Moreover, if the social status of the distracter exerts an effect on joint attention through a more cognitive/higher-level mechanism than that related to the age of the distracter, as we had hypothesized, then a
different modulation of saccadic eye movements over time should be observed by these two factors. Specifically, the magnitude of the distracter social status effect should increase as the latency of correct saccadic eye movements increases, whereas the magnitude of the distracter age effect should decrease.

To this end, we computed median RT values of correct saccades for the first to the second bin of the individual rank-ordered raw data, separately for each combination of Distracter Age, Distracter Social Status, and Congruency between gaze direction and instructed direction. One subject was excluded from the analysis since the number of his correct saccades was not sufficient to appropriately compute median values of RTs for each combination of the experimental factors. An index of the interference effect of the distracting gaze was then obtained by subtracting the median RT values in the congruent trials from the median RT values in the incongruent trials for each of the Distracter Age and Distracter Social Status conditions, and each participant. These data were entered in a three-way repeated measures ANOVA, with Distracter Age (younger adults, middle-aged adults, and older adults), Distracter Social Status (low and high), and Bin (first and second) as within subjects-factors. Post-hoc comparisons were performed using the Duncan's test with an alpha level of .05 . The ANOVA showed a main effect of Distracter Age \([F(2,60)=\) 8.56, \(M S=10482, p<.001\) ], indicating a higher interference index for both the younger ( 30.15 ms , effect size \(=.56)\) and middle-aged distracters ( 23.94 ms , effect size \(=.44)\) compared to the older distracters \((12.05 \mathrm{~ms}\), effect size \(=.21, p<.001, p<.01\), respectively). In addition, the analysis showed a significant two-way interaction between Distracter Age and Distracter Social Status \([F(2,60)=4.35, M S=5150, p<.02]\), and a significant three-way interaction between Distracter Age, Distracter Social Status and Bin \([F(2,60)=3.64, M S=2441, p<.04]\), Noticeably, as specifically suggested by the three way interaction (Figure 2), the social status of the distracter had an effect on saccadic eye movements with higher latency only. Indeed, post-hoc comparisons showed that, for trials belonging to the second bin, younger distracters with a low social status produced a higher interference index (42.76 ms , effect size \(=.64\) ) than the same distracters with a high social status ( 24.32 ms , effect size \(=.34, p<.02\) ). By contrast, middle-aged distracters produced a higher interference index when they were associated with a high social status ( 33.83 ms , effect size \(=.45\) ) than a low one \((9.93 \mathrm{~ms}\), effect size \(=.13, p<.01)\). No difference between high and low social status was found for older distracters. For trials belonging to the first bin, post-hoc comparisons indicated a higher interference index for both the younger (low status \(=29.10 \mathrm{~ms}\), effect size \(=.68\); high status \(=24.41\) ms , effect size \(=.59\) ) and middle-aged distracters (low status \(=23.74 \mathrm{~ms}\), effect size \(=.52\); high status \(=28.26 \mathrm{~ms}\), effect size \(=.66\) ) compared to older distracters (low status \(=\) 9.61 ms , effect size \(=.21\); high status \(=14.88 \mathrm{~ms}\), effect size \(=.31\) ), independent of social status (all \(p \mathrm{~s}<.05\) ).

Figure 2: Mean index of the interference effect exerted by the distracting gaze (median RT values of correct saccades in the incongruent trials minus median RT values of correct saccades in the congruent trials) as a function of Distracter Age (younger, middle-aged, and older adults), separately for
each Distracter Social (and Bin. Error bars represent the standard errors of means across participants.

Finally, to confirm the finding that the distracter social status modulates joint attention only at a later stage, we focused on the RTs of GFE. Since no effect of the distracter status was found on GFE percentage, one might predict that GFE latencies squarely match those of correct saccades which were placed in the first bin. To this end, we computed the number of GFE with latencies falling in the correct saccades' first bin, separately for each subject. A chi-square test revealed that GFE had latencies which fell in the first bin more frequently ( \(85.3 \%\) ) than would be expected ( \(\chi^{2}=\) \(110.75, d f=30, p<.0001\) ), further supporting the idea that the social status of the distracter exerts a high-level effect on gaze following behaviour.

\section*{Discussion}

In this study, we investigated the impact of face age and social status information on gaze following behaviour in young adults performing an oculomotor task. This was achieved by presenting distracters of different ages whose faces were associated with a fictional biography which could describe the distracter as a high or low status person.

Our results confirmed the automatic nature of gaze following behaviour as the percentage of gaze following errors was higher than the percentage of generic errors (Ricciardelli et al., 2002; 2012). Interestingly, participants made less GFE with older distracters compared to all other distracters. Older distracters also interfered less with the execution of correct saccades, suggesting that older distracting faces are easier to ignore. This result is in line with previous studies that investigated the effect of distracter's age on gaze cueing in young adults (Slessor et al., 2010; Ebner et al. 2010), and reported less distracting effect of averted gaze for elderly faces. It has been proposed that young adults may find it easier to ignore gaze cues from elderly distracters as they are less familiar with their facial features (Deaner et al., 2007). Similar differential results have been observed also for face recognition and processing (for a review see Anastasi \& Rhodes, 2012).
In addition, we found that young adults made more GFE with middle-aged distracters than with younger distracters, indicating a general other-age bias on gaze following
behaviour, rather than an own-age bias. The lack of an ownage bias was confirmed also by the results relative to saccadic eye movement latencies. The occurrence of a super-ordinate categorization (Gaertner \& Dovidio, 2000) of younger and middle-aged distracters may provide a viable explanation of this unpredicted pattern of results. According to Gaertner and Dovidio's (2000) common in-group identity model, when people perceive others as out-group members on the basis of a certain identity cue, and, simultaneously, can form, together with these out-group members, a common super-ordinate super-ordinate group on the basis of another identity cue, the favouritism these people have for their in-group members would be redirected toward outgroup members included within the super-ordinate superordinate group. Therefore, we can surmise that participants of our study classified younger and middle-aged distracters as in-group and out-group members, respectively, on account of face age estimation, and as members of the same super-ordinate group on account of another facial cue estimation, such as facial similarity.

The novel result of our study is that face age, but not social status information, affects GFE. Social status has an effect on saccadic eye movements with higher latency only. Previous studies investigating the role of social status on gaze-mediated covert orienting of attention (Dalmaso et al., 2012) reported that high status individuals produced a stronger gaze cueing effect (Dalmaso et al., 2012); by contrast, our results indicate that in young adults gaze cueing is facilitated (i.e. slower saccadic reaction times) by own-age low-status distracters. The contrast between our results and those of Dalmaso et al.'s (2012) study could be due to differences in the stimuli used. In Dalmaso et al.'s (2012) work, photos depicting only male faces were used as stimuli, while in our study we used both female and male distracters. Indeed, gender is an element from which social status could also be perceived implicitly, and it was established that male faces are perceived to be more dominant (i.e. higher social status) than female faces (Jones et al., 2010). It is possible that the influences on gaze following behaviour of information about social status may also depend on how it is induced, i.e. whether explicitly or implicitly. Alternatively, own-age low status faces could represent a threat to the social identity of high-status groups (Scheepers et al., 2004); as a source of threat, such lowstatus individuals should be monitored continually.

In conclusion, our findings extended previous joint attention studies by indicating that the overt orienting of attention driven by gaze could be differently modulated both by perceptual features and high-order socio-cognitive factors of the seen face. Taken together, our results indicate that a perceptual manipulation of an identity cue (i.e. age), exerts an effect on gaze following parameters in the early stages of saccade programming and execution. By contrast, higher-order manipulation of another identity cue (i.e. social status) affects gaze following parameters at the later stages of saccade programming and execution. This could be due either to the kind of manipulation (perceptual vs. higher-
order) or to the kind of identity cue (age vs. social-status). Future studies are needed to clarify the role of different identity cues (such as age, race, gender, celebrity or political affiliation) and manipulations on the time course and patterns of gaze following parameters, in order to explore the possibility that different identity cues fit into a few broad categories or continua, such as identity valence, which have different effects on overt orienting of attention.

\section*{Acknowledgments}

\title{
Towards a Statistical Model of Grammaticality
}

\begin{abstract}
The question of whether it is possible to characterise grammatical knowledge in probabilistic terms is central to determining the relationship of linguistic representation to other cognitive domains. We present a statistical model of grammaticality which maps the probabilities of a statistical model for sentences in parts of the British National Corpus (BNC) into grammaticality scores, using various functions of the parameters of the model. We test this approach with a classifier on test sets containing different levels of syntactic infelicity. With appropriate tuning, the classifiers achieve encouraging levels of accuracy. These experiments suggest that it may be possible to characterise grammaticality judgements in probabilistic terms using an enriched language model.
\end{abstract}

Keywords: enriched language models, probability distribution, grammaticality judgements, probabilistic syntax

\section*{Introduction}

The past two decades have seen a lively debate over whether linguistic knowledge is probabilistic or categorically rulebased in nature (see the papers in Bod, Hay, and Jannedy (2003) for some of this discussion). Given the success of probabilistic accounts of learning, representation, and inference across a wide range of cognitive domains, this debate has considerable importance for the way in which knowledge of language is integrated into our general view of human cognition.

On the classical view of syntax developed within linguistic theory over the past sixty years, the grammaticality and the probability of a sentence are entirely distinct properties with no direct relationship. Chomsky (1957) presents the original argument for the irrelevance of probability in determining grammaticality. \({ }^{1}\) This argument depends on the inability of a simple word n-gram model to predict a distinction in probability between a syntactically well-formed but unlikely (semantically anomalous) sentence like Colorless green ideas sleep furiously, and a word salad like Furiously sleep ideas green colorless. Pereira (2000) shows that a smoothed classbased n-gram model trained on a newspaper corpus predicts a significant distinction in probability between the two sentences.

While it is certainly the case that grammaticality cannot be directly reduced to probability, the question of whether there is a significant correlation between the two remains open and interesting. Our general approach is as follows. We train a smoothed class-based trigram model on a filtered subclass of the BNC. We test this model on two corpora. One is divided into original sentences of part of the BNC and their reversed counterparts. The second consists of a subset of orig-

\footnotetext{
\({ }^{1}\) See Fong, Malioutov, Yankama, and Berwick (2013) for a recent discussion of some of the issues involved in identifying grammaticality with probability of occurrence.
}
inal BNC sentences and their permuted variants in which a word in each sentence is randomly exchanged with another word three positions away from it. These distortions constitute syntactic infelicities. The first case involves gross structural ill-formedness similar to the word salad example, while the second introduces subtler, more local mistakes. We score the test corpora using three alternative conditions. Our binary classifiers predict that a string is well-formed (original) or distorted (either reversed or permuted) on the basis of a score derived through normalising its log probability (logprob) value in various different ways. We also test different standard deviations from the distributional norm in setting cut off points for our binary classifiers In our best cases we obtain an accuracy rate of \(98.9 \%\) for the original-reversal test set, and \(79.1 \%\) for the original-permutted test set.

These results suggest that by looking at the internal components of a probability distribution and the stages through which it is computed we can identify additional information that may be used to specify significant correlations between probability and grammaticality. This opens up an interesting set of research questions on the relationship between speakers' knowledge of the probability distribution for a language and their grammaticality judgements.

\section*{Probability and Grammaticality}

As has often been noted, it is not possible to reduce grammaticality directly to probability. First, short ungrammatical sentences generally receive higher probability values than long, complex grammatical sentences containing words with low frequencies. Second, if one specifies a probability value (or even a range of such values) as the minimal threshold for grammaticality, then one is committed to the existence of a finite number of grammatical sentences. The sum of the probabilities of the possible strings of words in a language sum to 1 , and so at most \(1 / \varepsilon\) sentences can have a probability of at least \(\varepsilon\).

On the other hand, probabilistic inference does appear to be pervasive throughout all domains of cognition (Chater, Tenenbaum, and Yuille (2006)). Moreover, language models do seem to play a crucial role in speech recognition and sentence processing. Without them we would not be able to identify speech sounds, and meaningful syntactic and semantic structures in noisy environments. Finally, grammaticality appears to track speakers' acceptability judgements, and these are, in many cases, graded. Probability provides a natural basis for generating such a gradient (Crocker and Keller (2006)).

Our starting point is a language model: a statistical model that defines a probability distribution over sentences.

We construct a log-linear model, parameterised by some vector of parameters \(\Theta=\left\langle\theta_{1}, \ldots, \theta_{k}\right\rangle\). This framework covers a wide range of different models from n-gram models to PCFGs. \({ }^{2}\)

The probabilities defined by this model cannot be used to define a notion of grammaticality for several reasons. First, as the sentences increase in length, the probability of the sentence will always decrease exponentially, for sufficiently long sentences, while we assume that long sentences can be as grammatical as short sentences. Second, one can often substitute a rarer semantically related word for an open class word of the same POS without affecting grammaticality, but the substitution will reduce probability. Figure 1 shows that the log probabilities for sentences that have been reversed or permuted, and are thus generally ungrammatical, overlap completely with the log probabilities of normal sentences (see the next section for details of the experimental protocols). We need to augment our model with an additional component to convert probability into a score that correlates with grammaticality in an interesting way.

Figure 1: Histograms for the distributions of \(\log\) probabilities under the three conditions.

We use statistical properties of the parameters of the model. In order to compute the probability of a sentence with respect to a model we do calculations on the parameters. For a log linear model, this gives a linear function of certain indicator variables; a weighted sum. To compute a score that correlates with grammaticality, we consider other functions, such as a weighted mean, or a minimum over certain scores.

In a trigram model each parameter will then correspond to the \(\log\) conditional probability of one word, given the two

\footnotetext{
\({ }^{2}\) We use smoothing techniques that, in general, can take the model outside the class of log-linear models, but we pass over this technical detail here.
}
preceding words: \(\theta_{w_{i} \mid w_{i-1} w_{i-2}}\). To compute the probability of a sentence we sum the relevant parameters to obtain the log probability. For a sentence \(\left\langle w_{1}, \ldots, w_{n}\right\rangle\) the log probability is
\[
\log P_{\text {TRIGRAM }}\left(\left\langle w_{1}, \ldots, w_{n}\right\rangle\right)=\sum_{i=1}^{n} \theta_{w_{i} \mid w_{i-1} w_{i-2}}
\]

We take the sequence of relevant parameters \(\left\langle\theta_{w_{1} \mid w_{0} w_{-1}}, \ldots, \theta_{w_{n} \mid w_{n-1} w_{n-2}}\right\rangle\), and, rather than summing them, we perform other computations. We consider the average or the minimum of the set of parameters as alternatives for defining values that correspond to grammaticality.

Our most basic score is the mean of this value, the logprob divided by the word length of the sentence:
\[
\text { Meanlogprob }=\frac{1}{n} \log P_{\text {TRIGRAM }}\left(\left\langle w_{1}, \ldots, w_{n}\right\rangle\right)
\]

This eliminates the dependence of the logprob on the length. Our next score divides the logprob of the original trigram model by the logprob with respect to a unigram model.
\[
\text { Normalised }=\frac{\log P_{\text {TRIGRAM }}\left(\left\langle w_{1}, \ldots, w_{n}\right\rangle\right)}{\log P_{\text {UNIGRAM }}\left(\left\langle w_{1}, \ldots, w_{n}\right\rangle\right)}
\]

This removes the variation in logprob caused by rare lexical items. Note that if the unigram model is uniform (if we had equal numbers of each word in the training corpus), then the log of the unigram model would be a multiple of the length, and so it would reduce to the previous value.

Our third score uses the observation that a sentence with one grammatical error in it is ungrammatical. In order to measure grammaticality we look at the minimum of some score over the parts of the sentence. We take the minimum of the ratio of the log trigram probability to \(\log\) unigram probability.
\[
\text { Minimum }=\min _{i}\left[\frac{\log \theta_{w_{i} \mid w_{i-1} w_{i-2}}}{\log \theta_{w_{i}}}\right]
\]

None of these measures will produce a score which is in the range \([0,1]\), though it would be possible to map them into this range. This value will also vary even for grammatical sentences. The scores will be numbers that are distributed in some way. Figure 2 shows the distribution of these scores for the test data. As this score specifies a continuum of values, we are able to accommodate a gradient notion of grammaticality.

Given these three measures we use various standard techniques to see whether new sentences are anomalous or not. For a collection of naturally occurring grammatical sentences we train our models, and then we consider the distribution of these scores. We estimate the mean and standard deviation of the score. We can then judge new sentences as ungrammatical if they are unusually low in score- more than a few standard deviations away from the mean.

Pauls and Klein (2012) apply a related approach to another problem. They use scores based on the logprob values of a language model to discriminate between grammatical and ungrammatical sentences in order to improve the performance of natural language processing systems.

\section*{Experiments and Results}

For our experiments, we use the standard n-gram language model, which is an instance of a Markov model for sequences. To estimate the probability of a sequence of words \(w_{1} \ldots w_{k}\) we use the chain rule of probability, as in (1).
\[
\begin{equation*}
P\left(w_{1} \ldots w_{k}\right)=P\left(w_{1}\right) P\left(w_{2} \mid w_{1}\right) \ldots P\left(w_{k} \mid w_{1} \ldots w_{k-1}\right) \tag{1}
\end{equation*}
\]

The problem with this approach is that we have to estimate the conditional probability of an extremely large number of possible subsequences. Therefore a common method is to reduce the conditional dependencies to a smaller predefined sequence of a given length \(n\), the so called order of a model. Using this assumption we approximate the components in (1) using (2).
\[
\begin{equation*}
P\left(w_{i} \mid w_{1} \ldots w_{i-1}\right) \approx P\left(w_{i} \mid w_{i-n+1} \ldots w_{i-1}\right) \tag{2}
\end{equation*}
\]

The probability assigned to a sequence of words is given by the product in (3)
\[
\begin{equation*}
P\left(w_{1} \ldots w_{k}\right) \approx \prod_{i=1}^{k} P\left(w_{i} \mid w_{i-n+1} \ldots w_{i-1}\right) \tag{3}
\end{equation*}
\]

A common choice for \(n\), that we adopt for our experiments, is three (trigrams).

The standard strategy to estimate the probability of each ngram is maximum likelihood estimation (MLE), which counts the number of times the n -gram appears in a training corpus, and normalizes the count by the sum of the counts of all \(n\) grams that share the same initial subsequence:
\[
\begin{equation*}
P\left(w_{i} \mid w_{i-n+1} \ldots w_{w-1}\right)=\frac{C\left(w_{i-n+1} \ldots w_{i}\right)}{\sum_{w} C\left(w_{i-n+1} \ldots w\right)} \tag{4}
\end{equation*}
\]

To avoid assigning 0 probability to unseen n -grams (a common case, given the huge number of possible n-grams) we use smoothing or discounting, which transfers a small portion of probability mass from seen n -grams to unseen ones. A large number of smoothing techniques have been proposed in the literature (see Chen and Goodman (1999) for a thorough overview). In our experiments we use a form of interpolated smoothing known as Interpolated Kneser-Ney (Goodman (2001)), which has been shown to give consistently good results with different types of metrics.

To reduce the search space of our language model we also employ clustering, which groups together words that occur in similar contexts. In this way we can better estimate the probability of a word following a certain sequence, given the observations we have made of similar words in the same context. Brown, deSouza, Mercer, Pietra, and Lai (1992) introduced the standard technique for using clustering in language models. The general form of a cluster-based language model is given in equation (5), where \(C_{i}\) is the cluster to which word \(w_{i}\) is assigned to.
\[
\begin{equation*}
P\left(w_{i} \mid w_{i-n+1} \ldots w_{i-1}\right)=P\left(w_{i} \mid C_{i}\right) P\left(C_{i} \mid C_{i-n+1} \ldots C_{i-1}\right) \tag{5}
\end{equation*}
\]

The probability \(P\left(w_{i} \mid C_{i}\right)\) is given by the count of occurrences of \(w_{i}\) divided by the count of occurrences of \(C_{i}\), while the other factor of the product can be estimated with a smoothed model like Interpolated Kneser-Ney. Brown et al. (1992) describes a technique for generating the optimal clustering in a corpus, given a parametrically specified number of classes.

We implemented our own procedures for the training and the assessment of \(n\)-gram language models, using Interpolated Kneser-Ney as the smoothing technique. For clustering we applied the improved version of Brown et al. (1992)'s algorithm described in Liang (2005).

Both the training of the language models and the measurement of their performance in the given tasks are performed on portions of the BNC. The BNC is a heterogenous collection of linguistic data. To obtain a more consistent sample of English we first restricted the available texts by excluding transcriptions of spoken language, poetic texts and technical/scientific material. The corpus used for training and the one used for testing were generated from this subset of the BNC by randomly selecting 600 k sentences for training, and 60k for testing. This gave us a training corpus of slightly less than 13 million words, and a testing corpus of approximately 1.3 million words.

To avoid the problem of unknown words in testing, we reconstructed both the training and the testing corpus. We substituted, in both the training and the test corpus, the POS tag for each word which appears less than five times in the training corpus. This insures that the test corpus vocabulary is a subset of the training corpus vocabulary.

Three different types of test corpus (conditions) were generated. The original condition is left intact, and we assume that it contains only grammatical sentences. The permuted condition is generated from the original by randomly swapping two words, separated by two intervening words, in each sentence. The sentences in this corpus are taken to be less grammatical than those in the original condition. Finally, the third test corpus was produced by reversing the order of the words in the original sentences. This reversed condition is considered to be the most syntactically distorted of the three.

We used a simple binary classifier to measure the performance of our language model in predicting the grammaticality of a sentence. After calculating the three scores (Mean log prob, Normalised, and Minimum) in all three conditions we designed two different binary classifiers that assign a label to every sentence in each condition. The first classifier is a simple threshold set to different values for the mean and the standard deviation of the distributions of the alternative normalised scores for the original condition. For each binary comparison the classifier assigns a label to the sentence \(z\) using the following rule:
\[
c_{1}(z)= \begin{cases}\text { original } & \text { if } \operatorname{score}(z) \geq m-S \cdot s  \tag{6}\\ \text { other } & \text { otherwise }\end{cases}
\]
where \(m\) is the mean for the score in the original condition, \(s\) is the standard deviation and \(S\) is a factor by which we move
the threshold away from the mean. The principle of this classifier is that the normalised logprob scores for ungrammatical sentences will be lower than those for grammatical ones, making it possible to distinguish between the two conditions. We adapted this procedure to distinguish between local ungrammaticality (permutation), and more global ungrammaticality (reversed cases).

The second classifier is a simple linear classifier constructed on the basis of the first one. It combines the information from two different scores. This second classifier uses the following general rule:
\[
c_{2}(z)= \begin{cases}\text { original } & \text { if } \operatorname{score}_{2}(z) \geq-\operatorname{score}_{1}(z)+t_{1}+t_{2}  \tag{7}\\ \text { other } & \text { otherwise }\end{cases}
\]
where \(\operatorname{score}_{1}(z)\) is the first of the scores assigned to the sentence, \(\operatorname{score}_{2}(z)\) is the second one, \(t_{1}\) is the best performing threshold for this specific comparison as found in the case of the first type of classifier for the first score, and \(t_{2}\) is the same kind of threshold for the second score. We simply check whether the two scores are above or below the bisector of the second and the fourth quadrant in the space formed by the two scores, and translated by the best thresholds for the same two scores. The intuition here is, again, that grammatical sentences will have consistently better scores than ungrammatical ones.

We performed experiments using both the standard and the cluster-based language models. For the standard case we trained models using words and part-of-speech tags as tokens. In what follows we report only the results for the cluster-based experiments, as these achieved better accuracy. We used 250 clusters. The language model was trained on the training corpus, and the three scores are computed for the sentences in each condition (original, permuted and reversed). Figure 2 summarises the distributions of the three scores for each condition of the cluster-based language model. It is clear that all scores are reasonably good at distinguishing between the original and the reversed conditions, given the small overlap between the distributions. As expected, the overlap between the original and permuted conditions is much higher. It is also interesting to note that the while in the case of Mean log prob and Normalised score the distributions for all the conditions are roughly normal (with some degree of skewing), the Minimum score gives a more irregular distribution, at least for the ungrammatical cases.

On the basis of these distributions we created the first type of classifier. The results for the two comparisons we performed (original/permuted and original/reversed) are summarised in figure 3. The graphs show the accuracy for each score obtained by varying the \(S\) parameter as described in (6). In our experiments we let \(S\) vary in the interval \([0,2.75]\), using a step interval of 0.25 .

In the case of the original/permuted comparison we obtained the best accuracy ( \(77.3 \%\) ) by using the Normalised score and setting the threshold at 0.75 standard deviations to the left of the mean. However the Minimum score seems

Table 1: Linear classifier accuracy
\begin{tabular}{lrr} 
Accuracy & permuted & reversed \\
\hline Mean log prob + Normalised & 71.2 & 97.9 \\
Mean log prob + Minimum & 77.1 & 97.2 \\
Normalised + Minimum & \(\mathbf{7 9 . 1}\) & 98.1 \\
\hline Threshold classifier baseline & 77.3 & \(\mathbf{9 8 . 9}\)
\end{tabular}
to perform better in general for this comparison, obtaining a maximum accuracy of \(77.1 \%\).

Not surprisingly, all three scores perform very well when distinguishing between the original and the reversed version of the sentence, with accuracies above \(95 \%\). The sharp drop in accuracy in the case of the Minimum score that we observe when setting the \(S\) parameter to 2.75 is due to the spike we have in the case of the reversed condition (see rightmost graph in figure 2).

Table 1 reports the accuracy for the linear classifier that combines the results of two threshold classifiers (with the best single classifier scores listed in the bottom row as a baseline comparison). Despite the simplicity of this linear classifier, we observe an improvement in the original/permuted comparison.

\section*{Error analysis}

It is interesting to analyse the cases where our classifiers fail. We looked at the cases that form the tails of the distributions for the Normalised threshold, as it is this score that gives the best general level of classifier accuracy.

The following ten sentences receive the lowest Normalised score according to our language model for the original condition: interview \(\cdot\) Swims \(\cdot / \cdot\) contracts \(\cdot\) then \(\cdot\) TELEPHONE - 75\% • Hotel deal • mimic each item across • Ian ! 90\% These cases are very marginal English sentences. Their presence in the corpus may well be due to transcription error in the BNC, or to the idiosyncratic nature of the text from which they are extracted. However, other cases of false ungrammatical sentences include perfectly acceptable sentences like the following: Amnesty has been given Greetings Magazine's "Best Charity Card of the Year" award .

For permuted sentences, when we analyse the tail of the distribution, we encounter many cases where the permutation produces the same sentence as the original, because the permuted words are identical. In other cases the permutation generates semantically odd, but otherwise well-formed sentences, as in It should be a match of a humdinger. These are the ten permuted sentences that receive the highest Normalised scores (and they are therefore mislabelled as original): He glanced round the bar from the door. He said that he had not been informed of the dissolution of the National Assembly on Jan. 4. • There 's something I hear you to want. - Sometimes, of course, it does not work. • Don't know, I worry why. I I assure you I'm not. - It should be a match of a humdinger. • She put her hand to her brow. • "Yes, I understand ," said Drew quietly. But there was nothing there.

Finally in the case of reversed sentences, we observe that sentences that are assigned extremely high Normalised scores tend to be proper names. Due to their low frequency in the training corpora, proper names are most likely to be replaced by their POS tag in the training and testing phase. Therefore, the language model cannot distinguish the original and the reversed versions of the sequence, given that they appear identical. Again we report here the ten reversed sentences that receive the highest Normalised score. Terrazze Alle . seven - eight - nine • 2 TN. WOKINGHAM , 3 TN. FARNHAM • Debts : MAIDSTONE • Gloucester / BROCKWORTH - FLAUBERT MME • VALLI FRANKIE • PATEL GARGY • BATTERSEA HORSMAN UDO • REUNITE / JAFFE LUCKY

\section*{Discussion and Conclusions}

Clark and Lappin (2011) propose an outline for a stochastic model of indirect negative evidence. In this outline a function maps the probability value of a string, and a set of properties of the string and of the probability distribution over strings of the language, to a threshold value that gives the minimum frequency with which the string must occur in the primary linguistic data in order to be well-formed. The threshold specifies the normalised minimal expectancy of occurrence for a sentence of a certain type (length, lexical class sequence, etc.). This model provides a language learner with a procedure for querying the data to which he/she is exposed in order to determine the extent to which the absence of a string in the data indicates its ungrammaticality.

Here we effectively invert this strategy. We identify a set of structural properties of a string together with parameters for the distribution of logprob-derived scores, in order to define a grammaticality threshold, which we use to classify strings as grammatical or ill-formed. This model offers a stochastic characterisation of grammaticality without reducing grammaticality to probability. It represents a core element of what speakers know about the syntax of their language through a set of parameters in a model whose values correspond to properties of the modified probability distributions that the model generates.

We are not, of course, suggesting that enriched n-gram models are adequate to express the full content of speakers' syntactic knowledge. However, the fact that simple models of the sort that we have used are able to achieve a relatively high degree of accuracy on wide coverage, domain general grammaticality classification tasks suggests that there is an interesting correlation between properties of the probability distribution over the sentences of a language and a speaker's grammaticality judgements.

Should the correlation prove robust it suggests that grammatical knowledge is, to a significant extent, determined by the stochastic patterns of the primary linguistic data to which speakers are exposed. This result will have significant consequences for both the representation of syntactic competence and the nature of the language acquisition process.

In current work we are exploring this correlation further with more sophisticated language models, different distri-
butional parameters and stochastic classifiers, and test data that includes realistic syntactic infelicities. We are evaluating these models against native speakers' acceptability judgements.

\section*{Acknowledgments}

The research described in this paper was done in the framework of the Statistical Models of Grammaticality (SMOG) project at King's College London, funded by grant ES/J022969/1 from the Economic and Social Research Council of the UK. We are grateful to Rens Bod, Stephen Clark, Aarne Ranta, Khalil Sima'an, and Jelle Zuidema. for helpful comments on an earlier draft of this paper. We also thank our PhD students, Jekaterina Denissova and Monika Podsiadlo, for useful discussion of the experimental design of this work, and for logistical support.

Figure 2: Histograms for the distributions of sentence scores. Each graph shows the distribution of a single score for the three conditions. The \(x\)-axis represents the value of the score and the \(y\)-axis gives a measure of the frequency with which the score is represented in the data. On the left are the scores given by taking the mean (equivalently normalising by length). In the middle are the scores given by normalising with the unigram probability. On the right are the scores using the minimum condition. These scores still overlap significantly, but much less so than the raw logprobs as shown in Figure 1.

Figure 3: Results for the threshold classifier. The two graphs show two comparisons: original/permuted and original/reversed. The \(x\)-axis represents the different values that control the distance from the mean of the threshold, while the y-axis shows the accuracy expressed in percentages.

\title{
Knowledge Helps: Mechanistic Information and Numeric Evidence as Cognitive Levers to Overcome Stasis and Build Public Consensus on Climate Change
}

\begin{abstract}
A clear, growing consensus indicates an urgent need for humans to reduce the burgeoning effects of global climate change ("global warming" or GW). Apt public instruction seems central to achieving critical behavioral changes, but some researchers suggest that U.S. climate attitudes are doomed to cognitive stasis (i.e., that little will be gained by educating the public). Herein are four studies that counter the stasis view. Our laboratory has previously reported findings that (1) virtually no Americans know the basic climate change mechanism, yet it (2) is quickly learned (in a few minutes, e.g., with a 400 -word text), which (3) increases climate change acceptance. Below, Studies 1 and 4 replicate and extend these results to demonstrate (a) efficacy with an online presentation and broader populations and (b) retention up to a month after learning the mechanism. Studies 2-4 explore roles for germane numerical information using estimation with feedback. Study 2 shows that (d) misleading, cherry-picked, statistics can decrease climate change acceptance (and shake metacognition), while Studies 3 and 4 show that (e) surprising scientific information must be presented with care for it to foster beliefs in line with climate science's consensus. In sum, contrary to unnecessarily pessimistic (and correlational) "stasis" arguments, highly germane science information can clearly change the public's understandings and opinions.

\section*{Climate Change as a Behavioral Problem}

Our atmosphere's carbon dioxide \(\left(\mathrm{CO}_{2}\right)\) concentration is higher now than in any of the past 15 million years (World Bank, 2012). Global warming (GW) akin to recent trends last occurred over 17 million years ago, when a \(3-4^{\circ} \mathrm{C}\) gain occurred over 1,500,000 years. Standard models show that continuing our current behavior will yield similar warming in just 100 years. In previous warming periods of this magnitude, widespread extinctions occurred. With imminent warming \(10,000+\) times faster than historical timescales, the biological systems we depend upon (e.g., for food) will clearly be severely impacted (Barnosky, 2009). Nearly all climate researchers have concluded that the problem is urgent and anthropogenic (i.e., essentially \(100 \%\) humancaused). It is thus behavioral, and will be "solved" only by changes in human behavior. The IPCC (Intergovernmental Panel on Climate Change) and Skeptical Science have assembled and disseminated the scientific consensus on GW, but, sadly, the U.S. public is still divided on both GW's existence and its cause (cf. Hoffman, 2011).

A group of climate communication researchers, oddly, suggests that educational ventures would be of little or no
help. Kahan et al. (2012) found (through correlational means) that, for the U.S. (a high per-capita carbon user), direct cognitive approaches (including numeracy and science education) seem to solidify biased viewsreinforcing a kind of cognitive stasis for GW attitudes. This is reminiscent of Lord, Ross, and Lepper (1979), in which people with a strong position tended to polarize further after receiving (not particularly factual) information contrary to their views. Similarly, McCright and Dunlap (2011) highlight data indicating that climate-relevant effects of "education level" are moderated by conservatism or party. (Conservative or "Republican" GW denial was slightly positively related, if at all, with education.) This (also correlational) evidence, they claim, disproves a naïve "knowledge deficit" view-the view that more education can shift the public's beliefs toward the scientific consensus about climate change. However, their own work shows that liberals and conservatives tend to obtain different kinds of information. This split leaves open the possibility that wellconstructed interventions may well induce conservatives to accept the scientific consensus (with little challenge to their core values). Indeed, Lewandowsky, Gignac, and Vaughan (2013) show that offering climate scientists' consensus boosts anthropogenic climate change acceptance.

Our laboratory has provided arguments and many experimental findings that run counter to these "polarization" and cognitive stasis views: For instance, even a small amount of true information can quickly act as a cognitive "lever" to enhance one's understanding and perspective on climate change (Ranney et al., 2012a)—and many other social issues (e.g., abortion and immigration)and even using just a single number/statistic (Garcia de Osuna, Ranney, \& Nelson, 2004; Munnich et al., 2003; Ranney et al., 2008). Below, we offer further experimental results that counter the stasis view for climate education. Notably, we analyze the full spectrum of participants, rather than filtering for those who are already relatively extreme.

Note that new knowledge often facilitates societal shifts and that science "education" has historically driven major social changes-from heliocentrism replacing church doctrine to the acceptance of a tobacco-cancer link in spite of industry obfuscation. (We offer more such germane evidence below.) These data-driven shifts demonstrate how sociologists and social psychologists who hold the stasis view must be incorrect or overly pessimistic. Whether or not they realize it, theorists are haggling over speed, and some
nations learn (e.g., to accept evolution or climate change; Ranney, 2012) faster than others. Of course, learning or acting too slowly can exacerbate existing problems.

We partially agree, though, with those who critique a "knowledge deficit" view of public attitudes (cf. Dickson, 2005). Arbitrary or propaganda-like information need not drive one toward a more empirically supported view. We see the problem, rather, as a wisdom deficit, for which cognitively sophisticated educators can provide the tools that help the public better evaluate the evidence and make choices that match their values. (See Lewandowsky et al., 2012, for a fine discussion of such tools, particularly the correction of misinformation.) We believe that the findings described here will demonstrate that a well considered educational approach is critical for public engagement.

\section*{The GW Mechanism: Extra Greenhouse Effect}

Much of our laboratory's prior research has sought to foster worthwhile, notable conceptual changes with short activities that involve estimations, predictions, or explanations. These activities are followed by small amounts of feedback: Numerically Driven Inferencing studies (NDI; e.g., Ranney et al., 2008) have provided numeric feedback. RTMD (Reinforced Theistic Manifest Destiny) theory, which examines why people in the U.S. are less likely to accept evolution and climate change than are people in peer nations (e.g., Ranney, 2012), has yielded mechanistic interventions.

Ranney et al. (2012a) found that almost no Americans seem to understand the basic mechanism of global warming. Ranney et al. (2012b) includes a 400-word explanation (and experimental stimulus) of the physical-chemical mechanism of the greenhouse effect, here summarized: (1) Earth's surface absorbs (mostly visible) sunlight and then emits infrared light, which greenhouse gases absorb, causing heat energy to leave the atmosphere more slowly than it arrived; (2) as people add more greenhouse gases, the Earth experiences climate change (an added greenhouse effect). In one survey, not a single person out of 270 (mostly public park visitors) could correctly describe (1) and (2). Virtually none of those surveyed could explain a key conceptual piece: the asymmetry of how energy can reach Earth yet then get "trapped" after it arrives (like a "leaky one-wayvalve"), due to the visible-to-infrared energy conversion.

\section*{Mechanism Knowledge is Related to GW Attitudes}

Ranney et al. (2012a) found that the correlation between mechanistic climate change knowledge and attitude toward climate change was robust even when taking into account political party. Mechanistic knowledge correlates with acceptance that global warming is occurring ( \(r=0.22\), \(p=0.0002\) ) and is anthropogenic ( \(r=0.17, p=0.005\) ). Anthropogenic climate change acceptance also predicted financial "willingness to sacrifice" \(\left(\chi^{2}(4)>32, p<0.001\right.\) for each of four items), and one's knowledge score predicted two of these items \(\left(\chi^{2}(1)>3.8, p<0.05\right.\) for both). Further, acceptance of biological evolution (another controversial science topic) was found to predict beliefs and attitudes
toward climate change (as RTMD hypothesizes, and, e.g., Ranney, 2012 found). These findings suggest that the effects of well-chosen aspects of education are both significant and somewhat independent of political affiliation. Indeed, though not reported previously, Ranney et al.'s (2012a) data also showed that evolution acceptance was a significant predictor of climate change acceptance even in a model including the two major political parties \(\left(\chi^{2}(4)=12.3\right.\), \(p<0.02\); N.B., including other parties dramatically reduces quality of fit for any model, likely due to small bin sizes).

\section*{Efficacy in Learning Climate Change's Mechanism}

Ranney, et al. (2012a \& 2012b) also provided two divergent undergraduate samples (from UT-Brownsville, a "HispanicServing Institution," and UC-Berkeley) with the aforementioned 400-word description. Strikingly, this threeminute intervention roughly tripled their mechanistic knowledge on the assessment metric. The intervention also caused both Texas and California undergraduates to increase their climate change acceptance. Contrasting with others' studies noted above, our intervention focused on a fundamental, well-researched knowledge gap, and our assessment focused on acceptance/belief. Such contrasts may explain the difference between observing instructional benefits (as we have) or polarization (as others occasionally have; cf. Lundmark, 2007). We provide further evidence below that such interventions are applicable across broader settings, time-frames, and populations, and that global warming understandings and attitudes are far from static.

\section*{Study 1: A Web-based and Longevity Extension}

Given the replicated demonstrations of significant attitude changes described above, we proceeded to assess whether the mechanism-explanation effects we had obtained were durable or transient. This study extended prior work by delaying the post-test several days. We were also concerned that an "experimental demand" from the classroom setting might have driven our prior results, so we provided the intervention on-line; that is, we assessed whether our materials would elicit significant attitude change even though students participated via their own computers, without experimenter observation. Thus we concurrently explored both the longevity (via delay) and format (on-line) aspects of our phenomenon. We also extended our prompts to incorporate more demographic and introspective queries.

Methods. The instructional materials were those reported in Ranney et al. (2012a \& 2012b; the latter includes the full 400 -word text of our intervention). The empirical differences were that (a) the study was conducted online, via the Qualtrics Inc. (Provo, UT) system, (b) eight items were added to pre- and post-test attitude surveys to add reliability to the related RTMD metrics (specifically, national and religious affinities; these metrics will be reported elsewhere), and (c) five further items were introduced immediately following the instructional material to elicit introspection (about embarrassment, disagreement, etc.).

Undergraduates ( \(\mathrm{N}=80\) ) were recruited via the Research Participation Program (RPP), of the University of California, Berkeley (UCB) psychology department, which allowed us to administer a pre-test to about half of the students (38) between eight and 26 days ( \(\mu=18.5\) days) prior to the study, which may have allayed test-retest effects (although Ranney et al., 2012a, found little evidence for them). Thus, as with Ranney et al. (2012a), some students received the full survey testing "sandwich" while others had no pre-test. A delayed post-test was given to all participants between one and eight days later ( \(\mu=4\) days); this range was used to assess the timecourse of retention in planning subsequent studies. We lack the power to test forgetting over time here (although numerically, we did not find any!).

Results and Discussion. In general and as anticipated, we replicated Ranney et al.'s (2012a) results and extended them by finding that gains were retained over the mean, four-day, delay. (Note: all of this piece's measures use 1-to-9 Likert scales.) Scored knowledge was again linked to self-rated knowledge ( \(r=0.5, p<0.0001\) ) and was similar to that of prior UCB students. Scored knowledge soared from 3.8 (pre-test) to 6.5 (post-test) and 6.3 (delayed post-test); gains were significant ( \(p\) ' \(s<0.0001\), simultaneous comparisons). Stated GW beliefs followed a similar pattern. Mean ratings rose from 6.20 (pre-test) to 6.54 (post-test) and were mostly retained at 6.44 (delayed post-test)—notable gains (again) for a 400 -word text \((t(79)=2.5, p=0.006\) for immediate, and \(t(79)=1.7, p=0.05\) for delayed). The largest post-test gains were found in agreeing with "Human activities are largely responsible for the climate change..." (a 0.25 gain) and certainty that global warming is occurring (a 0.19 gain). The self-rated knowledge mean similarly increased markedly from pre- to post-test ( 4.5 to 5.6 ). This gain's retention, gratifyingly, was also noted on the delayed post-test (5.2; simultaneous comparisons for both the gain and retained gain were again significant; \(p\) 's \(<0.0001\) ). The immediate increase in self-rated knowledge replicates results from Ranney et al. (2012a; the results were not reported then).

In sum, Study 1 extends the finding that well-considered information, even received online, increases anthropogenic GW acceptance and behaviorally relevant attitudes. Further, the conceptual changes that result from reading even 400 words have notable longevity. These effects have been replicated with the general public as well (unpublished data). Computer-based interventions often scale well, enhance reliability, and prove cost-effective; so, given our results, we recommend the online distribution of mechanistic explanations, especially about climate change.

\section*{Altering Beliefs with Factual Numbers}

The aforementioned NDI paradigm has yielded marked attitudinal and conceptual shifts with quite minimalist interventions. NDI and one of its procedures, EPIC (both introduced by Ranney and students), represent a particularly compact, well-specified intervention. EPIC participants (1)
provide an Estimate for each policy-relevant item's quantity, (2) state a preferred target (or monetary allocation) Policy (or Preference) for each quantity, (3) receive true feedback quantities to Incorporate (as new "Information"), and (4) indicate whether their policies have Changed due to the feedback. With just a single wellselected quantity, the EPIC procedure's feedback often shifts one's attitudes. EPIC-spawned conceptual changes are often remarkably durable for such a small intervention (e.g., Ranney et al., 2008), as evidenced by increased estimation accuracy 12 weeks after the procedure (Munnich, Ranney, \& Bachman, 2005). Therefore, we sought to employ NDI interventions in addition to the mechanism intervention from Study 1 and prior studies. Specifically, we presented different participant groups with numerical information that is relevant to global climate change acceptance. We used numbers that were likely to boost acceptance (Studies 3 \& 4), as well as numbers that we thought might erode individuals' acceptance of climate change (Study 2).

\section*{Study 2: Eroding Beliefs with "Evil" True Numbers}

Some organizations publicize out-of-context facts to try to undercut the reality or gravity of human-caused GW. These are usually blatantly cherry picked, such as that Earth slightly cooled by \(0.2^{\circ} \mathrm{F}(.04 \%\) re: absolute-zero terms) from 1940 to 1975 (Jastrow, Nierenberg, \& Seitz, 1991). While surprising, this fact hardly contradicts the ever more obvious warming trend over the last \(125+\) years: one can easily pick endpoints that are oddly high or low in a noisy time series. (The slight decrease is also explained by a planetary motion trend.) Given this rather clear intent to mislead (Oreskes \& Conway, 2010), we (partly tongue-in-cheek) label these numbers "evil." Thus, Study 2's hypotheses are that a few misleading facts can reduce one's (1) climate change acceptance, (2) ratings of knowledge of the issue, and (3) climate-change funding preferences. Of course, lest we erode participants' acceptance of anthropogenic climate change more than fleetingly, we debriefed them right afterward with more complete information-including the mechanism and a large dose of (non-evil) relevant facts.

Methods. The survey and instructional materials were analogous to those used in Ranney et al.'s (2012a) paper-and-pencil second study. The main difference was that the mechanism was replaced with one of two interventions. For one version, part ( \(\mathrm{n}=59\) ) of a UCB college class ( \(\mathrm{N}=104\) ) estimated each of eight items before receiving the feedback values, with an emphasis on maximizing the quantity of feedback numbers given to the student. To this end, this eight-item survey included only a post-test (i.e., no pre-test), and lacked a policy component (thus, it was an EI intervention, lacking " P " or " C "). A more comprehensive engagement containing only two items was administered to the rest of the class ( \(\mathrm{n}=45\) ), and this version included a pretest and extra questions about each item; we asked these students about their surprise level after each feedback value and requested both their climate-change funding Policies
and post-feedback policy Changes regarding/versus various UN (e.g., UNDP millennium) goals.

Results and Discussion. As predicted, preferences for funding GW-related UN goals dropped ( \(\chi^{2}(1)=22, p<0.01\) ) versus all eight non-climate UNDP funding alternatives. (Unfortunately for GW as a social priority, the highest mean pre-test preference for funding climate change initiatives reached only a \(50-50\) split of available funds.) Also as predicted, climate change acceptance significantly dropped, from a 6.5 pre-test mean to a 6.2 post-test mean for the twoitem group \((5.5 \%\) of the available room to drop on the \(9-\) point scale, \(t(42)=-4.3, p<0.001\) ), and significantly to 5.9 for the eight-item group \((11 \%\) of the available room, \(t(88.6)=-2.61, p<0.005)\); note that these shifts were also in the direction of ambivalence (a " 5 " rating), and may reflect confusion rather than disagreement. Our third hypothesis was also supported: self-rated knowledge fell from a mean of 5.0 on the pre-test to 4.5 for the two-item group ( \(12 \%\) of the available room, \(t(44)=-2.5, p<0.01\) ), and plummeted to 2.9 on eight-item survey \((t(87.2)=-5.3, p<0.001)\). This latter drop of 2.1 is \(53 \%\) of the available room to drop on a \(9-\) point scale, which is exceptionally large.

It is clear that even relatively educated members of the public (e.g., undergraduates at a top-tier university) are highly susceptible to misleading, cherry picked facts. Such facts are clearly known to organizations attempting to undermine the overwhelming scientific consensus about climate change. Thus, it seems incumbent upon cognitive science to counter the increasing sophistication with which such organizations distribute misleading information.

\section*{Study 3: "Saintly" Numbers Supporting GW}

Given Study 2's observed efficacy for "evil" numbers and the NDI paradigm's prior successes, this study assessed the utility of numbers that support claims of global warming. Again partly tongue-in-cheek, we call these "saintly" numbers. Given prior NDI studies of similarly "shocking" magnitudes (e.g., Garcia de Osuna, et al., 2004), our hypothesis was that the accurate feedback would increase participants' climate change acceptance, but diminish selfconfidence in their knowledge of the issue.

Methods. Like Study 1, Study 3 was both online and used a UCB-RPP pre-test survey (for a subset of 30 students); however, we increased the delay between pre-test and intervention to a mean of 18 days. We queried the individuals \((\mathrm{N}=60)\) about eight quantities. The eight items also included questions directed at participants' surprise and their reactions to each number. (Monetary preferences were left out of this version because we already observed attitude shifts in the simplified eight-item "evil" intervention.) An added feature of the on-screen intervention is that we could more saliently remind individuals of each of their estimates on the same page on which they incorporated numerical feedback, better ensuring that they contrasted the two. As with Study 1's online survey, a post-test about attitudes and
beliefs was administered both immediately after our intervention and after the 18-day retention interval.

Results and Discussion. Attitudes, acceptance, and beliefs about climate change were stable after this intervention with "saintly" numbers (pre-test: 6.71; post-test: 6.67). This stability was unexpected (but see below for explanations), especially because these items (as with the "evil items) were, as anticipated, able to significantly erode self-rated knowledge ( 5.3 to \(4.0, t(29)=-3.6, p<0.01\) ). This erosion was comparable to that found with the "evil" numbers. These items were also relatively high regarding participant surprise, compared to Study 1's 400-word intervention. The mean surprise rating across Study 3's items was 4.8 , while the mean surprise rating for the 400 words was 2.9. (All ratings above " 1 " indicate some level of surprise.)

One of the most surprising numbers (a 5.2 mean) was the near- \(100 \%\) of active researchers who support anthropogenic climate change's tenets, reflective of the strong relationship between the perceived scientific consensus and climate change acceptance, as Lewandowsky, Gignac, and Vaughan (2013) report. The two numbers most similar to the statistics in the 400 words were similarly surprising, with the rises in atmospheric methane \((+151 \%)\) and \(\mathrm{CO}_{2}(+40 \%)\) yielding respective surprisingness means of 5.9 and 5.1.

Despite these powerful impacts, Study 3 yielded no effect on beliefs or attitudes. This lack of effect is counter to prior NDI studies, in which individuals' preferences and beliefs were often markedly shifted by even a single number. (An experimental silver lining here is the finding that participants will not report greater climate change acceptance by mere dint of experimenter demand!) One possible explanation regards an unintended method change: Participants in prior NDI and RTMD studies were usually told the particular scientific/literature source-both for each statistic that was sought and each true value provided as feedback. Study 3 omitted this, so is possible that participants were less compelled by the authority of this study's statistics, compared to those in Study 2. Another possibility is that these UCB students were near ceiling for acceptance, with a reluctance to admit the disturbing effects of GW. Further, it may be that, as in Study 2, participants were left feeling less knowledgeable-weakening any boost these surprising numbers could have had on climate change acceptance. Finally, perhaps students lacked an appropriate context for integrating this information. The next study illustrates one way to contextualize such feedback statistics.

\section*{Study 4: Consolidating Knowledge-Gain Effects}

Study 4 explores combining (a) the replicated effect of explaining global warming's mechanism and (b) the promising effect of offering representative statistics that support understanding of GW's effects and dangers. Participants were 63 urban San Francisco Bay Area highschool students, who likely better represent the general public than do the prior studies' university undergraduates.

Methods. The students were in three junior-level chemistry classes. Much of the school ( \(40 \%\) ) is on free/reduced lunch (a low-income marker), \(95.1 \%\) is "non-white," and just \(35 \%\) lists English as their primary language. We presented them with (1) a more elaborated mechanistic explanation/minicurriculum, and (2) six key GW statistics. A control group received (1) from above, with (3) six unrelated statistics. We predicted that (i) the mechanistic explanation would yet again yield gains in climate-change understanding and more pro-environmental attitudes, (ii) the key statistics would enhance such effects, and (iii) the effects would remain a month later. Felipe (2012) describes the intervention and results more completely. Everyone received 15 minutes' instruction on climate change's mechanism for each of three days. After estimating each of the six critical climate change quantities, the experimental group ( \(n=33\) ) received the true values as feedback. The control group ( \(\mathrm{n}=30\) ) received six estimation-feedback values that proved equally surprising but which were unrelated to climate (drawn from Ranney et al., 2008). Each student filled out a pre-test, a post-test (three days later; \(\mathrm{N}=63\) ), and a delayed post-test ( 34 days later; \(\mathrm{N}=59\) ). Of each test's many measures, we focus here on scientific mechanistic knowledge, attitudes toward global warming, and Environmental Behavioral Intentions (EBI). We report below only the gist of some of Felipe's (2012) notable findings, yet provide some newer findings about the effects of relevant, surprising numbers on the retention of gains from the mechanistic knowledge curriculum.

Results and Discussion. Pre-test mechanism knowledge was so close to zero that the curriculum hugely increased both groups' GW-mechanism understandings-by \(1,619 \%\), on average (combined \(t(62)=9.31, p<0.0001\) ). Gains in both groups' mean EBI scores were also quite notable \((t(62)=5.91, p<0.0001)\); the effects emphatically replicate our prior three studies' findings that show the importance of mechanistic information in enhancing a person's GW understanding and "pro-environment" attitudes. Even more importantly, the gains were significant 34 days later for both groups (control \(t(27)=3.01\), experimental \(t(28)=5.2\), both \(p\) ' \(<0.002\) ), which seems an especially impressive effect for less than one day's class out of about 170 instructional days. (One might imagine the curriculum's effect if it were extended or reinforced multiple times-or given to the general public.) Interestingly, although the control group greatly gained by learning the mechanism, the experimental group's retention of their mechanistic knowledge was significantly greater than-about twice-that of the control group ( \(t(48.7)=-2.61, p=0.01\); planned comparison after a significant ANOVA interaction term), suggesting that the experimental group's critical statistical information helped reinforce and secure the mechanistic information. Thus, the numbers may have "primed the pump" for learners to more durably encode their new GW mechanism knowledge. The differences show separate utilities for both the mechanistic information and the statistically pertinent information-and the suitability of our brief intervention for high school students, and, likely, the wider public.

Students' acceptance of climate change and concern about its effects were both near ceiling on the pre-test ( 8.3 and 8.1, respectively, thus range-restricted on the 1-9 scales); even so, the experimental group exhibited a significant gain \((t(32)=1.76, \quad \mathrm{p}<0.05)\). Interestingly, the curriculum inadvertently slightly increased students' acceptance that climate change is "just part of a natural cycle" (but to only a modest 3.7 on the 9 -point scale) rather than anthropogenic (which slightly dropped, yet remained at about 7 on the 9 point scale). Upon analysis, this modest, counterproductive result was due to the curriculum focusing on how, prior to humans' influences, Earth's evolution already yielded greenhouse gases and a greenhouse effect. The curriculum failed to communicate carefully that humans have caused an extra greenhouse effect, which represents anthropogenic climate change. This finding highlights the importance of understanding that, while the greenhouse effect in which our species evolved had long kept Earth from being a virtual snowball, the extra greenhouse gases that humans have pumped into the atmosphere during the past \(250+\) years are disturbing a narrow thermal balance. Educators should emphasize that, as with drinking ten gallons of water, a beneficial substance can turn deadly in excess.

\section*{General Discussion}

Our studies have provided an evidential medley that effectively disconfirms the idea that GW-relevant knowledge and attitudes are locked in cognitive stasis. Contrary to those who over-problematize a "knowledge deficit" (or "information deficit") view of global warming communication, we see a "wisdom deficit." Here (and in Ranney et al., 2012a) we have markedly un-problematized any deficit with our interventions' "cognitive levers." In contrast, it is unlikely that offering an ill-structured list of uncompelling facts to an unprepared mind (or thinly veiled rhetoric; cf. Lord, Ross, \& Lepper, 1979) will notably alter beliefs or behaviors-especially for the difficult topic of climate change. Rather, one must be sensitive to specific (mis)understandings that may be relevant to a learner grappling with a domain. Ultimately, we will likely need to engage virtually all people, aiding them in connecting their long-term values to the long-term effects of their behaviors.

Disturbingly, Study 2 showed that climate change acceptance can be readily eroded by misleading, cherrypicked data. To guard against such "evil" misinformation, people need the context to recognize them as the clever propaganda that they are. Such prophylactic interventions may represent promising targets for further educational research initiatives (cf. Lewandowsky et al., 2012).

We are currently studying ways to disseminate the information that we have found to elicit worthwhile cognitive and belief changes. For instance, we are developing on-line instructional materials (e.g., videos) that can widely convey both global warming's mechanism and the statistics that reflect the scientific consensus of climate change-so the public can more fully join that consensus. Even if people forget an offered statistic or a mechanistic
aspect, we hope they will recall being rationally convinced of climate change's reality, danger, and need for action.

We have shown above that on-line survey interventions, brief curricula, and classroom lessons can have a marked and persistent effect on one's knowledge, understanding, beliefs, and attitudes about global warming. Despite arguments to the contrary, some simple cognitivelyinformed interventions may well be fundamental in building humanity's resolve to tackle global climate change.

\begin{abstract}
The current experiments investigated the fractal structure in the nested actions of tapping behavior. The results revealed that task constraints (e.g., tapping to a metronome) alter the fractal structure of a given aspect of the behavior (e.g., intertap interval) and decouple its long-term interactions with other aspects of the behavior (e.g., key-press duration). These results support the idea that fractal structure reflects the dynamical organization of complex systems.
\end{abstract}

Keywords: complex systems, fractal scaling, finger tapping

\section*{Introduction}

There is certainly no shortage of complexity for the student of human mind and behavior. The human system is at once physical, chemical, biological, psychological, and social. We cognitive scientists carefully design experimental tasks and manipulations to gain an empirical purchase on the many forces that shape human behavior. Traditionally, the field has relied on classical techniques of linear statistics. We take different averages or degrees of variability in reaction time to be indicative of the cognitive processes underlying performance in our experimental tasks. Recently, however, researchers have turned to examining more subtle and complex statistical facets of data to understand the processes involved in the organization of human behavior; namely, fractal structure.

Comprehensive review of this statistical property, the available mathematical techniques for its assessment, and the potential implications for theories of cognitive science is not possible in the limited space provided here (see Brown \& Liebovitch, 2010; Delignieres \& Marmelat, 2013; Holden, 2005; Van Orden Kloos, \& Wallot, 2010). Nonetheless, a brief introduction to the topic is warranted. The term "fractal structure" is here being used loosely to refer to patterns of variability in repeated measurements of human behavior. Most traditional, linear statistical
techniques operate on the assumptions that deviations from mean performance will obey a Gaussian distribution and that these "errors" will be uncorrelated with one another. Data displaying fractal structure violates these assumptions. That is, fluctuations in repeated performances exhibit "longterm dependencies" such that errors in early observations are correlated with errors in much later observations. Fractal data obey power-law scaling such that size of a given error is inversely proportional to how often errors of that size occur. Thus, like geometric fractals, these data are said to be "self-similar" and "scale-invariant". Fractal data entail nested patterns of variability wherein small variations in measurement have the same structure as large variations. Such structure in repeated measurements is often referred to as "pink noise", as contrasted against the random variation entailed in "white noise" (Holden, 2005).

In part, these patterns are important to researchers in cognitive science as they have been discovered in a plethora of human data from the simplest of reaction time tasks taking place over the course of minutes (Van Orden, Holden, \& Turvey, 2003) to measurements of self-esteem over a many months (Delignieres, Fortes, Ninot, 2004). More importantly, experimental manipulations of the type typically employed by cognitive scientists have been shown to affect fractal structure. For instance, Kello et al., (2007) demonstrated that reaction times to unpredictable cues were not only slower, but also closer to white noise (i.e., random) variation, than reaction times to predictable cues.

Despite their widespread occurrence, there is not yet a unified account of how these fractal patterns get into the data or what they imply for theories of cognitive science (e.g., Van Orden, Holden, \& Turvey, 2005; Wagenmakers, Farrell, \& Ratcliff, 2005). The current experiments are intended to contribute to the on-going discussion by examining the fractal structure in the nested actions in a tapping task, their dynamical interaction with one another, and the impact of employing different task constraints.

\section*{Experiment 1}

Most statistical techniques used to assess fractal structure require very many observations made under relatively constant task conditions. As such, research revealing these structures in human behavior has typically preferred very simple tasks. One frequently studied task is finger tapping (e.g., Chen, Ding, \& Kelso, 2001; Chen, Repp, \& Patel, 2002; Gilden, Thorton, \& Mallon, 1995; Lemoine, Torre, \& Delignieres, 2006; Madison, 2001; Musha, Katsurai, \& Teramachi, 1985; Ogden \& Collier, 1999; Yamada, 1995).

Generally, studies have found evidence of fractal structure in continuation tapping, wherein participants attempt to keep a steady beat briefly demonstrated to them by a metronome stimulus at the beginning of a trial. In this case, the intervals between taps take on a "persistent" structure (i.e., longer taps tend to be followed longer taps). Interestingly, the fractal structure is different during synchronization tapping, wherein participants synchronize their taps to a constant metronome stimulus. In this case, the intervals between taps take on an "anti-persistent" structure, (i.e., longer taps tend to be followed by shorter taps) whereas the asynchronies between the participant's taps and the metronome show a persistent fractal structure. These findings have been interpreted and modeled as the result of the metronome serving as a corrective feedback mechanism for the maintenance of a given tapping interval (Torre \& Delignieres, 2008).

While these results are reasonably well-understood, to date there have been no investigations of the nested actions comprising finger tapping. That is, most tasks require a behavior that consists of many "sub-actions", all of which may not be measured or examined. In tapping, the task requires striking the key, holding it down for some period of time, releasing the key, and waiting some period of time before striking the key once more. Our first experiment was designed to investigate the fractal structure in these nested actions during continuation tapping, how these nested behaviors might interact with one another across the measured span of behavior, and what differences might be evident during synchronization tapping.

\section*{Method}

\section*{Participants}

Sixteen undergraduate students from the University of Cincinnati participated in the study for partial course credit. All participants were over 18 years of age and right-handed.

\section*{Apparatus}

The participants' tapping behavior was recorded using a USB midi keyboard. The keyboard was connected to a PC computer running Ableton Live (Ableton, Berlin Germany). This software was used to simultaneously record the timeseries of the participants' taps (with a \(\pm 5 \mathrm{~ms}\) error) and present the auditory metronome stimulus to the participant through a pair of headphones.

\section*{Procedure and Design}

After informed consent, participants were instructed that they would complete two trials of tapping behavior while being presented different auditory stimuli. They were then shown how to produce the desired tapping behavior; namely, by resting their right hand on the table and producing taps with their index finger on a key marked with a small piece of tape, being sure to depress and release the key entirely on each tap. Each participant first completed the continuation tapping condition. The stimulus consisted of 10 seconds of a 2 Hz metronome ( 500 ms between beats) followed by 10 minutes of silence. Participants were instructed to synchronize their taps to the metronome for the first 10 seconds, and then to maintain that same beat without the metronome for the remainder of the trial. Each participant then completed the synchronization condition. In this trial, the stimulus simply consisted of 10 minutes and 10 seconds of a 2 Hz metronome. Participants were instructed to synchronize their taps to the metronome for the duration of the trial. At the conclusion of the experiment participants were thanked and debriefed.

\section*{Data Analysis}

The data output by the recording software were collated to yield three different time-series for each trial. The first series contained inter-tap intervals (ITI) where data signified the time elapsed between each tap and the following tap. The second series consisted of key-press durations (KPD) where data signified the time the key was depressed on each tap. The third series consisted of key-release intervals (KRI) where data signified the time between the release of the key of each tap and the following tap. The relationship between these three measures of tapping behavior is depicted in Figure 1. Note that these variables are not independent. For any given tap, determining any two of the variables completely determines the third as well. Thus, we consider this data set to properly consist of only two pieces of information. Nonetheless, we will use all three variables for reasons that will become apparent.

Time

Figure 1: The figure portrays a sequence of three taps and the three measurements collected for each tap.

Prior to fractal analysis, each time-series was subjected to several pre-processing steps to eliminate outliers and linear trends that might otherwise affect the outcome of the test (see Eke et al., 2000; Delignieres et al., 2006). Specifically, individual taps were removed from the data set when either the corresponding ITI was outside the range of \(300-700 \mathrm{~ms}\), or the corresponding KPD was greater than 500 ms . These values were chosen to reflect instances in which the participant failed to either depress or release the key entirely or failed to keep their taps close to the prescribed tempo. When a tap met either of these exclusion criteria, it was removed from each of the three measurement series. Following outlier removal, each time-series was trimmed to 1024 taps as the fractal analysis employed requires series of a length equal to a power of two. Finally, a linear bridge detrending was applied to each series.

The pre-processed series were submitted to a power spectral density (PSD) analysis to assess fractal structure. First, each series is standardized by Z-scoring each value. Then each series is approximated by a set of sinusoids with variable power and frequency by a Fourier transformation. As described above, fractal data obey power-law scaling wherein the size of each deviation is inversely proportional to how often deviations of that size occur. This relationship can be expressed mathematically between the power ( P ) and the frequency (f) of the sinusoids generated by Fourier transformation, where \(\mathrm{P}=1 / \mathrm{f}^{\alpha}\). The "scaling exponent" \((\alpha)\) summarizes the nature of the fractal structure evident in the series with persistent fractal structure indicated by \(\alpha \approx 1\), with random, white noise structure indicated by \(\alpha \approx 0\), and anti-persistent structure indicated by \(\alpha \approx-1\). An estimation of \(\alpha\) can be obtained by plotting power against frequency on double-logarithmic axes, and finding the slope ( S ) of the regression line that best fits this "spectral plot", with \(\alpha=-\mathrm{S}\). In accordance with past research, we estimated \(\alpha\) from only the lowest portion ( \(25 \%\) ) of the power spectrum (Eke et al., 2000; Delignieres et al., 2006).

We also sought to investigate the dynamical interaction of the three measures (ITI, KPD, KRI). To this end, we used cross-correlation analyses. Similar to auto-correlation, cross-correlation computes the correlation between two series across a range of time-lags. The cross-correlation function therefore can capture dependencies between the different tapping variables that exist across several taps.

\section*{Results and Discussion}

Participants generally had no trouble completing the task and there were on average only 5.5 outlier taps per trial. Generally, there were no significant differences in either the means or standard deviations for any of the three variables as a function of experimental condition (all \(p\) 's \(>05\) ). The sole exception was that the standard deviation for ITI was smaller during synchronization ( \(M=26.5 \mathrm{~ms}, S D=4.58\) ) than during continuation tapping ( \(M=31.4 \mathrm{~ms}, S D=8.12\) ), \(t(15)=2.57, p=.021\).

\section*{PSD Analysis}

The change in the fractal structure in ITI across experimental conditions was consistent with the findings of past research (e.g., Chen et al., 2001; Gilden et al., 1995). Specifically, there was a significant decrease in \(\alpha\) from persistent structure during continuation tapping ( \(M=.60\), \(S D=.20\) ) to anti-persistent structure during synchronization tapping ( \(M=-.48, S D=.58\) ), \(t(15)=7.79, p<.001\). Both KPD and KRI showed different patterns of results. There was a small but significant increase in \(\alpha\) for KPD from continuation ( \(M=.71, S D=.23\) ) to synchronization tapping ( \(M=.88, S D=.22\) ), \(t(15)=-2.41, p=.03\). Conversely, there was no difference in \(\alpha\) for KRI between continuation ( \(M=.66, S D=.18\) ) and synchronization tapping ( \(M=.60\), \(S D=.30)\). This pattern of effects is depicted in Figure 2.

Figure 2: Change in \(\alpha\) for ITI, KPD, and KRI from the continuation to synchronization tapping conditions.

Although the observed difference in the fractal structure in ITI is in line with the results of the past tapping research, the effects for KPD and KRI are new findings without established theoretical interpretations. One proposal endorsed by several researchers is that the fractal structure evident in ITI during continuation tapping, and in the asynchronies to the metronome during synchronization tapping, is the empirical signature of the emergent behavior of complex systems (e.g., Chen et al., 2001; Gilden, 2001; Lemoine et al., 2006; Yamada, 1995). Briefly, this account asserts that the structures present in the data are reflective of the dynamical organization of the behavioral system that produced them. The implication is thus that the observed fractal structure does not issue from one particular cognitive or physiological component. Rather, the variation in behavior is the collective result of the interaction of many interdependent processes (Holden, Van Orden, Turvey, 2009). To attempt to extend this account to the results of KPD and KRI, we examined the cross-correlations between the three measures of tapping behavior in hopes of revealing the nature of their dynamical interaction.

\section*{Cross-Correlation Analysis}

The cross-correlation functions for ITI-KRI and for KPDKRI are depicted in Figure 3. As these functions were found to be roughly symmetrical across negative and positive lags, only the positive half of the function is shown here.

Figure 3: Cross-correlations for ITI-KRI and KPD-KRI.
As discussed above, "long-term dependencies" are entailed in fractal variation within a single behavioral measure. The upper panel of Figure 3 suggests that similar long-term dependencies exist between the nested actions involved in continuation tapping behavior. Specifically, the full interval between taps (i.e., ITI) is moderately correlated with the sub-interval (i.e., KRI) out to 15 taps and later. Interestingly, all of this long-term structure is absent during synchronization tapping. This suggests that the constraint of the metronome effectively "decouples" these two dynamics of the tapping behavior. The same basic pattern was evident in the cross-correlation function for ITI and KPD, although it was less pronounced.

In contrast, the cross-correlation function for the two subintervals (KPD and KRI) reveals a fundamentally different pattern across task conditions (lower panel Figure 3). During continuation tapping these variables reveal a moderate negative long-term correlation with one another. Most interestingly, this long-term structure is not damped out by the advent of the metronome in synchronization tapping, but rather grows stronger (i.e., more negative).

It is important to note that the measurement variables analyzed in this experiment are just one window into the processes underlying the tapping behavior. Recall, these
variables are not strictly independent. As such, one might contest that the cross-correlation between KPD and KRI does not reflect the relationship of two separate variables, but simply variation in the times when the key was released. This is essentially correct. As revealed by PSD, and explicated by cross-correlation, the persistent structure in these sub-intervals is unaffected, or is actually stronger, when the metronome constrains the interval between taps (i.e., ITI). Interestingly, this structure in key release times cannot simply be accessed by taking the difference of the key release times (IRI). Submitting IRI to PSD reveals the exact same pattern of effects found for the ITI variable; persistent structure during continuation tapping ( \(\alpha=.55\) ), and slightly anti-persistent structure during synchronization tapping ( \(\alpha=-.33\) ). As such, this variable accesses the same structure in the time between taps as does ITI. Thus, the two independent (sub)behaviors entailed in this task might be best construed as the "tap-to-tap" behavior and the "between-taps" behavior, with our measurement variables being only convenient windows into these dynamics.

\section*{Experiment 2}

Experiment 2 was designed to further investigate the interplay of these nested actions and how task constraints affected their fractal structure. To our knowledge, only one other study has investigated the fractal structure in multiple, nested actions. Kello et al., (2007) conducted a series of reaction time experiments in which they recorded not only the time taken to respond to a stimulus, but also the length of time the participants depressed the key on each response. Taken together, these experiments suggested that reaction times and key contact times were not correlated with one another, and that the fractal structure in reaction times could be affected independently of the structure in key contact times. They did not, however, actually attempt to alter the fractal structure of the key contact times directly. The purpose of Experiment 2 was thus to attempt a manipulation that might constrain the between-taps behavior (i.e., KPD) in our tapping task and thereby investigate the relationship between task constraints and fractal structure generally.

\section*{Method}

\section*{Participants}

Twenty-two undergraduate students from the University of Cincinnati participated in the study for partial course credit. All participants were over 18 years of age and right-handed.

\section*{Procedure and Design}

The design was nearly identical to that of Experiment 1. The primary difference was that half of the participants were instructed not only to synchronize their taps to the metronome during the synchronization condition, but also to attempt to keep the key depressed for the length of the metronome tone. So that the length of the tone would be salient to the participants, the metronome stimulus consisted of alternating 400 ms tones and 400 ms periods of silence.

Prior to this additional manipulation, each participant first completed the continuation tapping condition. In this trial, participants were played the metronome for 10 seconds, and then attempted to maintain the same beat for 8 minutes. Each participant was then given task instructions according to their experimental group and completed the synchronization condition. Participants in the "hold" group both synchronized their taps with the metronome and held the key down for the length of the tone, while participants in the "tap" group simply synchronized with the metronome.

Due to the change in the prescribed tempo of the tapping behavior, the criteria for outlier taps changed. Here, taps were discarded from the data set when either the corresponding ITI was outside the range of \(600-1000 \mathrm{~ms}\), or the corresponding KPD was greater than 800 ms . Also, as this frequency of tapping yielded approximately 600 taps within each trial, the time-series were trimmed to 512 points rather than 1024. The final, pre-processed time-series were submitted to PSD and cross-correlation analyses as before.

\section*{Results and Discussion}

As in Experiment 1, participants had little difficulty with the task and there were on average only 9.8 outlier taps per trial. There were, however, several effects in the linear statistics of the tapping variables. Most importantly, there was a significant interaction effect for mean \(\operatorname{KPD}, F(1,20)=8.84\), \(p=.008\). Mean KPD for the hold group increased strongly from continuation tapping ( \(M \approx 270 \mathrm{~ms}\) ) to synchronization tapping ( \(M \approx 440\) ). In contrast, the tap group KPD only slightly increased from continuation \((M \approx 250)\) to synchronization tapping \((M \approx 300)\). This finding is important in that it indicates that the manipulation between groups was successful in altering their tapping behavior. There were other significant effects in the linear statistics, but as their theoretical import is less germane to the discussion at hand they are not reported.

\section*{PSD Analysis}

As depicted in Figure 4, both groups showed a significant decrease across condition for ITI, and no significant change across condition for KRI. The groups differed, however, in the change in \(\alpha\) for KPD. As in Experiment 1, the tap group showed a (marginally) significant increase in \(\alpha\) from continuation ( \(M=.59, S D=.23\) ) to synchronization tapping ( \(M=.75, S D=.24\) ), \(t(10)=-2.08, p=.064\). Remarkably, this effect was reversed for the hold group, showing a significant decrease from continuation \((M=.93, S D=.33)\) to synchronization tapping ( \(M=.78, S D=.27\) ), \(t(10)=2.25\), \(p=.05\). This effect buttresses the results of Experiment 1 . The fractal structure of KPD changes in the same direction as that of ITI when both of these aspects of tapping are constrained by the metronome (i.e., for the hold group).

\section*{Cross-Correlation Analysis}

The results of the cross-correlation analysis compliment the findings of the PSD analysis. As in Experiment 1, the longterm dependencies between ITI and KPD or KRI evident
during continuation tapping are absent during synchronization tapping. Recall, in Experiment 1 this pattern was reversed for the KPD-KRI cross-correlation. That is, the long-term correlations were stronger during synchronization tapping. This same effect is evident in the cross-correlations for the tap group (upper panel Figure 5). For the hold group, however, this effect is largely absent (lower panel Figure 5). As suggested by the PSD analysis, the KPD of the hold group was constrained by the metronome stimulus. As with ITI, this task constraint appears to have lessened the long-term dependency between these two aspects of the tapping dynamics.

Figure 4: Change in \(\alpha\) for ITI, KPD, and KRI across tapping conditions by experimental group.

Figure 5: KPD-KRI cross-correlation function by experimental group.

\section*{General Discussion}

The current experiments support and extend the previous findings on the fractal structure of finger tapping behavior. Although the measurement variables used in these analyses (i.e., outputs of the MIDI keyboard) might prove only a convenient window into the dynamics of finger tapping behavior, the results do reveal a consistent relationship between the long-term interplay between the different parts of the tapping behavior and how changes in task constraints affected this long-term structure. Specifically, these experiments suggest that when control of any (sub)behavior can be sustained with the aid of task constraints that behavior is effectively decoupled from other parts of the action and shows a reliable shift in its fractal structure.

Though superficially finger tapping may not seem to bear weightily on the issues of interest to the cognitive sciences, these findings do speak to larger theoretical questions about the organization of human mind and behavior. In particular, several researchers have proposed that fractal structure in human behavior reveals the "interaction-dominant" nature of the human system (see Van Orden et al., 2010). That is, these findings suggest that the behavioral in question is not the result of one dominant process (e.g., an internal timer), but instead is organized by many interdependent processes. Whereas more traditional views promote a modular, disembodied impression of the cognitive process, these findings suggest that a behavior as simple as keeping the beat is the product of non-linear interactions across the participant-task system. In short, these ideas invite reconsideration of the nature of the cognitive process and hold promise for addressing the vast complexity inherent in the complete human system.

\section*{Acknowledgments}

We thank Guy Van Orden and Christopher Kello for their kind and insightful contributions to this research.

\begin{abstract}
Recent theory suggests that action prediction relies of a motor emulation mechanism that works by mapping observed actions onto the observer action system so that predictions can be generated using that same predictive mechanisms that underlie action control. This suggests that action prediction may be more accurate when there is a more direct mapping between the stimulus and the observer. We tested this hypothesis by comparing prediction accuracy for two stimulus types. A mannequin stimulus which contained information about the effectors used to produce the action and a point stimulus, which contained identical dynamic information but no effector information. Prediction was more accurate for the mannequin stimulus. However, this effect was dependent on the observer having previous experience performing the observed action. This suggests that experienced and naïve observers might generate predictions in qualitatively difference ways, which may relate to the presence of an internal representation of the action laid down through action performance.
\end{abstract}

Keywords: Joint action; embodied cognition; perceptionaction; action prediction.

\section*{Introduction}

Many types of joint action require two actors to coordinate their actions. Such coordination is especially demanding for joint actions, such as ensemble music and dance performance, where successful completion of the joint action requires precise temporal synchronisation. In these contexts, it is not possible for individuals to observe and then react to the actions of their co-actors because this would introduce disruptive delays. Rather, individuals must anticipate the actions of their co-actors so that they can plan actions that will align with those actions. Because of these time constraints, researchers have emphasised the role of prediction in recent theoretical accounts of joint action coordination (Csibra, 2008; Wilson \& Knoblich, 2005).

Models of predictive mechanisms in motor control, such as forward models and inverse models, can greatly inform our understanding of joint action coordination. Both classes of models are contained within the model of motor control developed by Wolpert and colleagues (e.g., Wolpert, 1997). According to this framework, forward and inverse models are used in tandem to achieve goal-directed behaviour when regular feedback is unreliable because of delays or inaccuracies.

Inverse models act as controllers by transforming a goal state into a series of control commands that are then sent to the controlled system to produce the desired behaviour. In the motor control system, this is implemented by a system that takes the goal state and transforms it into a series of motor commands. Forward models, on the other hand, take the motor commands and transform them into a goal state. The limb also performs a forward mapping from motor commands into a goal state. Therefore, the forward model can be used to predict how the limb is expected to behave. A forward model is particularly useful in motor control where it can be used to bypass delays that occur because feedback must be transmitted from the periphery to centrally located motor control regions. This can compensate for these delays by generating predicted feedback that can be substituted for the delayed feedback.

\section*{Motor involvement in action prediction}

In addition to their role in intrapersonal action prediction, forward models and inverse models are also implicated in the interpersonal action prediction needed for joint action. Csibra (2008) has suggested that during action observation, an inverse model allows observers to reconstruct the motor codes used to produce the observed action. To support this claim, Csibra cites evidence from electrophysiological studies on monkeys as well as neuroimaging studies from humans that show that neurons in motor regions are active not only when actions are produced but also when the same, or similar, actions are passively observed (for a review, see Rizzolatti \& Craighero, 2004). Additionally, Wilson and Knoblich (2005) have proposed that observers are able to construct an internal model of observed actions by mapping the actions onto their own motor systems in a part-by-part, or isomorphic, manner. This internal model acts as a forward model by generating a real-time simulation of the observed action that runs in parallel with incoming sensory information. Information from this model can be substituted for incoming sensory information that reaches the observer through observation. By using internally generated information to drive action planning, delays that result from the processing of external actions can be overcome, and this allows co-actors to plan and coordinate

Figure 1: The zigzag (left) and wave (right) patterns used as stimuli during the recording session.
joint actions in time critical situations. Taken together, forward and inverse models provide an effective mechanism that allows actors to use their own action systems in order to emulate \({ }^{1}\) the actions of others. We refer to this proposal as the emulator hypothesis of action prediction.

A key prediction of the emulator hypothesis is that traces of the observer's motor system should be manifested in the predictions that they generate. The authorship effect provides a means of assessing this. The authorship effect refers to the finding that observers are more accurate at generating predictions about recordings of self-generated actions relative to other-generated actions. More generally, the greater the alignment between the motor dynamics of the observer and the motor dynamics of the agent producing the observed action, the more accurate the predictions generated by the observer (Flach, Knoblich, \& Prinz, 2003; Keller, Knoblich, \& Repp, 2007; Colling, Sutton, \& Thompson, 2010, submitted).

\section*{Motor involvement in event prediction}

In addition to the motor system's role in predicting the actions, evidence from paradigms employing abstract stimuli suggest that the motor system might also be used for sequence prediction in general. For example, findings from fMRI implicate ventral premotor regions in tasks that require participants to generate predictions about abstract sequences (Schubotz \& von Cramon, 2004). Similarly, lesions in premotor regions are associated with deficits in sequence prediction (Schubotz, Sakreida, Tittgemeyer, \& von Cramon, 2004).

Based on these findings, Schubotz (2007) has suggested that motor simulation is a general mechanism for predicting events. In the case of reproducible events-that is, human actions-these events are simulated using the same means that were initially employed to create the event, by using an internal model of the action. However, in the case of event that can't be mapped onto the body Schubotz argues that predictions are generated using an action model of an effector that best matches the general dynamics of the stimulus. Similarly, impoverished action stimuli lacking detail about which effectors were used to produce the action, or actions that are not in the observers repertoire, might be simulated using this more general mechanism. While this might provide a good general description of the stimulus dynamics it may fail to replicate fine-grained details of the stimuli.

\footnotetext{
\({ }^{1}\) Emulate to refers to the process of replicating the functions of a system (e.g., a conspecific's motor system) using different means (e.g., the observer's motor system).
}

Figure 2: Marker positions for recording session.

\section*{Aims of the current study}

The primary aim of the present study is to examine the nature of the internal model that observers use during action prediction. In particular, our aim is to examine whether action prediction is achieved via a general purpose predictive system that, although implemented with the motor system, does not rely on a part-by-part simulation of the observed action. The present study measured prediction accuracy by means of an action synchronisation task similar to that reported in Colling et al. (2010, submitted); however, rather than examining differences in synchronisation accuracy for self-produced and other-produced actions, all participants viewed other-produced actions and we instead varied the properties of the stimulus as well as the relevant motor experience of the observers. Both manipulations were designed to modify the information that participants could access to allow them to map the observed actions onto their own action systems. The motor experience manipulation was designed to provide observers with an internal representation of the action onto which they could map the stimulus, while the stimulus manipulation was designed to modify whether the stimulus could be directly mapped onto the observers' bodies.

To modify the information content in the stimulus, we constructed two sets of stimuli so that the stimulus either contained information about what effectors were employed to produce the action (full information) or only contained the motion information required to perform the synchronisation task, but excluded any information about the effectors used to produce the action (point information).

A manipulation was also designed to examine the role of motor experience on action emulation. This was achieved by dividing the participants into two groups and only providing one of the groups with experience with actually performing the action that they would later observe. Schubotz (2007) has suggested that when observers predict actions that are part of their action repertoire, they emulate the actions using an internal model of that action that has been laid down by the experience of producing the action. Naïve observers, on the other hand, might only employ motor regions that match the general dynamics of the movement. If this is the case, then we can predict that the effect of stimulus content would be modulated by motor experience. In particular, we can predict that naïve observers would not incorporate information about the effectors used to produce the movement into their predictive

Figure 3: Example stimuli from the full information condition (left) and the point information condition (right).
model; thus, the addition of this information should provide no additional benefit on the synchronisation task.

\section*{Methods}

\section*{Participants}

The motor experience group contained of 13 participants (11 females, mean age of 28.1 years). The naïve group contained of 12 participants ( 8 females, mean age of 20.7 year). All participants were right-handed, and all procedures were approved by the Macquarie University Human Subjects Ethics committee.

\section*{Stimuli}

In order to create the stimuli for the test session, five righthanded females (mean age of 24.8 years) performed the movement task while their movements were tracked with motion capture.

The movement task involved tracing out wave and zigzag patterns (see Figure 1) as if drawing them on an imaginary blackboard. The patterns were displayed on two large sheets of cardboard measuring \(0.594 \mathrm{~m} \times 0.841 \mathrm{~m}\). Both patterns contained five upward and five downward movements alternating between long and short. The two patterns differed in terms of the nature of the direction change at the apex of each upward movement. The direction changed sharply for the zigzag pattern, while there was a smooth, flowing direction change for the wave pattern \({ }^{2}\).

Movements were recorded using an 8-camera 3-D passive optical motion capture system (Vicon MX with 4 Vicon MX-F20 and 4 Vicon MX13+ cameras) at a sampling rate of 200 Hz from markers placed on the subject's shoulders, right arm, right hand, and waist (see Figure 2). Raw motion capture data was resampled to 25 Hz and processed with CMotion Visual 3D (C-Motion INC, Rockville MD) to create the test stimuli. For the full information condition, the motion

\footnotetext{
\({ }^{2}\) The difference between the wave and zigzag patterns is of no theoretical interest. Two movement patterns were used only to increase task variety during the stimulus creation phase and ensure participants remained engaged with the task. Statistical analyses confirmed that there were no systematic differences in performance on the test phase as a result of stimulus form (wave, zigzag) and, therefore, this factor was dropped from the analyses reported below.
}

Figure 4: Improvement in synchronisation accuracy for the full information condition relative to the point information condition for the motor experience group and the naïve group. Error bars indicate the \(95 \%\) confidence interval.
capture data was rendered as an animated character consisting of an upper torso, right arm and hand, while the stimuli for the point information condition consisted of only a single point tracking the hand (see Figure 3).

\section*{Procedure}

Participants in the motor experience group undertook a movement session that was identical to the task employed during stimulus creation. Participants performed 3 blocks containing 5 repetitions of each pattern (in random order) with their eyes closed to limit visual experience. The movement session and the test session were on average separated by 15.85 days ( 7 to 27 days).

The task in the test session was to press the response button when the hand of the mannequin, or the marker tracking the hand, reached the apex of each upward movement. Participants were instructed to synchronise the button-press with the display as accurately as possible and were told that this may require them to anticipate when the peak will occur. Each participant performed 4 blocks containing 40 unique stimuli, with equal numbers of full and point stimuli, and equal numbers of wave and zigzag stimuli. Participants in the naïve group were given a brief verbal description of the movement task.

\section*{Results}

Timing error was calculated as the absolute difference between the timing of the peak in the motion capture trajectory and the timing of the button-press. Absolute timing error was used as a dependent measure because it has been shown to provide a good index of accuracy of hitting the target (Spray, 1986). Absolute timing error was analysed by means of a 2 \(\times 4 \times 2\) mixed ANOVA with the within-subjects factors Information Content (full information, point information) and Block (1, 2, 3, and 4), and the between-subjects factor of Experience (motor experience, naïve). The Greenhouse-Geisser procedure was used to correct for violations of sphericity.

Figure 5: (A) Evenly spaced button-presses results in timing errors that vary as a function of peak number. (B) Timing error that does not vary as a function of peak number is a result of the timing of button-presses varying as a function of peak number.

Where appropriate, we report uncorrected \(d f\) s along with the corrected \(p\) value.

There were no systematic differences in synchronisation accuracy related to experimental block, as indicated by the non-significant main effect for Block ( \(F_{3,69}=0.250, p=.861\), \(\varepsilon=.518, \eta_{G}^{2}=.002\) ), and the non-significant interactions for Information Content \(\times\) Block \(\left(F_{3,69}=0.368, p=.777\right.\), \(\left.\eta_{G}^{2}=.001\right)\), Block \(\times\) Experience ( \(F_{3,69}=1.024, p=.352, \varepsilon=\) \(\left..518, \eta_{G}^{2}=.006\right)\) and Information Content \(\times\) Block \(\times\) Experience \(\left(F_{3,69}=0.609, p=.611, \eta_{G}^{2}=.001\right)\). There were also no systematic differences in synchronisation accuracy between the naïve group and the group with motor experience, as indicated by the non-significant main effect of Experience \(\left(F_{1,23}=0.460, p=.504, \eta_{G}^{2}=.016\right)\). Furthermore, there were no systematic differences in synchronisation accuracy between the full information displays and point information displays when the data were collapsed across group and block, as indicated by the non-significant main effect for Information Content ( \(F_{1,23}=8.573, p=.008, \eta_{G}^{2}=.003\) ).

As predicted, the results showed that the effect of information content was modulated by motor experience, as indicated by the significant interaction for Information Content \(\times\) Experience ( \(F_{1,23}=5.413, p=.029, \eta_{G}^{2}=.002\) ). To decompose this interaction, the data were collapsed across block and two paired t-tests were conducted to examine the difference between the two levels of Information Content (full information, point information) for each Experience group. The results of these \(t\)-tests showed that the information content effect was found only for the motor experience group ( \(t_{12}=2.943, p=.012\) ) but not the naïve group \(\left(t_{11}=-0.411\right.\), \(p=.689\) ). This indicates that timing error was significantly higher for the point stimuli relative to full stimuli for the motor experience group ( \(M_{\Delta}=6.855\), 95CI[1.779][11.930]) but not for the naïve group ( \(M_{\Delta}=-1.007\), 95CI[-6.399][4.385]). Therefore, only the motor experience group was able to take

Figure 6: Timing error as a function of peak position for the motor experience group and the naïve group.
advantage of the presence of limb and joint information to enhance synchronisation accuracy (See Figure 4).

A further attempt was made to quantify the difference in task performance between the motor experience group and the naïve group. We examined whether there were differences in task performance that related to whether participants primarily responded to local aspects or global aspects of the stimulus. In the stimuli, the duration of each upward movement alternated from long to short. This irregular pattern leads to local variations in peak timing. Basing responses on global aspects of the stimuli, such as average tempo, would produce a pattern of timing errors that fluctuates from peak to peak. However, by adjusting responses according to the local variations in the stimuli would produce timing errors that are approximately equal for each button-press (see Figure 5). Timing error for each of the final four button-presses (corresponding to each of the final four peaks) was analysed separately for each group by means of a one-way ANOVA with the factor Peak Position (The first peak was dropped from the analysis because the movement leading up to the first peak is neither clearly long nor short).

Analyses showed a significant effect of Peak Position for the naïve group \(\left(F_{3,33}=5.083, p=.031, \varepsilon=.453, \eta_{G}^{2}=.108\right)\), and not for the motor experience group \(\left(F_{3,36}=1.449\right.\), \(p=.254, \varepsilon=.371, \eta_{G}^{2}=.020\) ). This suggests that for the naïve group timing error changed in a low-high-low-high pattern as the trial progressed, while for the motor experience group peak position did not significantly affect timing error. These results are consistent with the naïve group responding to global aspects of the stimuli and the motor experience group responding to local aspects of the stimuli (see Figure \(6)\).

\section*{Discussion}

The primary aim of the present study was to investigate the nature of the action emulation employed during action prediction. In particular, we wanted to investigate whether action prediction relies on observers mapping the stimulus onto their body in a part-by-part manner, or whether they just model
the general dynamics of the action without modelling the specifics of the effectors used to create the stimulus. Furthermore, our aim was to investigate the influence of motor experience on action emulation. Schubotz (2007) has suggested that while abstract stimuli and actions that are not part of the observer's repertoire might be simulated using a general purpose mechanism, actions an observer has experience producing are instead simulated using a model that incorporates the specifics of the effectors used to produce the movement. In order to examine these questions, we varied both the information content of the stimuli and the motor experience of the observers.

\section*{The effect of stimulus information}

In the full information condition, the visual stimulus contained not only the movement information required to perform the task, but also information about the effector used to produce the movement. In the point information condition, the visual stimulus only contained a single moving point. While the point information condition also contained all the movement information required to perform the task, it lacked the additional information about the state of the effectors. As predicted, the results showed enhanced prediction accuracy when observing the full information stimuli.

An alternative explanation for these results is that a difference in the low-level visual features of the stimuli might account for the differences in prediction accuracy. For example, it might be the case that the point information stimulus, which overall contains less visual information, is harder to visually track, and this may manifest as decreased prediction accuracy. However, this could account for the differences in synchronisation accuracy, then this difference should be present in both the experienced and the naïve groups. This was not the case; therefore, the results are not consistent with an explanation based on low-level visual features.

The finding that limb and joint information was able to enhance synchronisation accuracy is also consistent with what is known about the mirror-neuron system, the putative substrate of the action prediction system (Csibra, 2008; Wilson \& Knoblich, 2005). Studies by Buccino and colleagues (e.g., Buccino et al., 2004) have shown that during action observation, regions of the motor cortex are activated in a somatatopic fashion. That is, certain regions show specificity for particular effectors in a manner similar to Penfield's (1954) motor homunculus.

\section*{The effect of motor experience}

A secondary aim of the present study was to examine what influence motor experience would have on prediction accuracy. The results show that motor experience modulated the effect that stimulus type had on prediction performance. In addition, motor experience had an effect on how participants performed the task. In particular, these data show that while the timing error for experienced participants was not affected by the serial position of the peak, the timing error for naïve participants varied according to peak number, and the tim-
ing error for the small peaks was significantly different to the timing error for large peaks.

A pattern of fluctuations would arise if participants kept a relatively steady pace throughout the trial because the spacing of the peaks was not constant throughout the trial, but instead changed according to the height of the peaks. A relatively steady pace for button-presses might occur if participants responded to the global properties of the stimuli, such as the average rhythm (that is, the pace of movement production), or to the general stimulus dynamics. In order to maintain a relatively constant timing error, as seen in the experienced group, participants would need to adjust the timing of each button-press according to the local timing variations in the stimuli that result from the alternating heights of the peaks. This pattern of data, therefore, suggests a global/local bias in stimulus processing that is modulated by motor experience.

The effect of motor experience on processing visual stimuli has recently been noted in several studies. For example, Casile and Giese (2006) have shown that motor training enhances a participant's ability to make a fine-grained visual discrimination of action. In their study, participants were asked to make same/different judgments about gait patterns that they either did or did not have motor experience with. The results showed that participants performed significantly better for trained, or familiar, gait patterns compared with unfamiliar gait patterns, suggesting that in order to make fine-grained visual judgments about the kinematics of an action, observers need to have an internalised model of the action. Similarly, Calvo-Merino, Ehrenberg, Leung, and Haggard (2010) found superior performance on a visual discrimination task of dance moves when those dance moves were part of the observers action repertoire compared with dancers who only had visual experience with the dance moves.

Our findings build on these earlier results, and suggest that observers with motor experience for the observed action are also better able to make fine-grained predictions about the dynamics of a stimulus. This result is consistent with the notion that experienced observers generate predictions about observed actions by employing an internal model of that action that is acquired through motor experience. By mapping the observed action onto their internal model for that action they are better able to capture the fine-grained timing variations in the stimulus because their predictive model more completely captures the constraints specific to the effectors used to produce the action.

\section*{Motor experience modulates stimulus effects}

We have argued that participants with motor experience are more sensitive to the fine-grained timing differences present in an action because they, unlike naïve observers, employ an internalised model of the observed action in order to generate their predictions. This might also help to explain why the influence of limb and joint information was restricted to the group with motor experience. Several neuroimaging studies have shown experience-related differences in motor system activation when observers view actions performed by other
people. For example, Calvo-Merino, Glaser, Grézes, Passingham, and Haggard (2005) asked expert dancers and nondancer controls to view videos of dancers performing in one of two styles (ballet or capoeira). The results showed that activation in motor regions was greater when dancers viewed performers of their own style, suggesting that the motor system is preferentially engaged when observing actions that are familiar. A follow-up study (Calvo-Merino, Grézes, Glaser, Passingham, \& Haggard, 2006), using male and female ballet dancers extended this finding by showing that motor regions were preferentially activated when viewing gender-specific dance moves. As both male and female dancers presumably have equal visual experience with opposite gender dance moves, but different motor experience, this finding suggests that motor engagement with visually presented stimuli is selective for actions for which observers have specific motor familiarity over and above the effects of visual familiarity.

Studies by Schubotz and colleagues (for a review, see Schubotz, 2007) have also implicated premotor regions in prediction of abstract stimuli and in sequence prediction in general. These stimuli cannot be mapped onto the observer's body and, therefore, they might rather be predicted by using a predictive model that exploits the dynamics of an effector that most closely matches the dynamics of the stimulus. Similarly, differences in motor system activation related to motor experience might suggest that inexperienced observers employ general predictive mechanisms, such as those used for sequence prediction, even when the observed action can, at least in principle, be mapped onto their body in an isomorphic, or part-by-part, manner. The addition of limb and joint information was designed to assist the process of mapping the observed action onto the observer's body; however, if, as the neuroimaging data cited above suggests, naïve observers less readily map the observed action onto their body in an isomorphic manner, then providing information to assist this process should provide no additional benefit. This is indeed what was found in the present study.

\title{
Models of Human Category Learning: Do They Generalize?
}

\begin{abstract}
Generalization to new examples is an essential aspect of categorization. However, recent category learning research has not focused on how people generalize their category knowledge. Taking generalization to be a critical basis for evaluating formal models of category learning, we employed a 'minimal case' approach to begin a systematic investigation of generalization. Human participants received supervised training on a two-way artificial classification task based on two dimensions that were each perfect predictors. Learners were then asked to classify new examples sampled from the stimulus space. Most participants based their judgments on one or the other dimension. Varying the relative levels of dimension salience influenced generalization outcomes, but varying category size ( 2,4 , or 8 items) did not. We fit two theoretically distinct similarity-based models (ALCOVE and DIVA) to aggregate learning data and tested on the generalization set. Both models could explain important aspects of human performance, but DIVA produced a superior overall account.
\end{abstract}

Keywords: generalization; categorization; formal models of category learning; similarity; cognitive modeling.

\section*{Introduction}

Categorization is an essential cognitive function categories serve to organize knowledge and, critically, as a basis for extending knowledge to make sense of new experience. A full understanding of human categorization depends on developing models and theories that account for systematic patterns of human learning and generalization performance (for an overview of generalization, see Levering \& Kurtz, 2010).

In classic research, Roger Shepard \((1957,1987)\) put forth the idea of a universal law in which stimulus generalization follows an exponential function of distance in psychological space. This work has had broad implications for theoretical models of categorization. Highly influential reference point models (such as the exemplar view) compute classification in a manner that closely follows Shepard's proposal. Specifically, the class membership of a known item is likely to be generalized to a new item if the two items are highly similar. The key additional design feature needed to account for human classification performance is the inclusion of a selective attention mechanism such that particular dimensions can matter more or less in the computation of similarity. Generalization performance (classification of previously unseen items) has been one of the most important important testing grounds in the debate between exemplar- and prototype-based accounts
(e.g., Homa, 1984; Nosofsky, 1992; see also Medin \& Schaffer, 1978 and the ensuing literature on behavioral experimentation and model-fitting with the 5-4 classification problem).

In a somewhat different approach to studying the generalization of category knowledge, researchers have investigated whether exemplar models can account for rulelike generalization after category learning (Erikson \& Kruschke, 1998, 2002; Nosofsky \& Johansen, 2000). In these studies, participants were asked to classify novel instances after learning an artificial two-way classification based on a unidimensional rule with exceptions. The critical test items were highly similar to the exceptions, but clearly classifiable using the rule. The outcomes of these studies were somewhat mixed and appear to depend on stimulus attributes and also on the structure of the categories that are learned.

The goal of the present research is two-fold: 1) to explore a different approach to investigating the psychology of category generalization; and 2) to use generalization performance as a basis to compare and differentiate models that are highly successful in fitting human learning data. Toward the first goal, our experimental approach is broadly comparable to the psychological studies of generalization discussed above: after a learning phase, participants are asked to classify novel examples. However, our work differs in that we use minimal category learning conditions (small numbers of examples that are readily assigned to two fully coherent classes). Our primary aim is to identify basic, systematic properties of generalization performance.

Regarding the second goal, the field presently offers a small group of formal models of category learning that are general purpose (applicable to any classification problem), that provide explanation at the level of process/mechanism, and that yield good fits to established benchmarks for human category learning. Within the realm of fitting human classification learning performance, there is some sense of having hit the ceiling in terms of differentiating among these models despite their having distinct explanatory elements. Our rationale is that models that do quite well in fitting learning data may diverge in their ability to account for patterns of generalization performance. In particular we are compelled by the prospect of fitting model parameters to the learning data and then holding the models to these values in evaluating ensuing generalization (as discussed below). Toward this end, we evaluate two successful models: a canonical representative of the reference point approach, ALCOVE (Kruschke, 1992) and an updated
version of a competing theoretical alternative, DIVA (Kurtz, 2007).

ALCOVE. ALCOVE is an exemplar based adaptive network model. According to the model, categories are represented by individual exemplars stored in memory. ALCOVE learns to classify by adjusting association weights between exemplar nodes and category nodes, as well as by adjusting a set of attention weights that determine the importance of each stimulus dimension.

DIVA. DIVA offers a more generative than discriminative approach to classification learning and deals in distributed rather that localist internal represenations. Learning to classify examples is accomplished by minimizing reconstructive error along the channels of a divergent autoencoder that is comprised of recoding (input \(\rightarrow\) hidden) weights shared for all categories and separate sets of decoding (hidden \(\rightarrow\) output) weights dedicated to each category. Classification judgments are based on which category channel yields the lowest error, i.e., which channel has been tuned to expect (and successfully reconstruct) a set of features like those of the current item.

DIVA is similarity-based in the sense that the model learns, for each category, how to effectively predict feature values for particular regions in recoding space - when an input item projects into a region that is well handled by a category, the reconstructive error in predicting the features will be low. DIVA does not apply Shepard-like stimulus generalization to categorization - an item is likely to belong to a category because its feature values conform to what a category channel has been optimized to successfully recode and decode, not because it is highly similar to a known member of the category.

Our approach to model comparison. We compare models based on their ability to account for human generalization after category learning. An important advantage of focusing on generalization performance is that we avoid the traditional reliance on post-hoc fits. In all cases, we first fit DIVA and ALCOVE to averaged learning data from each condition in order to find best-fitting parameters across the full set of conditions. This procedure allows us to separate out the parameter fitting process, so that the generalization performance is genuinely a prediction based on a selected model.

We elected to fit ALCOVE using a grid search over its response mapping ( \(\phi\) ), specificity constant (c), association weight learning rate, and attention learning rate parameters. We also fit DIVA using a grid search over the parameters: learning rate, weight range, number of hidden nodes, and a new focusing parameter ( \(\beta\) ) that gives DIVA the ability to account for sensitivity to differences in dimension diagnosticity (Kurtz, 2008).

DIVA's focusing parameter ( \(\beta\) ) allows it to selectively attend to stimulus dimensions based on the disparity in the output activations for that dimension across category channels. DIVA's focusing mechanism differs significantly from selective attention in ALCOVE in that it does not change the encoding of the stimulus or manipulate the representation learned by the model. DIVA's form of focusing is decisional, rather than perceptual or representational in nature, as it operates at the level of the classification response.

\section*{Experiment 1}

This experiment was designed to explore generalization under two conditions: when all stimulus dimensions are diagnostic and equally salient; and when all dimensions are diagnostic, but unequally salient. Figure 1 depicts the two category structures.

Stimulus scaling is an important aspect of our salience manipulation. In order to determine the relation between the stimulus dimensions, we scale the examples in a pairwise similarity study. The similarity study generates a full set of scaled examples, which allows us to manipulate the distance between examples on any dimension. The salience of a dimension can be specified by the distance between the categories on that dimension.

In a pilot study, we explored an extreme case of classification learning in which both stimulus dimensions were diagnostic, but one dimension was much less salient. Participants were generally insensitive to variation in the less salient dimension. In light of these findings, we expected that generalization gradients would show sensitivity given a relatively moderate difference in dimension salience.

Participants and Materials. 108 undergraduates from Binghamton University participated in partial fulfillment of a course requirement. Stimuli were rectangles varying in shading and the distance between two lines within the rectangle. Examples were generated at 8 positions on each dimension ( 8 shading \(* 8\) line spacing \(=64\) examples). The category structures are depicted in Figure 1 along with sample stimuli.

Procedure. Participants were randomly assigned to either the equal salience group or the unequal salience group. In the equal salience condition, the category prototypes were separated by distances of 0.64 and 0.54 on the first and second dimensions (shading and line spacing), respectively. In the unequal salience condition, the category prototypes were separated by a distance of 0.65 and 0.34 on the first and second dimensions. In each condition, there were 4 training examples in each of the two categories.

Figure 1: Top: Four examples of stimuli (taken from the corners of the stimulus space). Bottom left \& center: Category structures with equally and unequally salient dimensions. Bottom right: Test set used for Experiments 1 and 2. Note that all training items are included in the test set. Positions of examples reflect prior scaling.

Each participant completed 32 learning trials. On each trial, a training item was presented on the computer screen and participants were prompted to make a classification decision by clicking one of two buttons (labeled 'Alpha' and 'Beta'). After responding, participants were given corrective feedback on their response. In the test phase, participants classified the 64 examples sampled across the stimulus space (test set depicted in Figure 1). The 8 training items were also presented during the test phase.

Gradient Analysis. In the test phase, participants provide data that yield a generalization gradient of their classification responses. For each participant, we calculated the standard deviation of classification responses at 8 positions on each dimension of the gradient. We then estimated sensitivity to each dimension by calculating the mean of these 8 values. Insensitivity to a dimension is indicated by uniformity of classification responses across that dimension.

Results and Discussion. 24 participants were excluded
from the subsequent analyses for failing to correctly classify 7 out of 8 training items presented during the test phase. The remaining participants were more than \(96 \%\) accurate during the last training block in both conditions.

There were significant individual differences in the generalization data. A k-means analysis revealed three profiles based on the sensitivity estimates described above: these were unidimensional generalization based on either one or the other stimulus dimension (shading or spacing) and multidimensional generalization based on both dimensions. We compared the k-means findings across salience conditions (results are shown in Figure 2).

While a very few participants were sensitive to both dimensions at test, the majority of participants generalized undimensionally. A Fisher's Exact test revealed that the rate of each unidimensional profile differed between salience conditions ( \(p<.001\) ). Participants in the unequal salience condition were more likely to be sensitive to the salient dimension (shading) than participants in the equal salience condition.

We observed a bias towards the line spacing dimension in the equal salience group that is not consistent with the scaling. Interestingly, this may reflect a task difference between pairwise similarity and classification learning that renders participants differentially sensitive to our stimulus dimensions.

The main conclusions we can draw from this study of a 'minimal case' category structure are that: 1) participants tended to generalize according to a single dimension despite an optimal diagonal bound; and 2) dimension salience increased the likelihood of the dimension serving as the basis for generalization.

Modeling Analyses. We tested DIVA and ALCOVE for their ability to account for these generalization findings. Specifically, we sought to determine whether the models could account for: (1) the tendency of learners to generalize based on a single dimension; (2) the substantial degree of selection of each of the two dimension as the focal one by different sets of learners; and (3) the effect of salience on dimensional sensitivity.

Before generating predictions for generalization, we obtained optimal parameter sets by fitting the models to the aggregate learning data (minimizing the sum of squared deviations, SSD, across learning blocks). We then generated predictions for generalization across a range of optimal

parameter sets to gain a full understanding of how the two models performed.

Figure 2: Results of k -means clustering results for Experiment 1. Number of participants shown below each chart.

Both ALCOVE and DIVA provided good fits to the learning data under a range of parameters. The best fitting parameter sets are shown in Table 1. When we tested the models on generalization using these parameters, we found that both models were sensitive to the salience of each dimension, but neither predicted the unexpected bias toward the line spacing dimension that was observed behaviorally.

ALCOVE's attention learning parameter largely governed the model's ability to generalize to a single dimension. ALCOVE produced unidimensional gradients with high levels of attention learning and multidimensional gradients with low levels of attention learning. Given a high attention learning parameter, ALCOVE generalized based on whichever dimension was most salient. We note that ALCOVE lacks any random element such as initial weight values, so the output is deterministic; for this reason, the model does not account for the heavy use of both possible unidimensional rules in the generalization data. Future research will explore generalization using a stochastic version of ALCOVE.

Similar to ALCOVE's use of attention, DIVA's focusing parameter allowed the model to generate either unidimensional or multidimensional gradients. But unlike ALCOVE, DIVA is initialized with random weights on every run. An analysis of results on individual runs revealed that when DIVA's focusing parameter was large and the dimensions were equally salient, the random initial weights sometimes lead to unidimensional generalization based on
either dimension. With larger weight ranges, DIVA produced varied distributions of generalization profiles.

Our analysis of DIVA's generalization also revealed that, with a high focusing parameter, the model is more likely to generalize based on a salient dimension than a less salient dimension. This trend resembles the effect of salience that was observed previously. When the dimensions are equally salient, DIVA tends to produce multidimensional profiles at a greater rate than would be predicted given our behavioral findings.

Figure 3: Category structures for Experiment 2.
These modeling results confirm that generalization provides a promising basis for model evaluation. We found that DIVA and ALCOVE produce generalization gradients that are consistent with the salience of each dimension, and that attentional mechanisms allow similarity-based models to generate unidimensional gradients. Furthermore, a random component can partially explain variability in dimensional selection.

\section*{Experiment 2}

This study was designed to replicate and extend Experiment 1. As in the first study, we manipulated the salience of dimensions by modifying the distance between the two categories. We extend the design by incorporating category size as a between-participants facto (Figure 3 depicts the category structures that were employed). Category size is a potentially interesting factor in our studies because increasing the number of examples in each category also increases variation in representational demands for exemplar models like ALCOVE without altering the solution that the model is required to find. Furthermore, increases in category size should decrease the memorizability of each example (see Homa, 1984 for background on category size effects).

Our primary predictions were that: (1) generalization after learning would reflect sensitivity to a salient
dimension; and (2) shifts in category size would impact the prevalence of integrated, multidimensional generalization.

Table 2: Distance between opposite-category prototypes on each dimension.
\begin{tabular}{|l|l|l|l|l|}
\multicolumn{1}{c}{} & \multicolumn{2}{c}{ Equal Salience } & \multicolumn{2}{c}{ Unequal Salience } \\
\cline { 2 - 5 } \multicolumn{1}{c}{} & Shading & Spacing & Shading & Spacing \\
\hline 2 eg & 0.70 & 0.55 & 0.72 & 0.34 \\
4 eg & 0.67 & 0.55 & 0.69 & 0.34 \\
8 eg & 0.64 & 0.54 & 0.65 & 0.34 \\
\hline
\end{tabular}

Participants and Materials. 228 undergraduates from Binghamton University participated in this experiment toward partially fulfillment of a course requirement. The materials were like those used in Experiment 1.

Procedure. Participants were randomly assigned to one of six conditions ( 2 levels of salience x 3 levels of category size). The category structures are depicted in Figure 3. Participants learned a classification based on two, four, or eight unique examples per category.

Figure 4: Experiment 2 k -means clustering results. Number of participants shown below each chart.

The salience manipulation was similar to that used in Experiment 1 with one departure - we partially re-arranged the members of the second category so that the category prototypes would more evenly spaced apart in the equal salient condition. The distances between prototypes for each condition are shown in Table 2. All other aspects of the procedure are identical to Experiment 1.

Results and Discussion. 56 participants were excluded from subsequent analyses because they made more than one error on training items presented during the test phase. The remaining participants were more than \(94 \%\) accurate during the last training block.

The analysis of the generalization data was conducted as in the first study. Results are displayed in Figure 4. The data do not reveal an effect of category size on generalization. Consequently, our discussion focuses on the salience manipulation across category size conditions.

As in Experiment 1, the majority of participants generalized to a single dimension. A Fishers Exact test (conducted across size groups) reveals a significant effect of salience ( \(p<.01\) ). Participants in the unequal salience group tended to generalize using the salient dimension over the less salient dimension.

We observed the same bias towards the line spacing dimension in the equal salience conditions: our participants were highly sensitive to the line spacing dimension, even when the scaling revealed that the dimensions were equally salient.

Modeling Analyses. We again tested DIVA and ALCOVE on their ability to match human generalization performance. In general, the modeling results for Experiment 2 parallel the results of Experiment 1. Both models found good fits to the aggregate learning data, but neither model predicted the unexpected bias towards the line spacing dimension during generalization. Neither model was affected by our category size manipulation. Parameter information can be found in Table 1.

As in Experiment 1, ALCOVE's attention learning parameter allowed it to account for unidimensional generalization. Given a high attention learning parameter, ALCOVE generalized based on whichever dimension is most salient. But due to the lack of a random component, ALCOVE could not account for the use of either single dimension.

As was the case for attention learning in ALCOVE, DIVA's focusing parameter allowed it to account for unidimensional generalization. Replicating our findings from Experiment 1, we found that when DIVA's focusing parameter was large and the dimensions were equally salient, the random initial weights lead to a distribution of generalization profiles based on either or both dimensions. With larger initial weight ranges, DIVA produced more varied patterns of generalization.

The distributions produced by DIVA reflected the salience of the stimulus dimensions. Specifically, DIVA was more likely to generalize using a salient dimension than a less salient dimension. This trend is similar to the effect of salience that we observed behaviorally. Lastly, as in Experiment 1, DIVA tended to produce more multidimensional profiles when the dimensions were equally salient.

\section*{General Discussion}

Our behavioral results revealed that: (1) category knowledge tends to be generalized based on a single dimension; and (2) the salience of a dimension affects the probability that it is selected. We compared DIVA and ALCOVE on their ability to account for these findings. We learned that these similarity-based models are sensitive to salience differences between dimensions and can use attention to generate unidimensional gradients. We also found that a random component can help predict arbitrary dimension selection: DIVA's initial weights randomly offset the models salience appraisal and allowed it to generalize to a single dimension.

These results help to establish generalization as an important basis for formal model evaluation. By requiring that models account for generalization and learning based on the same parameter fits, we systematically widen the scope of what models are held accountable for explaining. In our work, generalization proved not only to be area where DIVA and ALCOVE made different predictions, but it also provided an opportunity to reduce our reliance on post-hoc fits by searching for parameters using aggregate learning data. In future work, we plan to conduct simulations using a stochastic modification of ALCOVE in order to determine how well the model matches our distributions of human generalization performance. We also plan to conduct new simulations based on fitting the models to individual learning curves rather than aggregate data.

\begin{abstract}
In this paper, we examine the impact of three learning activities designed to foster more robust learning in a Genetics Cognitive Tutor module on pedigree analysis problem solving, in an experimental study. The three activities are (1) interleaved worked examples with student explanations; (2) enhanced feedback with tutor-provided explanations of problem solving steps; and (3) explicit scaffolding of the reasoning steps in this abductive proc-ess-of-elimination reasoning task. The study included four between-subject conditions, a baseline condition in which students exclusively solved standard problems, and three conditions in which students engaged in one of the new learning activities along with standard problem solving. The scaffolded-reasoning condition was most successful in fostering robust learning, as measured by transfer, retention, and preparation for future learning tests. The enhanced feedback condition, in contrast, yielded the poorest performance on the robust learning measures.
\end{abstract}

Keywords: Education; Problem solving; Robust Learning; Intelligent Tutors.

\section*{Introduction}

Problem solving is an essential learning activity across STEM domains. Successful problem solving results in "robust" knowledge: knowledge that is well-grounded in domain knowledge, and as a consequence, is wellretained by students, transfers more readily to related problem situations and prepares students for more successful future learning (Koedinger, Corbett \& Perfetti, 2012). One of the well-documented risks in problem solving, across STEM domains, is that students can develop superficial knowledge that fails these tests of robust learning. In particular, when students are not well-prepared for problem solving, they can develop problem solving knowledge which focuses on surface elements in problem situations, formal representations, and features of the learning environment itself (Chang, Koedinger \& Lovett, 2003; Chi, Feltovich \& Glaser, 1981; Rittle-Johnson \& Siegler, 1998).

In this paper we examine how to structure problem solving in an intelligent tutoring system to support robust learning in the domain of genetics. Because of its foundational place in the biological sciences, genetics is a large and growing component of high school biology courses, but it is also viewed as one of the hardest topics in biology by both students and instructors, at the secondary and at the post-secondary level (Tsui \& Treagust, 2006). Genetics problem solving is characterized by abductive reasoning. In contrast with deductive hypothesis testing, abductive reasoning starts with a set of observations and reasons backwards to infer properties of the genetic processes that produced the data (e.g., whether a trait is dominant or recessive).

In this paper, we study these issues within a tutor lesson for pedigree analysis in the Genetics Cognitive Tutor (Corbett, Kauffman, MacLaren, Wagner \& Jones, 2010), which has been successfully piloted in both high school and college classrooms. Pedigree analysis relies on a complex reasoning process, which nonetheless lends itself to straightforward natural language description. This study examines whether robust learning is supported by a scaffolded reasoning activity prior to conventional problem solving, or by incorporating explicit explanations during problem solving.

\section*{The Domain: Pedigree Analysis}

Basic pedigree analysis problems pose an interesting challenge both for students and for an intelligent tutoring system. Figure 1 displays a typical pedigree analysis problem, in the Genetics Cognitive Tutor (GCT). This pedigree chart displays four generations in a small family. Females are represented as circles and males as squares. In this family, the founding parents have a daughter affected by a rare genetic trait, as represented by the dark circle. No other family members are affected. The student's task is to determine whether this genetic trait is dominant or recessive, and whether it is X-linked, or transmitted on one of the twenty-two autosomal chromosomes in humans.

Figure 1. The GCT Interface for Pedigree Analysis.
This appears to be a reasonably simple task; the features of the problem representation are readily interpretable and there are only two problem-solving actions, but the task involves complex abductive reasoning. It requires students to employ their knowledge of genetic transmission to reason by process of elimination. For example, the student can eliminate the possibility that this is a dominant trait, because the daughter must inherit the trait from one or both parents, and if the trait were dominant the parent(s) who have the trait allele would be affected.

This is also an atypical and challenging task for an intelligent tutoring system to effectively support. The task involves a complex multi-step reasoning process, but since there are just two solution steps, there are no natural opportunities (that is, no behavioral correlates of intermediate reasoning steps) for the tutor to provide assistance in the form of feedback and advice along the way. Instead, the task is subject to shallow learning, since students can readily memorize conclusions, (e.g., when an affected daughter has unaffected parents, the trait must be autosomal recessive), without any understanding of the underlying genetics that supports the conclusion. Finally, the task is subject to gaming the system (Baker, Corbett, Koedinger \& Wagner, 2004), since each solution step consists of a menu with only three alternatives - "dominant," "recessive," or "cannot be determined," in one case, and "autosomal," "Xlinked," or "cannot be determined in the other case." Unmotivated students can readily click through the menu options to find correct answers.

Summative evaluations of Genetics Cognitive Tutor modules are consistent with these risks; pretestposttest learning gains for basic pedigree analysis are only about half as large as the average gain across all topics (Corbett, et al, 2010).

\section*{Pedigree Analysis Learning Activities}

In this study we developed and evaluated three Cognitive Tutor activities intended to support robust learning in pedigree analysis problem solving. Two activities integrate explicit reasoning explanations into the conventional problem-solving task - worked examples, in which the student explains tutor-generated problem solutions, and enhanced feedback, in which the tutor provides explanations for student problem-solving steps. The third activity, in contrast, explicitly scaffolds the intermediate steps in this abductive process-of-
elimination task and is designed to precede conventional problem solving. As in Cognitive Tutors more generally (Anderson, Corbett, Koedinger \& Pelletier, 1995), in these activities, students receive immediate accuracy feedback on each problem-solving step and can request hints on any problem-solving step.

Interleaved Worked Examples It is well-documented that integrating worked examples with problem solving serves to decrease total learning time and yields improved learning outcomes (Pashler, Bain, Bottge, Graesser, Koedinger, McDaniel \& Metcalfe, 2007; Renkl \& Atkinson, 2003; Sweller \& Cooper, 1985). Recently, several studies have examined the benefits of incorporating worked examples into intelligent tutoring systems (ITSs) for problem solving across a variety of math and science domains, including topics in algebra, geometry, statistics, biology, chemistry and physics (Anthony, 2008; Conati \& VanLehn, 2000; Corbett, MacLaren, Wagner, Kauffman, Mitchell, Baker \& Gowda, 2011; Mclaren, Lim \& Koedinger, 2008; Reed, Corbett, Hoffman, Wagner \& MacLaren, 2013; Salden, Aleven, Schwonke \& Renkl, 2010; Schwonke, Renkl, Krieg, Wittwer, Aleven \& Salden, 2009; Weitz, Salden, Kim \& Heffernan, 2010). In these ITS studies, the chief benefit of incorporating worked examples has been to reduce learning time for a fixed set of activities compared to problem solving alone, but unlike the classic worked-example literature, these ITS studies generally do not find that incorporating worked examples leads to more accurate posttest performance than problem solving alone. The exception is Salden, et. al (2010), which found that adaptively fading examples led to some relative improvement on posttest problem solving. Similarly, the evidence that students learn more deeply when worked examples are integrated into ITSs is mixed at best, although Anthony (2008) and Salden, et al (2010) report better retention of problem solving knowledge and Schwonke, et al (2009) found some evidence of greater conceptual transfer in one of two studies.

Pedigree analysis is a promising domain in which to further explore worked examples, since each step in problem solving depends on a complex, but readily describable reasoning process. Figure 2 displays the worked example interface. Each worked example displays a standard pedigree analysis problem and displays the correct dominance and linkage of the trait directly below the pedigree. These examples also identify a key nuclear family in the pedigree and describe the pattern of affected and unaffected individuals in the family that allows the student to identify the dominance and linkage of the trait. Students select entries in the three menus at the bottom of the screen to explain how to determine the dominance and linkage from the pattern, based on their knowledge of genetics transmission.

Feature Focusing We developed a contrasting activity in which the student generates problem solutions and the tutor provides explanations of the student's correct actions, to directly address two characteristics of basic

Figure. 2. The GCT Interface at the conclusion of a pedigree analysis worked example.
pedigree analysis. The first is that the tell-tale patterns can be hard to identify. For instance, Figure 3 displays two pedigrees, which look similar, each with four affected males, but the trait on the left is autosomal dominant, while the trait on the right is X -linked recessive.

Figure 3. An autosomal dominant pedigree (left) and an X -linked recessive pedigree (right).

The second challenge is that the immediate accuracy feedback generally delivered by Cognitive Tutors (cf. Anderson et al., 1995), is not all that informative in this lesson, since there is a reasonably high probability that the student performed the right action for the wrong reason. Debriefing sessions revealed that students in high school classrooms are aware of the latter risk, and sometimes would like to receive an explanation after selecting a correct menu entry, rather than a hint before.

To address these problems, we developed an enhanced feedback interface displayed in Figure 4. The pedigree is initially displayed entirely in black and without any explanatory text. Following each of the two problem-solving steps, the tutor highlights the relevant pattern in the figure, and provides an explanation. In this example, after the student concluded that the trait is recessive, (1) the relevant pattern was highlighted in green, (2) the conclusion was summarized at the top of the screen in green, and (3) an explanation of the conclusion was displayed in green in the window to the right. After the student concluded that the trait is Xlinked, the relevant pattern remained highlighted in green, the prior dominance conclusion and explanation were grayed out, the linkage conclusion was summarized in green near the figure, and the linkage explanation was presented in green in the adjoining window.

Figure 4. The GCT interface at the end of a pedigree analysis problem with enhanced feedback.

Abductive Reasoning Scaffolds Finally, we developed a problem-solving activity that directly engages students in the reasoning-by-process-of-elimination task. While the other two interventions were integrated with conventional problem solving, this is a separate task that was designed to precede conventional problem solving. Each problem in this task presents the phenotypes of three family members, two parents and a child, as displayed in Figure 5. Immediately to the right, the four possible modes of transmission are listed (autosomal dominant, X-linked dominant, autosomal recessive and X-linked recessive). For each of the four modes, the student enters what the underlying genotype of each of the three family members would have to be, given their respective phenotypes, and under the mode of transmission. (For example, if the trait were autosomal dominant, the two unaffected parents would have to be homozygous recessive, while the affected daughter would have to have a dominant allele.) Then to the far right, the student indicates whether the observed pattern of phenotypes is possible under each mode of transmission, that is, whether the child could inherit its genotype from its parents. (The observed pattern in Figure 5 is impossible for an autosomal dominant trait, since neither parent has a dominant allele to transmit to the daughter.) Finally, at the bottom of the screen the student summarizes which modes of transmission are possible for the observed phenotype pattern.

Figure 5. The GCT Pedigree Analysis Scaffolded Reasoning task at the end of a problem.

This study includes four between-subject conditions and evaluates the success of each of these three interventions in supporting the acquisition of problem-solving skills, and robust learning, compared to standard problem solving.

\section*{Method}

\section*{Participants}

Sixty-four high school students enrolled in high school biology courses were recruited through newspaper ads and classroom handouts to participate in this study for pay. Students were randomly assigned to one of four between-subject treatment groups.

\section*{Procedure}

Students participated in two 2.5 -hour sessions on consecutive days in a CMU computer lab. In Session 1, students:
- viewed an instructional video and read instructional text on basic pedigree analysis;
- completed a conceptual knowledge pretest and a basic problem-solving pretest;
- completed basic pedigree analysis Cognitive Tutor activities, which differed by condition;
- completed a basic problem-solving test and a transfer problem-solving test.

The second session was devoted to an extended preparation for future learning (PFL) activity, as well as a delayed basic problem-solving test. The PFL task was an advanced carrier-probability pedigree analysis task. Each problem in the task displays a large pedigree chart with five or six generations and students calculate the probabilities that various unaffected individuals in the chart carry a single recessive trait allele. Students:
- read instructional text on carrier probabilities pedigree analysis;
- completed an initial PFL paper-and-pencil test
- completed PFL Cognitive Tutor problems;
- completed a second PFL paper-and-pencil posttest;
- completed a delayed basic problem-solving test

\section*{Design}

There were four between-subject conditions in the study, defined by students’ Cognitive Tutor learning activities in the first session.
- Basic Problem Solving (PS): Students completed a set of 78 basic pedigree analysis problems.
- Enhanced Feedback (EF): Students completed the same 78 problems as in the PS group, but completed the first 20 with enhanced feedback.
- Interleaved Worked Examples (WE): Students completed a problem set with 14 interleaved worked
examples and problems to solve, followed by 18 standard problems.
- Scaffolded Abductive Reasoning (SR): Students completed six problems in which the abductive reasoning process was explicitly scaffolded as described above, followed by a set of 18 standard problems.

In Session 2, all students completed the same set of activities focused primarily on the PFL task.

\section*{Tests}

We developed four types of paper-and-pencil tests for the study:
- Problem Solving Tests: Three forms were developed. Each form served as the pretest for \(1 / 3\) of the students in each condition, the session-1 posttest for \(1 / 3\) of the students, and the session-2 delayed test for \(1 / 3\) of the students.
- Conceptual Knowledge Tests: A conceptual knowledge pretest was developed to evaluate students' knowledge of genetic transmission.
- Transfer Tests: A transfer test was developed with two types of problems: one type asked students to solve basic pedigree analysis problems with novel patterns requiring novel reasoning; a second asked students to identify whether family pedigrees were possible or impossible under the four modes of transmission.
- Preparation for Future Learning (PFL): Two forms of a PFL problem-solving test were developed. Each form served as the initial test for \(1 / 2\) of the students in each condition, and as the second test for \(1 / 2\) of the students.

\section*{Results}

Table 1 displays mean accuracy (percent correct) for the tests administered in the study. The conceptual knowledge (CK) and problem solving (PS1) pretests are displayed to the left, followed by the problem solving posttest (PS2) and the problem-solving learning gain from pretest to posttest (PS2-PS1).

The four robust learning tests follow, including the transfer test (TR); the initial PFL test (PFL1), which preceded the session-2 PFL tutor problems; the second PFL test (PFL2), which followed the GCT PFL problems; and finally the delayed basic problem-solving test (PS3). The final column displays students' change in basic problem-solving accuracy over the retention interval (PS3 - PS2).

Table 1: Student test accuracy (percent correct).
\begin{tabular}{cccccccccc}
\hline & & & \multicolumn{4}{c}{ PS } \\
Cond & CK & PS1 & PS2 & Gain & TR & PFL1 & PFL2 & PS3 & \begin{tabular}{c} 
retention \\
change
\end{tabular} \\
& \(\% \mathrm{C}\) & \(\% \mathrm{C}\) & \(\% \mathrm{C}\) & PS2-PS1 & \(\% \mathrm{C}\) & \(\% \mathrm{C}\) & \(\% \mathrm{C}\) & \(\% \mathrm{C}\) & PS3-PS2 \\
\hline SR & 92 & 47 & 47 & 0 & 54 & 36 & 60 & 53 & 6 \\
EF & 86 & 41 & 53 & 12 & 44 & 19 & 40 & 49 & -4 \\
PS & 91 & 43 & 48 & 5 & 47 & 34 & 52 & 48 & 0 \\
WE & 92 & 49 & 56 & 7 & 46 & 31 & 61 & 50 & -6 \\
\hline
\end{tabular}

Average scores on the Conceptual Knowledge pretest (CK) were quite high, averaging about \(90 \%\) correct, indicating that students were very familiar with the transmission genetics underlying pedigree analysis. An ANOVA revealed no significant difference among the four conditions on this pretest, \(\mathrm{F}(3,60)=1.33\), ns.

Average scores on the Problem Solving pretest (PS1) were much lower, averaging \(45 \%\) correct. Again, an ANOVA revealed no significant difference among the four conditions on this pretest, \(\mathrm{F}(3,60)=1.31\), ns.

\section*{Pedigree Analysis Posttest Performance}

We performed an ANOVA on the five paper-andpencil posttest measures of student learning, including the Problem Solving posttest (PS2), and the four robust learning measures: the Transfer test (TR), the Preparation for Future Learning tests (PFL1 \& PFL2) and delayed Problem Solving test (PS3). The main effect of condition is not significant, \(\mathrm{F}(3,60)=1.26\), ns, but the interaction of condition and test type is significant \(F(12,240)=2.25, p<.01\). (The main effect of test type is also significant, \(\mathrm{F}(4,240)=28.59, \mathrm{p}<.001\), but not of particular interest.)

As can be seen in the table, the new enhanced feedback (EF) and scaffolded reasoning (SR) had contrasting impacts. The EF activities yielded the largest prob-lem-solving learning gain, but generally led to the lowest scores on the robust learning tests. In contrast, the new SR activities led to no discernible learning gains from PS1 to PS2, but generally led to the best performance on the robust learning tests.

Basic Problem Solving The new EF condition led to the largest problem-solving learning gains, while the new SR condition led to no discernible learning gains. However, in an ANOVA on the PS gain displayed in Table 1, the effect of condition was not significant, \(\mathrm{F}(3,60)=1.74, \mathrm{p}<.17\).

Robust Learning The SR condition generally outperformed the familiar PS and WE conditions, which in turn outperformed the EF condition on the robust learning measures. The difference is fairly pronounced on the transfer task, and in the retention change scores, where the SR condition is the only condition that displays a small increase in scores over the retention interval. We performed an ANOVA on the transfer test, two PFL tests and the retention change scores, and the effect of condition is significant, \(\mathrm{F}(3,60)=2.80, \mathrm{p}<.05\). The interaction of condition and test measure is not significant.

We performed an ANOVA on each of these four robust learning measures separately and condition was significant only for the retention change measure, \(\mathrm{F}(3,60)=3.41 . \mathrm{p}<.05\), where the SR group is the only one which shows any sign of improving on basic problem solving by virtue of completing the intervening Cognitive Tutor PFL task.

\section*{Tutor Performance}

Session 1 Total Time Table 2 displays the total time that the students in the four conditions spent on session1 GCT pedigree analysis learning activities. The ses-sion-1 tutor activities were designed to hold learning time constant. As can be seen, average time was reasonably constant across conditions, ranging from about 24 to about 27 minutes. We performed an ANOVA on session 1 time on task, and condition was not reliable, \(F(3,60)=0.74\), ns.

Table 2: Student performance on GCT activities in Session 1 and Session 2
\begin{tabular}{c|c|ccc}
\hline & Session 1 & \multicolumn{3}{|c}{ Session 2 (PFL GCT) } \\
Cond & Min. & Min. & \%C & \%hints \\
\hline SR & 27.4 & 25.4 & 58 & 19 \\
EF & 24.9 & 31.2 & 41 & 41 \\
PS & 26.0 & 26.6 & 49 & 32 \\
WE & 23.7 & 26.1 & 55 & 26 \\
\hline
\end{tabular}

Session 2 PFL Tutor Problems Student performance in the session-2 carrier probabilities GCT task provides an additional PFL measure with respect to the four ses-sion-1 learning activities. All students completed the same set of 14 carrier probability problems in the second session. Table 2 displays the average time to complete the problems, student accuracy (the percentage of problem-solving steps on which students' first action was correct), and help requests (the percentage of steps on which a student requested a tutor hint). The students in the SR condition were the most successful in session 2 , responding most accurately, while requiring the least time, and least assistance. In contrast, students in the EF condition performed least successfully on all three measures. In three ANOVAs, the main effect of condition is significant for accuracy, \(\mathrm{F}(3,60)=2.77, \mathrm{p}<.05\), and for hint requests, \(\mathrm{F}(3,60)=3.55, \mathrm{p}<.05\), but not significant for total time, \(F(3,60)=1.86\), ns.

\section*{Summary and Discussion}

Among the three new GCT tasks, the scaffolded reasoning task was the most successful in preparing students for more robust learning in problem solving. The SR combination of a scaffolded reasoning task, in conjunction with a single set of conventional problems, yielded the most robust understanding of pedigree analysis, as measured by transfer, preparation for future learning, and retention of problem-solving skill.

However, design work remains to be done, since the scaffolded reasoning task did not prepare students well for conventional problem solving. Despite their robust learning, students in this condition performed surprisingly poorly on the problem solving posttest, displaying no learning gains.

A more promising design may be to insert the worked example task between the scaffolded reasoning task and conventional unassisted problem solving, to provide students the opportunity to reflect on, and describe how to apply their abductive reasoning skills in
the full problem-solving task. While students in the WE condition did not perform discriminably better than students in the baseline PS condition across the board, there was at least a trend for the WE students to outperform the PS students on the PFL measures.

Finally, the newly designed enhanced-feedback problem solving condition was disappointing. There was a modest and non-significant trend for the EF condition to yield larger learning gains on the problem solving test, but the EF condition led to generally poorer performance on measures of robust learning, especially the PFL test and tutor activities. This may indicate that, to the extent there is a benefit of the enhanced feedback, students are learning to identify the key patterns in pedigrees and to associate them with the corresponding conclusions, but are not developing an understanding of the underlying reasoning. Again, inserting the interleaved worked example activity between the EF task and conventional problem solving might help students build more effectively on any benefits of the EF condition.

\title{
Dimensions of specificity in musical memory: Evidence from metrical restoration
}

\author{

}

\begin{abstract}
How is musical memory organized? While classic studies of music perception appealed to schematic or symbolic knowledge structures, recent work suggests that listeners form highly-detailed auditory representations of music. Studies of metrical restoration-memory fill-in of the "beat" of a metrically-ambiguous melody-suggest some organizing dimensions in musical memory. However, many potential dimensions remain unexplored. The current study looked for effects of mode (major vs. minor) - a substantial organizing force in Western music-and timbre (what instrument is playing) on metrical restoration. Both mode and timbre can signify particular musical styles. In Experiment 1, listeners showed timbre specificity in metrical restoration, but not mode specificity. However, in Experiment 2, when timbres were extremely unique (one per melody), restoration effects were not observed, suggesting that too much variability leads to diffuse representations which are too weak to support metrical restoration. Implications for the nature of musical memory are discussed.
\end{abstract}

Keywords: perceptual restoration, meter, music perception, metrical restoration

\section*{Introduction}

Recent research suggests that listeners form rich, detailed representations of perceptual information. These details later facilitate recognition (Creel, Aslin, \& Tanenhaus, 2008; Goldinger, 1998; Gjerdingen \& Perrott, 2008; Krumhansl, 2010; Schellenberg et al., 1999) and allow fill-in of ambiguous or absent information (Creel, 2011, 2012; Samuel, 1981). In music particularly, Creel (2011, 2012) has shown that listeners who hear particular metrical (or harmonic) information with a melody will later, upon hearing the melody alone, fill in the missing contextual information (harmony or meter) previously heard with that melody.

These findings are interesting in a number of respects. First, meter is a property previously thought to be largely signal-driven, with listeners extracting metrical regularities via statistical analysis of the signal itself. Creel's work suggests that memory influences meter perception. Second, these findings suggest that similarity-based organization of detailed auditory-temporal memories can support knowledge of distinct genres, such as different musical styles or different languages.

Yet many questions remain. What factors allow listeners to keep particular musical patterns distinct in memorywhat keeps them from bleeding together? Inversely, what factors allow listeners to generalize metrical information?

On first glance, a simple answer to both questions is degree of similarity: listeners generalize to similar musical patterns, and maintain specific representations of less-similar patterns. However, determining equivalent degrees of similarity on varied dimensions is not trivial, as perceivers' use of dimensions can change depending on task and attentional factors (Nosofsky, 1986). That is, we do not know what weights listeners assign to different dimensions in musical memory. Further, some dimensions may be processed integrally, such that their combined effect is not a simple sum of their individual effects. The current study aims to explore the relative strength of various auditorymusical properties on metrical restoration, providing insights into similarity-based organization in musical memory.

Figure 1. First four measures of a melody, in (a) major key with \(6 / 8\) metrical context; (b) minor key with \(3 / 4\) metrical context. Metrical grids indicate perceived emphasis in each meter: large X's denote strong beats, small x's weaker beats,
and .'s indicate the subdivision of each beat. Beat subdivisions are identical in duration in both versions.

\section*{Known influences on metrical restoration}

Previous work in my lab (Creel, 2011, 2012) has examined some factors in memory restoration of meter. In those experiments, as well as the new experiments described here,

I exploit the \(3 / 4-6 / 8\) ambiguity, a musical "ambiguous figure." Certain musical passages with repeating series of 6 sub-beats can be interpreted as being in \(3 / 4\) meter (beats alternating evenly with sub-beats, X . x . x .) or in \(6 / 8\) meter (each beat is followed by two sub-beats: X . . x . . ). Figure 1 shows examples of each meter.

In my experiments, each listener heard a set of 8-12 melodies. Half were presented in a musical context suggesting \(3 / 4\), and half in a context suggesting \(6 / 8\). Melodies were constructed to fit either metrical pattern, allowing a carefully counterbalanced design where, across listeners, each melody was heard in each meter equally often (Table 1). A listener heard each melody multiple times during an exposure phase. Next, all listeners heard each melody without its meter-implying context, followed by probe drumbeats in either \(3 / 4\) or \(6 / 8\). They were asked to rate how well the drumbeats fit with the preceding melody. The question was whether listeners would provide higher ratings for the drumbeats (meters) that matched the contexts that they had previously heard.

Table 1: Example conditions in a metrical restoration experiment. If listeners restore melodies' metrical contexts, then Listener 1 should provide higher probe ratings to the shaded probe trials, and Listener 2 should provide higher probe ratings to the unshaded probe trials.
\begin{tabular}{cccc}
\hline & \multicolumn{2}{c}{ Exposure phase } & Test phase \\
\hline \(\begin{array}{c}\text { Mel- } \\
\text { ody }\end{array}\) & Listener \(\mathbf{1}\) & Listener 2 & All listeners \\
\hline 1 & \(3 / 4\) context & \(6 / 8\) context & \(\begin{array}{c}\text { melody alone melody alone } \\
+3 / 4 \\
\text { melobe }\end{array}\) \\
2 & \(3 / 4\) context & \(6 / 8\) context \(\begin{array}{c}\text { malone } \\
\text { melody alone } \\
+3 / 4 \text { probe }\end{array}\) & \(+6 / 8\) probe
\end{tabular}\(\}\)

In Creel (2011, Experiment 2), listeners heard a set of 8 melodies that were very distinct from each other in terms of timbre, note rate (speed), mode (major, minor, other), and rhythmic patterns. Listeners provided higher ratings for drumbeat probes that matched the contexts they had heard with those specific melodies during the exposure phase. This suggests melody-specific memory for meter.

A second study (Creel, 2012) examined the role of crossmelody similarity on metrical restoration, and so presented melodies with a stronger similarity structure: two timbres, a single note rate, and similar rhythmic patterns across melodies. Listeners associated metrical information with timbre: they showed metrical restoration for a melody played in its original timbre, but not when it was played in the other timbre (as long as timbre and meter patterned consistently across melodies). Further, when melodies were constructed from two different sets of motifs (defined in that study as brief rhythm+contour patterns), listeners showed
metrical restoration for new melodies with those motifs (Experiment 5).

Interestingly, the magnitude of the metrical restoration effects in the 2011 study was much larger than the effect in Creel (2012). Though there were a number of differences between the two sets of studies, one possibility is that the denser similarity structure of the melodies in the second paper led to greater generalization, but, conversely, less individuation. However, it is not clear which one (or more) of the unique properties of the melodies in the 2011 paper generated such strong restoration effects: rate, timbre, mode, rhythmic patterns. Do all dimensions of variation contribute additively to specificity/individuation in memory, or is one particular factor the "smoking gun"?

\section*{Unknown effects on metrical restoration}

As seen in Creel (2011, 2012), timbre and motif content seem to be integral to musical memory. That is, metrical restoration shows timbre specificity and motif specificity. However, numerous dimensions of substantial musictheoretical importance remain untested. First, is there mode specificity? Mode, the particular pitch collection used in a musical piece, may be a signature of musical style: in Western music, the most common modes are major and minor. Other musical styles and cultures are characterized by yet other pitch collections (e.g. Castellano et al., 1984). Mode also contributes to emotional processing: Western listeners associate the major mode with happiness, and the minor mode with sadness (e.g. Hunter et al., 2008).

A second factor not previously examined is rate-the speed at which a musical piece is executed. Do listeners store melodies rate-specifically?

Finally, the role of timbre bears further exploration. Is timbre simply one of many cues that differentiate music in memory? If hearing melodies in two timbres allows listeners to keep metrical patterns distinct, then does hearing melodies in even more timbres create even more distinct metrical representations?

\section*{The current study}

The current study examined influences of mode, rate, and timbre on the metrical restoration effect. Experiment 1 asked whether differences in mode (major or minor), alone or in combination with timbre cues, show specificity effects in metrical restoration. Experiment 2 asked whether maximal differences in timbre ( 1 vs. 12 timbres), and differences in rate, allow even more specificity in memory.

\section*{Experiment 1}

The first experiment compares metrical restoration as a function of timbre-specificity (shown in Creel, 2012) and mode-specificity (not yet explored). We know that listeners show timbre-specific metrical restoration when timbre patterns consistently with meter. Does mode serve a similar function? That is, if mode patterns consistently with meter (e.g. major melodies are always heard in \(3 / 4\), minor melodies in \(6 / 8\) ), will listeners only restore the meter when a
melody is heard in its original mode? Further, do timbre and mode combine additively to provide even more distinct musical memories, and even stronger restoration effects?

\section*{Method}

Participants \(N=107\) participants from the UCSD human participant pool received course credit for participation. Roughly equal numbers of participants took part in Experiments 1a \((n=36), 1 \mathrm{~b}(n=35)\), and \(1 \mathrm{c}(n=36)\).

Stimuli The 18 melodies used here were originally used in Experiments 1-3 of Creel (2012). Melodies were edited slightly to generate clearer metrical contexts. The originals were all composed in major mode. Minor-mode versions were created by lowering the pitch of scale degree 3 , and 6 and 7 in certain contexts, by \(1 / 2\) step, or about \(6 \%\). Melodies were exported from Finale software (MakeMusic, Inc.) in the key of C, played both in a vibraphone timbre and a muted-trumpet timbre. These two timbres were chosen to be highly distinct, based on Iverson and Krumhansl's (1993) perceptual scaling study of timbres.

Design Each participant heard only 12 of the 18 melodies during exposure. Test trials presented all 18 melodies, with manipulations as described below (examples in Table 2). All melodies were presented during the test phase followed by metrical probe drumbeats in \(6 / 8\) and \(3 / 4\).

Experiment la: different timbres. There was a consistent mapping of timbre to meter. For example, a participant might hear six major-mode vibraphone melodies in \(3 / 4\), and six major-mode muted-trumpet melodies in \(6 / 8\). A given participant heard only one mode (major or minor). Test trials presented each melody four times: two probe meters (original meter, other meter) x two timbres (original timbre, other timbre). Mode did not change from training to test.

Experiment 1b: different modes. There was a consistent mapping of mode to meter. For example, a participant might hear six major-mode vibraphone melodies in a \(3 / 4\) metrical context, six minor-mode vibraphone melodies in a \(6 / 8\) metrical context. Thus, the roles of mode and timbre were reversed relative to Experiment 1a. Test trials presented each melody four times: two probe meters (original meter or other meter) x two modes (original mode or other mode). Timbre did not change from training to test.

Experiment 1c: different mode + timbre combinations. There was a consistent mapping of timbre and mode to meter. For example, a participant might hear six majormode vibraphone melodies in \(3 / 4\), and six minor-mode muted-trumpet melodies in \(6 / 8\). Thus, \(3 / 4\) melodies all had the same mode and timbre, while \(6 / 8\) melodies had the other mode and timbre, giving listeners two attributes to link to metrical information. Test trials presented each melody four times: twice for each probe meter, with either the original mode+timbre combination or the opposite mode+timbre combination.

Table 2: Example exposure conditions in Experiment 1.
\begin{tabular}{cccc}
\hline Melody Exp. 1a listener & Exp. 1b listener & Exp.1c listener \\
\hline 1 & major, vib., \(3 / 4\) & major, vib., \(3 / 4\) & major, vib., \(3 / 4\) \\
2 & major, vib., \(3 / 4\) & major, vib., \(3 / 4\) & major, vib., \(3 / 4\) \\
3 & major, tpt., \(6 / 8\) & minor, vib., \(6 / 8\) & minor, tpt., \(6 / 8\) \\
4 & major, tpt., \(6 / 8\) & minor, vib., \(6 / 8\) & minor, tpt., \(6 / 8\) \\
\hline
\end{tabular}

Note. Vib. \(=\) vibraphone; tpt. \(=\) muted trumpet.
Procedure The experiment was run in Matlab using Psychtoolbox3 (Brainard, 1997; Pelli, 1997). Sounds were presented via Sennheiser HD 280 headphones. Before the experiment proper, listeners completed a questionnaire on their academic and performing music experiences. They then went on to an exposure phase, followed by a test phase.

The exposure phase presented each of 12 melodies 6 times each ( 72 trials total). On each trial, listeners were asked to rate, by clicking in a 2 -dimensional grid, the melody's affective quality (sad to happy, on the x-axis) and their subjective judgment of it (like to dislike, on the \(y\) axis). This cover task aimed to keep participants attentive without alerting them to attend specifically to the meter. They were not told that they would later be tested on their knowledge of the melodies.

After exposure, participants were asked to rate drumbeats following each melody. Before beginning the test, they were presented with four example drumbeat probe trials, in order: four bars of Happy Birthday ( \(3 / 4\) meter) followed by "good" drumbeats (in 3/4); Happy Birthday followed by "bad" drumbeats (in 6/8); four bars of Greensleeves ( \(6 / 8\) meter) followed by "good" drumbeats (in 6/8); Greensleeves followed by "bad" drumbeats (in 3/4). They were prompted to consult the experimenter if they had any questions. After this, they proceeded to the test phase.

The test phase presented all 12 melodies that the participant had heard during learning, plus the 6 held-out melodies. Each melody was presented four times: once in the original mode and timbre followed by \(3 / 4\) probe drumbeats ( 4 measures plus a downbeat, or 13 beats); once in original mode and timbre with \(6 / 8\) drumbeats ( 4 measures plus a downbeat, or 9 beats); once in the other mode and/or timbre with \(3 / 4\) drumbeats; and once in the other mode and/or timbre with \(6 / 8\) drumbeats. For each participant, the mode/timbre and meter either matched or mismatched the contexts they had heard at training.

\section*{Results}

All ratings were converted from raw pixel values to a scale ranging from -1 to +1 to allow easier interpretation.

Cover task Participants rated liking and affective content during exposure. Participants rated major melodies happier than minor melodies (1a: between-participants: \(t(33)=4.79\), \(\mathrm{p}<.0001 ; 1 \mathrm{~b}: \mathrm{t}(35)=15.07, \quad \mathrm{p}<.0001 ; 1 \mathrm{c}: \quad \mathrm{t}(35)=11.30\), \(\mathrm{p}<.0001\) ). These ratings differences suggest that participants were attentive during exposure, and further, that they readily distinguished major and minor modes from each other.

\section*{Probe ratings}

Experiment 1a. To determine whether probe ratings differed as a function of prior exposure and instrument match, an analysis of variance (ANOVA) on probe ratings was conducted with Exposure Meter ( \(3 / 4\) or \(6 / 8\) ), Probe Meter ( \(3 / 4\) or \(6 / 8\) ), and Timbre (original, switched) as within-participants factors. Bear in mind that, if there is a metrical restoration effect, then the interaction of Exposure Meter x Probe Meter should be significant. If restoration was timbre-specific-that is, if restoration was stronger when the melody was presented in the original timbre-then there should be a three-way interaction. For ease of interpretation, the restoration effect (Figures 2 and 3) is plotted in this paper as the average difference between the exposed probes (Exposure \(=3 / 4\), Probe \(=3 / 4 ; 6 / 8,6 / 8\) ) and the unexposed probes (Exposure=3/4, Probe=6/8; 6/8, 3/4).

An Exposure Meter x Probe Meter interaction \((F(1,34)=\) 5.30, \(p=.03\) ) verified an overall metrical restoration effect. An interaction of Exposure Meter x Probe Meter x Timbre \((F(1,34)=4.57, p=.04)\) suggested differences in metrical restoration as a function of timbre match. Considering each timbre individually, the Exposure Meter x Probe Meter interaction was only significant for original-timbre trials \((F(1,34)=9.29, p=.004)\), but not for switched-timbre trials \((F(1,34)=.06, p=.80)\). This replicates previous work (Creel, 2012) suggesting that, when meter and timbre covary, listeners do not generalize metrical restoration across a timbre change. Data from "new" melodies (heard for the first time at test) are not discussed due to space restrictions.

Experiment lb. An ANOVA was conducted on probe ratings with Exposure Meter, Probe Meter, and Mode (original or switched) as factors. The ANOVA showed an Exposure Meter x Probe Meter interaction \((F(1,35)=6.84\), \(\mathrm{p}=.01\) ), consistent with metrical restoration. If restoration was mode-specific, there should be a significant Exposure Meter x Probe Meter x Mode interaction. However, this interaction did not approach significance \((F(1,35)=0.00\), \(p=.98\) ), implying that there was no decrement in metrical restoration when a melody was presented in the opposite mode as in training. Bearing this out, the Exposure Meter x Probe Meter interaction was significant for original-mode \((F(1,35)=4.76, p=.04)\) and switched-mode \((F(1,35)=4.66\), \(p=.04\) ) trials individually. This suggests that, in contrast to timbre specificity, listeners do not show mode specificity, but rather mode generality, in meter perception.

Experiment 1c. One might wonder if mode, while not showing specificity effects alone, might augment a timbrespecificity effect. An ANOVA with Exposure Meter, Probe Meter, and Mode+Timbre Combination (original, switched) was conducted on probe ratings. An Exposure Meter x Probe Meter interaction \((F(1,35)=4.44, p=.04)\) suggested an overall metrical restoration effect. The Exposure Meter x Probe Meter x Mode+Timbre Combination interaction did not approach significance \((F(1,35)=0.68, p=.42)\). However, considering each mode+timbre combination individually suggested that the metrical restoration effect was carried by
original mode+timbre trials (significant Exposure Meter x Probe Meter interaction, \(F(1,35)=4.65, p=.04)\), rather than switched mode+timbre trials (not significant; \(F(1,35)=0.46\), \(p=.50\) ). This is numerically consistent with timbre specificity, as in Experiment 1a and Creel (2012). However, it is not at all consistent with stronger specificity effects when both mode and timbre pattern with meter.

Figure 2: Experiment 1, metrical restoration as a function of whether the melody was presented in its original mode and timbre, or in a different mode and/or timbre.

\section*{Discussion}

Experiment 1 replicated previous findings of timbre-specific metrical restoration (Creel, 2012). However, metrical restoration seems to generalize readily across a change in mode. Given the theoretical and affective importance of the major/minor mode distinction, and listeners' demonstrated sensitivity to the affective connotations of mode in the affect-rating cover task, this is somewhat surprising. One possible explanation is that, while harmonic cues to mode in the context were quite strong, cues to mode in the melody alone were weaker. (Note that timbre cues were still available in the melody alone.) If so, stronger harmonic contexts might reveal evidence of mode-specific metrical restoration. Another possibility is that in real musical styles, other factors that covary with mode carry the weight of mode's apparent stylistic impact. For instance, minor-mode melodies might use particular note sequences that are rare in major-mode melodies, and vice versa. Because the melodies used here were changed to minor mode simply by shifting certain pitches down by a small amount, no such stylistic differences were evident here.

\section*{Experiment 2}

While Experiment 1 found no effects of mode on metrical restoration, there were effects of timbre: listeners did not generalize metrical restoration across a change in timbre. One might take this to imply that timbre differences alone could be used to keep different musical styles separate from one another. If this were true, then even more diversity should lead to highly-specific metrical storage. The current experiment addressed this hypothesis.

Listeners were exposed to \(123 / 4\) and \(6 / 8\) melodies either in a single timbre, or in 12 different timbres (one per melody). If more timbres yields more distinct melody representations, then twelve-timbre listeners should show stronger metrical restoration than one-timbre listeners. Crossed with this was a rate-variability manipulation: listeners heard melodies at a single presentation rate, or in three different rates (consistent for a particular melody). If listeners store melodies rate-specifically, then multiple rates should yield more distinct representations, and hence, stronger metrical restoration.

\section*{Method}

Participants \(\mathrm{N}=72\) listeners from the UCSD human participant pool took part in the experiment.

Stimuli Stimuli were 12 major-mode melodies, a subset of those in Experiment 1. The 12 timbres were selected to be discriminable (Iverson \& Krumhansl, 1993) and to span multiple instrument families (percussion, strings, brass, woodwinds) which have timbres similar to each other. For a given participant, each melody had a single rate and timbre.

Design Participants were randomly assigned to one of four combinations of timbre variability ( 1 timbre or 12) and rate ( 1 rate or 3 ). Timbres and rates were counterbalanced such that each timbre, rate, and timbre-rate combination occurred roughly equally across participants and melodies.

Procedure The procedure was identical to that in Experiment 1, except for differences in the stimuli heard.

Figure 3: Experiment 2, metrical restoration effect as a function of timbre and rate variability.

\section*{Results}

Metrical restoration (Figure 3) was assessed in an ANOVA on probe ratings with Exposure Meter and Probe Meter as within-participants factors, and Timbre (one or twelve) and Rate (one or three) as between-subjects factors. As in Experiment 1, an Exposure Meter x Probe Meter interaction \((F(1,68)=14.52, p=.0003)\) indicated a metrical restoration effect overall.

However, none of the higher-level interactions-which would indicate timbre diversity or rate diversity effectswere significant: Exposure Meter x Probe Meter x Timbre \((F(1,68)=2.47, p=.12)\), Exposure Meter x Probe Meter x Rate \((F(1,68)=0.58, p=.45)\), or Exposure Meter x Probe Meter x Timbre x Rate \((F(1,68)=0.34, p=.56)\). Further, the direction of the Timbre interaction effect was numerically opposite that predicted: metrical restoration was more robust for listeners who heard a single timbre than for those who heard 12 different timbres. Individually, metrical restoration was significant only in the two single-timbre conditions (novariability: \(F(1,17)=14.64, p=.001\); rate-variability: \(F(1,17)\) \(=7.25, p=.02\) ). Thus, the strongest evidence for metrical restoration was carried by the low-diversity conditions.

\section*{Discussion}

The results of Experiment 2 were counter to predictions of timbre specificity and rate specificity. There was no effect of rate diversity, which one might think would be closely linked to meter as both properties emerge from musical timing. Further, instead of stronger metrical restoration when each melody had a unique timbre, metrical restoration was numerically smaller-absent-when each melody had a unique timbre. Why wouldn't 12 moredistinct melodies ( 12 unique timbres) generate stronger metrical restoration, due to specificity, than 12 less-distinct (identical-timbre) melodies?

One possible answer is that listeners were not associating timbres themselves with meter, but were associating timbrespecific motifs with meters. That is, listeners were aggregating traces that grouped according to perceptual similarity. Recall that Creel (2012) showed that motif similarity influenced metrical restoration. Suppose that listeners in the current experiment also associated meter with motif-like rhythmic patterns. The melodies in the current study were built from a small set of moderatelyambiguous rhythmic patterns, many of which occurred across multiple melodies. If the same rhythmic patterns were stored separately for separate timbres, then listeners who heard few timbres (Experiment 1; one-timbre condition of Experiment 2) might build up relatively strong motif representations. On the other hand, listeners who heard multiple timbres (the 12-timbre condition of Experiment 2) would store a larger number of timbre-specific motif representations, but these would be weaker because they had been exposed too few times. Thus, the 12-timbre condition may have yielded motif representations that were too weak to generate significant metrical restoration.

\section*{General Discussion}

I began by asking what factors influence metrical restoration. Experiment 1 suggests that timbre may be a stronger influence than mode (major vs. minor), at least in listening situations with limited harmonic information. Further, Experiment 2 suggests that similarity-based grouping of musical memory by timbre may decrease metrical restoration due to too little representational overlap.

Listeners may need many repetitions of motifs in a given timbre (and perhaps in a given rate) for metrical restoration to occur. As shown in Creel (2012), too much motif overlap between two meters blocks metrical restoration. The current study suggests that too little timbre-specific motif overlap in melodic patterns may also thwart metrical restoration. However, I hypothesize that this occurs for two different reasons: too much motif+timbre overlap between meters causes interference, while too little timbre-specific motif overlap within a meter yields representations too weak to generate restoration.

Ongoing work explores the roles of pattern (motif) overlap in metrical restoration. When Experiment 2 presented listeners with multiple rhythmic motifs in diverse timbres-i.e., rhythmic motifs were scattered across melodies and timbres-no metrical restoration was found. A new experiment ( \(N=96\) participants) again uses multiple timbres, but each rhythmic motif is in the same timbre, which should boost representation strength by increasing representational overlap. The magnitude of metrical restoration is .23 , far exceeding (nonsignificant) diversetimbre restoration observed in Experiment 2. This suggests that timbre uniqueness does not inhibit metrical restoration as long as timbres and motifs consistently cooccur. Whether distinct timbres facilitate motif encoding is still unknown.

\section*{The nature of musical memory}

These results speak not only to restoration of metrical information, but also to the organization of musical memory itself. I have argued previously (Creel, 2012) that fine auditory detail in musical memory is not an epiphenomenon, but an organizing force, where similaritybased grouping leads to emergent clusters in memory which shape recognition and processing. Like the "phoneme restoration effect" (Samuel, 1981), metrical restoration and other varieties of musical restoration (harmonic; Creel, 2011) indicate the strength of memory in the processing of auditory events. While the incoming signal itself certainly shapes music processing, memory too is a sizable influence on perception. My studies thus far suggest that musical memory is organized along at least two dimensions: timbre and motif. Future work should assess additional factors in metrical restoration, and also whether metrical restoration and other types of musical restoration-particularly, harmonic restoration-are influenced by the same musical dimensions. If they are not, this might suggest differing attentional weights across dimensions (Nosofsky, 1986) for processing of metrical vs. harmonic information.

An additional question concerns the nature of motifs. Motif structure appears to be a strong organizing force in musical memory, but it is unclear what, functionally, counts as a motif. Creel (2012) defined it as a rhythmic pattern with a particular pitch contour, but many other possibilities are equally consistent with the data: a rhythmic pattern alone; clusters of similar but not identical rhythmic patterns.

Finally, these investigations have implications for other temporal perception phenomena. For instance, Brochard et
al. (2003) showed an ERP signature of listeners' illusory perception of strong-weak alternations in a series of tones of equal amplitude. The research described here suggests that this effect may arise from memory activation of duple meters, the most common meter in Western music. Future studies of restoration effects should continue to reveal how temporal events are represented in the mind.

\begin{abstract}
This study investigated the role probabilistic and deductive relations play in the reasoning process. It was predicted that when taking an analytic stance to a problem, it would take longer to evaluate inferences when asked how probable it is that the conclusion is true, than when asked whether the conclusion follows or not from the premises. Contrary to this prediction, people responded faster when the response format was continuous. However, there was no effect of argument type with continuous response format, suggesting people did not assess entailment relations in this condition. Options to address the issue further are discussed.
\end{abstract}

Keywords: deductive/inductive reasoning; dual process theories; task effects; response times.

\section*{Introduction}
"If the animal is a whale, then it must be a mammal"; "If I stay for five more minutes, I shall still catch the train"; "If you exchange these two cables, the telephone will work again". We go about the world constantly making judgments about what might be the case and what consequences we may expect from different situations and actions. Sometimes the reasoning involved occurs rather automatically, at other times it is effortful and time consuming. A lot of it involves conditionals, i. e. statements of the form "if p then q", with " p " and " q " standing for individual propositions such as "you stay 5 more minutes" and "you catch the train".

There is a debate in reasoning research regarding what criteria, or norms for when an inference is correct, people employ when drawing inferences - and, if they employ different criteria, then under what circumstances they reason according to what criterion and in what way the criteria may interact. The two main norms under discussion are a deductive, deterministic one (the conclusion is correct if it follows necessarily from the premises) and a probabilistic one (e. g. the conclusion is correct if its uncertainty is not greater than the sum of the uncertainties of the premises, Adams, 1975). People's answers to reasoning problems are generally sensitive both to the structure of deductive entailment relations involved and to the subjective probability or plausibility of the contents appearing in the relations (i. e. Thompson, 1994; Singmann \& Klauer, 2011).

In some approaches it is argued that people reason using a single norm for argument validity across situations. A major proponent of this position, the theory of mental models (Johnson-Laird \& Byrne, 2002), postulates this to be the deductive norm and accounts for the effect of contextual and probabilistic information on people's inferences by
proposing that people integrate such information in their models of the situation, either by adding or subtracting possibilities considered, or by tagging the models with probabilities (Girotto \& Johnson-Laird, 2004; JohnsonLaird, Legrenzi, Legrenzi, Girotto, \& Caverni, 1999). A further major proponent of the single-criterion position is the probabilistic theory of Oaksford and Chater (Oaksford, Chater, \& Larkin, 2000; Oaksford \& Chater, 2007), which postulates that the effect of contextual and probabilistic information is a consequence of that people generally reason not deductively but probabilistically, in a way that is ecologically rational and that can be modeled using Bayesian theory together with a few further assumptions.

The idea that people use a single norm for argument validity across situations is put into question by a number of findings. Rips (2001) found that when given the same list of arguments which were valid/invalid as well as plausible/implausible, a group of people given deductive instructions endorsed the valid but implausible arguments more often than the invalid but plausible ones. The opposite was the case for a group of people given inductive instructions. Vadeboncoeur and Markovits (1999) found that emphasizing the deductive nature of a task in the instructions led to answers in stronger accordance with such instructions, but that also then the availability of counterexamples to the arguments (making them less plausible even though they were valid) still had an effect. Also the availability of probabilistic information was found to have an effect on people's approach to reasoning problems. For instance, Wolf and Knauff (2008) found that people's strategy of belief revision with conditional inferences was a function of the probability of the conditional when this probability was high or low, but was better explained by the theory of mental models when the probability of the conditional was close to .5 and thus perhaps less informative. A further factor found to influence people's reasoning is the task employed. For example, across several studies the theory of mental models offered a better explanation of reasoning in the conditional inference task, while the probabilistic approach could explain better findings in the truth table task, which is related more directly to the interpretation of conditionals (Geiger \& Oberauer, 2010). Finally, also the response format for otherwise identical tasks, especially whether this is dichotomous or not, has been found to play a role. Oberauer, Geiger, Fischer, and Weidenfeld (2007) found that in the truth table task, the same participants who answered in accordance with a probabilistic interpretation of the
conditional having the three response options "true", "false", and "irrelevant", answered in accordance with a mental model interpretation when the response option "irrelevant" was not available. Further, Markovits and Handley (2005) found that while probability ratings of the arguments of the conditional inference task where uniformly high, proportion of endorsement of the same inferences having binary response format was significantly lower, especially when the inferences where deductively invalid.

Findings like the ones described have led to increasing attempts to find integrative approaches, often in the form of dual-process theories, which assume that people may employ different criteria and ways of thinking under different circumstances. Hereby one process is often described as analytic, under more conscious control, more dependent on working memory resources and more context independent, and the other as heuristic, fast, automatic, context dependent and not much affected by working memory constraints. For instance, Klauer, Beller, \& Hütter (2010) distinguish between a process based on the "logical form" or entailment relations in an argument and one based on content and context information. Sloman (1996, 2002) distinguishes between an associative and a rule based process. The two processes can be related in different ways. For instance, Evans and Over (Evans, 2006; Evans, Handley, Neilens, \& Over, 2010) advocate a defaultinterventionist relation, in which the heuristic process is used as the default, and the analytic process may intervene if there is enough time and the heuristic answer seems insufficient to solve the task. Verschueren, Schaeken, and d'Ydewalle (2005) propose that both processes operate in parallel on a given task, and if the analytic process has enough time and leads to a different result than the heuristic process, it will override the answer arrived at by the heuristic process.

One difficulty with dual-process theories is that they often only explain the effect of deductive validity through the analytic system, while the construction of a representation of the problem to be evaluated can be better attributed to the heuristic system. This puts into question their role as independent forms of solving the same reasoning problem. Also, findings from de Neys (e. g. 2012) suggesting people have not only intuitive heuristics but also logical intuitions, question the idea of an association between the heuristic and the probabilistic on the one hand, and the analytic and the deductive on the other.

The present study aims at investigating further the role of deductive and probabilistic aspects of the reasoning process. Although in general it is plausible that people may approach a task in different ways depending on their goals and constraints of the situation, it is hypothesized that at least some of the findings proposed as evidence for two systems of reasoning may also be explained by making a less strong assumption: through the idea that the reasoning process is a composite one, in which different processes take over different components of the reasoning task, instead of reflecting different approaches to the same task. The two
components considered here are assessment of the probability that a statement is the case (related to the interpretation of the statement) and assessment of what follows from the assumption that a statement is the case. The task of assessing whether something is the case is considered probabilistic: in the context of a conversation, it would be a matter of debate and subject to varying degrees of confidence. In contrast, the task of assessing what follows from the assumption that something is the case is considered (given a deductive task) as deductive and thus in a way deterministic, not probabilistic (something follows or it does not follow from given assumptions). In daily life we are often interested not just in what follows from assuming a certain piece of information, but also in how probable the conclusion itself is: we want to take into account also the uncertainty in the premises and transfer it to the conclusion. However, this is proposed to be a separate task within the reasoning process.

Thus, we hypothesized that, provided people approach a task analytically, it should take longer to answer to the question: "how probable is it that the conclusion from the premises is true?" than to the question: "does the conclusion follow from the premises?" Conversely, if people are given not inferences but only statements to evaluate, it should be faster to answer to the question: "how probable is it that this statement is true?" than to the question: "is this statement true or false?" since the latter case would involve the additional task of setting a threshold - above which one says "yes, it is true" and below which one says it is false - and of comparing the probability of the statement with this threshold. In order to raise the probability that people approach the task analytically, people are often given no time pressure as well as deductive instructions emphasizing the importance of assuming the truth of the premises for the sake of argument. We gave participants no time pressure, but could not emphasize deductive instructions since we wanted to assess the effect of taking into account premise probabilities in addition to entailment relations. We hoped that enough participants would nonetheless take an analytic stance given that in dual-process theories the weight obtained for the parameter representing an analytic approach to the task was often above \(50 \%\) for both binary (Oberauer, 2006) and continuous (Klauer, Beller, \& Hütter, 2010) response formats.

\section*{Method}

\section*{Participants}

Thirty-two students from the University of Giessen took part in the experiment in exchange for payment or course credit. Their mean age was 23.6 years (range: 19-31). They came from different majors, with the exclusion of mathematics, informatics, physics and philosophy. One participant \({ }^{1}\) had taken a course in logic; sixteen had taken at least one course in statistics.

This participant did not show a deterministic response pattern, and her exclusion did not change the pattern of results.

\section*{Design}

The above hypotheses were assessed through a within subject design involving the two main variables task (evaluation of statements or of inferences) and response format (continuous, dichotomous). For statements, a further distinction was made between conditional statements ("if p then \(\mathrm{q}^{\prime}\) ) and the two statements the conditional is composed of ("p" and "q"). For inferences, one could further distinguish inference form. There were four inference forms: "Modus Ponens" (MP: "if p then q", "p", therefore "q"), "Modus Tollens" (MT: "if p then q", "not-q", therefore "not-p"), "Affirmation of the consequent" (AC: "if p then q", "q", therefore "p"), and "Denial of the antecedent" (DA: "if p then q", "not-p", therefore "not q"). Only the first two are deductively valid, because in the other two cases also the negation of the conclusion is compatible with the premises (However, if the conditional is interpreted as a biconditional: "p if and only if q " then all four inferences are deductively valid). The main dependent variable was response latency, but degree of resp. frequency of endorsement was also examined.

\section*{Material and procedure}

Participants viewed either statements or inferences on the computer screen, and were asked to evaluate them on a continuous or dichotomous scale. Statements and inferences were embedded in one of four contexts involving concrete materials but describing arbitrary relations. For example, one such context was the following:

In a workshop in Soko there is a cupboard with blue and yellow drawers for storing the nails and screws. One drawer of the cupboard is opened...
On the next screen appeared the statement or inference to be evaluated, e. g. "If the drawer is blue, then there are nails in it". There were three types of statements: conditionals like the one above ( \(\mathrm{p}->\mathrm{q}\) ), and two statements corresponding to the antecedent ( \(p, ~ e . ~ g . ~ " t h e ~ d r a w e r ~ i s ~ b l u e ") ~ a n d ~ t o ~ t h e ~\) consequent ( \(q\), e. g. "the drawer has nails in it") of the conditional, respectively. There were four kinds of inferences, corresponding to MP, MT, AC and DA. For statements, participants were asked "How probable is it that this statement is true?" with continuous response format (cont), and "Is this statement true or false?" with dichotomous response format (dic). For inferences, the task was to "Consider the statements. How probable is it that the conclusion is true?" with continuous response format and "Assume the statements are true. Does the conclusion follow necessarily from them?" with dichotomous response format. Here we spoke of an evaluation of "the conclusion" and not of a specific statement per se, to make explicit that both response formats involve the evaluation of inferences and not just of statements grouped with other statements.

The continuous response scale was a horizontal line with the endpoints " \(0 \%\) " and " \(100 \%\) " and was divided into 101 points that could be clicked with the mouse. The dichotomous response scale consisted of two adjacent boxes, together as long as the horizontal line of the
continuous response scale, below which stood the words "false" and "true" for statements, and "does not follow" and "follows" for inferences. To the right of each statement and each premise stood a small box filled up to a certain point, representing the probability of the statement (the fuller the box, the more probable the statement). There were four boxes representing the probabilities \(.2, .4, .6\) and .8 . The aim of these boxes was to provide premise probabilities in a non-numeric and yet relative standardized way.

Each of the four contexts was associated with the three statement types, yielding 12 statements for each response format. Further, each context was associated with the four inference types, leading to 16 inferences for each response format. For each participant, one of the four probabilities was randomly assigned to the conditional of one of the four contexts and held constant across the experiment, mimicking the reliability of conditional relations. For each context, the other three probabilities were distributed randomly without replacement across statements, such that e. g. for the context of the workshop, the second premise had a different probability for each of the four inferences. The order of occurrence of the statements and of the inferences was varied randomly for each participant.

Participants were tested individually in two sessions. One session involved evaluation of the 24 statements, the other evaluation of the 32 inferences. The order of sessions was counterbalanced across participants. Within each session, response format was blocked. Instructions at the beginning of each block included familiarization with the response scale and a sample trial. At the end of the second session, all participants worked through 20 trials in which the two response scales were presented alone on the screen (10 times each in random order) and they were to click with the mouse on them as quickly and as randomly as they could. This served to assess differences in response time to the two scales due to processes unrelated to the reasoning task (i. e. motor affordances). This difference was later subtracted from the answers to the reasoning task by centering the values of each participant in each response format around their mean for that response format when presented alone. The experiment was self-paced and lasted about 50 minutes.

\section*{Results and discussion}

The data were analyzed separately for response times and for endorsement ratings as dependent variable. Prior to the analysis of response times, responses faster than 100 ms were eliminated, leading to exclusion of two data points. Elimination of response times outside the interval of the mean plus minus 3 SD for each variable led to no further data exclusions. Since response times have a lower threshold, they do not follow a normal distribution. To compensate for this, the inverse of response times: speed (1/RT), was taken for analysis. This normalizes somewhat the distribution and reduces the impact of outliers while preserving power and ease of interpretation (Whelan, 2008). Measures of speed were then multiplied by 1000 to avoid
working with only very small values (Baayen \& Milin, 2010). Prior to the analysis of endorsement ratings, it was necessary to represent the probability ratings obtained with continuous response format, and the endorsement frequencies obtained with dichotomous response format on the same scale. This was done by transforming mean frequency of the dichotomous items into a percentage value. For example, if a person answered three times yes (coded 1) and one time no (coded 0 ), the mean frequency of acceptance was \((1+1+1+0) / 4=.75=75 \%\) (Markovits \& Handley, 2005). It is thereby important to keep in mind that probability ratings and endorsement frequencies are different measures and may not be directly comparable. Results from such comparisons can be illustrative and useful, but should be interpreted with caution (Singmann \& Klauer, 1010).

Separately for both response speed and endorsement ratings, three ANOVAS were conducted: a general ANOVA across tasks, assessing the effects of task (statements, inferences) and of response format (continuous, dichotomous); an ANOVA for statements assessing the effect of statement type ( \(p->q, p, q\) ) and response format (cont, dic); and an ANOVA for inferences assessing the effect of inference type (MP, MT, AC, DA) and response format. The Greenhouse-Geisser correction of degrees of freedom for lack of sphericity was applied when appropriate. The results are depicted in Figure 1.
in speed due to the scales alone. This analysis (not represented in Figure 1) yielded a main effect of task, \(F(1\), \(31)=134.72, p<.001\), partial \(\eta^{2}=.81\) : answers to statements were faster than to inferences; a main effect of response format, \(F(1,31)=14.96, p=.001\), partial \(\eta^{2}=.33\) : answers were faster when the response format was dichotomous than when it was continuous; and an interaction between task and response format, \(F(1,31)=\) \(6.58, p=.015\), partial \(\eta^{2}=.18\) : the extent to which answers were faster when the response format was dichotomous was greater when evaluating statements than when evaluating inferences. This same ANOVA was then repeated correcting for differences in speed due to the scales alone, i . e. centering the values of each participant in each response format around the participant mean for that response format when presenting the scale alone. This analysis is shown in the upper left panel of Figure 1. It yielded a main effect of task, \(F(1,31)=134.72, p<.001\), partial \(\eta^{2}=.81\) : answers to statements were faster than to inferences; a main effect of response format, \(F(1,31)=15.1, p=.001\), partial \(\eta^{2}=.33\) : answers were faster when the response format was continuous; and an interaction between task and response format, \(F(1,31)=6.58, p=.015\), partial \(\eta^{2}=.18\) : the extent to which answers were faster when the response format was continuous was greater when evaluating inferences than when evaluating statements.

Thus, while in absolute terms it took longer to answer to

Figure 1. The upper panel shows mean speed (adjusted for RT differences between scales when presented alone) of responses for continuous (cont) and dichotomous (dic) response format, across tasks (left column), for statements (middle column) and for inferences (right column). The lower panel shows probability ratings (when response format \(=\) cont \()\) resp. endorsement frequency (when response format \(=\) dic) for the same conditions. Error bars show within subject standard errors (Bakeman \& McArthur, 1996).

For the sake of exposition clarity, only results considered relevant for the hypotheses will be reported in detail. The main hypothesis concerns the effect of task and of response format on response speed. Initially, this analysis was conducted using response speed not adjusted for differences
the continuous than to the dichotomous scale, this relation was reversed when adjusting for differences in response times to each scale when presented alone, such that participants were faster when the response format was continuous. This is in accordance with our hypothesis for
judgments about statements, but contrary to our hypothesis for judgments about inferences.

A possible explanation for why responses where faster with continuous response format both when evaluating statements and when evaluating inferences lies in the lower right panel of Figure 1, depicting endorsement ratings resp. endorsement frequency of the four inferences (MP, MT, AC, DA) as a function of response format. This analysis yielded no effect of response format, \(F(1,31)=1.07, p=\) .31, partial \(\eta^{2}=.03\); an effect of inference type, \(F(3,93)=\) 4.26, \(p=.007\), partial \(\eta^{2}=.12\); and an interaction between inference type and response format, \(F(1,31)=5.77, p=\) .001, partial \(\eta^{2}=.16\). The graphic shows the typically observed pattern of response to the four inferences for dichotomous response format (Bonferroni corrected \(t\)-tests only yielded a significant difference between MP and AC ratings, \(t(31)=4.3, p<.001\) ), whereas there was not a trace of an effect of inference type for continuous response format. Thus, people seem to have taken into account differences in the entailment relations making up the structure of the arguments only when the response format was dichotomous, but not when it was continuous. This finding renders it understandable that people were faster when the response format was continuous.

Finally, it is interesting to note that there was no effect of response format in all three analyses of endorsement ratings resp. endorsement frequency (lower three panels of Figure 1): In the ANOVA across tasks: \(F<1\); In the ANOVA for statements: \(F(1,31)=3.44, p=.07\), partial \(\eta_{2}=.1\); and in the ANOVA for inferences: \(F(1,31)=1.07, p=.31\), partial \(\eta_{2}=.03\).

The absence of an effect of response format in all three analyses speaks against the idea that people build a threshold close to certainty in the condition with binary response format, as had been suggested by Markovits and Handley (2005), who also compared answers in the conditional inference task with binary and continuous response format and found lower levels of inference endorsement when the response format was binary. It rather suggests people endorsed a probabilistic interpretation of the statements throughout: No effect of response format is expected when people judge a statement as true when they judge its probability to be above \(50 \%\) and as false when they judge its probability to be below this value. This is a sensible strategy from a probabilistic perspective because then one's judgments will be right over \(50 \%\) of the time on average. One explanation for the difference between our results and those of Markovits and Handley is that in our experiment one could explicitly see a representation of the statements' probabilities, and this may have made it more likely that they were taken into account as criteria for the judgments. One could assess the issue further using other means of providing probability information, such as through the introduction of a probability learning phase to simulate natural sampling, or through the use of familiar relations for which people can readily build probability estimates.

Although the absence of an effect of inference type for judgments with continuous response format provides a reason for why people's answers were generally faster when the response format was continuous, this absence of an effect is itself surprising and therefore worthy of further consideration. In the study from Markovits and Handley (2005) a similar pattern was observed, with the exception of ratings for MP, which were higher than for the other three inferences. Singman and Klauer (2011), using only a continuous response format, found a more pronounced effect of inference type. No effect of inference type can be expected in the framework of dual-process theories when people take a heuristic stance to the task. A heuristic stance could have been promoted in this experiment through the complexity of the task: In contrast to the two studies above, the relations employed here were arbitrary and each premise was provided with explicit probability information. This may have made it more difficult to explicitly both assess the entailment relations involved in the argument and integrate their probabilities. Thus, one could assess what effect results from simplifying the task, e. g. by providing probability information implicitly by using familiar conditional relations for which people readily build an idea of their probability. This would have the additional benefit that the validity and the soundness of the inferences would converge, ruling out the possibility that people's answers showed no effect of inference type because they were judging not their validity but their soundness, which in the arbitrary relations employed was set to be constant \({ }^{2}\).

The main prediction of this study was that, provided people take an analytic stance to a problem, it would take longer to evaluate inferences when asked how probable it is that the conclusion is true, than when asked whether the conclusion follows from the premises, because integrating probabilities is an additional task to assessing entailment relations. In contrast, we predicted it to take less time to evaluate the truth of a statement when asked how probable it is that the statement is true than when asked whether the statement is true or false, since the latter would involve the additional task of setting a threshold and comparing it with the statements probability. We found that people where generally faster with continuous response format, and that when judging inferences, the entailment relations constituting the structure of the arguments had an effect for dichotomous but not for continuous response format. The results were in accordance with the hypotheses for statement evaluation, but not for inference evaluation. However, they suggest that when evaluating inferences, people did not take an analytic stance to the task when the response format was continuous. One way to promote an analytic stance could be through instructions introducing the task explicitly as one aimed at investigating how analytic reasoning differs from intuitive reasoning, making it important to engage in the former for the sake of the experiment. Such a manipulation was successful in eliciting a heuristic stance in a study from

\footnotetext{

}
de Neys and Franssens (2009). One could then assess whether this would make a difference.

\begin{abstract}
Systems of noun classification serve to categorize entities based on a set of semantic and/or phonological features. Previous work, for the most part focused on gender-based classes, has suggested that learners acquiring such systems rely primarily on phonological cues, while semantic cues are used only weakly. We show, using an artificial language learning task with adults, that semantic information alone is sufficient to learn a realistic shape-based classification system, challenging the view of phonology bias. Further, our results show that compared to learners exposed to semantically cohesive categories, learners trained on randomly assigned classes are less successful at recalling the category of exposure items. This finding suggests that, contrary to memory-based theories of learning, categories are not necessarily formed by abstraction from memorized exemplars, but can instead be constructed from lower-level properties that category members share.
\end{abstract}

Keywords: classifiers; noun classes; language acquisition; artificial language learning; semantic features

\section*{Introduction}

Systems of noun classification-such as gender, noun class, and classifier systems-distinguish or categorize objects according to salient semantic and/or phonological features. Though such systems may differ in their formal realization, the semantic features on which they are based draw from a common pool that includes physical features (e.g. shape, size), function (e.g. food, tool, habitation), as well as animacy and sociocultural status (Denny, 1976; Dixon, 1986; Lakoff, 1987; Comrie, 1989; Aikhenvald, 2000; Senft, 2000).

For example, in Cantonese, the use of a classifier morpheme is required in constructions involving a numerical or definite noun phrase, as in example (1) below. \({ }^{1}\) The choice of classifier in Cantonese is largely determined by the head noun; for example the classifier \(g o[3]\) is used for people, while the classifier zek[3] is used primarily with animals. Additional classifiers target shape properties like length, dimension, and flexibility.
(1)

> a. sam[1] go[3] jan[4]
> three CL people
> 'three people'
b. sam[1] zek[3] gau[2]
three CL dogs
'three dogs'

\footnotetext{
\({ }^{1}\) Although English does not use them productively, there are nevertheless a number of nouns which can appear with a classifier, e.g. "four strands of hair", "two sheets of paper", "a school of fish".
}

Similarly, in the classifier system of Navajo (Mithun, 1986) nouns are classified according to animacy and shape (among other properties); class marking in this language is found on the verb. Signed languages also commonly have noun classification systems based on shape and other functional properties (Supalla, 1986).

\section*{Acquisition of noun classification systems}

Previous work on the acquisition of systems of noun classification has largely focused on genders and noun classes. Such studies have documented developmental stages including a period of phonological underspecification, and overgeneralization of frequent or default marking, and have highlighted the apparently weak role of semantic (as opposed to phonological or distributional) information (KarmiloffSmith, 1981; Perez-Pereira, 1991; Demuth \& Ellis, 2008; Mariscal, 2009; Gagliardi, 2012). The acquisition of classifier systems, although perhaps less well-studied, indicates a similar developmental trajectory. For example, Tse, Li, and Leung (2007) report that Cantonese-speaking children \((3 ; 0-5 ; 0)\) tend to show early use of classifiers in required contexts but are not adult-like in their choice of classifier until quite late. In particular, children tend to over-use the classifier go3-used for people, but also sometimes referred to as a 'general' classifier (C. Li \& Thompson, 1989)—and to over-generalize other more frequent classifiers. Although P. Li, Huang, and Hsiao (2010) show that Mandarin-speaking children generalize classifiers to novel nouns on the basis of shape features, Tsang and Chambers (2011) argue that adult speakers of Cantonese tend to rely on cues other than the semantic features of the nouns when processing classifiers.

In this paper we investigate the extent to which adult learners can use semantic information alone to acquire category distinctions instantiated in a miniature classifier system. Previous work on artificial language learning suggests that, although the population of most interest may be children within any sensitive period for language acquisition, behavioral patterns exhibited by adults can shed light on both general and language-related learning mechanisms (Wilson, 2006; Culbertson, Smolensky, \& Legendre, 2012; Finley \& Badecker, 2010). The motivation for using an artificial language learning task rather than natural language learning data in this case comes from our hypothesis of why it has been found that phonological cues-even when these are less statistically reliable than semantic properties-are preferentially used by
learners acquiring noun classification systems (Braine, 1987; Frigo \& McDonald, 1998; Gagliardi, 2012). It seems likely that children process a great deal of phonological information about dependencies between nouns and nominal modifiers (such as gender-marked determiners or classifiers) before they acquire the meanings of these elements (Polinsky \& Jackson, 1999). In some sense, then, it is unsurprising that children privilege phonological information at first during language development. Adults may continue to privilege phonological cues, not because they fail to attend to semantics, but simply because their knowledge of noun classes was initially based in phonological processing.

Here, crucially, we use adult English-speakers and construct a miniature language from known objects and their linguistic labels. This removes the problem of acquiring the semantics of nouns and, if our hypothesis is correct, should expose an ability to learn cohesive noun categories on the basis of semantic features alone. While some previous work has suggested that adults can use semantic information to learn classification systems in an artificial language, these studies have exclusively focused on gender-based noun classes (Braine, 1987; Brooks, Braine, Catalano, Brody, \& Sudhalter, 1993). Here we target instead shape-based classifiers, which are likely to be less familiar to English-speaking college students (the population typically targeted).

The system is modeled on Cantonese (sortal) classifiers, in particular those which pick out shape properties of objects. As mentioned above, the particular shape properties indicated by Cantonese classifiers-related to the length, flexibility, and dimensions of objects-are representative of those found in classifier systems typologically (Craig, 1986; Dixon, 1986; Comrie, 1989). Table 1 shows the two Cantonese classifiers, along with the semantic features with which they are associated, on which our system was modeled. The examples provided represent nouns which take the relevant classifier in Cantonese, and are also nouns actually used in the task.

Table 1: Shape-based classifiers tested
\begin{tabular}{lll}
\hline Classifier & Semantic features & Examples \\
\hline zi[4] & rigid, narrow, long & knife, twig, candle \\
jeung[4] & broad, flat, flexible & sheet, card, table \\
\hline
\end{tabular}

\section*{Experiment 1}

In Experiment 1, we tested whether adults could learn and generalize categories of nouns, distinguished by their use of the classifiers in Table 1. We compare learning of a system in which classifier use is conditioned on shape-based semantic properties of nouns to learning a random assignment of nouns to classifier categories. We hypothesized that if learners perceive and make use of semantic information in acquiring noun classification systems, they should succeed in learning the semantically-conditioned language. The
random-assignment condition was used to establish an experimental baseline against which performance in the shapebased condition can be compared, and in particular to assess the role of memory for individual category members in this task. Exemplar-based models of learning argue that category formation begins with a set of memorized exemplars, abstract categories emerging later due to, e.g., computation of featural similarity among exemplars in a given category (Nosofsky, 1986). This predicts that learners exposed to conditioned and random classifier categories should perform equally well when tested on familiar items-in both cases, the set of exemplars presented during exposure should be stored-but should of course differ on their ability to generalize to novel items.

\section*{Participants}

Participants were 20 native English-speaking undergraduates from the Johns Hopkins University. They received a small amount of course credit or extra credit for their participation. No subjects reported difficulties hearing or seeing the stimuli.

\section*{Materials}

The miniature language was comprised of the English numeral words "one" and "two", two nonce classifier morphemes "ka" and "po", and 96 English nouns representing familiar objects. Utterances in the language consisted of a numeral word directly followed by a classifier morpheme, and a noun, as in example (2) below. Utterances were auditorilyusing mac text-to-speech, speaker "Alex"-and orthographically presented and were accompanied by a visual image. The image was a single object for numeral "one" or two of the same objects for numeral "two".
(2) a. one-ka hammer one-CL hammer
b. two-po towel two-CL towel 'two towels'

Figure 1: Example trial

\section*{Design \& Procedure}

Participants were seated in front of a computer, and were instructed that the task was about learning a language similar to English but with two ways of saying the words "one" and "two". They then listened to examples of "one-po", "one-ka" and "two-po", "two-ka". This was followed by 48 familiarization trials, half with objects using the classifier "ka" and half using "po". Half of the trials featured a single object and the other half two objects. On each trial, a visual image appeared with four choices below it, one for each possible numeral-classifier combination followed by the object noun pictured. Participants listened to the auditory stimulus and were required to click the choice which matched what they heard. Figure 1 shows an example trial.

After familiarization, participants took a brief break, and were then instructed that they would see a visual image and four choices below it, as in the familiarization phase, but they would hear no audio. Instead they were required to choose the phrase they thought was most likely to be used in the language. This testing phase was made up of 96 trials, including all the objects seen during familarization, and 48 novel objects. The seen objects were the same as those seen in the familiarization phase, but appeared with the other numeral (e.g. if a participant heard "one-ka hammer" and saw a single hammer during exposure, they saw two hammers at test). No feedback was given.

Participants were randomly assigned to one of two conditions. In the shape condition, the use of "ka" and "po" was conditioned on the semantic properties shown in Table 1 above. The object nouns in each class were a subset of those which actually use the corresponding classifier in Cantonese. As such, although they generally exhibited the relevant properties, there was some amount of variation in the extent to which they did so. For example, the noun "table" takes the classifier jeung[4] in Cantonese even though it does not perfectly exemplify the semantic features of the class.

In the random condition, the use of "ka" and "po" was unconditioned, and nouns were randomly paired with a particular classifier.

\section*{Results}

In analyzing the results of this experiment we were interested in two main questions: (i) Do learners in the shape condition-in which classifier choice is determined by semantic features of nouns-succeed in learning and generalizing the correct categories? (ii) Are the categories learned those which were intended, namely the shape-based categories shown in Table 1? To address the first question, we compared first the performance on seen items across the two conditions. Performance on seen items gives an indication of how well the familiarization set was learned by a given participant. The light colored bars in Figure 2 shows proportion choice of the correct classifier on average for participants in each condition. Analysis of this data using mixedeffects logistic regression (with participants and items as ran-
dom effects) reveals a significant effect of condition ( \(\beta=\) \(1.47, z=5.32, p<0.01\) ), with participants in the shape condition choosing the correct classifier on seen items much more often than those in the random condition ( 0.86 vs .0 .45 ). A significant interaction between condition and number was also found ( \(\beta=-0.29, z=-2.63, p<0.01\) ), indicating the participants in the random condition tended to be less accurate on items with the number "two" compared to "one".

We are also interesting in the extent to which participants in the shape condition could generalize the categorization information they learned during familiarization to novel (unseen) objects at test. As Figure 2 suggests, there was little difference in participants' choice of the correct classifier on seen item, and their choice of the classifier which matched the relevant semantic features on novel nouns. Analysis using mixed-effects logistic regression revealed no significant effect of item familiarity ( \(\beta=0.27, z=1.13, p=0.26\) ). A significant interaction between item familiarity and number was found however ( \(\beta=-0.47, z=-1.98, p<0.05\) ), indicating the participants tended to be less accurate on seen items with the number "one" compared to "two". Note that for participants in the random condition, there is no expected correct classifier for novel items, as the noun categories used in familiarization were random, containing no semantic cues.

Figure 2: Correct choice of classifier for seen and novel nouns in the shape condition, and seen items in the random condition (NB: there is no correct choice for novel nouns in the random condition, since nouns were categorized randomly).

If participants in the shape condition in fact consistently inferred the same set of shape-based categories, we expect to see that their responses on novel test items are highly correlated. On the other hand, participants in the random condition were not expected to infer cohesive categories, and thus we do not expect correlated responses. To assess this, for each pair of participants in the shape condition, we computed the proportion of novel test items that they assigned to the same category. The average agreement proportion for this condi-
tion was high \((0.74, \mathrm{SE}=0.04)\). In contrast, a parallel analysis revealed much lower agreement among participants in the random condition \((0.50, \mathrm{SE}=0.02)\); note that \(50 \%\) agreement would be expected from purely random responding.

\section*{Experiment 2}

In Experiment 2, we sought to replicate our findings in a more diverse population, namely workers on Amazon Mechanical Turk (a service pairing workers with tasks over the internet). This population includes a range of ages and socio-economic backgrounds that may be more representative of the population at large (Mason \& Suri, 2012). In addition, this experiment serves to add to the growing body of linguistic and cognitive research using Mechanical Turk.

\section*{Participants}

Participants were 24 native English-speaking workers recruited through Amazon Mechanical Turk. They received \(\$ 1.00\) for their participation in the study.

\section*{Materials}

The materials were the same as those used in Experiment 1, and participants were again randomly assigned to either the shape condition or the random condition.

\section*{Results}

The results of Experiment 2 replicate the major findings of Experiment 1, as shown in Figure 3. Analysis of this data reveals a significant effect of condition \((\beta=0.91, z=3.77, p<\) 0.01 ), with participants in the shape condition choosing the correct classifier on seen items much more often than those in the random condition ( 0.82 vs. 0.55 ). A significant interaction between condition and number was also found ( \(\beta=0.17, z=2.08, p<0.05\) ), indicating that the participants in the random condition tended to be less accurate on items with the number "one" compared to "two". This interaction is in the opposite direction as what was found in Experiment 1 , suggesting that the effect of number may not be reliable.

In terms of generalization to novel items, participants in the shape condition again show a relatively modest but significant increase in accuracy of classifier choice for seen items in comparison to novel items ( \(\beta=0.38, z=2.08, p<0.05\) ). No other significant effects were observed, again suggesting that differences in performance driven by number in Experiment 1 may not be reliable.

As in Experiment 1, for each pair of participants in a given condition we computed the proportion of novel test items that were assigned to the same category. Average agreement was above chance for the shape condition \((0.65, \mathrm{SE}=0.04)\), but note that this represents a lower level of agreement than that found in Experiment 1 for the same condition. Just as in Experiment 1 , average agreement for the random condition was at the expected chance level \((0.50, \mathrm{SE}=0.02)\).

\section*{Discussion}

In the experiments reported above, we exposed adult Englishspeakers to a miniature artificial noun classification system.

Figure 3: Correct choice of classifier for seen and novel nouns in the shape condition, and seen items in the random condition in Experiment 2 (NB: there is no correct choice for novel nouns in the random condition).

In order to investigate the role of semantic features of nouns in the acquisition of classification systems, we used English words, removing an obstacle present in natural language learning. Child language learners likely go through a stage of development in which phonological but not semantic information is available for the acquisition of noun classification and other grammatical features. The results of our experiments indicate that, when exposed to a realistic classification system (based on two Cantonese sortal classifiers) over known nouns, participants are able to learn the correct categories based on semantic information alone, and can readily generalize this information to new nouns. Learning did not extend to participants exposed to randomly generated noun categories which lacked supporting semantic cues. Our findings were robust in both a population of college students, and among the more diverse population found on Amazon Mechanical Turk-despite a relatively small sample size.

This finding suggests that semantic features of nouns can be quickly used by learners as the basis of a classification system, calling into question the apparently privileged role of phonology cues argued to hold in previous work on this topic (Karmiloff-Smith, 1981; Perez-Pereira, 1991; Tsang \& Chambers, 2011; Gagliardi, 2012). While here we have shown that semantically based noun classification can be learned in the absence of phonological cues, in future work we will ask whether phonological information is nevertheless used preferentially over semantic information when both are simultaneously accessible.

We believe our results are also relevant to understanding the initial stages of category formation. In particular, the dramatic difference in performance for seen items-items which were part of a participant's exposure set-between the two conditions calls into question theories of learning in which
categories are formed by abstraction over a set of stored exemplars (Nosofsky, 1986) (see also (Rouder \& Ratcliff, 2004) for relevant discussion and detailed model comparison). Under such a view, the prediction would be that learners should store the set of exemplars presented during familiarization regardless of whether the particular classifier-noun pairings are random or semantically conditioned. It would then remain unexplained why participants in the random condition fail to use the stored pairings to perform with high accuracy on seen items at test. Our participants succeeded at remembering (or reconstructing) particular examples only when those conformed to a more abstract generalization across items.

\section*{Acknowledgments}

The authors would like to acknowledge Kelly Glazer and Allison Widen for assistance in constructing the experimental materials and running participants.

\begin{abstract}
Arguments, claims, and discussions about the "level of description" of a theory are ubiquitous in cognitive science. Such talk is typically expressed more precisely in terms of the granularity of the theory, or in terms of Marr's (1982) three levels (computational, algorithmic, and implementation). I argue that these ways of understanding levels of description are insufficient to capture the range of different types of theoretical commitments that one can have in cognitive science. When we understand these commitments as points in a multi-dimensional space, we find that we must also reconsider our understanding of intertheoretic relations. In particular, we should understand cognitive theories as constraining one another, rather than reducing to one another.
\end{abstract}

Keywords: Level of description; Marr; Philosophy of cognitive science; Reduction; Intertheoretic constraint

\section*{Limitations of Levels}

It is customary within science to talk about our theories as falling at different "levels of description": biology is at a higher level of description than chemistry, which is itself at a higher level than physics. Moreover, talk of levels is not restricted to the relationships between these large-scale domains of science; a sub-symbolic model of causal cognition can be said to be at a lower level of description than some symbolic model of the same cognition or behavior.
"Levels talk" is particularly widespread in the cognitive sciences (as noted by many authors, such as Bechtel, 1994; Bickle, 1998; Marr, 1982). The proliferation of talk about levels is quite unsurprising, given the many different methodologies used to develop theories of human behavior and cognition. At the same time, exactly what is meant by a "level" is often left somewhat vague. Levels of description are sometimes identified with the ontological granularity of a theory, where its level is determined (largely) by its objects. This characterization misses important distinctions, however, such as the difference between a rational analysis that says how one should act, and a process model that describes the cognitive mechanisms generating behavior.

One of the most precise characterization of levels in cognitive science-and certainly the most influential such characterization-was given by Marr (1982), and captured this key distinction. Marr's three levels characterize information-processing devices in general, and processes in the human mind more specifically. The computational level identifies the input and output of the process, as well as constraints on the types of computation done on the input to get the output. The algorithmic level (also called the representation level) specifies an implementation of the computational theory, as well as the representation of the
input and output of the process. Finally, the implementational level describes the physical realization of the representation and the algorithm.

Roughly speaking, the computational level specifies what problem is being (appropriately) solved; the algorithmic level explains how it is solved; and the implementational level gives the details of the physical substrate that does the solving. As a concrete (non-cognitive) example, we can understand a word-processing program as (i) a process for entering, editing, and rendering text documents (the computational level); (ii) a bunch of lines of code that produce the appropriate behavior (the algorithmic level); or (iii) changes of 1 's and 0 's in the internal memory registers of the computer (the implementational level).

As a more cognitive example, consider the problem of learning causal structure from observational data (e.g., Cheng, 1997; Griffiths \& Tenenbaum, 2005). A computational-level model of this problem would characterize the relevant inputs (case-by-case observations or a summary of a sequence of such cases), the output that should result given such input (a representation that can be used for causal inference, decision-making, explanation, etc.), and any relevant cognitive constraints (though in practice, computational-level models rarely incorporate such constraints). An algorithmic-level model would characterize the internal representations and cognitive processes by which we humans happen to solve this challenge. And an implementation-level model would show how the relevant computations are performed in particular brain regions (e.g., frontal cortex as suggested by Fletcher, et al., 2001 or Satpute, et al., 2005).

Marr's three levels were a significant advance in part because they are based on the recognition that the mathematical or computational specification of a cognitive theory significantly underdetermines the commitments that are implied by it. A Bayesian model of causal learning could, for example, be at the computational or algorithmic level, depending on the intended interpretation of the terms in the model. Moreover, these differences in interpretation (and so commitments) can matter: whether some experiment or behavioral measure is a test of a model depends in part on the commitments of that model.

Marr's levels were also intended to help show that there can be distinct models of the same phenomenon that are not competitors. That is, models \(M_{1}\) and \(M_{2}\) can be incompatible (whether mathematically or ontologically) and yet both be correct as long as they are at different levels. For example, Bayesian and associationist models of causal learning are mathematically incompatible-they posit different representations and different learning processes-but can
both be correct if one is at the computational level and the other is at the algorithmic level (Danks, Griffiths, \& Tenenbaum, 2003; Griffiths \& Tenenbaum, 2005).

Unfortunately, Marr's levels suffer from at least two significant flaws. First, and more importantly, they assume that multiple distinct aspects of theoretical commitment must vary together, rather than being able to vary independently (see also McClamrock, 1991). For example, suppose model \(M_{1}\) is a standard computational-level model of human causal learning: it characterizes the relevant inputs and shows which (behavioral) outputs would solve the causal learning task, all while being agnostic about the underlying representations and processes.

Now consider \(M_{2}\) that is mathematically identical to \(M_{1}\), but which claims only that people do generate this (behavioral) output, not that this behavior is how people should solve the causal learning task. That is, \(M_{2}\) is a relatively standard instrumentalist model that characterizes the human behavior without explaining precisely how or why it is generated. \(M_{2}\) is not a computational-level model, as it does not explain why people act as they do (i.e., one of the putative hallmarks of a computational-level model). At the same time, \(M_{2}\) is not an algorithmic-level model, as it does not characterize the underlying representations or cognitive processes. There thus does not appear to be any place to put \(M_{2}\) in the standard three Marr levels.

More generally, Marr's three levels force three different dimensions of variation in theoretical commitment-extent of realism, tightness of approximation, and (importance of) closeness to optimality (all discussed in the next section)to change in lockstep when they can, in practice, vary relatively independently. This observation points towards the second concern about Marr's levels: namely, each of these dimensions has many more than just three levels, as theories can differ (in their commitments) in relatively finegrained ways. Marr's levels are sometimes helpful for providing a quick characterization of the commitments of some theory, if the theory happens to fit one of those templates. But in general, we need a subtler characterization of the types of theoretical commitments we can have for a given cognitive model.

\section*{Dimensions of Variation in Commitments}

In this section, I consider in more detail these three dimensions of variation in one's theoretical commitments. At the end, I show how we can use these dimensions to better understand how Marr's levels force these different dimensions to vary together, though they should be independent in theory (though not always in practice).

\section*{Realist Commitments (or, What Does It Mean to Be a Cognitive Realist?)}

The first dimension is arguably the easiest to understand: the extent of realism about the theory is simply which parts of the theory are supposed to refer to representations or cognitive processes that "really exist" in a standard metaphysical sense. As a simple example, consider a
cognitive model of an individual being asked to add two plus two, and then responding with four. A completely minimal realist commitment for such a model would be to regard it instrumentally: one could commit only to the model offering a correct characterization of the input-output function for human addition. A substantially more realist commitment would claim that there are internal cognitive representations of the numbers ' 2 ' and ' 4 ', as well as some process by which the former representation (perhaps with a copy) is manipulated so as to yield the latter representation. This interpretation presupposes that there is really a representation there (in a sense discussed below) and that there is some process corresponding to addition.

As we see in this example, simply giving the mathematical specification of a cognitive theory is insufficient to determine the realist commitments; those are, in an important sense, outside of the scope of the computational part of the model. At the same time, to fully understand how to interpret a cognitive model, one needs to know what realist commitments to attribute to it. Such specification rarely occurs explicitly for theories in cognitive science (or at least, rarely in journal papers), but is nonetheless an important step. Some information about realist commitments can be conveyed implicitly through the variables in the model, or by asserting that the theory holds at some level of description. "Levels" of description are, however, much too coarse to convey potentially finegrained metaphysical commitments, at least in the sense of stating what things there are held to be in the world.

This dimension of variation is still under-specified, as it is not yet clear which epistemological commitmentscommitments about what we could come to learn or knoware implied by attributing "reality" to cognitive representations or processes. We can usefully understand epistemological commitments in terms of the predictions they license, as prediction is at the core of many epistemic activities, including control, learning, inference, and even parts of explanation.

By looking at constraints on prediction, we see that there are two different types of realist commitments in the cognitive sciences-realism about processes, and about representations. A rough characterization of the distinction between representations and processes suffices for capturing realist commitments: representations are the relatively stable, persistent objects that encode information, and processes are dynamic operations involving those objects that can potentially (but need not) change the state of those objects. That is, representations are whatever encodes information stably over some reasonable timescale, and processes are whatever manipulate that information. This high-level characterization covers most of the standard accounts of cognitive representations and processes; even embodied (e.g., Barsalou, 2008) and dynamic systems (e.g., Port \& van Gelder, 1995) theories of representation (or its apparent absence) fit this general schema, if we focus on the structure of the theory rather than the language used to describe it.

Given this distinction, representation realism implies commitments about the stability of predictions for different types of cognition that use the information encoded in that representation. If the representation "really exists," then the same object is presumably used for (potentially) many purposes, and so predictions in these different contexts should reflect that shared informational basis. For example, realism about the concept 'DoG' implies that behavior in a categorization task involving dogs should be correlated (in various ways) with performance in a feature inference task involving dogs. More generally, representation realism licenses us to use behavior on one task to make predictions about (likely) behavior on different tasks that use the same representations, at least ceteris paribus. Importantly, realism about our cognitive representations does not imply that every one is available for every process; it is certainly possible that we have multiple representational stores, some of which are process-specific. But if the same representation is supposed to be available to multiple processes, then representation realism implies a set of epistemological commitments about correlations or stabilities between predictions about the behaviors that the different cognitive processes generate.

Process realism similarly implies epistemological commitments of inter-prediction correlations and stabilities, but rather for the same task given different inputs, backgrounds, or environmental conditions. That is, if one is committed to the reality of a given cognitive process, then that process should be stable and persistent in its functioning across a range of inputs and conditions. For example, realism about a particular process theory of concept learning implies that this particular process should be active for a variety of inputs that trigger concept learning. Whether I am learning about the concept 'DOG' or the concept 'CAT', the same process should be engaged (since that is the process that is "really there"). Of course, process realism does not imply that every process is triggered for every input or in every condition; rather, process realism is the more minimal claim that there should be correlations and stabilities between the predictions for the different performances of the same task, ceteris paribus.

Critically, the epistemological commitments of process realism and representation realism are separable, at least in the abstract. One could think that the appropriate predictive correlations obtain within a cognitive task but not between them (i.e., process realism without representation realism). For example, performance on a categorization task involving dogs might not imply anything stable for predictions about how people do causal inference about dogs. Alternately, the appropriate stabilities might obtain across tasks for the same information, but not within a task (i.e., representation realism without process realism). For example, there might be correlations between predictions for categorization and feature inference tasks involving dogs, but no stable correlations between the predictions for categorization involving dogs and cats.

One can make realist commitments about only some of the representations or processes in one's theory; process and representation realism are not all-or-nothing affairs. To take a concrete example, consider associative models of contingency (or causal) learning, such as the well-known Rescorla-Wagner model (Rescorla \& Wagner, 1972). At a high level, associative learning models posit that one learns contingencies or correlations (possibly including causal strengths) by updating associative strengths between various factors. Computationally, whenever one observes a new case, the cognitive agent (i) uses some of the observed factors to predict the state of other factors using the appropriate associative strengths, and then (ii) changes associative strengths based on the prediction error.

Most standard interpretations of associative learning models are realist about the associative strengths, but not about the predictions "generated" in step (i) in order to change strengths in step (ii). That is, the former representations "really exist" and are encoded somewhere, but the latter are just a computational device. Similarly, most are realist about the update process that changes the associative strengths, but not about the prediction process that uses some of the associative strengths to predict the states of other factors.

\section*{Degree of Approximation}

A second dimension of variation in the commitments of a cognitive theory is in the intended closeness (to reality) of the theory's approximations. All theories are approximate in some ways, in that they exclude certain factors or possibilities; there is no complete theory that incorporates everything. We can nonetheless distinguish (for a particular theory) different commitments about what is supposed to be captured by that theory. We can think about this dimension as tracking either which factors have been excluded, or the intended scope of the theory.

As a concrete example, suppose one has a model of human addition that predicts that people will respond '93' when asked "what is \(76+17\) ?" A question thus arises when someone responds (erroneously) '83': what does this behavior imply for the theory? One response is to hold that this represents a (partial) falsification of the model, as it made a prediction that was not borne out. A different response is to argue that the behavior is due to some factor that was not included in the model because it falls outside of the intended scope of the model (e.g., a momentary lapse of reason due to distraction). The mathematical or computational specification of a theory does not include what was (deliberately) omitted, but that information is important when deciding how to respond to an apparent mismatch between theory and reality.

This dimension is clearly related to the performance/ competence distinction, but it is also not identical with it. Roughly speaking, a competence theory aims to characterize what people are capable of doing, while a performance theory aims to describe what they actually do. Typically, the former is a theory that aims to explain and predict people's
ideal behavior if they did not face, for example, limits on memory and attention, cognitive processing errors, and other deleterious factors. The latter is supposed to be a theory that accounts for these various factors so as to capture (approximately) actual human behavior in all its messy glory. The mathematical specification of a theory does not entail that it is either a performance or competence theory, and some historical debates in the cognitive sciences occurred precisely because of a misunderstanding about whether (the mathematical specification of) a theory was intended as a competence or performance theory.

The performance vs. competence distinction can be understood as picking out two possible commitments along this dimension of variation (i.e., about the intended scope of a theory). But there are many other intended approximations that one could have in mind, including ones that arise from abstracting away from only some human cognitive limitations and peculiarities, rather than all of them (as in competence theories). The performance vs. competence theory distinction marks an important pair of possible intended commitments of a theory, but fails to capture the full range of possible commitments.

\section*{Importance of Optimality}

The third dimension of variation in a theory's intended commitments is in the putative or claimed optimality of the theory (if any): that is, is the theory additionally claimed to be optimal (or rational), and if so, for what task(s) and relative to what competitors? This additional claim is important because claims about optimality (help to) license so-called "why-explanations." We are often interested not just in how some behavior occurs (i.e., the underlying representations and processes that actually generate it), but also in why that behavior occurs.

Actually tracing the causal history (whether ontogenetic or phylogenetic) of a process or representation can be remarkably difficult, if not impossible. An alternative path to reach a why-explanation is to show that some cognition is optimal relative to competitors, and that there are sufficiently strong pressures on the individual (or lineage) to push the individual to the optimal cognition (and that those pressures actually obtained in these circumstances). If these elements can be shown, then we can conclude that the cognition occurs because it is optimal. This alternative path is a standard way to demonstrate, for example, that some physical trait constitutes an evolutionary adaptation (Rose \& Lauder, 1996).

In practice, many optimality-based "explanations" in the cognitive sciences fail to demonstrate all of the elements; in particular, they frequently fail to show that there are actual "selection pressures" that would suffice to drive an individual towards the optimal cognition, or even to maintain an individual at the optimal cognition. Nonetheless, the intended closeness to optimality (relative to a class of alternatives) of a theory-and so its ability to function in a possible why-explanation-is a critical theoretical commitment about a model that is not implied
simply by its mathematical/computational specification. And clearly, variation in this dimension induces different metaphysical and epistemological commitments, as claims that some theory is optimal imply facts about the causal history of the cognition, and about how the cognition should plausibly change under variations in the environment or learning history.

\section*{Connecting the Dimensions and Marr's Levels}

Marr's levels force these three dimensions of variation to change together, rather than allowing them to vary independently. For example, a theory at the computational level is understood to have a relatively weak set of realist commitments (particularly about processes), significant approximation (since the theory is about how the system should solve a problem, rather than what it actually does), and a fairly strong expectation of optimality. Theories at the implementational level, in contrast, are strongly realist (since they hopefully focus on the underlying biological mechanisms), aim to minimize approximation by incorporating relatively contingent influences, and emphasize causal mechanisms ("how") rather than optimality ("why").

As a result, one must be careful about using Marr's levels to characterize a theory. Use of the terminology can force proponents of a theory into particular commitments that they would prefer to deny, as the levels bundle together commitments that should be kept separate. At the same time, anything that encourages more precise specification of the extra-computational commitments for a theory is a positive. The overall usefulness of Marr's levels principally depends on whether the theory's proponent happens to endorse one of the limited sets of possible commitments that can be expressed in that trichotomy. In many actual cases in cognitive science, however, we have subtler, more finegrained variations in our theoretical commitments.

\section*{From Reduction to Constraint}

Throughout this discussion, I have largely ignored one of the most important uses of levels, whether Marr or otherwise: namely, they provide a framework in which we can understand intertheoretic relationships. That is, we care not only about the commitments of a scientific theory, but also about the ways in which theories are related to one another, and "levels talk" provides an excellent way to understand such relations.

Of course, it is possible that there are no such (interesting) intertheoretic relations in cognitive science, as implied by various claims that psychology is "autonomous" (or other related term) from the underlying neuroscience (e.g., Fodor, 1974, 1997). Proponents of rational analyses often suggest a similar sort of disconnect, as they sometimes hold that the rational analysis says nothing about how the behavior is generated (e.g., Anderson, 1990). There are many theoretical concerns about the autonomy position (see, e.g., the long list in Bickle, 1998). In addition, it is arguably descriptively incorrect: cognitive scientists frequently attend
to the ways in which their theories matter for one another. Regardless of whether it is logically necessary that there be interesting intertheoretic relations, it certainly seems to be contingently true that there are such relations.

The more common way to think about intertheoretic relations in cognitive science is in terms of reduction: roughly, a theory \(H\) at a higher level must (eventually, somehow) "reduce" to a theory \(L\) at a lower level. More precisely, \(H\) reduces to \(L\) when the latter is a finer-grained version of (something approximately equivalent to) the former. There are many different ways of explicating "reduction" with more precision, whether in terms of syntactic equivalence (Nagel, 1961); semantic equivalence (Bickle, 1998); similar causal powers (Schaffner, 1967); replaceability (Churchland, 1985; Hooker, 1981a, 1981b); or even as implementation of a computer program (Danks, 2008). In all of these cases, there is a close connection, or at least sympathy, between talk of "levels" and the focus on reduction as the key intertheoretic relation.

At least two general concerns arise, however, for all of these accounts of "reduction." First, scientific practice (particularly in the cognitive sciences) often does not involve definite, positive, theoretical proposals to serve as the relata of the "reduction" relation. One might claim, for example, that two variables are associated, or that some functional relationship falls in some (perhaps large) family, or that some previously considered theoretical possibility is incorrect (but without any further information about which theoretical possibility actually is right). These different types of theoretical claims can all imply commitments at other levels even if there is no particular broad theory in which they fit (and so no appropriate relata for reduction).

Second, and more importantly, "reduction" is always understood as a between-level relation: \(H\) and \(L\) are theories at different levels about roughly similar phenomena. \({ }^{1}\) Intertheoretic relations arise, however, between theories that do not stand in this type of "hierarchical" arrangement. For example, theories of causal learning and reasoning (e.g., Cheng, 1997; Griffiths \& Tenenbaum, 2005) and theories of "causal" concepts (e.g., Rehder, 2003a, 2003b) investigate different phenomena, and so cannot possibly stand in a reductive relationship in either direction. Nonetheless, these types of theories clearly constrain one another; at the very least, they both depend on representations of causal structure, and so information about one theory can be informative about the other. The focus on "levels of description" or Marr's levels makes it easy to focus on the hierarchically structured theories, but they are not the only ones that constrain one another. Just as we needed a more sophisticated understanding of the dimensions of variation in theoretical commitment, we need a more general account of intertheoretic constraints.

\footnotetext{
\({ }^{1}\) We also sometimes speak of a more general theory "reducing" to a more specific one at the same level in particular conditions (e.g., general relativity reduces to Newtonian dynamics in the limit of \(\left.(v / c)^{2} \rightarrow 0\right)\). Nickles (1973) shows how to keep this type of reduction separate from the type I have been discussing.
}

\section*{Towards an Account of "Constraint"}

At a high level, one cognitive theory \(S\) constrains another theory \(T\) if the extent to which \(S\) has some theoretical virtue \(V\) (e.g., truth, predictive accuracy, explanatory power) is relevant for the extent to which \(T\) has the same theoretical virtue \(V\). More colloquially, \(S\) constrains \(T\) just when, if we care about \(T\) along some dimension, then we should also care about \(S\) along that same dimension (because \(S\) could be informative about \(T\) ). Suppose, for example, that \(T\) reduces to \(S\). Reductions clearly involve constraint in terms of truth: \(S\) and \(T\) plausibly have the same truth-value when \(T\) reduces to \(S\). At the same time, reductions arguably do not always involve constraint in terms of explanatory power: the explanatory powers of the two theories in a reduction can vary relatively independently. Thus, it is important to relativize each application of intertheoretic constraint to a particular theoretical virtue.

To see how a more general notion of "constraint" could be made precise, consider the theoretical virtue of truth. I propose (without argument) that: \(S\) truth-constrains \(T\) if and only if a change in belief in \(S\) from time \(t_{1}\) to time \(t_{2}\) would, for a fully-knowledgeable agent, rationally produce a change in belief in \(T\) from \(t_{1}\) to \(t_{2}\). Note that there is no assumption here that the change in belief in \(S\) is rational; rather, this account of 'constraint' essentially models it as a conditional: "if an individual's belief in \(S\) changes (for whatever reason), then belief in \(T\) should rationally change as well, assuming that she understands the implications of her beliefs."

This proposal clearly includes reduction as a special case constraint: if \(H\) reduces to \(L\) given conditions \(C\), then an increase in belief in \(L \& C\) (alternately, full acceptance of \(L \& C\) ) should rationally lead to an increase in belief in (or full acceptance of) \(H\). For example, if some psychological theory \(P\) reduces to some neuroscientific theory \(N\), then if we come to believe \(N\), then we should also (rationally) believe \(P\). Moreover, in some contexts, a reductive relation can also lead to a downward constraint: if we come to believe \(H\), then that can rule out certain \(L\) s (i.e., any that \(H\) cannot reduce to).

This account of truth-constraint applies much more broadly than just reduction. For example, causal learning theories and theories of causal concepts that use the same representational framework (e.g., causal Bayesian networks) can be understood as mutually supporting: each makes the other more probable. More generally, one regularly finds arguments in cognitive science that are based on converging evidence from disparate domains, measurement methods, or processes. In this model of truth-constraints, the theories in the different domains place symmetric constraints on one another: increases (or decreases) in belief in one theory should rationally lead to increases (or decreases) in belief in others that point in the same direction. That is, the broader intertheoretic relation of "constraint" enables us-in contrast to the more narrowly focused "reduction"-to explicate and justify one of the most common argumentative techniques in cognitive science.

\section*{Conclusions}

The core idea of this paper is that the commitments that we have about our cognitive theories extend far beyond their mathematical or computational specification. Instead, we must be clear about where we are located in a multidimensional space of theoretical commitments. Our degree of realist commitment, permissible degree of approximation, and intended degree of optimality all can vary relatively independently, though they are tightly coupled in the traditional Marr levels.

Moreover, we need a more fine-grained notion of intertheoretic relations to complement this more nuanced picture of theoretic commitments. Cognitive theories sometimes reduce to one another, but more commonly they inform one another only indirectly. I have suggested that a theory of intertheoretic constraints would be most appropriate, but have only sketched how such constraints might look in one particular case. Substantial work remains to be done to characterize the ways that theories can relate to one another, and then to show how these constraints can be used to guide actual practice in cognitive science.

\begin{abstract}
Infants and children are avid learners. This constant aggregation of new knowledge, however, can interfere with past and future learning. Proactive interference (PI) occurs when past learning interferes with new learning, while retroactive interference (RI) is the attenuation of memory for previous learning as a result of new knowledge. Previous work has demonstrated that adults and children display PI and RI effects, but the developmental trajectories of these effects are less clear. The current study developed a new associative learning paradigm to concurrently test PI and RI in preschoolers and adults. Results demonstrated the presence of RI, and these effects were stable across age groups, suggesting that the mechanisms that modulate RI effects may already be mature in these age groups. No PI effects were found in either group, however. This surprising result suggests the role of associative complexity as a possible modulator of PI in these age groups.
\end{abstract}

Keywords: Learning; memory development; proactive interference; retroactive interference.

\section*{Interference effects}

Infants and children are avid learners: they constantly acquire new knowledge. This new knowledge not only expands their sense of the world, but also affects what they already know and what they will learn in the future (Wixted, 2004). Some of these effects are counterintuitive: (1) acquired knowledge may interfere with future learning, the process known as proactive interference (PI), and (2) acquired knowledge may attenuate memory for previously learned information, the process known as retroactive interference (RI). PI and RI effects are particularly important to study in early development because doing so will help determine what factors benefit or detract from the aggregation of early knowledge.

These sources of forgetting may play a role in many early cognitive domains, such as categorization (Mareschal, Quinn, \& French, 2002) and word learning (Levy-Gigi \& Vakil, 2010). Imagine, for example, that a child with bilingual parents learns the word "cat," but is later introduced to the word "gato." Mapping "gato" onto the child's category of cats may be more difficult than learning an entirely new concept in Spanish since the category is already associated with "cat" (PI). Additionally, the mapping between the word "cat" and the category of cats will likely be weakened as a result of learning to associate the category with a second word (RI).

Interference effects have been the focus of a great deal of research. It is clear, for example, that interference occurs in many different learning systems, including connectionist networks (French, 1999; Ratcliff, 1990) and human adults (Bower, Thompson-Schill, \& Tulving, 1994; Wixted, 2004). In adults, RI effects may be modulated by similarity between learning sets as well as mental effort, such that more interference is demonstrated with greater similarity and increased cognitive load (Dewar, Cowan, \& Della Sala, 2007; French, 1999; Wixted, 2004). Additionally, RI seems to be modulated by the engagement of networks in the hippocampal region and surrounding cortices (McClelland, McNaughton, \& O'Reilly, 1995; Wiskott, Rasch, \& Kempermann, 2006). Conversely, PI effects seem to be modulated by executive functions such as attentional control and inhibition of prepotent responses (Baker, Friedman, \& Leslie, 2010; Dick, 2012; Kiesel et al., 2010), and appear to be attenuated by activity in prefrontal regions of the cortex (Badre \& Wagner, 2005).

\section*{Interference in development}

Although the majority of research concerning PI and RI has focused on adults, some evidence suggests that interference effects may also be present early in human development. For example, infants demonstrate RI in a visual recognition task (Turati, 2008) as well as a mobile reinforcement paradigm (Rossi-George \& Rovee-Collier, 1999), and demonstrate PI in visual facial recognition (Tyrrell, Snowman, Beier, \& Blanck, 1990).

Despite the fact that interference occurs across development, the development of the ability to resist each kind of interference is less clear. There is some evidence that RI effects are relatively stable between preschool and school years. Howe (1995) demonstrated that RI effects were similar in preschoolers (approximately 4.5 years) and kindergarteners (approximately 6 years old) in a pairedassociate recall task. Similar findings were reported in 4and 7 -year-olds, using a game-based paradigm (Lee \& Bussey, 2001). It is unclear, however, whether there are developmental differences in RI if a wider age range is considered. In contrast, developmental differences in PI have been reported. Kail (2002) performed a meta-analysis on PI effects in children ages 4-13 years old, as well as an experiment with children in grades 3-6 and undergraduate adults. Both the meta-analysis and experimental results
indicated a decrease in PI effects across these developmental time scales.

The current study was conducted to investigate any differences in PI and RI between preschoolers (5-year-olds) and adults. To do so, we developed a new associative learning paradigm that would be appropriate to measure interference effects in both children and adults (Experiment 1) as well as provide a control for memory decay when specifically measuring RI (Experiment 2). This paradigm has the advantage of testing for both types of interference in a manner that is appropriate for children and adults.

\section*{Experiment 1}

To examine developmental differences in PI and RI, we developed a new associative learning task that allows us to study both types of interference within a single paradigm. In this task pairs of objects were associated with an outcome in three phases. In the first phase, participants learned to predict outcomes based the identities of paired objects; in the second phase, objects were re-paired to stimulate new learning, while in the final phase participants were presented again with the original pairs.

We expected to finds both types of interference in children, whereas the extent to which these effects are present in adults was less clear. Previous research suggests that RI effects are present in adults, to the extent that the learned material is sufficiently similar and cognitively challenging across phases (Dewar et al., 2007; French, 1999; Wixted, 2004). Also, given that cognitive control abilities are substantially more advanced in adults and given that PI effects depend on cognitive control (Baker et al., 2010; Dick, 2012; Kiesel et al., 2010), we expected that PI effects, if found, should be greater in children than in adults.

\section*{Method}

Participants Twenty-six undergraduates at The Ohio State University ( 20 females) and 34 children ( \(m=5.2\) years, SD \(=0.23\) years, 14 females) from the surrounding Columbus community participated in this experiment. Children were tested at local preschools. Adults received course credit and children received stickers for their participation.
Six children did not complete the task due to fatigue ( \(\mathrm{n}=5\) ) or computer error ( \(\mathrm{n}=1\) ). The data from these children were removed from all analyses. Additionally, since the focus of this study was on interference between new and previous learning, we required that participants demonstrate accuracy greater than \(70 \%\) in the initial learning phase of the experiment to be included in the analysis. In this way, we only included participants who demonstrated learning that could induce PI or be subject to RI. This learning criterion resulted in the removal of three adults and ten children. Our final experimental sample, therefore, consisted of 23 adults ( 17 females) and 18 children ( \(\mathrm{m}=5.3\) years, \(\mathrm{SD}=0.27\) years, 8 females).

Stimuli Experimental stimuli consisted of eight objects with common shapes and colors (e.g. blue circle). Each trial
consisted of the presentation of a pair of objects and a visual occluder that resembled a pipe splitting into two ends (see Figure 1). This occluder design was implemented such that an object disappearing behind the occluder could reappear on either side. Crucially, the outcome of the trial (i.e. where the object reappears) depended on the identities of the object pairings.
The object pairings, color of the visual occluder, and color of the background varied by phase: In the first phase, four object pairs were presented along with a white occluder on a dark grey background. In the second phase, objects were repaired and presented with a black occluder on a light grey background. Stimuli in the third phase were identical to those presented in the first phase. The purpose of varying the object pairings was to create interference between learning sets, while contextual information was varied so that new learning would not be too difficult to encode.

Figure 1: An example trial in phase 1
Procedure The task was computer-based, and stimuli were presented using E-Prime. To encourage interest in the task, children were tested using a touch-screen computer (adults were tested with a standard screen). In each trial two objects were presented with a visual occluder as described above. One object was situated directly above the second object, and the relative position of each object in the pair was counter-balanced across trials. The participant was told that one object would move into the occluder and come out on one side, and was asked to predict on which side of the occluder the object would reappear. Responses were made using the left or right arrows on a keyboard (adults) or by touching the relevant area of the touch-screen (children). Immediately after a response was given, the bottommost object would rise and hit the topmost object, which would move directly into the occluder before reappearing on one side approximately one second later. In addition to seeing the outcome of the object movement, participants were given explicit feedback: adults heard a high or low tone corresponding to correct and incorrect responses, respectively, while children were given explicit verbal feedback by the experimenter (e.g. "That's right, it does go
to that side!") in addition to the tone. The side of the object's reappearance was predicted by the object pair. In this way, subjects were able to learn the contingency between object pairs and outcomes.

The identity of the object pairings depended on the phase of the experiment: phase 1 consisted of learning four pairs of objects (such that two pairs reappeared on the left side of the occluder and two on the right). The objects were repaired in phase 2 , such that new learning required subjects to create new associations with the same objects and potential outcomes. The third phase was identical to the first phase, except that order of stimulus presentation varied between phases. Table 1 illustrates the abstract structure of object and outcome pairings in this experiment. For phases \(1-3\), each letter represents an object, while the outcome indicates the side of the object's reappearance from the occluder. Note that each pair in phase 2 includes an object that was associated with the opposite outcome in phase 1.

As noted above, the visual context of these stimuli changed between the phases to facilitate learning and recognition of different learning outcomes in the different phases. Participants were not informed that the context would change between the phases, nor were they told that they would be learning new associations in phase 2 or that they would be relearning the associations from phase 1 in the third phase. Forty trials (10 per pair of objects) were presented to each participant per phase, for a total of 120 trials. Subjects were invited to take short breaks between phases.

Table 1: Abstract object and outcome structure for Experiment 1.
\begin{tabular}{llll}
\hline Phase 1 & Phase 2 & Phase 3 & Outcome \\
\hline A - B & A - F & A - B & Left \\
C - D & C - H & C - D & Left \\
E - F & E - B & E - F & Right \\
G - H & G - D & G - H & Right \\
\hline
\end{tabular}

\section*{Results}

The central question of interest was whether children and adults would demonstrate differing amounts of proactive and retroactive interference effects. To address this question, trials in each phase were divided into 5 blocks (8 trials per phase) to closely examine the learning trajectories of these groups (see Figure 2).

To measure PI we compared the beginning (i.e. first block) of phase 1 to the beginning of phase 2: a decrease in accuracy in the second block would indicate PI. To measure RI we compared the end (i.e. last block) of the first phase to the beginning of phase 3 : since the object pairs were identical in the two phases, a decrease in performance between these blocks would indicate RI. A series of analyses of variance (ANOVAs) and t-tests was used to statistically measure PI and RI.

Figure 2: Accuracy in Experiment 1 by block for each phase in children (top) and adults (bottom), with standard error bars.

Proactive Interference To test PI effects, an ANOVA with block as a within-subject factor and age as a betweensubject factor was performed on the proportion of accurate responses for the first block of the first and second phases (see Figure 3). There were no significant main effects of block or age, and no interaction between these factors ( \(p\) 's>.2). To more directly test PI effects we conducted paired-sample t-tests between the first blocks of phases 1 and 2 separately for children and adults. The difference between blocks was not significant for children, \(t(17)=1.17\), \(p>.2\), or adults, \(t(22)=.49, \mathrm{p}>.6\). These results suggest that PI was not a factor in this experiment in children or adults.

Retroactive Interference To test RI effects, an ANOVA with block as a within-subject factor and age as a betweensubject factor was conducted on accuracy scores in the last block of phase 1 and the first block of phase 3 for children and adults. A significant main effect of block, \(F(1,39)=20.53, p<.001\), indicated that accuracy decreased in
the beginning of phase 3 across age groups. There was also a main effect of age, \(F(1,39)=4.07, p=.05\), suggesting that overall accuracy in these blocks was higher in adults No interaction, however, was found between block and age, \(p>.3\), suggesting that the difference between blocks did not vary as a function of age. The strong main effect of block suggested that RI may be found in individual age groups. Indeed, separate paired-samples t-tests revealed a significant difference in accuracies between the end of phase 1 and the beginning of phase 3 for children, \(t(17)=2.94, p<.01\), \(d=0.69\), as well as adults, \(t(22)=3.55, p<.01, d=0.74\). These results suggest that RI did occur in both children and adults, and that interference did not differ between groups.

One possible explanation for these retroactive interference effects is that subjects simply forgot the relevant associations learned in phase 1 as a result of the time passed between phases 1 and 3 . If this is the case, then the information learned in phase 2 did not interfere with performance in phase 3 but merely served a placeholder for the passage of time. To determine if this was the case, a second experiment was performed to control for memory decay.

Figure 3: PI and RI effects in Experiments 1 and 2. PI effects were calculated as the difference in accuracy between block 1 of phase 1 and block 1 of phase 2; RI effects were calculated as the difference in block 5 of phase

1 and block 1 of phase 3 . Positive values indicate interference; negative values indicate facilitation. \({ }^{*} p<.05\)

\section*{Experiment 2}

One potential interpretation of the RI effects found in Experiment 1 is that participants did not experience interference from learning new associations in phase 2 but simply forgot the associations learned in the first phase due to memory decay. To determine if this was the case, Experiment 2 minimized new learning while retaining the same task structure in the second phase of the task. If the RI effects found in Experiment 1 were due to memory decay, then performance in the beginning of phase 3 should also be
attenuated in this experiment in the absence of new learning. If accuracy has not declined at the start of phase 3, however, we can be confident that the results of Experiment 1 were indeed due to interference and not decay.

\section*{Method}

Participants Twenty-six adult undergraduates (17 females) and 215 -year-old children ( \(\mathrm{m}=5.3\) years, \(\mathrm{SD}=0.21\) years, 13 females) participated. Three children did not complete the experiment due to fatigue ( \(\mathrm{n}=2\) ) or because they were unable to complete the task before the end of the preschool session ( \(n=1\) ). Using the same learning criterion described above, three adults and eight children were further removed from the analysis for failure to demonstrate sufficient learning in the first phase of the task. The final analysis, then, included 23 adults ( 14 females) and 10 children ( \(\mathrm{m}=\) 5.2 years, \(\mathrm{SD}=0.13\) years, 6 females).

Stimuli The stimuli presented in phases 1 and 3 were identical to those in Experiment 1. In the second phase, however, pairs of objects were replaced with horizontally oriented arrows pointing to the left or right side of the screen. This was done so that participants could easily predict the outcome of each trial based on the direction of the arrows. In this way, participants continued performing the same task but with minimal new learning. The occluder and background colors in phase 2 were the same as in Experiment 1.

Procedure The procedure was the same as in Experiment 1: participants were presented with two objects (phases 1 and 3 ) or two arrows (phase 2), and predicted on which side of a visual occluder an object or arrow would reappear.

\section*{Results}

The purpose of this experiment was to determine if the attenuation of performance in Experiment 1 could be explained by memory decay. As such, accuracies in the last block of phase 1 and the first block of phase 3 were compared, as in Experiment 1 (see Figure 4 for the learning curves of each phase for children and adults, and Figure 3 for the differences between the target blocks). An ANOVA with block as a within-subject factor and age as a betweensubject factor revealed a main effect of block that was approaching significance, \(F(1,31)=3.77, p=.06\). However, in contrast to Experiment 1 (where performance dropped in phase 3 compared to phase 1), in this experiment, performance actually improved in phase 3 . There was a significant main effect of age, \(F(1,31)=6.5, p<.05\), indicating that adults' accuracy was higher across blocks, as in Experiment 1. The interaction between block and age was approaching significance, \(F(1,31)=3.77, p=0.6\), possibly reflecting a greater improvement in children's accuracy in the beginning of phase 3 from the end of phase 1. Individual t-tests indicated that the difference between these blocks was not significant in children ( \(p>.1\) ), or adults \((p=1)\). These
findings suggest that simple forgetting cannot explain interference effects observed in Experiment 1.

Figure 4: Accuracy in Experiment 2 by block for each phase in children (top) and adults (bottom), with standard error bars.

\section*{General Discussion}

This study investigated proactive and retroactive interference effects in preschoolers and adults. Results indicated comparable levels of RI in children and adults, but demonstrated no PI in either group. These results support recent claims that RI seems to be a particularly potent source of forgetting in humans (Wixted, 2004).

Additionally, our findings replicate and extend previous demonstrations that RI seems to produce consistent levels of interference across age groups. Specifically, these results provide new evidence that RI effects are stable from the preschool years into adulthood. This consistency may be the result of the early development of the neural systems involved in modulating RI, specifically the hippocampal formation (McClelland et al., 1995; Wiskott et al., 2006). Recent work suggests that the hippocampus and
surrounding areas in the medial temporal lobe have functionally developed by the age of five years (Alvarado, 2000; Bauer, 2008), which is consistent with our findings of stable RI effects following this age.

The results of this study are inconsistent, however, with the previous literature suggesting the presence of PI in children (e.g. Baker et al., 2010) and adults (e.g. Kiesel et al., 2010), as well as its decline with development (Kail, 2002). Why was PI not a factor in this task? One possibility is that the structure of the learned associations was not conducive to this type of interference. Each object in the stimulus set appeared only in a single pair (which was associated with a single outcome), such that each object in a pair was perfectly predictive of a given trial's outcome (see Table 1). As such, it was not necessary to encode an association between the two objects in the pair. This simple structure may have reduced demands on executive function, which might not have been the case if more complex structures were presented. Recall that PI is typically linked to executive functions (Baker et al., 2010; Dick, 2012; Kiesel et al., 2010), which are sub-served by the prefrontal cortex (Badre \& Wagner, 2005). Also recall that the areas of the prefrontal cortex sub-serving executive function mature relatively late (Bunge \& Zelazo, 2006). Therefore, it is quite surprising that PI effects did not transpire in young children. Perhaps the task was too easy to yield such effects (although it was not too easy to yield RI effects).

More broadly, the study of interference effects in development can potentially shed light on a number of important developmental phenomena. Word learning, for example, may depend in large part on associations between sounds and referents (Smith, Jones, Yoshida, \& Colunga, 2003). Recent work has suggested that 12- and 14-month old infants raised in a monolingual or bilingual environment do not differ in their ability to learn simple word-object pairings (Byers-Heinlein, Fennell, \& Werker, 2013). An intriguing possibility is that language background may instead influence the ability to form more complex associations (e.g. between words, referents, and identity of the language).

Many questions await future research. For example, creating more complexity in the structure of associations, such that three-way bindings between object \({ }_{1}\), object \({ }_{2}\), and the outcome are necessary for learning, will help us test the hypothesis that PI is modulated by associative complexity, possibly through increased demands on executive function. Additionally, mapping interference effects in more (particularly younger) age groups will allow us to determine whether interference effects are subject to developmental change and the time scales at which such change occurs. Understanding the mechanisms and developmental time course of these effects will allow us to understand a potentially fundamental aspect of learning and memory and how these processes interact early in life.

\section*{Acknowledgements}

This research was supported by a National Science Foundation (NSF) grant (BCS-0720135) to Vladimir Sloutsky. We thank the children, parents, and preschools that participated in this research.

\begin{abstract}
Graphical overviews have been studied as a method to improve hypertext learning and digital search. Although previous studies have found learning benefits to graphical overviews of single hypertext, it is unclear if these benefits extend to online learning across multiple (independent) documents. Previous research also has found that graphical overviews facilitate domain focus during online search, but it has not been established whether these benefits are derived from the spatial organization of the graphic or its textual content. This research examined the impact of using graphical overviews organized either spatially (i.e., network view) or textually (i.e., outline view) during self-regulated online learning. Assessments focused on deep understanding of science concepts and the relationships between them. Results indicated that the outline view promoted deeper understanding of science concepts and fewer errors about the relationships between them. Implications are discussed for the design and implementation of instructional materials to support self-regulated learning.
\end{abstract}

Keywords: self-regulated learning; graphical representations; online learning; conceptual browsing; comprehension

\section*{Introduction}

As individual learning tasks increasingly are performed in online environments (Graham \& Metaxas, 2003), there is a strong need to understand how the format of different materials impacts successful self-regulated learning (Pintrich, 2000; Winne, 2001). Self-regulated learning refers to learning situations in which students themselves must organize and manage the learning task (Azevedo \& Cromley, 2004); it can be contrasted with learning in structured environments such as intelligent tutoring systems, where the computer system typically chooses the problems and decides when the student has reached mastery and is ready to move on to new materials (Anderson et al., 1995).

When students work with online learning materials - for example, hypertext documents - the learning task is inherently self-regulated by virtue of non-linear links that allow the learner to choose a unique path through the digital content. Research has found that students have great difficulty in self-regulating their learning with hypermedia, often utilizing ineffective strategies during self-regulated learning tasks (Azevedo et al., 2008). Other research has demonstrated the potential of organizational materials to facilitate more effective self-directed learning in online environments. For example, graphical overviews have been found to facilitate learning when presented before students
work with a hypertext document (Salmerón et al., 2009). However, it is unclear if graphical overviews will have similar facilitative effects in online environments with limited coherence between independent online resources (rather than within a single hypertext document).

There is some evidence that a graphical interface can facilitate learning with varied, independent online resources. Research studying the use of a graphically-organized interface for online browsing showed that it facilitated processing of domain information in a digital library environment when compared to a keyword search interface (Butcher, Bhushan, \& Sumner, 2006). However, it remains unclear if results were driven by the spatial formatting of the graphical interface or its conceptual (textual) content.

This research investigates the effects of a graphical overview (presented as either a text-based outline view or a spatially-organized network view) on students’ selfregulated learning with online digital resources drawn from an educational digital library.

\section*{Self-Regulated Learning with Hypermedia}

When students are asked to self-regulate their learning from hypermedia, they often struggle to organize and process information in ways that support deep understanding (Azevedo et al., 2008). Although successful self-regulated learners engage in strategies such as planning and prior knowledge activation (Azevedo, Guthrie, \& Seibert, 2004), students engaged in self-regulated learning with hypermedia frequently choose to prioritize their reading based upon personal interest or text location (Salmerón, Kintsch, \& Cañas, 2006). Not surprisingly, this failure to attend to conceptual relationships and coherence in the domain can lead students to miss important semantic connections between ideas and to form a more shallow understanding of hypermedia content (Salmerón et al., 2006).

Students may need significant help - especially in activating prior knowledge, organizing knowledge, and processing conceptual relationships - in order to learn effectively with online content. One way to offer this support is to provide the student with useful organizational materials that can be used to guide study and learning. Graphical overviews, which illustrate high-level ideas and the relations between them for a given text or topic, provide one form of organizational materials that has been shown to support learning among students with low prior knowledge (Salmerón et al., 2009).

\section*{Graphical Overviews and Hypertext Learning}

Salmerón and colleagues have examined the impact of graphical overviews as the method of navigation through a hypertext (Salmerón et al., 2009; Salmerón \& Garcia, 2012). These graphical organizations provided students with freedom to choose navigational paths through the hypertext but organized the content that could be viewed across the hypertext using a conceptual overview of the content. Salmerón and Garcia (2012) found that providing young (sixth grade) learners with a graphical overview of a hypertext document improved their knowledge integration during a comprehension task. These results complement earlier findings which showed that providing students with a graphical overview before hypertext study led to increases in comprehension for undergraduate learners (Salmerón, et al., 2009). Salmerón and colleagues have proposed two potential explanations for the observed benefits of graphical overviews: first, graphical overviews may facilitate learning by providing an organizational framework to support online study; second, graphical overviews may facilitate active processing of difficult texts by providing a text macrostructure that frees up additional resources for comprehension processes.

If graphical overviews facilitate learning by providing learners with an organizational framework for domain knowledge, studying their effects within a single hypertext may underestimate their potential benefits. Whereas a single hypertext likely has an overall coherence and topical focus, self-regulated learning in more authentic online environments requires working across independent digital resources that may not be easily integrated. Thus, it is important to consider whether graphical overviews may facilitate learning when students work with multiple online resources (i.e., independent web pages and sites).

\section*{Graphical Overviews and Digital Search}

There is some evidence that graphical overviews change learners' processing when engaged in learning tasks that require work with multiple online resources. Butcher, Bhushan, and Sumner (2006) studied the impact of graphical overviews on students' search and evaluation processes as they attempted to locate useful online resources in an educational digital library. Students used either a graphical representation (a domain overview in the form of a node-link diagram) or a keyword interface to search for relevant digital content. Results showed that using the graphical representation as a search interface increased the depth of domain-relevant processing. Whereas students who navigated digital resources using a keyword interface tended to focus on superficial features of the resources, students navigating the resources with the graphical interface focused on analyzing domain concepts. Changes in the depth of students' processing of digital resources does not provide direct evidence of deeper learning with these resources; however, novice learners engaged in educational search tasks likely are engaged in "search to learn" processes which include iterative rounds of cognitive processing and
interpretation (Marchionini, 2006). Recent research (Butcher et al., 2011) has confirmed the impact of graphical overviews on digital search and evaluation: when graphical representations were used as the basis for preservice teachers' navigation of resources in an educational digital library, students were more likely to identify educationallyuseful online content and to focus on domain-level content when evaluating a web page or site.

\section*{Format and Content of Graphical Overviews}

Although Butcher and colleagues (Butcher et al., 2006; Butcher et al., 2011) have found clear evidence that graphical representations can impact the processes that students use during online search and the overall success of online searches during educational tasks, it remains unclear whether these observed benefits were derived from the spatial format of the graphic (i.e., the spatial organization of the graphical overviews) or its (textual) domain content. Because keyword interfaces may require significant cognitive effort to generate relevant search terms (Marchionini \& White, 2007), it is possible that the benefits of graphical overviews for self-regulated, online learning tasks may be derived from reallocation of cognitive effort from keyword generation to concept analysis. If this were the case, we would expect that removing spatial organization could facilitate even greater benefits by removing processing difficulty associated with examining and understanding spatial information.

If it is largely the textual content of graphical overviews that facilitates learning, more complex spatial formats actually may hurt novice learners. Graphical overviews in the form of a network map (see Figure 1) may depict interrelationships that are too complex for novice learners to understand. Novice learners may be better served by formats that emphasize organizational information in a hierarchical (i.e., linear) manner (see Figure 2). In a comparison of learning from linear and non-linear conceptual overviews, Amadieu and colleagues (2009) found that domain novices reported increased disorientation when learning from a network conceptual overview that depicted important relationships. In contrast, learners reported less disorientation and achieved better recall when learning with a hierarchical conceptual overview. Still, if it is true that graphical overviews promote learning by providing a conceptual framework for domain content, we would expect that a hierarchical graphical overview that removes spatial information would cease to be effective.

The current research extends prior research by examining two forms of graphical overviews during an online learning task: a spatially-organized network view vs. a textuallyorganized (linear) outline view. The use of these two conditions facilitates a direct comparison of whether the spatial format or the domain content of the graphical overviews has the greatest impact on learning outcomes. In addition, this research examines impact within a more authentic online environment, using the graphical overview to facilitate learning across a variety of independent online
resources. Because the network view is designed to demonstrate key conceptual relationships between multiple learning goals, we hypothesized that this graphical overview would facilitate greatest understanding of domain relationships.

\section*{Factual Knowledge vs. Deeper Understanding}

When considering learning outcomes, it is important to recognize that comprehension research has established that different levels of knowledge can be formed during learning (Kintsch, 1998). In this work, we draw upon a well-known, established model of comprehension - ConstructionIntegration (CI) - that distinguishes between three levels of knowledge representation: the surface level, the textbase, and the situation model (Kintsch, 1994). A surface level representation is formed by encoding the specific details of a text (e.g., exact words and sentences). A textbase representation consists of the semantic meaning of a text; thus, a textbase representation drives recall of basic ideas derived from learning materials. The most flexible and durable knowledge representation is the situation model, which is formed when the learner integrates to-be-learned content with prior knowledge. A well-developed situation model drives inference, application, and transfer; as such, students who develop the situation model can be considered to understand materials rather than simply remember them.

The outcome assessments in this research target knowledge at the textbase and situation model levels. As described below, textbase assessments focus on factual knowledge learned during study and recalled during testing. Situation model assessments focus on students' application of learned knowledge, through explanation of concepts and relationships. Errors in student explanations, which may result from superficial reasoning about perceived relationships, also are examined.

\section*{Method}

\section*{Participants}

Twenty-six undergraduate students (8 males, 18 females, \(M\) age \(=23\) ) at a large public university in the western United States participated in this study in partial fulfillment of a class research requirement. One participant was excluded because his major was geology.

\section*{Design}

This study utilized a two-condition, between-subjects experimental design. Participants were randomly assigned to one of the two experimental conditions upon arrival to the study.

\section*{Materials}

Graphical Overviews The graphical overviews in this study were drawn from the Science Literacy Maps published on the National Science Digital Library (NSDL) website. NSDL is a digital library which seeks to provide
access to up-to-date, high-quality, online resources in varied formats that will support education and learning in science, technology, engineering, and mathematics (Zia, 2000). The NSDL Science Literacy Maps are derived from strand maps developed by the American Association for the Advancement of Science (AAAS, 2001); these maps take the form of node-link diagrams. Nodes contain text that describe key learning goals in a topic area. The spatial organization of the nodes and the links between them demonstrate how student knowledge (as evidenced by the learning goals) should progress over time in a given domain.

In the NSDL, the Science Literacy Maps serve as a conceptual browsing interface (Zia, 2000); that is, the maps serve as a graphical search interface. To retrieve relevant digital resources using a conceptual search interface, users select a specific learning goal from the graphical overview (i.e., the Science Literacy Map). Clicking a learning goal brings up a small window that lists the NSDL-catalogued resources relevant to the conceptual information contained in the learning goal; much like a commercial search interface, each listed result provides users a title, a linked URL, and a short description of the resource.

Network Graphical Overview. The network view of the search interface utilizes the standard form of the Science Literacy Maps as found on NSDL.org. Learning goals are represented as nodes and are connected to one another with arrow links (see Figure 1); links between nodes indicate conceptual relationships between the learning goals. The overall spatial organization of the network indicates a more global knowledge organization, showing how learning goals develop over time, across grade levels and subtopics in the domain (see Figure 1).

Outline Graphical Overview. The outline view of the search interface contains the same node content as the network view. That is, all nodes contain the same text describing the same learning goals. However, in this view, the learning goal nodes are listed vertically rather than spatially. Learning goals in the outline view still are grouped by grade level (see Figure 2), but there are no links indicating conceptual relationships and spatial organization has been removed. As in the network view, clicking a learning goal in the outline view will bring up a window showing relevant resources catalogued in the digital library (see Figure 2). The learning goals in the outline view retrieved the same digital resources as in the network view (i.e., both interfaces searched over the same collection of digital resources and used the same algorithms to retrieve content relevant to each learning goal).

Reference Versions of Network and Outline Views Before students used the graphical overview as a search interface to find online digital resources, they were given ten minutes to familiarize themselves with a non-interactive version of the graphic. The non-interactive forms of the graphical overviews utilized the same formatting and content as the interactive (search interface) versions of the graphical overviews as described above (see Figures \(1 \& 2\) ).

Figure 1: The network conceptual search interface is on the left. On the right is its associated noninteractive reference.

Figure 2: The outline conceptual search interface is on the left. On the right is its associated non-interactive reference.

Learning Assessments Learning assessments were administered at the beginning and end of each session. Questions tested participants' factual knowledge of plate tectonics, as well as their understanding of important plate tectonics concepts and relationships between them

Factual Knowledge. Factual knowledge items were designed to capture participants' textbase-level knowledge of plate tectonics. Factual items consisted of generative as well as non-generative (multiple choice and true/false) questions. Generative questions provided participants with images, such as a cross-section of the Earth, and asked them to generate labels for specific components or processes. Participants were asked to generate 13 diagram labels; correct labels received one point and partially-correct labels received half a point, for a total of 13 points. Nongenerative questions tested students on their general knowledge (e.g., the number of Earth's tectonic plates). The non-generative factual assessment consisted of 33 items; participants received one point per correct item, for a total of 33 points.

Conceptual Understanding. Conceptual understanding items were designed to elicit participant explanations about key plate tectonics processes, thereby reflecting participants' situation models. These items asked students to interpret a diagram and explain the plate tectonics processes pictured. Conceptual understanding items were scored using a rubric that categorized explanations from most shallow to most deep, with a maximum of 5 points available per item. See Table 1 for examples of shallow, moderate, and deep answers. There were four conceptual understanding items, for a total of 20 points possible.

Table 1: Conceptual Explanation Examples
\begin{tabular}{|c|l|}
\hline Shallow & \begin{tabular}{l} 
It is showing the movement and direction \\
in which Earth is moving caused by heat.
\end{tabular} \\
\hline Moderate & \begin{tabular}{l} 
The arrows are drawn in a circular pattern \\
because that is how the convection heat \\
current travels beneath the surface.
\end{tabular} \\
\hline Deep & \begin{tabular}{l} 
The rock in the mantle is heated up and \\
due to its then lighter density rises to the \\
surface where it is cooled because it is \\
further away from the core and starts to \\
become more dense and sinks. This \\
process is repeated over and over again \\
and is called convection.
\end{tabular} \\
\hline
\end{tabular}

Relationship Explanations. These items were designed to assess the depth with which students understood conceptual relationships between the learning goals. Relationship explanation items provided students with two distinct learning goals from the graphical overview and asked them to explain the relationship between the learning goals. This assessment presented students with 3 pairs of learning goals at pretest and 6 pairs at posttest. Relationship explanation items were scored as shallow or deep (see Table 2 for examples). Because novice learners often fail to identify and understand important relationships during learning, and because the conditions differed in the explicit portrayal of these relationships, the accuracy of relationship explanations was also examined. Explanations containing incorrect reasoning or mechanisms were marked as containing errors.

Table 2: Relationship Explanation Examples
\begin{tabular}{|c|l|}
\hline Shallow & \begin{tabular}{l} 
They both talk about the movement of the \\
earth and what is causing the earth to move.
\end{tabular} \\
\hline Deep & \begin{tabular}{l} 
Because of heat flow and gravity, we see a \\
pattern of movement within the earth's \\
mantle (convection). The plates ride on the \\
mantle, so this movement translates into the \\
plates interacting with each other.
\end{tabular} \\
\hline
\end{tabular}

\section*{Procedure}

To begin the study session, participants completed a brief survey which gathered demographic information. Next, the pretests were administered to assess participants' prior knowledge of plate tectonics. The learning task included 10minute study of the reference version of the graphical overview (as appropriate to randomly assigned conditions), followed by forty minutes of learning with online digital resources as facilitated by the (condition-appropriate) graphical overview acting as the search interface. During online study, the reference version of the graphical overview was displayed on a second monitor so that participants could refer to it when reading/examining a digital resource.
Following the learning task, posttest assessments were administered.

\section*{Analysis}

As a check of random assignment, factual knowledge at pretest was analyzed using a MANOVA. Posttest learning assessment components also were analyzed using a repeated measures analysis of variance (RMANOVA) and a MANCOVA (see below). Alpha level was set at \(p=.05\) for all analyses.

\section*{Results}

\section*{Prior Knowledge of Plate Tectonics}

A MANOVA for performance on both types of factual knowledge items at pretest did not show an overall condition difference \(\left(F_{(2,22)}=2.50, p=.11\right)\); however, univariate tests indicated that the two conditions did differ significantly on pretest diagram labels \(\left(F_{(1,23)}=5.19, p=\right.\) .03). At pretest, the network overview condition correctly labeled a higher percentage of diagrams ( \(M=.29, S D=.19\) ) than the outline overview condition ( \(M=.15, S D=.10\) ). To control for the variance in learning due to prior knowledge, pretest performance in diagram labels was used as a covariate in a MANCOVA for posttest performance.

\section*{Posttest Performance on Learning Assessments}

Factual Knowledge A RMANOVA was used to examine pre- and posttest performance on the non-generative factual knowledge items. Overall, participants showed a slight but significant learning gain from pre- to posttest ( \(M_{\text {diff }}=.05\); \(\left.F_{(1,23)}=5.30, p=.03\right)\) but there was no significant effect of condition ( \(F<1\) ).

\section*{Conceptual Understanding \& Relationship Explanations} A MANCOVA was used to examine posttest performance on measures of deep comprehension. There was a significant main effect of condition ( \(F_{(3,20)}=4.32, p=.02\) ). Univariate tests showed a main effect of graphical overview condition on conceptual understanding (see Table 3).

Students in the outline graphical overview condition produced conceptual explanations that evidenced deeper understanding of plate tectonics concepts ( \(M=.38, S D=.19\) ) than the network graphical overview condition ( \(M=.34, S D\) \(\left.=.24 ; F_{(1,22)}=9.42, p<.01\right)\). There also was a significant

Table 3: M and (SD) for Assessments of Learning
\begin{tabular}{|lll|}
\hline Assessment Scores (\%) & Network & Outline \\
\hline Factual Knowledge & & \\
Non-generative (pretest) & \(.56(.09)\) & \(.53(.11)\) \\
Non-generative (posttest) & \(.62(.13)\) & \(.57(.06)\) \\
Conceptual Understanding* & \(.34(.24)\) & \(.38(.19)\) \\
& & \\
\begin{tabular}{c} 
Relationship Explanations \\
\% Deep Relationships \\
\% Conceptual Errors*
\end{tabular} & \(.17(.25)\) & \(.24(.25)\) \\
\hline
\end{tabular}
condition difference in the percentage of errors when explaining relationships between plate tectonics concepts \(\left.F_{(1,22)}=8.12, p<.01\right)\). Students in the outline condition generated a smaller percentage of errors ( \(M=.14, S D=.16\) ) than students in the network condition ( \(M=.27, S D=.17\) ).

A non-significant but note-worthy trend was found in the percentage of deep explanations of relationships between concepts \(\left(F_{(1,22)}=3.34, p=.08\right)\). The outline condition produced a higher percentage of deep relationship explanations ( \(M=.24, S D=.25\) ) than the network condition ( \(M=.17, S D=.25\) ).

\section*{Discussion}

After learning from multiple resources online, students in both conditions evidenced a similar increase in factual (textbase level) understanding of plate tectonics concepts. Overall, this is consistent with previous research finding that providing a graphical overview before hypertext study supports textbase comprehension (Salmerón et al., 2009). However, the current results also demonstrate that a spatially-organized graphical representation does not facilitate textbase learning more than a linearly-organized representation. Thus, it may be the textual content of the graphical organizer that facilitates macrostructure processing and leads to learning gains.

Although spatial format does not vary learning outcomes when considering factual (textbase-level) knowledge, it does impact the depth of understanding for important concepts and relationships between them. However, the pattern of results was opposite of hypothesized findings. Current results show that an outline graphical overview provided a learning advantage over a network (spatially-organized) overview: students learning with the outline view produced more deep explanations of science concepts and evidenced fewer erroneous ideas about inter-conceptual relationships.

This is a surprising result, since only the network view visually depicted the conceptual relationships among the learning goals. Indeed, previous studies have hypothesized that a schematic representation of relationships between concepts may provide novice learners with a framework for assimilating knowledge (Salmerón et al., 2009; Butcher et al., 2011). In this study, the spatial depiction of domain relationships compromised deep understanding. Concepts depicted in a network organization resulted in more errors when students explained conceptual relationships; students working with the network view also demonstrated less evidence of deep thinking about concepts. It may be that the graphic illustration of relationships actually precluded students from thinking deeply about the nature of those relationships. By explicitly depicting the conceptual relationships between learning goals, the network view may have caused students to generate fewer of their own inferences or predictions during learning. Alternatively, the network representation of content may have been too complex for novice learners. Previous research has found that students report feeling more disoriented with a network organization than with a more linear representation of
information (Amadieu et al., 2009). Because the network view did not specify the nature of potentially-complex relationships, students may have resorted to more shallow strategies of reasoning, integrating concepts based on superficial, easily-perceivable common features such as shared keywords.

When searching for information online, students typically learn from varied sources (Marchionini, 2006). Creating a deep, flexible understanding of the situation under investigation requires that self-regulated learners be able to synthesize multiple sources of information and integrate their learning with prior knowledge (Butcher \& Kintsch, 2012; Perfetti, Rouet, \& Britt, 1999). By demonstrating potential drawbacks to network-based graphical organizers during online learning, this study contributes an important initial finding to the literature on how to externally support self-regulated learning with multiple online resources. However, more research is needed to understand the specific relationship between the format of graphical overviews and their impact on learning outcomes.

\title{
Associative strength and semantic activation in the mental lexicon: evidence from continued word associations
}

\begin{abstract}
In a word association task, the probability of producing a certain response to a cue is considered to be a direct measure of associative strength between words in the mental lexicon. The common single word association procedure is limited, since the number of words connected to a cue might be underestimated when a single response is asked. The continued association task overcomes this limitation by asking a person to generate multiple associative responses. To test whether continued strengths allow a better approximation of our lexicon, an experiment was conducted in which participants judged the associative strength between words.
Our results show that in contrast to other semantic tasks, continued strength predicts weak to moderate judgments only. Two explanations based on the sampling of information and differential semantic activation of later responses in continued association are proposed. Theoretical implications for semantic activation and methodological implications for derivation of strength are discussed.
Keywords: associative strength, semantic relatedness; word associations.
\end{abstract}

The free word association task has been used extensively to investigate processes and structure in semantic and episodic memory. The task is attractive because it is unconstrained and straightforward, and no apriori restrictions are formulated about what types of relationships between words are deemed relevant. It leads to a rich and varied source of information. Compared to constrained tasks such as feature generation, it tends to provide more thematic relations like DOCTOR NURSE. There is increasing agreement that this thematic information determines much of how natural language concepts are used both in daily life and in language phenomena studied in the lab including semantic priming, metaphor comprehension, categorization and induction (e.g. Lin \& Murphy, 2001; Wisniewski \& Bassok, 1999).

An influential metaphor for the representation of this knowledge presents the mental lexicon as a weighted graph, where the structure of the links between the nodes (words) determines how words relate to each other and get their meaning. Obviously, the value of such a representation hinges on how the words are connected and on what determines the strength of these connections. The key assumption underlying the word association task, is that the number of people that generate a specific response to a cue is an indication of the strength between cue and response. Approximating the relations in the lexicon through word associations explains numerous phenomena: facilitation of word processing in associative priming (Hutchison, 2003), the probabil-
ity of recall in cued-recall tasks (Nelson, Zhang, \& McKinney, 2001), reaction times in lexical decision (De Deyne, Navarro, \& Storms, 2012) and generation frequencies in fluency tasks (Griffiths, Steyvers, \& Tenenbaum, 2007). Moreover, the overlap of the distributions of these strengths for two words indicates how semantically related they are and this is the basis of the success of lexico-semantic models such as Latent Semantic Analysis (LSA, Landauer \& Dumais, 1997) and topic models (Griffiths et al., 2007).

Associative strength is central to how we process the meaning of words, but the traditional way of measuring it, through asking a participant a single word association, is not without limitations. The response frequencies from the single word association task are considered reliable only for the very strong associates, since weaker responses are often missing (Nelson, McEvoy, \& Dennis, 2000). This lack of weak associations is seen as a general drawback of the word association procedure (Aitchison, 2003, p. 101) and has been responsible for questioning the results of previous findings in numerous tasks such as mediated priming (e.g., Chwilla, Kolk, \& Mulder, 2000). Presumably, this reflects dominance effects where for a cue like umbrella a single strong associate such as RAIN accounts for almost all responses (Nelson \& Bajo, 1985). While the exact causes of dominance effects are not well understood, it is obvious that they make the response distributions overly sparse, and bias all kinds of association derived strength measures.

Recently, a large-scale continued word association database was completed involving over 70,000 participants and 3 million responses (De Deyne, Navarro, \& Storms, 2012). In contrast to previous studies, a continued word association task was used in which subjects were presented a short list of stimulus or cue words and asked to give three different responses to each of these cues. The goal of the present study is to investigate how word association frequencies in continued tasks map onto associative strength. If single word associations tend to underestimate or be unreliable for weaker responses, then we would expect that using information encoded in later responses might alleviate this problem. This would support previous findings where semantic relatedness derived from continued association norms results in a better predictor of semantic tasks including pair-wise similarity judgments (De Deyne, Peirsman, \& Storms, 2009), prototypicality judgments (De Deyne, Voorspoels, Verheyen, Navarro,
\& Storms, 2011), and response times in the lexical decision task (De Deyne et al., 2012).

Since continued word association data only became available recently (cfr. De Deyne et al., 2012), few have studied strength derived from multiple responses and how it relates to other measures of associative strength. For instance in the study of Garskof (1965) calculated strength using continued associations to 20 cues and found that a weighted sum depending on the rank of the response correlated higher than a measure of strength that did not take into account response position. In contrast to previous work, this study presents a systematic comparison of measures of strength by looking at the contribution of continued responses alongside that of single responses using a recently proposed task in which participants judge associative strength of word pairs directly (Koriat, 2008; Maki, 2007) and compare it to single associate strength measures.

Sometimes the best way to understand a phenomenon is to take a step back. To aid the interpretation of the pattern of results from the judgment of associative strength task, the second part of this paper describes additional evidence by comparing expected strengths of continued responses with the observed strengths of these responses in the continued task. This analysis allows us to interpret quantitative differences (due to the sampling regime in continued association), and qualitative differences in terms of the types of semantic information activated in later responses.

\section*{Judgment of Associative Strength Experiment}

In a series of experiments on associative strength, Maki (2007) asked subjects to estimate how many people out of 100 would consider two words to be associated. Using a similar judgment of association strength task, our goal was to find out whether continued responses provide a better approximation compared to a single response procedure.

To test this hypothesis we compared various models, starting with a simple one that predicts judgments using the word association counts of the first three response positions ( \(R_{1}\), \(R_{2}, R_{3}\) ). Strength can be forward strength \((F S)\), or the probability that a certain response is generated given a cue or backward strength \((B S)\) : the probability of a certain cue given a specific response. These measures are easily derived by dividing the frequency of a certain response by the total number of responses for that cue.

\section*{Method}

Participants Fifty native Dutch speaking psychology students participated in exchange for course credit.
Stimuli and Materials The stimuli were selected from a set of more than 12,000 Dutch cues that were part of a large scale continued word association database described in De Deyne et al. (2012). Similar to De Deyne et al. (2012) single and multiple response strength were derived from the graph \(G_{1}\) based on the first response \(G_{2}\) based on the secondary and \(G_{3}\) for tertiary responses. These graphs were obtained by con-
verting the bimodal cue by response matrix to a unimodal cue by cue matrix by retaining those responses present in the set of cues. This makes it possible to get estimates of both backward and forward strength since all responses are also present as a cue in such a graph. For each cue, \(F S\) was calculated using only the first response \(\left(G_{1}\right)\) or including the sum of all three responses \(G_{123}\). The cues were determined randomly subject to following conditions. Only responses that were present both in \(G_{1}\) and \(G_{123}\) were considered. The difference in response strength was calculated and responses were selected that differentiated between both graphs.

A total of 80 associated cues and responses were chosen to cover the entire range of forward and backward strength between 0 and 1. All words in the judgment tasks were unique and only Dutch words were admitted that had a word frequency larger than one in the SUBTLEX-NL word frequency norms (Keuleers, Brysbaert, \& New, 2010). Similar as in Maki (2007), 20 unrelated pairs such as RAFT-LION or TASK-SIN were added to the 80 related pairs. Since these do not share any associations, their forward and backward strengths equaled zero. \({ }^{1}\)

Procedure Participants were tested during a collective session in a computer room using an online survey. Similar to Maki (2007) the subjects were familiarized with the word association task. Each participant was asked to give three responses to a set of 15 cues in a task identical to the one described in De Deyne et al. (2012). Upon completion of the word association study they were directed to the instruction page for the judgment of associative strength study and asked to estimate how many out of a hundred persons from Belgium, would give a certain association. An example was shown for a highly related pair (CAPTAIN-BOAT) and a weakly related pair (CAPTAIN-HAT). Finally, they were told to use a sliding scale to indicate their judgments and to consider the entire range of the scale from 0 to 100 . A total of 100 items were presented in a randomized order and had the following format: In a word association task, the word X was presented. How many people out of 100 responded with the word Y? The judgment of associative strength task took about 10 minutes on average to complete.

\section*{Results and Discussion}

The average of all ratings was calculated and the SpearmanBrown formula for split-half reliability was applied on the data from 50 subjects. The result showed that the ratings were highly reliable: \(r_{\text {splithalf }}(100)=.99\).

The judgment of association strength as a function of normed association based on single response strength \(F S_{1}\) is plotted in Figure 1. This Figure shows that weak and moderately strong normed associates are overestimated in the judgments of strength (as indicated by their relative position toward the diagonal), while strong associates tend to be underestimated. This is in line with the previous findings reported

\footnotetext{
\({ }^{1} \mathrm{~A}\) full list of the stimuli is available from http://www .smallworldofwords.com/experiments/
}

Figure 1: Scatter plot for judged and normed \(F S_{1}\) together with regression line and confidence bounds.
by Maki (2007). The relative contribution of different instantiations of associative strength measures based on continued association was investigated through a series of regression analyses where we focused on straightforward predictors that corresponded to interpretable and theoretically interesting aspects of strength. \({ }^{2}\)
Strength in related pairs In a first series of analyses, only the related items are considered as these data have non-zero values for both forward and backward strength measures. The results of the analyses are presented in Table 1. The simplest model predicts judgments of associative strength by the normed strength of the first response \(\left(F S_{1}\right)\). Model 1 accounts already for \(56 \%\) of the variance and found a significant effect of \(F S_{1}, \beta=.75, p<.01\). A second model is one where strength is averaged over all three responses: \(\left.F S_{123}=\left(F S_{1}+F S_{2}+F S_{3}\right) / 3\right)\). This predictor was significant ( \(\beta=.70, p<.01\) ), but the model only captured \(49 \%\) of the variance. In contrast to previous studies (cfr. De Deyne et al., 2011, 2012), the added information from \(R_{2}\) and \(R_{3}\) does not improve the prediction of the judgments of associations strength. Model 3 considers the possibility that judged strength is a function of both forward and backward strength of \(R_{1}\). Both \(F S_{1}(\beta=.70, p<.01)\) and \(B S_{1}(\beta=.21, p<.01)\) were significant predictors and provided the best account of the data so far.

Next, we investigated if \(R_{2}\) and \(R_{3}\) responses provide additional information beyond that captured in \(R_{1}\). Model 4 expands Model 1 by including \(F S_{2}\), resulting in significant effects for \(F S_{1}(\beta=.75, p<.01)\) but not \(F S_{2}(\beta=.11, n s)\) resulting in little extra variance accounted for (see Table 1). Similarly, no effect was found for \(F S_{3}\) in any additional analysis that was not accounted for by either \(F S_{1}\) or \(F S_{2}\). So these will not be discussed further.

\footnotetext{
\({ }^{2}\) To reduce the skew in the count-based strength measures a logtransformation was used.
}

Table 1: Regression models (\#M) for the prediction of judged associative strength. Only significant models are reported and adjusted \(R^{2} \mathrm{~s}\) are used throughout.
\begin{tabular}{rllr}
\hline & & \multicolumn{2}{c}{\begin{tabular}{rlr} 
Related \\
Regression Equation
\end{tabular}} \\
\hline 1 & \(F\)-test & \(F(1,78)=99.8\) & \(69+22 F S_{1}\) \\
2 & \(F(1,78)=75.9\) & \(88+14 F S_{123}\) & .556 \\
3 & \(F(2,77)=58.9\) & \(83+21 F S_{1}+16 B S_{1}\) & .487 \\
4 & \(F(2,77)=51.7\) & \(74+22 F S_{1}+7 F S_{2}\) & .594 \\
5 & \(F(3,76)=52.0\) & \(90+17 F S_{1}+8 B S_{1}+29\) Rel & .562 \\
& & \(\mathbf{2 5 \%}\) Quantile & \\
1 & \(n s\) & - & - \\
2 & \(F(1,37)=6.4\) & \(71+91 F S_{123}\) & .125 \\
3 & \(F(1,37)=4.3\) & \(59+14 F S_{2}\) & .080 \\
4 & \(F(2,36)=8.5\) & \(102+16 F S_{2}+43 B S_{1}\) & .284 \\
5 & \(F(3,35)=11.3\) & \(107+17 F S_{2}+22 B S_{1}+38\) Rel & .448 \\
\hline
\end{tabular}

A final model considered the role of relatedness. It is quite possible that when faced with uncertainty about exact strength, participants use the semantic relatedness between the cue and target to infer how strongly associated they are. Semantic relatedness was calculated as the cosine between the cue and response vector (see De Deyne et al. (2012) for additional details). Intuitively a high cosine indicates many shared associates between two words, while a low cosine indicates few shared associates. Model 5 gave the best fit of the data ( \(R^{2}=.66\) ), with significant effects for both \(F S_{1}\) ( \(\beta=.59, p<.01\) ) and relatedness (Rel, \(\beta=.31, p<.01\) ). \(B S_{1}\) was no longer significant ( \(\beta=.10, n s\) ).
Modeling weak strengths Still, it might be too early to conclude that normed strength from later responses never predicts strength judgments. As can be seen from Figure 1, \(F S_{1}\) at the low end of the scale does not distinguish much of the observed judged data. Possibly, strength derived from later responses results in more stable estimates for those responses that occur less frequent as \(R_{1}\). At this low end of the \(F S_{1}\) scale, participants might make use of richer information, corresponding to information encoded in \(F S_{2}, F S_{3}\), backward strength, or semantic relatedness.

To investigate if the weak strengths are better captured by \(R_{2}\) and \(R_{3}\), a subsection of the data presented was selected by placing a cut-off at the first quartile of \(F S_{1}\), as most of the remaining data were not explained by \(F S_{1}\).

The same models as presented before were now used to predict these data. The results for \(F S_{1}\) in Model 1 confirmed the pattern in Figure 1, as it was unable to predict any data. A significant effect for summed strength \(F S_{123}(\beta=.38, p<\) .05) was found in Model 2, explaining \(13 \%\) of the variance. Since \(F S_{1}\) did not explain the data, a new model consisting of \(F S_{2}\) was tested and found significant ( \(\beta=.32, p<.05\) ). The following models therefore use \(F S_{2}\) rather than \(F S_{1}\). In Model 4, both \(F S_{2}(\beta=.38, p<.01)\) and \(B S_{1}(\beta=.47, p<\) .01) were significant and accounted for \(28 \%\) of the variance.

The final model including relatedness explained most of the variance (45\%) with a significant effect of \(F S_{2}(\beta=.40, p<\) .01 ) and relatedness ( \(\beta=.47, p<.01\) ), but no significance for backward strength \(B S_{1}(\beta=.24, n s)\).

Together, these results support the idea that the judgment of association strength task is sensitive to normed associative strength, and closely replicates the previous findings of (Maki, 2007). However, our main goal was to investigate whether continued responses lead to better approximations of judged strength. Our findings support this hypotheses, but only for weak or moderate strengths. Since no large-scale studies have looked at the effect of continued associations, the next section will go into detail about which mechanisms might cause these results.

\section*{What factors determine the contribution of continued responses?}

A question that arises from the previous findings is why strength measures that include \(R_{2}\) and \(R_{3}\) responses systematically improve the prediction in a variety of semantic tasks such as similarity judgment tasks or lexical decision tasks (De Deyne et al., 2012), but not in the judgment of association task. Can we provide an explanation why they capture no additional information compared to \(R_{1}\) strengths at the high range of the scale?
Sampling without replacement hypothesis. A first explanation is based on the idea that continued responses are biased due to the continued nature of the task. More precisely, participants are not allowed to repeat a response. Especially when a certain \(R_{1}\) association is very dominant, the proportion of participants who did not generate it as \(R_{1}\) but could generate it as \(R_{2}\), will be very low. Summing strengths in these cases might bias strength for such a response. In other words, the strength measures for \(R_{2}\) and \(R_{3}\) do not take into account this sampling without replacement. As consequence of the restriction of sampling without replacement, we expect \(F S_{2}\) to be heavily biased for the strong responses, but at least capture moderate and weak strengths. If sampling without replacement is the main factor governing the observed frequencies for continued responses, then the derived expected strengths for the secondary and tertiary association response should closely agree with the observed strength for \(R_{2}\) and \(R_{3}\).

Given a specific cue with \(N\) different responses one can derive the expected \(R_{2}\) response count for \(x\) from its probability as a first response \(R_{1}\) as follows:
\[
\begin{equation*}
P\left(R_{2}=x\right)=P\left(R_{1}=x\right) \sum_{i=1, i \neq x}^{N} \frac{P\left(R_{1}=i\right)}{1-P\left(R_{1}=i\right)} \tag{1}
\end{equation*}
\]

The same principle holds for the derivation of the joint expected response for \(R_{3}\). For each of the 12,428 cues in \(G_{1}\), the expected \(R_{2}\) strengths were calculated using Equation 1. If differences between expected and observed \(F S_{2}\) strengths are primarily caused by the sampling without re-

Figure 2: Averages and \(S D\) for correlation between expected and observed \(F S_{2}\) (left-hand \(y\)-axis) grouped by entropy \((H)\). A histogram of entropy for each cue with counts was added (right-hand \(y\)-axis).
placement, then the expected and observed values should be similar up to some random noise. For each of the cues, the correlations between expected and observed strength distributions were obtained and had an average correlation of \(r(12428)=.71(S D=.13)\). At this point, it is not clear what determines high or low agreement. A corollary from the strength without replacement explanation is that the degree of bias in \(F S_{2}\) or \(F S_{3}\) will depends on the set-size or heterogeneity of the \(R 1\) response distribution which can be formalized as entropy \(H\) :
\[
\begin{equation*}
H=\sum_{i=1}^{N} p_{i} \log _{2} \frac{1}{p_{i}} \tag{2}
\end{equation*}
\]
where \(N\) is the size of the vocabulary or number of different responses and \(p_{i}\) is the probability for the \(i\) th response. \(H\) increases as the responses become more heterogeneous and equals zero if all responses were identical.

Figure 2 shows the average correlations binned as function of the entropy for the cues. For cues with few responses, the correlation between expected and observed counts is lower. Similarly, the cues with a very heterogeneous response set corresponding to the high entropy words at the right-hand side of Figure 2 also exhibit lower agreement than average entropy cues. A possible explanation of the former effect is due to dominance effects previously observed in cued recall (Nelson \& Bajo, 1985), where a single strong response inhibits the retrieval of other weaker ones. For these low entropy cues we expect higher utility of \(F S_{2}\) or \(F S_{3}\) in the judgment of associative strength assuming that the effect of dominance is removed once the response is generated and additional information becomes accessible. The latter effect could be due to unreliability, where at the high extreme cues elicit only idiosyncratic responses. Little benefit of \(F S_{2}\) can be expected for high entropy cues, since there is no reason to expect very heterogeneous responses to become more coherent in the later responses. For these cues it should be dif-
ficult predicting associative strength whether this strength is based on \(F S_{1}\) or \(F S_{2}\). New pilot studies seem to support this entropy interaction. However, there are number of reasons why sampling restrictions cannot completely explain the observed response distributions for continued responses. First of all, this does not explain why the heterogeneity or entropy increases when more than one response per cue is asked. Second, it might be the case that for different response positions, distinct types of semantic information becomes available.
Time course of Semantic Activation Hypothesis. A possible explanation why some \(R_{2}\) and \(R_{3}\) responses are generated much more (or less) frequent than expected based on \(R_{1}\) when sampling without replacement is taken into account stems from the idea that qualitatively different sources of information are accessed. A first possibility is that the type of response for \(R_{2}\) and \(R_{3}\) is influenced by the previous response beyond previously noted sampling restrictions. Such an order effect is called chaining, and can be illustrated for the cue SWISS, where mOUNTAINS is given more frequently as an \(R_{1}(57 \%)\) than \(R_{2}(16 \%)\), while it is expected \(26 \%\) of cases in \(R_{2}\). Together with the observation that SNOW is given less frequently than expected from its \(R_{1}\) counts, one can assume an associative chain: SWISS \(\rightarrow\) MOUNTAINS \(\rightarrow\) SNOW. The presence of chaining can be quite easily investigated, and previous research suggest this phenomenon is quite rare (De Deyne \& Storms, 2008).

Second, the different time course of automatic and qualitatively different types of semantic information might be a more important factor. Consider for example the cue GORILLA where MONKEY is generated in 72 times as \(R_{1}\). It is expected to occur 21 times as \(R_{2}\) yet occurs only 6 times. At the same time, BIG is generated 18 times as \(R_{2}\), but is expected to occur 6 times at most. Perhaps linguistic or superficial information like superordinate labels precede entity properties as in this example. Both behavioral (Santos, Chaigneau, Simmons, \& Barsalou, 2011) and fMRI studies (Simmons, Hamann, Harenski, Hu, \& Barsalou, 2008) support the idea that gradually deeper semantic information becomes activated. For example, in an experiment by Santos et al. (2011), participants generated about 1.7 responses in a continued time delimited task. In this study, later responses tended to convey a shift from primarily linguistic responses towards taxonomic- and especially thematic- and entity-related responses.

Perhaps a better way to study the time course of semantic activation is based on a comparison between observed and expected response frequencies for continued responses given the response distribution of the first response. Such a comparison is more accurate compared to previous approaches since it is not biased by (lack of) opportunity to generate a previous response in the continued procedure. To investigate what type of information is different in the second and third response of the word associations, we calculated the expected response frequencies for \(R_{2}\) and \(R_{3}\) (cfr. Equation 1) and compared them with the observed response frequencies by subtracting observed from expected \(R_{2}\) and \(R_{3}\). A positive value indicates

Figure 3: Distribution of semantic knowledge for observed responses in \(R_{2}\) and \(R_{3}\) that are either over- or underestimated based on expected \(R_{2}\) and \(R_{3}\) responses.
that the observed response in \(R_{2}\) or \(R_{3}\) is less likely to be generated than expected and this information is underestimated in \(R_{2}\) or \(R_{3}\). A negative value indicates that the response is generated more often than expected and is overestimated in the observed \(R_{2}\) or \(R_{3}\) counts. Since it is practical unfeasible to manually code all possible cue-response pairs only a subset of the data was used. For each of the \(+12,000\) cues the most extreme (one positive, one negative) responses were listed, once for \(R_{2}\) and once for \(R_{3}\). Both sets were sorted and only the 1,000 most negative and 1,000 most positive differences were retained for further analysis.

The relationship between \(2,000 R_{2}\) and \(2,000 R_{3}\) cueresponse pairs was coded as either as entity, introspective, lexical, thematic or taxonomic using similar guidelines as those described in De Deyne and Storms (2008) and Santos et al. (2011). Entity responses encode properties of the cue (e.g., MOON-YELLOW), introspective pairs encode evaluation or affect towards the cue (MOON-PRETTY), lexical attributes encode linguistic properties such as word compound completions, idioms, or rhyme (MOON-walk), thematic information could refer to agents, time and place of an action etc. (MOONASTRONAUT), taxonomic encodes super-,sub- and coordinates, synonyms and antonyms (MOON-PLANET). A detailed discussion of the implications for various types of semantic is beyond the scope of our illustration. For current purposes, we are mainly interested in identifying potential systematicity in qualitative response changes as a function of response position. The results in Figure 3 indicate that this is strongly the case. The largest effect is for taxonomic information which is much less likely to occur \(R_{2}\) and \(R_{3}\) than expected. To a lesser extend, there is also a shift where less lexical responses are generated as \(R_{2}\) or \(R_{3}\). The positive shift shows that entity and thematic responses are generated more frequent than expected for \(R_{2}\) and \(R_{3}\). These findings support the previous conclusions that linguistic information (encoded lexical) precedes conceptual types of information such as entity and thematic information. In contrast to the findings of Santos et al. (2011), our findings also show that taxonomic information is available early in the generation process.

This result also offer a potential qualitative interpretation of the contrast between a lack of effect of \(F S_{2}\) in the judged associative strength task and its significant contribution in similarity judgment and other more semantic tasks if semantic knowledge related to entity features and thematic roles is better encoded in \(R_{2}\) and \(R_{3}\). Clearly, follow-up studies are needed to further evaluate these hypotheses.

\section*{Discussion and Conclusion}

Using a judgment of associative strength task, we investigated the role of normed strength derived continued word associations. In contrast to previous reports where denser representations derived from second and third responses provided better estimates of distributional relatedness and lexical centrality (De Deyne et al., 2012), we found that the contribution of these responses is limited to weak or moderate response strengths. Moreover, in contrast to previous studies, simply summing response frequencies systematically resulted in inferior predictions for judgments of associative strength. Our interpretation of this finding is based on the notion that later responses are likely to underestimate the highest strengths due to sampling without replacement.

When comparing expected strengths under sampling without replacement against the observed strengths, the differences in \(R_{2}\) and \(R_{3}\) are very systematic and point out how semantic activation of types of knowledge changes over time, an issue which has been notoriously difficult to measure using other paradigms including priming. Importantly, using expected response frequencies for continued responses in comparison with actual observed response frequencies might provide a less biased baseline for tracking the time-course of semantic activation through continued association tasks. While different semantic information in continued responses strongly reflects the divergence between expected and observed counts for \(R_{2}\) and \(R_{3}\), it should be noted that other factors might also play a role. Since none of the responses in the association data is stemmed, it is quite likely that some part of the discrepancies will disappear when the data is processed this way. Our findings also result in a number of methodological recommendations as we have shown that ignoring sampling without replacement is problematic for low entropy cues and the use of single or combined strength measure depends on the type of task under consideration (ranging from associative to more semantic in nature).

At a theoretical level, our results challenge the main conclusions about the supposed overestimation bias of weak and moderate associates in judgments of associative strength (Maki, 2007; Koriat, 2008). The previous interpretation rests on the assumption that word association frequencies veridically reflect strength and only a small number of different responses are available (as is the case in single word association). Instead, we propose that this bias might not be due to the judgments themselves but could equally be an artifact of the single association procedure which underestimates low to medium responses.

\begin{abstract}
We investigate the effect of linguistic complexity on cognitive load in a dual-task scenario, namely simultaneous driving and language use. To this end, we designed an experiment where participants use a driving simulator while listening to spoken stimuli and answering comprehension questions. Online physiological measures of cognitive load, including the recently established Index of Cognitive Activity, as well as measures of performance in both tasks have been collected with high temporal resolution. The resulting aligned data streams can be used to test a vast array of different hypotheses about the relationship between performance, difficulty, and cognitive load in dual tasks at various levels of temporal resolution and linguistic structure. We present results of the data analysis, including evidence that different linguistic structures may cause measurable changes in cognitive workload on a very fine temporal scale in cases of increased primary task difficulty.
\end{abstract}

Keywords: relative clause; dual task; cognitive load; pupillometry; skin conductance; tracking task; driving; multitasking

\section*{Introduction}

Is there a relationship between psycholinguistic measures of language complexity and quantified cognitive workload in dual-task environments? To answer this question, we experimentally evaluate these measures of language processing in an environment where one task is language-related and the other not. Such language complexity measures have been shown in single-task studies to account for processing difficulty. This work represents a first step in which we investigate the effect of a grammatical structure (German locally ambiguous subject vs. object relative clauses) on a simplified, well-controlled non-linguistic task, a driving task.

Dual tasks are ubiquitous in everyday life, often in situations where attention and performance in the primary task is critical. An example is driving while engaging in dialogue, be it with a passenger, a dialogue-controlled interface, or remotely via mobile phone. Engaging in dialogue generally affects driving performance and safety (Just, Keller, \& Cynkar, 2008; Young, Regan, \& Hammer, 2007).

We manipulated the driving task difficulty and the structural complexity of the linguistic items. We also collected measurements of performance in both tasks and fine-grained physiological indicators of cognitive load, namely skin conductance levels and pupil sizes. We computed values from pupil size for the recent Index of Cognitive Activity (ICA). To our knowledge, this is the first study using the ICA measure in a setting with a language task.

\section*{Background and Related Work}

There is a rich literature on language use while driving a car, largely showing that speaking on the telephone has a negative effect on driving performance (Just et al., 2008; Kubose et al., 2006). Further studies found that this is specific to conversations with remote speakers (independent of whether one uses a hand-held device or free speaking), but that conversations with an in-car passenger are less problematic (Strayer, Drews, \& Johnston, 2003; Drews, Pasupathi, \& Strayer, 2004). It appears that passengers adapt their conversation to the traffic situation, leaving the driver more resources to deal with demands of the driving task when driving becomes difficult (Drews, Pasupathi, \& Strayer, 2008; Crundall, Bains, Chapman, \& Underwood, 2005; Villing, 2009). By contrast, remote conversational partners cannot adapt their speech, so that the driver may reach the point of cognitive overload more easily and thus commit driving errors. However, these lines of research have not taken into account how the fine-grained details of linguistic complexity affect cognitive load and driving task performance.

On the other hand, there is a very rich literature on linguistic processing difficulty in single tasks using brain imaging, ERPs, and reading time studies, as well as a number of dual task experiments generally showing that performance on the linguistic task deteriorates with increased complexity of the other task, see for example King and Just (1991). Finally, multiple models explain the effect of cognitive load in one task on performance in another (Baddeley, 2003; Wickens, 2008; Just, Carpenter, \& Miyake, 2003).

We see, however, unbroken ground in relating the effect of linguistic complexity on a realistic task (e.g., driving) and the size of the interference of linguistic processing with driving performance. This study takes a step in this direction in testing different methods for assessing cognitive load and the effect of one particular linguistic structure-incrementally ambiguous relative clauses-on driving performance in a simplified but controllable and continuous driving task.

\section*{The dual-task experiment}

\section*{The ConTRe task}

Our primary task was a tracking task (Jagacinski \& Flach, 2003) presented as a car driving scenario and called the "Continuous Tracking and Reaction" (ConTRe) task (Mahr, Feld,

Figure 1: A screenshot of the ConTRe steering task.

Moniri, \& Math, 2012). In this task, participants see a simulated 3-D road moving at a constant speed, intended to simulate a moving vehicle. Additionally, two bars of different color appear approximately 20 m in front of the simulated vehicle. The two bars represent the vehicle's position and the target (reference) position. They move laterally across the screen. The reference bar's movement is pseudo-randomly generated by an algorithm, while the "vehicle" bar is controllable by the participant by means of a gaming steering wheel. Participants were instructed to track the reference bar's movements with the controllable bar as closely as possible. To reduce noise in our data, we removed all other elements of the original ConTRe environment (e.g., buildings along the side of the road, and traffic lights), except for the road and the moving bars. A screenshot of the simulated environment can be seen in fig. 1.

This task is a useful abstraction of driving, since it allows a precise and continuous performance measure for steering, essential to driving. We manipulated the difficulty of the ConTRe task by changing the speed of the reference and vehicle bars in order to create a "difficult driving" condition and an "easy driving" condition \({ }^{1}\).

\section*{Language comprehension task}

The spoken comprehension task consists in listening to a sentence containing a relative clause followed by two thematically related 'filler' sentences and a yes/no comprehension question. Questions were related to the relative clause (50\% of the stimuli) or to the filler sentences. All sentences and questions are in German, inspired by Bader and Meng (1999). The stimuli are designed in pairs in such a way that the items in each pair are identical except for the form of the auxiliary of the relative clause (RC), which determines whether it is an object RC (ORC) or a subject RC (SRC). An example of such a relative clause pair is the following:

> Die Lehrerin, die einige Eltern wegen einer solchen Kleinigkeit angerufen [haben / hat], hat nun eine Elternversammlung einberufen.
> "The teacher \({ }_{\text {FEM }}\) [who called some parents / whom

\footnotetext{
\({ }^{1}\) Easy: reference bar maximum speed \(=1 \mathrm{~m} / \mathrm{s}\), controllable bar \(=\) \(2 \mathrm{~m} / \mathrm{s}\). Difficult: reference bar \(=2.5 \mathrm{~m} / \mathrm{s}\), controllable bar \(=4 \mathrm{~m} / \mathrm{s}\).
}
some parents called] because of such a trivial issue, has now called a parents' meeting."

The sentence is locally ambiguous between ORC and SRC until reaching the auxiliary; in previous experiments, increased reaction times in a speeded judgment task (Bader \& Meng, 1999) have been observed when subjects read "haben" (ORC) compared to "hat" (SRC). This is evidence for an interpretive bias toward SRC. All items were synthesized prior to the experiment using MARY TTS (Schröder, Charfuelan, Pammi, \& Türk, 2008) and pauses manipulated so that the critical region duration (hat / haben) is always identical.

\section*{Experimental setup}

Each experiment is divided into 4 recording phases, each lasting about 6 minutes, with short pauses in-between. Each phase is composed of a driving-only phase of 2 minutes followed by a driving-with-language phase of approximately 4 minutes, during which 10 blocks, consisting each of one relative clause, two fillers and one question. Participants answer the question verbally and their response is coded by the experimenter. In the first and the third phase, the driving difficulty is set to "easy", while in the second and fourth phase it is set to "difficult". The order of presented items in the language condition was randomized, and we ensured that each person only saw one condition of each item.

\section*{Measures of cognitive workload}

We have two principal sources of quantified cognitive workload data: physiological and task dependent. Our physiological measures are further divided into two subtypes: pupil area-based (pupillometry) and skin conductance-based, both of which have been widely used in cognitive workload studies, although principally on non-linguistic tasks. Our study is an opportunity to evaluate the relative efficacy of these data sources on linguistic tasks. We also take the opportunity to evaluate a novel form of pupillometric data processing: the Index of Cognitive Activity (ICA). To the best of our knowledge, ours is the first study to investigate the potential of the ICA as a measure of linguistically-induced cognitive load in a dual-task scenario.

Our task-dependent measure is driving performance in our simulated environment, which serves to confirm the "realworld" effect of variations in cognitive workload.

The Index of Cognitive Activity (ICA) Research in pupillometry (Just et al., 2003; Engelhardt, Ferreira, \& Patsenko, 2010; Palinko, Kun, Shyrokov, \& Heeman, 2010) has found that cognition-related changes in pupil size typically amount to a difference of \(20 \%\) relative to the typical pupil size (Laeng, Sirois, \& Gredebäck, 2010). However, light conditions also affect pupil sizes, with brightness-induced changes being much larger than cognitively induced ones (up to \(120 \%\) of typical pupil size).

The Index of Cognitive Activity (ICA; Marshall (2002)) is a patented measure which applies signal processing techniques to filter out slow, large light-induced changes and identify
the occurrence of short, abrupt changes in pupil size, held to be caused by cognitive load. The ICA measure is argued to be robust with respect to changes in light conditions and eye movement. It relates the frequency of rapid small changes in pupil size (also known as pupillary hippus) to cognitive load. The ICA measure has been used for measuring cognitive load in driving simulation tasks (Schwalm, Keinath, \& Zimmer, 2008), simulated driving and visual search (Marshall, 2007), detecting different levels of surgical skill (Richstone et al., 2010), and for measuring linguistically induced cognitive load (Demberg, Kiagia, \& Sayeed, 2013) among other uses. Demberg (2013) provides a more detailed analysis of the ICA measure in the dual task setting presented here.

ICA measurements have been shown to be relatively stable across several commonly used eye tracker models and sample rates ranging from 60 to 300 Hz (Bartels \& Marshall, 2012). We used a head-mounted Eyelink II and sampled at 250 Hz .
Skin conductance response Our second physiological proxy for measuring cognitive load is skin conductance response (SCR), which we calculate from skin conductance level (SCL). Changes in the electrical conductance of the skin are due to activity of the sweat glands, which are in turn controlled by the sympathetic nervous system. Skin conductance amplitude usually changes with respect to its "neutral" (tonic) level in response to unexpected, significant, or aversive stimuli. SCL has been previously used as a measure of cognitive load (Shi, Ruiz, Taib, Choi, \& Chen, 2007). In a dual task experiment with simulated driving and a secondary cognitive task, B. Mehler, Reimer, Coughlin, and Dusek (2009) found that skin conductance levels peaked in cases of mental overload caused by incrementally increasing secondary task difficulty, which was followed by a deterioration in the performance of the primary task. Son and Park (2011) found skin conductance levels along with steering wheel reversals (used as a measure of task performance) to be good input features for an artificial neural network built to predict task difficulty.

We used the Ledalab software (Benedek \& Kaernbach, 2010) to separate our raw skin conductance measurements into an estimate of the tonic component and the phasic component. The software also allows to calculate the number of skin conductance response events. SCR events are the "peaks" of the phasic component of skin conductance; both the number of such events per time unit and the amplitude of the peaks are used in the analysis below.

Driving performance We use performance on the ConTRe task as an additional measure of cognitive load. The task lets us define several measures of task success, including the distance between the reference bar and the controllable bar at each point in time and the speed and acceleration of the controllable bar.

\section*{Results}

We ran our experiment with 24 German native speakers aged 20-34, with the total duration of the recorded samples sum-
ming up to about 12 hours. We performed our data analysis in R using linear mixed effects (LME) modeling with lme4 (Baayen, Davidson, \& Bates, 2008) and mgcv (Wood, 2001).

\section*{Correlation between physiological measures}

The first question we explored was whether our physiological measures are correlated with one another. While there is no significant correlation between the raw skin conductance levels and the ICA, we do find a significant positive correlation between the number of skin conductance events and the ICA (using Spearman's \(\rho\); left ICA: \(\rho=0.06 ; p<0.0001\); right ICA: \(\rho=0.09 ; p<0.0001\) ). One important aspect to keep in mind is also possibly different latencies of the two measures in reaction to a stimulus.

We find a strong correlation between the ICA of the left and right eye (cor \(=0.74 ; p>0.001\), Pearson's product-moment correlation coefficient).

\section*{Response to experimental phases}

Driving performance The next hypothesis we tested was whether our task performance measure in the driving task, i.e., the steering deviation, is sensitive not only to the driving task difficulty, but also to the presence of language. In figure 2 , we have plotted the mean deviation for each of the difficulty settings (easy and difficult driving), with and without the secondary linguistic task. Using linear mixed effects models with a random intercept and random slopes by subject, we found a large significant main effect of driving difficulty (coef \(=0.3 ; t=20.33 ; p<0.001\) ), showing that steering was less accurate when driving was more difficult. We also found a significant positive main effect of whether we are in a language phase (coef \(=-0.05 ; t=-5.00 ; p<0.001\); steering is worse when people are listening to language, see also figure 3 ), as well as a significant interaction between driving difficulty and the language phase, indicating that the effect of language was more burdensome in the difficult driving condition (coef \(=-0.024 ; t=-6.98 ; p<0.001\) ). To confirm whether the effect of language is significant in both driving conditions, we also split the data into two subsets, easy driving and difficult driving, and found that the effect of language was significant in both linear mixed effects models.

This figure illustrates an obvious difference between steering deviation in the easy and difficult driving conditions.

Figure 2: Driving condition/language vs. steering deviation.

Table 1: ICA estimates for the driving plus language phases.
\begin{tabular}{l|rrr|rrr} 
& \multicolumn{4}{|c}{ right ICA } & \multicolumn{3}{c}{ left ICA } \\
& coef & t-value & sign & coef & t value & sign \\
\hline (Intercept) & 0.8116 & 123.40 & \(* * *\) & 0.7965 & 135.63 & \(* * *\) \\
sound playing & 0.0198 & 10.88 & \(* * *\) & 0.0186 & 10.10 & \(* * *\) \\
easy driving & -0.0057 & -2.44 & \(*\) & -0.0004 & -0.21 &
\end{tabular}

Table 2: \# of SCR events reduced during easy driving. (Random slope of driving condition by subject included.)
\begin{tabular}{l|rrc} 
& Estimate & t value & signif. \\
\hline (Intercept) & 0.68626 & 12.550 & \(* * *\) \\
difficulty=easy & -0.06495 & -4.274 & \(* * *\)
\end{tabular}

Pupillometry For the ICA, we find a main effect of driving difficulty in the ICA of the right eye, but not in the left eye (Table 1). Furthermore, we find significantly more blinks during the phases when language was playing. In-depth analysis of the pupillometric data reveals that overall dilation was larger when people were listening to language stimuli, but the number of ICA events was lower (Figure 3). If we look into the language phase, however, the ICA of both eyes went down significantly whenever language wasn't playing (e.g., between stimuli; Table 1: we factored out the effect of blinks or partial blinks on both the pupil area calculations and the ICA). This effect can also be seen in Figure 3, where the 10 ICA spikes in the language region coincide with our 10 blocks of language stimuli.

Skin conductance For skin conductance, we cannot easily compare the easy vs. difficult driving settings, as the skin conductance measuring device was removed between phases, and comparison of absolute values between phases is thus impossible. A measure that can be compared between driving conditions is however the number of skin conductance events. When running a linear mixed effects regression model with this measure as a response variable, we find that more such skin conductance events happened, as expected, in the difficult driving condition, see Table 2.

We do however not find any significant effect of the language vs. no language condition on this measure. Unexpectedly, we find that tonic skin conductance is lower in the driving plus language condition, see Figure 3.

\section*{Cognitive load and language processing difficulty}

To this point, we find that the measures largely behave as expected. Thus we come to our main question: can they detect the effect of fine-grained language complexity? To this end, we analysed the data to see whether we can find a) a correlate for higher processing difficulty in the ambiguous region or right after the disambiguation at hat/haben, and b) whether ORCs lead to less cognitive load than SRCs.

Disambiguating region Detailed analysis of the ambiguous region of the relative clause shows that the Index of Cognitive Activity is high during the ambiguous region of the

Figure 3: Spline plots ( 120 knots; with 0.95 conf intervals) showing the effect of language on physiological measures during an experimental phase ( 2 min driving only followed by 4 min of driving plus language).

Figure 4: SCR during time that stimulus is spoken.
relative clause (during the time span of -2000 msec to 0 msec ), and that the ICA sharply falls right after disambiguation (see Table 4 which shows a significant reduction in ICA of both eyes following disambiguation, encoded as time wrt. onset). These effects hold over and above effects of the steering task, which have been mathematically accounted for by including the task difficulty as a factor in the model. These results indicate that subjects encounter processing difficulty due to the ambiguity. (This is possibly also something they learn during the experiment.)

For skin conductance, we know that effects can be expected 2-4 seconds after the stimulus. Figure 4 shows a significant rise in skin conductance during the five seconds after

Table 3: Mixed effects regression analysis with steering deviation as response variable, for region of 2 s before the onset till 2 s after end of the critical region.
\begin{tabular}{l|lrl} 
& Estimate & t -value & \\
\hline (Intercept) & \(3.562 \mathrm{e}-01\) & 17.07 & \(* * *\) \\
phase time & \(8.459 \mathrm{e}-08\) & 3.44 & \(* * *\) \\
target velocity & \(3.832 \mathrm{e}-01\) & 205.08 & \(* * *\) \\
critical region & \(1.396 \mathrm{e}-02\) & 2.88 & \(* *\) \\
easy driving & \(-2.248 \mathrm{e}-01\) & -64.91 & \(* * *\) \\

& & & \(4.36 * * *\) \\
& & & & \\
& & &
\end{tabular}
the critical region, which would be consistent with an interpretation that the ambiguity causes higher cognitive load.

But can we see any effect of our linguistic stimuli on the driving performance? We compared steering accuracy at the time of the disambiguating region with steering accuracy during the two seconds before and after, and indeed found that deviation of the controllable bar from the reference bar was significantly larger during the disambiguating region than before or after; see the positive coefficient (Table 3) for the binary variable "critical region".

Subject vs. object relative clauses Finally, we test whether the ICA is sensitive to fine-grained linguistic complexity effects. We isolated the subset of the data which fell within the 1800 msec following the onset of the critical region hat / haben. The duration of this critical region at hat / haben is 650 ms in both conditions, which we imposed by manipulating the duration of the phrase boundary pause during synthesis. On this subset of the data, we built two LME models (one for each eye) with the ICA measure as the response variable and the relative clause type as the fixed effect, while also introducing a random effect per participant.

The results of this analysis are shown in Table 4. We can see that there is a negative effect for the SRC type in both cases, although only the result for the right eye is significant. The interpretation of the coefficient is that SRCs tend to occur with smaller values of ICA than ORCs.

We did not find any significant effects of relative clause condition on skin conductance, overall pupil dilation or steering performance.

Table 5: LME model for answer accuracy.
\begin{tabular}{l|rrc} 
& Estimate & t-value & Sig \\
\hline INTERCEPT & 2.663 & 5.72 & \(* * *\) \\
RC-TYPE (OBJ) & 0.445 & 1.17 & \\
VOICE (PASSIVE) & -1.802 & -3.11 & \(* *\) \\
DRIVINGDIFFICULTY (EASY) & -0.222 & -1.18 &
\end{tabular}

\section*{Performance in the language task}

A last link that we wanted to investigate was the one between performance in the linguistic task (i.e., answer accuracy) and the difficulty of the driving and language tasks. We built a binomial LME model with the answer accuracy as the response factor and driving task difficulty, relative clause type, and the voice (passive vs. active) of the question as fixed effects with a random intercept per participant and subject and a random slope for relative clause type by item \({ }^{2}\). The resulting coefficients are presented in Table 5. While answer accuracy was lower for object relative clauses (74\%) than for subject relative clauses ( \(78 \%\) ), and lower in difficult driving ( \(75 \%\) ) than in easy driving (77\%), these differences did not reach significance. (NB: questions related to relative clauses were only asked after half of the items; i.e., this analysis is based on relatively little data.) The only significant negative effect on answer accuracy was found for passive voice questions, which means that there are significantly more wrong answers to passive voice questions than to active voice ones (this is not unexpected, as it has long been known that passives are more difficult to process than actives (J. Mehler, 1963)).

\section*{Discussion and conclusions}

We designed the tasks in our experiment to require continuous attention. The language task clearly affects performance on the primary steering task: we see the effect of the secondary task in all of our measures. Furthermore, we find effects of linguistic ambiguity and complexity in our measures of cognitive load: during the ambiguous region in our stimuli, we see evidence for higher cognitive load in our pupillometric measure, which is also reflected in a slightly later galvanic skin response. During the disambiguating region, we observe significantly higher steering deviation, which indicates that people are allocating more mental resources to the linguistic task, hence impeding steering performance. We also found evidence for a measurable effect of linguistic complexity in our pupillometric measure ICA: the ICA was significantly higher during the disambiguating region and the following second for the ORC condition compared to SRC. This experiment provides early support for the ICA as a useful measure to assess language-induced cognitive load.

\title{
Pupillometry: the Index of Cognitive Activity in a dual-task study
}

\author{

}

\begin{abstract}
This paper reports experimental results on the index of cognitive activity (ICA), a recent micro-level measure in pupillometry, which relates processing load to the frequency of rapid small dilations of the pupil. We collected pupil size during a tracking task which was cast in a simulated driving context, as well as for a dual task of simultaneous tracking and language processing. The present results are the first to evaluate the ICA measure on these tasks. We find that the ICA is sensitive both to the simulated driving and the language task, and that it is more responsive to our driving task than overall pupil dilation. Overall, the use of the ICA as opposed to traditional pupillometry seems promising, as our data provide initial evidence that the ICA may be more responsive, and a more fine-grained measure of cognitive load than traditional macro-scale pupil dilation measures.
\end{abstract}

Keywords: Pupillometry, Index of Cognitive Activity, Dual Task, Language, Driving

\section*{Introduction}

The size of the pupil has long been known to reflect arousal (Hess \& Polt, 1960) and cognitive load in a variety of different tasks such as arithmetic problems (Hess \& Polt, 1964), digit recall (Kahneman \& Beatty, 1966), attention (Beatty, 1982) as well as language complexity (Schluroff, 1982; Just \& Carpenter, 1993; Hyönä, Tommola, \& Alaja, 1995; Zellin, Pannekamp, Toepel, \& der Meer, 2011; Frank \& Thompson, 2012), grammatical violations (Gutirrez \& Shapiro, 2010) and context integration effects (Engelhardt, Ferreira, \& Patsenko, 2010). All of these studies have looked at the macrolevel effect of the overall dilation of the pupil as response to a stimulus. Recently, another micro-level measure of pupil dilation has been proposed, called the "Index of Cognitive Activity" or ICA (Marshall, 2000, 2002, 2007), which does not relate processing load to the overall changes in size of the pupil, but instead counts the frequency of rapid small dilation, which are usually discarded as pupillary hippus (Beatty \& Lucero-Wagoner, 2000). The ICA has been argued to be robust to changes in ambient light and eye-movements, and can therefore be hoped to be more reliable and robust than overall pupil dilation. Furthermore, as it does not use the overall dilation of the pupil which can vary as a function of lighting and individual, the frequency of the rapid pupil dilations is argued to be more comparable across tasks and subjects.

If it reliably reflects processing load, the ICA would be a convenient method to assess processing load using an eyetracker, in naturalistic environments, e.g. while driving a car, and could therefore usefully complement the range of experimental paradigms currently used.

To our knowledge, the present paper is the first to test its response to a tracking task, and to analyze properties of the Index of Cognitive Activity such as its response delay to a
stimulus. The application of the method in a realistic scenario (measuring linguistically induced cognitive load during driving) also bears relevance for practical applications.

\section*{The Index of Cognitive Activity}

The Index of Cognitive Activity is a patented measure of cognitive load which has previously only been evaluated on a small range of tasks (Marshall, 2000, 2002, 2007; Schwalm, 2008; Schwalm, Keinath, \& Zimmer, 2008) including digit span tasks, and a simulated driving task. Using the ICA as a measure of processing load is motivated by the finding that pupil size can be affected by two different processes: lighting conditions and cognitive activity. In the overall pupil dilation, these two effects are confounded, even in stable lighting because there is a so-called "light reflex", meaning that the pupil oscillates irregularly and continually. Pupil dilation is controlled by two groups of muscles: circular muscles, which make the pupil contract and radial muscles, which make the pupil dilate. Furthermore, we know that the activation and inhibition patterns are different for reaction to light and reaction to cognitive activity (Marshall, 2000): dilations due to cognitive activity are very short and abrupt, while pupil size changes due to lighting are slower and larger. The ICA therefore tries to disentangle these patterns by performing a wavelet analysis on the pupil dilation record to remove all large oscillations and retain only the very short and rapid events (larger than a specified threshold), which are then attributed to the effect of cognitive activity.

The ICA events (rapid small dilations) per second are counted, divided by the number of expected ICA events per second (30), and the resulting number is then transformed using the hyperbolic tangent function, in order to obtain a number between zero and one \({ }^{1}\). To obtain a continuous measure, blinks are factored out by linear interpolation of adjacent events. When using the EyeTracking.Inc software, an ICA value per second is produced. To obtain finer granularity, we also calculated a per-100-msec ICA value from the ICA events (i.e. the rapid dilation events). Due to the short time span, we could not interpolate for blinks (which take about 100 msecs ) and therefore simply excluded from our analysis time all frames during which a blink or partial blink occurred.

\section*{Background on Pupillometry and the LC-NE area}

It has been observed that pupil dilation is strongly correlated with activity in the locus caeruleus (LC) region of the brain.

\footnotetext{
\({ }^{1}\) The method is patented, and the analysis program has to be licensed from EyeTracking, Inc., San Diego, CA. For details see (Marshall, 2000).
}

LC neurons is bilateral and emits the neuro-transmitter norepinephrine (NE) (Aston-Jones \& Cohen, 2005; Laeng, Sirois, \& Gredebäck, 2012). The LC-NE system is known to be activated by stress and is thought to also have a role in memory retrieval and memory consolidation. The activity of the LCNE system as reflected in pupil dilations can therefore be a valuable method of inspecting cognitive load, and might be particularly useful also in multi-tasking settings.

\section*{Experimental Setup}

We conducted an experiment with 24 subjects, during which participants had to simultaneously perform a tracking task as well as a language comprehension task. We also collected data for the tracking task in a single-task setting. Our tracking task was cast as a simulated driving task ("ConTRe task", (Mahr, Feld, Moniri, \& Math, 2012)). The screen displays a moving road with two periodically moving bars at the horizon. One of the bars moves randomly across the screen ("reference bar"), while the other bar is controlled by the subject with a gaming steering wheel. The task of the participants is to cover the reference bar with their "steering bar", as exactly as possible. Difficulty of the ConTRe task was manipulated by changing the intervals at which the bar moves, as well as the speed at which it moves (the bar then always travels at a constant speed to a randomly determined destination on the horizon), to create an easy and a difficult driving setting \({ }^{2}\).

The linguistic stimuli (loosely based on Bader \& Meng, 1999; see Example (1)) consisted of 40 locally ambiguous subject and object relative clauses in German, where the relative pronoun die is ambiguous between nominative and accusative case. The following NP (einige der Mieter) is also ambiguous between these cases. Accordingly, the relative clause type (subject vs. object relative clause) is ambiguous until the disambiguating verb (hat vs. haben) is encountered.
\[
\begin{align*}
& \text { Die Nachbarin, } \quad \text { [die } \text { dig, nom/acc }^{\text {einige }_{\text {pl, }} \text { nom/acc }}  \tag{1}\\
& \text { der Mieter auf Schadensersatz verklagt hat }{ }_{\text {sg }} / \\
& \text { haben } \left.{ }_{\text {pl }}\right]_{\text {relative clause, traf sich gestern mit Angelika. }}^{\text {"The neighbor, [whom some of the tenants sued }} \\
& \text { for damages / who sued some of the tenants for } \\
& \text { damages }]_{\text {relative clause }} \text {, met Angelika yesterday." }
\end{align*}
\]

The language stimuli were synthesized using the MARY text-to-speech system (Schröder \& Trouvain, 2003). Synthesized stimuli were used to control the exact duration and timing of stimuli and pauses, so that we could more easily align our data for analysis. In particular, we made sure that the disambiguating region (hat / haben) was equally long in both conditions, by manipulating the duration of the pause after hat/haben. Furthermore, using synthesized speech avoids problems with large differences in intonation.

Our experiment was conducted in four phases, between which participants were offered to take a break. Each phase

\footnotetext{
\({ }^{2}\) Driving speed was set to \(40 \mathrm{~km} / \mathrm{h}\) in easy setting, \(70 \mathrm{~km} / \mathrm{h}\) in the difficult driving setting; maximal speed setting for reference bar in easy setting was 1 , and 2.5 in difficult setting; maximal speed setting for steering bar was 2 in easy setting and 4 in difficult setting.
}
included 10 stimuli and 20 fillers, as well as 10 comprehension questions. The order of the stimuli was randomized. We recorded pupil dilations on both eyes using the head-mounted SR EyeLink II eyetracker at 250 Hz .

\section*{Data Analysis and Results}

Methods All analyses reported below were done using the lme4 (Baayen, Davidson, \& Bates, 2008) and mgcv (Wood, 2001) packages in \(R\).

Distribution of the ICA Figure 1 shows the distribution of the ICA calculated per second (top plot) and calculated for a window of 100 ms (bottom plot). While the aggregation is smooth for the 1 s window, there are only few possible distinct events in a 100 msec window (the bumps correspond to 0 events, 1 event up to 5 ICA events). Due to the tanh transformation of the ratio between observed and expected ICA events, the bulk of ICA values lies in a narrow range between 0.7 and 0.95 for the standard per-second aggregation.

The left and right ICA values are strongly correlated with each other (Spearman's rank correlation \(\rho=0.71 ; p<\) 0.0001 ; per-second ICA), but clearly not identical.

Figure 1: Understanding the distribution of ICA values: Density plot for the ICA for different aggregations.

Relationship between the ICA and pupil area Next, we inspect the relationship between the ICA and the overall pupil area. The correlation between these two measures are small (left eye per-second ICA: \(\tau=0.105 ; p<0.0001\); and right eye per-second ICA: \(\tau=0.0146 ; p<0.01 ;\) ). The autocorrelation plot in Figure 2 shows how dynamics of the two measures differ (Figure 2 only shows the left eye but the right eye looks very similar): while the ICA has little autocorrelation in the time-series analysis and changes dynamically, the overall pupil size has a high autocorrelation.

\section*{ICA and the ConTRe Driving Task}

The reference bar moves periodically at a constant speed (ca. every 4 seconds for 1-3 seconds in easy driving and every 2.5 seconds for .5 to 1 seconds in difficult driving). This periodicity can also be seen in the autocorrelation plots shown in

Figure 2: Auto-correlations for the ICA and pupil area.

Figure 4(a). More interestingly, we can also inspect the temporal relationship between the movement of the reference bar and any effect of this in the ICA or the overall pupil area, as shown in Figure 4(b). We can see that there is a time-shifted correlation between the movement of the reference bar and a reaction which we can measure in the ICA, starting at about 700 msec after a movement in the reference bar and peaking at about 1.1 seconds after reference bar movement. This effect is more pronounced in the difficult driving conditions than in the easy driving conditions (these results hold both for the driving only and the driving plus language conditions). As Figure 4(c) shows, there is however almost no discernible effect of the reference bar movement on overall pupil dilation.

These time series analyses are interesting because there was previously no published information on how quickly to expect an effect on the ICA. We however also don't yet know enough about what we actually see in the ICA: is it related to the reference bar stimulus? or maybe rather an effect of the action taken by the participant in the task? In order to shed some light on this question, we also ran an autocorrelation analysis for the ICA and the subject controlled steering bar. As Figure 4(d) shows, the correlation between the ICA and the steering bar is stronger than the correlation between the ICA and the reference bar. As people moved the

            velocity of reference bar
    left ICA ( \(1.3 \mathbf{~ s e c}\) shift)

Figure 3: Spline plot \((\mathrm{k}=10)\) for reference bar velocity and acceleration in the same model fitting the ICA.

(b) Correlation of the right eye ICA with the speed of the reference bar at different time lags; (left eye looks the same).

(c) Almost no time-series correlation can be found between movement of the reference bar and overall pupil size.

Figure 4: Time-series correlations left plots show easy driving, right plots show difficult driving.
steering bar as a reaction to the movement of the reference bar, the latency of the ICA with respect to the steering bar is also much smaller (starting right away and peaking at about 400 msec ). For further analysis, we re-aligned our measurements of the reference bar movement (shift by 1.3 s ) and steering bar movement (shift by 400 msec ) in order to align with the ICA.

Table 1: ICA estimates for the driving plus language phases.
\begin{tabular}{l|rrr|rrr|} 
& \multicolumn{3}{|c|}{ left ICA } & \multicolumn{3}{c|}{ right ICA } \\
& coef & t val & sig & coef & t val & sig \\
\hline (Intercept) & 0.704 & 49.30 & \(* * *\) & 0.730 & 50.49 & \(* * *\) \\
sound file playing & 0.034 & 9.18 & \(* * *\) & 0.033 & 8.99 & \(* * *\) \\
easy driving & -0.008 & -1.01 & & -0.012 & -2.08 & \(*\)
\end{tabular}

This adjusted alignment then allows us to enter these factors in regression and spline models. In a first analysis, we tested whether the ICA is explained only by the speed of the reference bar, or also by its acceleration. Figure 3 shows a spline plot for a model including both reference bar velocity and reference bar acceleration in fitting in turn left and right ICA. The patterns are independent of the driving condition (easy or difficult) and of the presence of language stimuli. We see a roughly linear relationship between reference bar speed and the ICA. The bottom plots of Figure 3 furthermore show a u-shaped correlation between the acceleration of the reference bar and the ICA, indicating that the ICA is larger when the reference bar starts moving or stops moving, and lower when it is not moving or moving at its constant top speed.

\section*{ICA and the language task}

The Effect of Language Figure 5 shows how the left and right ICA and left and right overall pupil sizes evolve during the phases of the experiment, which consist of approximately two minutes of driving followed by four minutes of driving and listening to speech and answering yes-no questions. The speech signal consists of 10 blocks of one item, two fillers and a yes-no question. The blocks are separated by a pause of 2 seconds. It is very interesting to compare the pupil area plots and the ICA plots: pupil area is large at the beginning of a phase, but the pupil contracts soon afterwards. At the beginning of the language phase, pupil dilation increases again, which is what we expected, given the additional load of language processing. Interestingly, this is not the case in the ICA data: The ICA only goes down very little during the drivingonly phase, and is overall lower in the dual-task section than in the single task section.

Another relevant observation is that we can observe 10 clear peaks in the ICA data, corresponding exactly to our 10 items. Such a relationship is not visible in the pupil area data (which also shows some periodicity but without a clear correspondence to stimuli). In a linear mixed effects model including only data from the driving plus language phase with the ICA as a response variable and two predictors (a flag whether a sound file is playing and a flag indicating whether the driving condition was easy or difficult), we find that the ICA is significantly higher when a sound file is being played than when it is not (i.e., between stimuli), see Table 1.

In regressions with pupil area as a response variable, whether the sound file is playing is a significant negative predictor on both the left eye (coef \(=-0.058 ; t=-4.9 ; p>\) \(0.001)\) and the right eye (coef \(=-0.067 ; t=-5.1 ; p>0.001\) ), while the driving difficulty manipulation does not reach significance on either eye.

Figure 5: Spline plot (120 knots) for ICA and overall pupil dilation as a function of the duration of the driving only followed by driving with language task.

Ambiguous Region Next, we would like to see whether the ICA reflects in some way our critical region, i.e. whether we see an effect to the relative clause ambiguity. To this end, we run a spline model showing the development of the ICA during the duration of an item, with three predictor variables: time-shifted steering bar velocity, time-shifted steering bar acceleration and the distance from the critical region. Reference bar velocity does not explain any of the variance in the ICA data once steering bar velocity has been included as a predictor, therefore, our models include only the steering bar data. Figure 6 shows that the ICA is relatively high during the ambiguous region but starts falling right after disambiguation.

Disambiguating Region Note that the two relative clause conditions are collapsed in Figure 6- but can we measure a facilitation in the subject relative clause condition as opposed to the object relative clause? We ran a mixed effects regres-

(b) Overall pupil dilation of left and right eye.

Figure 6: Spline plots with confidence intervals for the ambiguous and critical region. Sentences are aligned for the onset and end of the disambiguating word "hat" / "haben".
sion model with right and left ICA (in turn) as response variables and (time shifted) reference bar velocity and acceleration, (shifted) steering bar velocity and acceleration, relative clause type, phase time (indicating how far into the phase the measurement was taken) and driving difficulty as explanatory variables. We also enter item and subject as random effects, as well as a random slopes for relative clause condition under item and subject.

The mixed effects models shown in Table 2 include data from the time window of 100 msec till 1800 msec after the onset of the critical region. Due to co-articulation, we expect that differences of hat vs. haben should be audible from about 100 msec after the onset, and given our finding of the 1.3 s lag between the reference bar movement and the ICA reaction, the window up to 1.8 s after the onset of the critical region makes sure that we include the relevant part of the data in our model.
\begin{tabular}{l|rrr|rrr} 
& \multicolumn{4}{|c|}{ left ICA } & \multicolumn{3}{c}{ right ICA } \\
& Estimate & t val & sig & Estimate & t val & sig \\
\hline (Intercept) & \(7.247 \mathrm{e}-01\) & 39.24 & \(* * *\) & 0.718417 & 45.54 & \(* * *\) \\
subject RC & \(-3.777 \mathrm{e}-02\) & -2.26 & \(*\) & & & \\
phase time & \(-1.199 \mathrm{e}-07\) & -2.68 & \(* *\) & & & \\
steering velocity & \(2.541 \mathrm{e}-02\) & 11.08 & \(* * *\) & 0.022656 & 10.34 & \(* * *\) \\
steering accel. & \(1.094 \mathrm{e}-02\) & 2.01 & \(*\) & & & \\
SRC:phase time & \(1.411 \mathrm{e}-07\) & 2.23 & \(*\) & & &
\end{tabular}

Table 2: Mixed effects regression analysis with ICA as response variable, for region of \(100-1800 \mathrm{msec}\) after the onset of critical region. (Duration of critical region: \(0-600 \mathrm{msec}\) )

We found again that steering bar velocity is a better predictor of the ICA than reference bar velocity. For the left eye, we find that steering bar velocity, steering bar acceleration, phase time and our critical manipulation, the relative clause type, are significant predictors. In particular, we find that the left eye ICA is significantly lower when the item is a subject relative clause. We also find that the left ICA decrease as a function of when the item is presented within a phase (see also Figure 5). Additionally, we find a significant interaction between phase time and the relative clause condition, which indicates that the difference in ICA between the subject and object relative clauses gets weaker as the experiment proceeds - it is possible that this is a learning effect.

In the right ICA, we see similar tendencies, but, with the exception of steering bar velocity, the predictors fail to significantly improve model fit. It should be noted though that this finding replicates the finding of a language-only study using the same relative clause stimuli, which also found a significant effect of relative clause type on the left eye's ICA but not on the right eye (Demberg, Kiagia, \& Sayeed, 2013).

While we cannot find a significant main effect of relative clause type in a regression with overall pupil size as a response variable, but we do find that the pupil size decreases significantly more quickly in the subject relative clause condition than in the object relative clause condition (this holds for both right eye \((p<0.01)\) and left eye \((p<0.05)\) ).

\section*{Discussion and Conclusions}

In this paper, we have reported our first experimental results on using the index of cognitive activity (ICA) as a measure of cognitive load in a dual-task scenario. Our analysis results show that the ICA and pupil dilation are rather different measures. They have a very low correlation to each other, and also behave differently: the ICA is very dynamic, while pupil dilation changes only slowly. This observation is particularly interesting, as it indicates that the ICA might be used at higher time resolution than overall pupil dilation.

The distribution of the ICA however also shows that there are some limits as to how incrementally it can be used: When calculating the ICA events at 100 msec intervals, the distribution is not smooth, and there is little bandwidth of distinct events (in our data we observe between 0 and 6 such rapid movements per 100 msec window).

The time series analyses reported here furthermore indicate that the ICA is reflecting the ConTRe task steering events,
while no such effect is detectable in pupil area. The autocorrelation analyses also allowed us to understand more about the delay between stimulus and effect in the ICA: there is a lag of about 1.2 s between the movement of the reference bar and an effect in the ICA, and a lag of about 400 msec between the subject's steering action and the ICA. The fact that the correlation of the ICA and the steering bar is larger than the correlation with the reference bar indicates that the ICA might be related to the participants action execution (as opposed to their perception of the steering task). This is also confirmed by mixed effects regression models with the ICA as a response variable and re-aligned steering bar and reference bar velocity as predictors: the reference bar velocity predictor variable does not improve model fit over models which already include steering bar velocity.

Furthermore, we find that the ICA record reflects our secondary task, language comprehension. In a more detailed analysis, we find that the ICA is significantly higher within the dual task condition whenever the language stimulus is not playing, and that the ICA is high during the ambiguous region of our language stimulus and decreases following disambiguation. We also find a significant effect of our language manipulation, showing that the ICA of the left eye is significantly higher in the object relative clause condition than in the subject relative clause condition.

We also compare the ICA measure to traditional overall pupil dilation and find that our primary tracking task is not reflected in pupil dilation. For our language manipulation, the results in overall pupil dilation are consistent with our findings in the ICA: in the subject relative clause condition, the pupil contracts significantly faster than in the object relative clause condition.

}

\begin{abstract}
In their evaluation of the integration cost component of Dependency Locality Theory on the Dundee Corpus, Demberg and Keller (2008) found no significant main effect of DLT integration cost on reading times, but suggested that this might be due to auxiliaries incurring some of the full verb's integration cost and thus facilitating processing of the verb. This hypothesis however, has to date not been tested. The present paper fills this gap by reporting an experiment on subject vs. object relative clauses including auxiliaries, as well as by testing Demberg and Keller's hypothesis directly on the Dundee Corpus.
\end{abstract}

A further contribution of this paper is methodological: we replicate experimental results on the subject vs. object relative clause assymmetry in a self-paced-reading experiment run remotely on the web using WebExp.
Keywords: Dependency Locality Theory, Relative Clause, Auxiliary, WebExp, Dundee Corpus, Self-paced reading, Eyetracking

\section*{Introduction}

Dependency Locality Theory (DLT), proposed by (Gibson, 1998; Gibson \& Pearlmutter, 2000) is a theory of sentence processing which has received quite a lot of attention in the field of psycholinguistics, and has been argued to explain a range of phenomena including including the SRC/ORC processing difficulty asymmetry, difficulty of centre embeddings, cases of processing breakdown, filler-gap dependencies, heavy NP shift and extraposition.
(Demberg \& Keller, 2008) evaluated the integration cost component of DLT on an eye-tracked corpus of newspaper articles (Dundee Corpus; Kennedy and Pynte, 2005), and found that verbs which were preceded by nouns were read more slowly than verbs which were preceded by both auxiliaries and nouns. Demberg and Keller thus hypothesized that integration costs might not be incurred at the main verb (as predicted by DLT), but at the auxiliary, at which it should thus be possible to observe an integration cost effect.

They did however not test whether such an integration cost effect could indeed be detected on the auxiliaries. This paper fills this gap through two studies that test Demberg and Keller's hypothesis: a self-paced reading experiment of matched and controlled subject and object relative clauses containing auxiliaries, as well as a corpus study analysing the auxiliaries across various syntactic constructions in the Dundee Corpus for an integration cost effect.

\section*{Background and Related Work}

\section*{Dependency Locality Theory}

An important component for quantifying processing difficulty in DLT is the so-called "integration cost". Integration cost
(IC) measures the distance between a head its dependent in terms of new discourse referents (DR) that occur inbetween them. Figure 1 shows the dependencies for a subject relative clause (SRC) and an object relative clause (ORC). In the example, discourse referents are marked as either 0 (no new discourse referent) or 1 (new discourse referent). The dependency edge between reporter and the main clause verb admitted is annotated with " +2 " to express that two discourse referents occur between these words (namely, attacked and senator). The interesting case when comparing the subject and object relative clause is the embedded verb attacked: the integration cost is 1 in the SRC case (just the cost of constructing the discourse referent), while the it is 3 in the case of the object relative clause. There is a cost of 1 for constructing the discourse referent, plus a cost of 2 for integrating the relative pronoun who at the trace \({ }^{*} t^{*}\), at which point two discourse referents (senator and attacked) intervene. There are also integrations of senator and attacked and the trace and attacked, but no new discourse referents occur between them, so these integrations are cost-free.

Figure 1: Dependency Locality Theory Integration Cost.

\section*{Auxiliaries in DLT}

Most previous experimental studies on locality effects do not contain auxiliaries. An exception is Experiment 4 from (Warren \& Gibson, 2002), which compares self-paced reading times of an object relative clause with a full or pronominal embedded subject NP vs. a complementizer clause with full or pronominal subject NP, see example (1).
a. Relative clause: The woman who you/the boy had accidentally pushed off the sidewalk got upset and decided to report the incident to the policeman standing nearby.
b. Complement clause: The woman knew that you/the boy had accidentally pushed the girl

\section*{but gave him/you a long lecture anyway.}

Warren and Gibson found that the reading times were longest in the full NP in ORC condition, which is also the one in which highest integration costs are expected. On the auxiliary, the difference between the ORC with full NP and the ORC with pronoun is significant. While this would be in line with an integration effect already on the ORC auxiliary, Warren and Gibson also point out the possibility that the longer reading times on the auxiliary might be a spill-over effect.

The present study seeks to directly investigate whether integration costs can be measured on auxiliaries.

\section*{Result from Demberg and Keller, 2008}

Demberg and Keller's (2008) evaluation of Dependency Locality Theory on the Dundee Corpus showed that there was no general positive correlation between DLT integration costs and reading times. They however looked at integration cost at verbs in more detail, and found that verbs which integrate an auxiliary and a nominal dependent exhibit a reduced estimated reading time compared to verbs that only integrate a nominal dependent, while there seemed to be an overall effect of increased reading time at verbs with more nominal dependents, see Table 1.

Demberg and Keller therefore suggested that the relevant integration cost might not be incurred at the main verb, but at the auxiliary itself, which might integrate nominal dependents and thus incur a non-zero integration cost (DLT assume that auxiliaries are cost-free). When the auxiliary would then

Table 1: First pass durations for verbs (with non-zero integration cost) in the Dundee Corpus: coefficients for verbs grouped by verbal dependents ( \(N>20\) ) and their significance levels for a model fitted on residual reading times (with respect to a model including other predictors known to influence reading times). Abbreviations in the table refer to part of speech tags used by the Penn Treebank annotation: AUX: auxiliary, PRP: personal pronoun, NN: singular or mass noun, NNP: proper noun, singular, RP: particle, MD: modal, NNS: plural noun, RB: adverb, AUXG: auxiliary present participle, TO: preposition to, JJ: adjective, VBP: non-third person singular present verb. Table from Demberg and Keller (2008).

\hline
\end{tabular}
be integrated with the main verb, it would facilitate integration (hence the negative coefficient), as the main work of the integration of the nominal dependents has already happened at the auxiliary. They also point out that this explanation is compatible with syntactic theories such as Head-driven Phrase Structure Grammar (Pollard \& Sag, 1994), which assume that auxiliaries inherit the subcategorization frame of the main verb, and that dependents are unified (integrated) into the subcategorization frame at the auxiliary. Demberg and Keller did however not test this hypothesis in their study, so the contribution of this paper is to fill this gap and test both in a controlled experiment and on the Dundee corpus whether the hypothesis that the verb's integration cost can be measured on the auxiliary is true.

\section*{Experiment: Auxiliaries in Relative Clauses}

As a first experiment, we chose to use a strictly controlled experimental setting in which we compare the processing of subject vs. object relative clauses including auxiliaries. The processing difference in subject vs. object relative clauses is well-established: Object relative clauses (as in (2-b)) are more difficult to process than subject relative clauses (1a) (King \& Just, 1991), with increased reading times on the ORC embedded verb as opposed to the SRC embedded verb (Staub, 2010). Dependency Locality Theory (DLT; Gibson, 2000) accounts for this effect in terms of long-distance dependencies, see the explanation of this case in Section on Dependency Locality Theory.

We created 24 subject and object relative clauses with auxiliaries preceding the embedded verb, based on the experimental items from (Staub, 2010), see (2).
a. The mathematician who [aUX had] [v visited] [ NP the chairman] found a solution to the problem.
b. The mathematician who [NP the chairman] [AUX had] [ v visited] found a solution to the problem.

\section*{Data Collection}

We ran a self-paced reading experiment with 126 participants online, using WebExp, www.webexp. info (Keller, 1999), an experimental software that carries out psychological experiments over the internet. Keller, Gunasekharan, Mayo, and Corley (2009) demonstrate that response times collected with WebExp are sufficiently accurate to conduct reaction time experiments over the internet. Experiment 2 from (Keller et al., 2009) replicates results from a lab-based phrase-by-phrase self-paced reading experiment using the WebExp software.

Participants were recruited using Amazon MechanicalTurk, which we used to create HITs linking to the WebExp experiment. In order to encourage participants to complete the whole WebExp experiment, the HIT also contained a field that required participants to fill in a password which was provided on the last screen of the WebExp experiment. We restricted the HITs to workers who were based in the USA, and
have a HIT approval rate \(\geq 80 \%\). In the instructions, we additionally required workers to only participate if they were native speakers of English. We successfully collected data from 126 participants \({ }^{1}\) (approx. 60 per condition). Following recommendations in (Keller et al., 2009), we only allowed workers with a Windows or Linux operating system.
The experiment was programmed as a word-by-word selfpaced reading experiment. Due to a limitation of WebExp, each sentence within a set of sentences to be randomized has to contain the same number of words. In addition to inserting auxiliaries, we therefore edited the items from (Staub, 2010) to conform to this format by adapting the length of the region following the relative clause.

\section*{Mixed-effects modelling}

In order to test whether our manipulation of relative clause type has an effect on the reading times on the auxiliaries, we use linear mixed effects models from the R lme4 package (R. Baayen, 2008; R. H. Baayen, Davidson, \& Bates, 2008). This type of model can be thought of as a generalization of linear regression that allows the inclusion of random factors as well as fixed factors. We treat subjects and items as a random factors, which means that our models contain an intercept term for each subject and each item, representing the individual differences among the subjects and differences between our items. Furthermore, we include random slopes under both subject and item for our predictor (relative clause type), essentially accounting for idiosyncrasies of a participant or item with respect to the predictor, such that only the part of the variance that is common to all participants and all items is attributed to the main effect for our predictor.

We excluded as outliers any reading times shorter than 100 msec or longer than 1000 msec .

\section*{Results}

We found a significant effect of relative clause type on the auxiliary (AUX), the embedded verb (VB) and the determiner (DT), but not on the noun (NN) or the sentence's main verb (VBM), see Figure 2.

Auxiliaries and verbs were read significantly faster in the subject relative clause condition than in the object relative clause condition. We furthermore found that SRC determiners were read more slowly than ORC determiners; a similar effect was found on the noun region in early reading time measures in Staub (2010), see Figure 3. Differences in terms of the location of the effect may be due to differences in selfpaced reading vs. eye-tracking.

The faster reading times on the verb of the subject relative clause are in line with DLT integration cost, while the large and significant effect on the auxiliary seems to support also

\footnotetext{
\({ }^{1}\) There were some problems with WebExp, which sometimes failed to correctly transfer the collected data to our server. This resulted in loss of about \(30 \%\) of our data. This problem had been observed by others and reported earlier; it appears to be independent of the operative system and browser used by workers. Workers whose data failed to transfer were paid normal rates regardless.
}

Figure 2: Coefficients for relative clause condition shown as a bar plot, a negative value at the auxiliary means that the auxiliary was read faster in the subject relative clause condition than in the object relative clause condition.

Figure 3: Experimental results from Staub, 2010 using the same materials without auxiliaries in an eye-tracking study.
an account of an integration cost effect being observable at the auxiliary. There is however a confound in such subject vs. object relative clause stimuli: the regions preceding the auxiliary (or the verb, in other studies) differ in that the SCR auxiliary is preceded by the relative pronoun, while the ORC pronoun is preceded by a noun.

We therefore ran a second analysis which takes into account spill-over effects. We approximate the spill-over effect that a word can cause by calculating with mixed-effects models the effect of one word's log frequency on the following word's reading times \({ }^{2}\). In order to obtain an accurate estimate of typical spill-over effects, we ran this estimation on all words in our experiment, including fillers. used residual reading times for each of the words in our relative clause ma-

\footnotetext{
\({ }^{2}\) While it would be possible to approximate the spill-over effect given not only the previous word but also the word before that, note that for our stimuli, only the previous word can plausibly explain the longer reading times on the ORC auxiliary. (Word aux-2 in the ORC is shorter and more frequent than word aux -2 in the SRC.)
}

Figure 4: When taking spill-over effects into account, the effect on the auxiliary disappeared.
terials as a response variable and re-ran the earlier mixedeffects analysis on these residual reading times. The results then looked rather different: the facilitation effect on SRC auxiliaries, and difficulty effect on SRC determiners disappears when we account for spill-over effect, see Figure 4.

We furthermore find a significant effect of relative clause type on the reading times of the main verb, indicating that the main verb in the subject relative clause condition was read more slowly than the main verb in the object relative clause condition. This effect is puzzling as previous studies on selfpaced reading rather seem to suggest a tendency for longer reading times on the ORC main verb, while reading times in Staub's eye-tracking experiment were virtually identical.

\section*{Discussion}

We find that increased reading times on auxiliaries can be explained in terms of spill-over effects, thus not supporting the hypothesis of (Demberg \& Keller, 2008), who suggested that integration costs might occur at auxiliaries and facilitate integration at the verb. Instead, our findings support the original predictions of Dependency Locality Theory (Gibson, 2000). This result calls for a closer investigation of the Dundee corpus data to directly examine whether any integration cost effect is associated with auxiliaries in that data, see our Experiment 2.

In terms of experimental methodology, we provide evidence for the validity of self-paced reading using WebExp, by replicating the established relative clause asymmetry result on the embedded verb. Initial evidence that timing using WebExp is sufficiently accurate for self-paced reading studies is presented in (Keller et al., 2009). To the best of our knowledge, the present results are the first ones for word-by-word SPR using WebExp, as previous studies used much larger regions.

\section*{Corpus Study: Auxiliaries in Dundee Corpus}

\section*{Data}

For our data analysis, we used the Dundee Corpus (Kennedy \& Pynte, 2005), an English language eye-tracking corpus
based on text from The Independent newspaper. The texts contain about 51,000 words and were read by 10 native speakers of English. The text was presented on a computer screen, five lines at a time at a line length of 80 characters.

Since the corpus data is not syntactically annotated, we parsed the entire corpus with the Stanford parser (Klein \& Manning, 2003; De Marneffe, MacCartney, \& Manning, 2006), which generates both a phrase structure parse and a dependency representation. We calculated DLT integration cost based on the top-ranked dependency output for each sentence. We evaluated our integration cost implementation using a short text that had been hand-annotated with integration cost values (Wu, Bachrach, Cardenas, \& Schuler, 2010). This evaluation gives us an estimate of how well our automatic annotation tool performs, and also enables us to evaluate our new implementation based on the Stanford parser with an older implementation (Demberg \& Keller, 2008) which was based on the MiniPar parser (Lin, 1998), see Table 2.

Table 2: Evaluation on a text of 770 words, manually annotated with integration costs.
\begin{tabular}{l|c|c} 
Parser & \% correct IC & \begin{tabular}{l} 
correlation (Kendall) \\
to manual annotation
\end{tabular} \\
\hline MINIPAR & \(83 \%\) & \(\tau=0.77, p \ll 0.001\) \\
\hline Stanford & \(89 \%\) & \(\tau=0.84, p \ll 0.001\)
\end{tabular}

We then automatically aligned each auxiliary with the automatically determined integration cost calculated for its governing main verb, in order to measure whether any effect of increased integration cost at the verb might be measurable on the auxiliary. In order to decrease noise in the data set, we excluded any cases in which further discourse referents occurred between the auxiliary and the verb, or where no verb could be found within a window of three words after the auxiliary. We furthermore excluded contractions (e.g. we'll).

\section*{Methods}

We analysed the data using linear mixed effects models. Because the corpus data are not as closely controlled as the experimental data from the first study, and because the methodology differs (eye-tracking here vs. self-paced reading in experiment 1), we run mixed-effects models with a larger range of different predictors, including the length of a word in characters WordLength, its log frequency WordFreq, a flag indicating whether the previous word was fixated PrevFix, the frequency of the preceding word to account for spill-over effects PrevFreq, forward and backward transitional probabilities ForwTransProb and BackwTransProb, the word number within the sentence WordNo, the fixation landing position in relation to word length LandPos, the launch distance of the saccade LaunchDist, the surprisal \({ }^{3}\) at the word Surprisal as well as the verb's integration cost IntegCost.

\footnotetext{
\({ }^{3}\) Surprisal was calculated using the Roark parser (Roark, Bachrach, Cardenas, \& Pallier, 2009).
}

As response variables, we use four different measures of reading times: first fixation duration (duration of the first fixation, if any on the first pass through the sentence from left to right), first pass duration (sum of duration of fixations during first pass reading on a word before leaving the word), total duration (sum of the durations of all fixations on a word) and go past times (time spent between the first fixation in first pass reading on a word and first leaving it to the right).

We only analysed auxiliaries which had received at least one fixation. Before fitting LME models, we applied outlier removal: we computed the mean reading time (over all items and participants), and then removed all data points which deviated more than two standard deviations from the mean. Outliers can affect the results of analyses on the Dundee corpus, as (Roland, Mauner, OMeara, \& Yun, 2012) show. Furthermore, this way of trimming the data also reduces the long tail of the reading time distribution, resulting in a distribution that is closer to normal. This left us with 1257 data points.

\section*{Results}

None of our models support the hypothesis that higher integration costs at the verb increase reading times at the auxiliary preceding the verb. In none of the reading time models did the verb's integration cost come out as a significant predictor of reading times on the auxiliary, see for example the best fitting regression model for first pass times in Table 3. When we add the verb's integration cost as a predictor, model fit is not significantly improved ( \(p \approx 0.75\) ), and we even get a negative coefficient ( \(\beta=-0.33, t=-0.293\) ), so there is not much reason to believe at this point that the failure of finding a positive significant effect would simply be due to an insufficient number of data points.

Table 3: Final model for first pass times on auxiliaries, showing that reading times are longer when word length increases, and shorter when the previous word was fixated or was a highly frequent word.
\begin{tabular}{l|rrrc} 
& & & & \\
Predictor & Coeff & Std. Err & t value & Signif \\
\hline (Intercept) & 230.52 & 9.44 & 24.40 & \(* * *\) \\
WordLength & 5.46 & 2.40 & 2.27 & \(*\) \\
PrevFreq & -5.18 & 1.50 & -3.45 & \(* *\) \\
PrevFix & -25.19 & 4.04 & -6.23 & \(* * *\) \\
LandPos & -11.98 & 15.02 & -0.79 & \\
Surprisal & 2.00 & 1.33 & 1.50 & \\
WLen:LandP & -9.02 & 6.13 & -1.47 &
\end{tabular}

To more closely inspect the relationship between DLT integration cost and reading times and understand where the negative coefficient comes from, we ran a generalized additive model with a spline ( \(k=30\) ) for the verb's integration cost as a predictor and the auxiliaries' first pass times as the response variable. As can be seen in Figure 5, there is indeed a negative trend for increasing integration cost, at least for auxiliaries with the most common integration cost values one to
three. (An integration cost value of zero can only occur if the main verb of the sentence is a copula.)

Integration Cost and First Pass Times on Auxiliaries

Figure 5: Spline plot for the verb's integration cost fitting the first pass times on the auxiliary.

\section*{Overall Discussion}

Neither the results from the experiment nor the results from the corpus study support the hypothesis suggested in (Demberg \& Keller, 2008), that integration may already happen at the auxiliary and costs of such an integration would be measurable in reading times. The results from the corpus study are in line with the results from the closely controlled relative clause experiment. While the experiment compared auxiliaries in a specific syntactic construction, the corpus study complements the first experiment in that it includes auxiliaries from many different syntactic constructions. It also shows that the result can be replicated for contextualized reading in more naturalistic conditions.

In both studies, we took care to account for spill-over effects from previous words, and such effects indeed turned out to be important in both studies: in the relative clause study, the interpretation of results changes completely when taking into account spill-over effects, and in the corpus study, the variables capturing overspill effects significantly improve model fit.

Getting back to the fundamental question underlying these studies, these results lead to the following hypotheses about integration cost at auxiliaries:
a) Auxiliaries help integration at the verb in a way which is not directly reflected in their reading times.
b) Auxiliaries do in fact not help integration at the verb, and DLT integration cost, despite showing stable effects in experimental settings, does hence not have much general explanatory power for data of properly contextualized utterances such as those occurring in a corpus.
c) The integration cost estimate using automatic parsing tools is not accurate enough (in particular due to shortcomings in dealing with traces).

The last concern is unlikely to be valid, however, as it only applies to the corpus study, and doesn't explain failure to find an effect in the first experiment. Also, we have taken great care to re-implement integration cost based on a state-of-theart parser, and have used heuristics to account for traces.

Question a) could be addressed experimentally by manipulating constructions with respect to the presence of an auxiliary (the effects of spill-over could be diminuished by using an adverb before the verb such that the word immediately before the verb is always the same).

\section*{Conclusions}

The contribution of this paper is two-fold. We find that increased reading times on auxiliaries in subject vs. object relative clauses can be explained in terms of spill-over effects, thus do not support the hypothesis of (Demberg \& Keller, 2008), who suggested that integration costs might occur at auxiliaries and facilitate integration at the verb. Instead, our findings support the original predictions of Dependency Locality Theory (Gibson, 2000). These results are further supported by a corpus study of auxiliaries from the Dundee Corpus. We can not find any significant effect of the verb's integration cost on reading times at the auxiliary in any of our reading time measures. Given our evidence about the lack of any detectable integration cost effect on auxiliaries, we can no longer explain away the lack of an overall positive effect of integration costs on the verbs from the Dundee corpus as being due to the presence of auxiliaries.

Our second contribution is methodological: the self-paced reading study (Experiment 1) provides evidence for the validity of word-by-word self-paced reading via WebExp, by replicating the established relative clause asymmetry result on the embedded verb. While initial evidence that timing using WebExp is sufficiently accurate for self-paced reading studies is presented in (Keller et al., 2009), the present results are, to the best of our knowledge, the first ones for word-by-word self-paced-reading using WebExp.

\section*{Acknowledgments}

I want to thank Silas Weinbach for his contributions to this work in programming the WebExp and Mechanical Turk experiment, as well as Jesus Calvillo and Asad Sayeed for their contributions to the new integration cost component based on the Stanford parser.

\begin{abstract}
What information do people extract in the course of category learning? And how does training affect this process? The current study addressed these questions by examining the effects of training on the outcome of category learning in 4to 5 -year-olds and adults. In two experiments, participants were trained on either a classification task or an inference task and then tested with categorization and recognition tasks. The categorical information (i.e., deterministic and probabilistic features) was explicitly given to participants in Experiment 1 but not in Experiment 2. Results with adults replicate previous findings indicating that participants form different representations in the course of classification and inference training (rule-based representation in the former case and similarity-based representations in the latter case). In contrast, regardless of the type of training, young children form similarity-based representations.
\end{abstract}

Keywords: Cognitive Development, Categorization, Learning, Psychology.

\section*{Introduction}

The ability to form categories is an important component of human cognition (see Murphy, 2002, for a review). It has been well established that this ability appears early in development, with young infants capable of forming categories (Eimas \& Quinn, 1994; Oakes, Madole, \& Cohen, 1991). The study of how categories are learned and used can elucidate "a single main theme to cognitive science - the question of how people come to have knowledge" (Murphy, 2002, p. 272).

The relationship between category learning and use can be examined by contrasting two of the fundamental functions of categories - classification and inference (E. Smith, 1994). To test theories of categorization, researchers developed a variety of tasks (see A. Markman \& Ross, 2003, for a review), most of which are based on classification. In a typical classification learning task, participants are presented with stimuli, whose category membership is unknown, and are asked to predict a category each item belongs to. This situation is similar to that of sorting a set of squirrels and hamsters into two distinct groups. Whereas classification involves predicting the category of an item, inference involves predicting a missing feature using information from other features as well as the category. In this case, instead of determining
whether an animal is a squirrel or a hamster, participants predict a value of a given feature (e.g., the type of tail the animal has).

There is evidence that classification and inference learners result in different representations of categories and much of these findings stem from a paradigm developed by Yamauchi and A. Markman (1998). The paradigm is based on the following idea. Imagine two categories A (labeled "A") and B (labeled "B"), each having four binary dimensions (e.g., Size: large vs. small, Color: black vs. white, Shape: square vs. circle, and Texture: smooth vs. rough). The prototype of Category A has all values denoted by " 1 " (i.e., "A", 1, 1, 1, 1) and the prototype of Category \(B\) has all values denoted by " 0 " (i.e., "B", \(0,0,0,0\) ). There are two inter-related generalization tasks - classification and inference. The goal of classification is to infer category membership (and hence the label) on the basis of presented features. For example, participants are presented with all the values for an item (e.g., ?, \(0,1,1,1\) ) and have to predict category label "A" or "B". In contrast, in the inference task participants have to infer a feature on the basis of category label and other presented features. For example, given an item (e.g., "A", 1, ?, 1, 0), participants have to predict the value of the missing feature. It was found that inference learners were more likely than classification learners to infer prototypical features which were correspondingly associated with training items. Multiple studies using this paradigm found that classification learners are sensitive primarily to diagnostic features that distinguish between categories, whereas inference learners are also sensitive to within-category correlations of features, which are not diagnostic but prototypical (Chin-Parker \& Ross, 2002; Chin-Parker \& Ross, 2004; Sakamoto \& Love, 2006; Yamauchi, Love, \& A. Markman, 2002; Yamauchi \& A. Markman, 2000a, 2000b). Furthermore, there is also evidence that adults trained on a classification task attend to the most relevant features (A. L. Anderson et al., 2002). Adults learn to optimize performance in category learning by shifting their attention to different diagnostic features in different situations (Nosofsky, 1984; Rehder \& Hoffman, 2005; Shepard et al., 1961) or learn inattention to newly relevant features (Hoffman \& Rehder, 2010).
The argument that classification learning focuses on the diagnostic features distinguishing categories whereas
inference learning focuses on the prototypical features reflecting within-category information is consistent with the evidence that adults' categorization is often rule-based (Rips, 1989; Allen \& Brooks, 1991). Nosofsky and colleagues (Nosofsky \& Palmeri, 1998; Nosofsky, Palmeri, McKinley, 1994) have proposed a quantitative model of human concept learning that learns to classify objects by forming simple logical rules and remembering occasional exceptions to those rules.

However, there is little agreement on the categorization process in early development. According to knowledgebased approaches, early in development, categorization and inductive generalization is considered to be based on prior categorical knowledge thus to be category based (Gelman \& E. Markman, 1986; Gelman \& Heyman, 1999; Gelman 2004). According to another approach, early categorization is similarity-based (Sloutsky \& Fisher, 2004; Sloutsky, Kloos, \& Fisher, 2007). There is evidence that early generalization is often driven by appearance similarity (Gelman, 1988; Gelman \& E. Markman, 1987; Sloutsky \& Fisher, 2004). In particular, infants are more likely to group items together if the items have overlapping within-group distributions of properties and non-overlapping betweengroup distributions (French, et al., 2004, see also Mareschal \& Quinn, 2001; Mareschal, Quinn, \& French, 2002). Similarly, infants are more likely to generalize non-obvious properties when the two items look alike (Welder \& Graham, 2001) and they are more likely to extend a name to items that have similar shape (E. Markman \& Hutchinson, 1984; L. Smith, et al., 1996). Similar results have been reported with young children, with similarity supporting both categorization of items and induction of non-obvious properties (Gelman, 1988; Gelman \& E. Markman, 1987; Sloutsky \& Fisher, 2004; Sloutsky \& Lo, 1999).

Do children and adults show the same pattern of extracting and processing categorical information in category learning? How does training affect this process? And how do these effects change in the course of development? Does the asymmetry between classification and inference learning found in adults exist in children? Finding such an asymmetry would support the idea that, like adults, children treat classification and inference learning differently and tend to detect and rely on a defining feature to categorize items, whereas a symmetric performance in the classification and inference training would support the idea that children may perform similarity-based categorization and treat two types of category learning equally. The primary goal of this study is to address these questions.

\section*{Overview of the Current Study}

Experiments reported here explored how categories were learned and used under classification and inference training by adults and young children. The basic task consisted of two phases, a training phase and a testing phase. During the training phase, participants had to infer either the category
of a given item (in classification training) or a feature that the item has (in inference training). The testing phase consisted of categorization and recognition tasks and was administered immediately after the training phase. During the testing phase, which was identical for two training conditions, adult and child participants were asked to determine (1) which category the creature was more likely to belong to and (2) whether each picture was old or new. The structures of both training and testing stimuli will be described in the section below.

\section*{Experiment 1}

\section*{Method}

Participants There were 35 adults (16 women) and 21 preschool children ( \(M=56.6\) months, range 53.2-59.5 months; 13 girls) participating in this experiment. In this and the second experiment reported here, adult participants were undergraduate students from the Ohio State University participating for course credit and were tested in a quiet room in our lab on campus. Child participants were recruited from childcare centers, located in middle-class suburbs of Columbus and were tested in a quiet room in their preschool by a female experimenter.
Materials In both experiments reported here, the materials, similar to those used previously by Deng and Sloutsky (2012, 2013), consisted of colorful drawings of artificial creatures that varied in their appearance and in a categoryinclusion rule and that were accompanied by the novel labels "flurp" (Category F) and "jalet" (Category J). For these two categories, we created two prototypes (F0 and J0, respectively) that were distinct in the color and shape of seven of their features: head, body, hands, feet, antennae, tail, and button (see Figure 1). Two categories have a family-resemblance structure and stimuli were derived from the two prototypes by modifying the values of the seven features. The button is the deterministic feature (hereafter "D") and defines the category-inclusion rule: all members of Category F have raindrop-shaped button with the value of 1 whereas all members of Category \(J\) have cross-shaped button with the value of 0 . All the other varying features - the head, body, hands, feet, antennae, and tail - constitute the probabilistic features (hereafter " P ") and reflect the overall similarity among the exemplars.
The training stimuli consisted of High-Match items (i.e., \(\mathrm{P}_{\text {flurp }} \mathrm{D}_{\text {flurp }}\) and \(\mathrm{P}_{\text {jalet }} \mathrm{D}_{\text {jalet }}\) ). All members of \(\mathrm{P}_{\text {flurp }} \mathrm{D}_{\text {flurp }}\) items had four probabilistic features ( P ) consistent with the prototype F0 with the value of 1 and two features consistent with the prototype J0 with the value of 0 . And all of them have the deterministic feature (D) consistent with F0 valued 1. However, all members of \(\mathrm{P}_{\text {jalet }} \mathrm{D}_{\text {jalet }}\) items had four probabilistic features consistent with the prototype J0 with the value of 0 and two features consistent with the prototype F0 with the value of 1 . And all of them have the deterministic feature consistent with J 0 valued 0 .
The testing stimuli consisted of another four sets of items besides the High-Match items. The data analyses reported

Table 1. Example of category structure used in Experiment 1 and Experiment 2.

\hline
\end{tabular}

Note. The value 1 = any of seven dimensions identical to Category F (flurp, see Figure 1). The value \(0=\) any of seven dimensions identical to Category J (jalet, see Figure 1). The value \(\mathrm{N}=\) new feature which is not presented during training. \(\mathrm{P}=\) probabilistic feature; \(\mathrm{D}=\) deterministic feature. F0 is the prototype of Category F and J0 is the prototype of Category J.

Figure 1. Examples of Stimuli Used in this study.
here only focused on two of them: critical lures (i.e., \(\mathrm{P}_{\text {jalet }} \mathrm{D}_{\text {flurp }}\) and \(\mathrm{P}_{\text {flurp }} \mathrm{D}_{\text {jalet }}\) ), and all-new-P items (i.e., \(\mathrm{P}_{\text {all- }}\) \({ }_{\text {new }} \mathrm{D}_{\text {flurp }}\) and \(\left.\mathrm{P}_{\text {all-new }} \mathrm{D}_{\text {jalet }}\right)\). The High-Match items were used to examine participants' performance of category learning and to assess their recognition accuracy on the old items. Children were above \(91.1 \%\) categorization accuracy on these trials, and adults were above \(95.3 \%\), all above chance ( \(p \mathrm{~s}<.05\) ) and exhibited memory accuracy of \(82.2 \%\) and \(94.5 \%\), respectively. The all-new-P items were catch trials and consisted of six new probabilistic features which were not shown during training. Children and adults exhibited memory accuracy of \(91.0 \%\) and \(98.1 \%\), respectively. The critical lures were Low-Match items: Most of the members of \(P_{\text {jalet }} D_{\text {flurp }}\) items have the \(P\) with the value of 0 but all of them have D valued 1 ; whereas most of the members of \(\mathrm{P}_{\text {flurp }} \mathrm{D}_{\text {jalet }}\) items have P with the value of 1 but all of them have D valued 0 . This set of items was used to assess whether participants relied on overall similarity or category-inclusion rule to categorize new items. Table 1 shows example of category structure with P and D being combined to create three types of stimuli, and Figure 1 shows examples of each kind of stimulus.
Procedure The procedure consisted of two phases, a training phase and a testing phase. During the training phase, participants were given 30 trials (15 trials per category) and they had to infer either the category of a
given item (in classification training) or a feature that the item has (in inference training). Each training trial was accompanied by corrective feedback. The classification and inference training differed in the type of dimensions being predicted. In classification training, participants predicted the category label of a stimulus given information about all other features. In inference training, participants predicted one missing feature of a stimulus given the information about the remaining features as well as the label. The information about P and D was explicitly given to participants before training. They were told that all flurps (or jalets) had raindrop button (or cross button) and most of them had flurps' (or jalets') \(P\) by presenting corresponding probabilistic features one at a time. This information was repeated in the corrective feedback to each response during training. Adult and child participants were randomly assigned to one of the two training conditions. The testing tasks were not mentioned in the training phase of any of the conditions.
Testing phase, including categorization and recognition tasks, was administered immediately after training. During the testing phase, which was identical for two training conditions, adult and child participants were presented with 40 trials of creatures and were asked to determine (1) which category the creature was more likely to belong to and (2) whether each picture was old (i.e., exactly the one
presented during the training phase) or new. The order of the 40 items was randomized across participants. No feedback was provided during the testing phase.

The procedures were identical for both adult and child participants except the way the instructions were presented and the questions were asked. Adult participants read the instructions and questions on the computer screen and pressed the keyboard to make responses, whereas for children instructions as well as questions were presented verbally by a trained experimenter and the experimenter recorded children's responses by pressing the keyboard. The proportion of responses in accordance with the category from which the exemplar was derived (i.e., rulebased responses) was the dependent variable. If classification learners and inference learners process and represent categorical information differently, their performance should be asymmetric between Classification Training and Inference Training conditions. However, if there is no difference between classification and inference training, participants should show symmetric pattern between two training conditions. In addition, if participants rely on the deterministic feature, the proportion of rulebased responses should be high. However, if they rely on multiple probabilistic features, they should make low level of rule-based response.

\section*{Results and Discussion}

All results reported here only focused on performance of the categorization task, specifically on the critical lures (i.e., \(\mathrm{P}_{\text {flurp }} \mathrm{D}_{\text {jalet }}\) and \(\mathrm{P}_{\text {jalet }} \mathrm{D}_{\text {flurp }}\) items). Recall that if participants form a rule-based representation of a category, they should identify the \(\mathrm{P}_{\text {flurp }} \mathrm{D}_{\text {jalet }}\) item as a jalet, whereas if they formed a similarity-based representation, they should identify this item as a flurp.

The main results of Experiment 1 are shown in Figure 2. As shown in the figure, children tended to form similaritybased representations regardless of condition, whereas adults tended to form rule-based representations in the classification condition. These findings were supported by statistical analyses - data in the figure were analyzed with 2 (Training Type: Classification and Inference) by 2 (Age Group: 4-5-year-olds vs. Adults) between-subjects ANOVA. There was a main effect of training type, \(F(1,52)\) \(=5.56, M S E=0.38, p=.022, \eta^{2}=0.097\), and a main effect of age group, \(F(1,52)=24.49, M S E=1.65, p<.001, \eta^{2}=\) 0.320 . Specifically, adults made more rule-based responses in Classification Training than in Inference Training, independent samples \(t(1,31.2)=2.63, p=.013, d=0.92\), with the proportion of rule-based responses above chance in Classification Training, one-sample \(t(1,15)=4.28, p=\) \(.001, d=1.07\), but around chance in Inference Training, one-sample \(t(1,18)=0.94, p=.359\). However, for children, they made comparable rule-based responses in both training conditions ( \(p=.334\) ), with the proportion of rulebased responses significantly below chance in Inference Training, one-sample \(t(1,6)=5.46, p=.002, d=2.06\), and marginally below chance in Classification Training, onesample \(t(1,13)=2.03, p=.064, d=0.54\).

Figure 2. Proportion of rule-based responses by age group and training type in Experiment 1.
The results are consistent with previous evidence (Yamauchi \& A.Markman, 1998; Hoffman \& Rehder, 2010) pointing to the predicted asymmetry between classification and inference training for adults. As predicted, adults tended to process and represent categorical information differently, with classification learners being more likely than inference learners to focus on deterministic feature, which separates two categories. However, there was little evidence that children learned categories differently by classification and inference. The symmetric performance suggested that children treated classification training and inference training equally and, more importantly, unlike adults, children formed similaritybased representation of categories.
One possible limitation of Experiment 1 was that participants were told explicitly about the deterministic and probabilistic features. It is possible that only adults, but not children attended to this information, and as a result, only adults formed rule-based representations. Experiment 2 attempted to eliminate this possibility by not mentioning that there were probabilistic and deterministic features.

\section*{Experiment 2}

\section*{Method}

Participants Twenty-six adults (18 women) and twenty preschool children ( \(M=55.3\) months, range 49.8-60.2 months; 7 girls) participated in this experiment. Two additional adults were texting during experiments and these data were excluded from the analysis.
Materials and procedure The materials were identical to those used in Experiment 1. The overall procedure in Experiment 2 was identical to Experiment 1 except that neither the information of P nor D was given to participants before main experiment or in the feedback (i.e., participants were only given corrective feedback). For the old items (i.e., High-Match items) at test, children were above \(70.1 \%\) categorization accuracy on these trials, and adults were above \(83.9 \%\), all above chance ( \(p\) s \(<.05\) ) and exhibited memory accuracy of \(75.0 \%\) and \(71.1 \%\), respectively. For the all-new-P items, Children and adults exhibited memory accuracy of \(78.2 \%\) and \(82.2 \%\), respectively.

Figure 3. Proportion of rule-based responses by age group and training type in Experiment 2.

\section*{Results and Discussion}

The main results of Experiment 2 are shown in Figure 3. The data were analyzed with 2 (Training Type: Classification and Inference) by 2 (Age Group: 4-5-yearolds vs. Adults) between-subjects ANOVA. The results revealed a significant training type by age group interaction, \(F(1,42)=16.48, M S E=0.64, p=.001, \eta^{2}=\) 0.282 . Independent samples t test indicated that adults made more rule-based responses in Classification Training than in Inference Training, \(t(1,24)=6.14, p=.001, d=\) 2.58, with the proportion of rule-based responses above chance in Classification Training, one-sample \(t(1,9)=4.95\), \(p=.001, d=1.56\), but below chance in Inference Training, one-sample \(t(1,15)=2.30, p=.036, d=0.57\). However, children exhibited comparable proportions of rule-based responses in both training conditions ( \(p=.604\) ), with the proportion of rule-based responses around chance in Classification Training ( \(p=.125\) ) and Inference Training ( \(p\) \(=.140\) ).

The results in Experiment 2 revealed the same pattern as Experiment 1. For adults, there was an asymmetry between classification and inference training; whereas young children's performance in the two training conditions was symmetric, and, regardless of the training condition, they formed similarity-based representations.

\section*{General Discussion}

The reported study examines the effects of training on the outcome of category learning and changes in these effects in the course of development. To achieve this goal, we trained adult and child participants with a category learning task in which participants learned two categories. Each category had a single deterministic feature that differed between the categories and multiple probabilistic features that partially overlapped between categories. Participants who were trained on a classification task were asked to classify items into one of two categories; whereas participants who were trained on an inference task were asked to infer a missing feature of items. Following training, participants were tested on their ability to categorize novel items.

Two major findings stem from the reported results. First, in both reported experiments adults exhibited an asymmetric pattern between classification training and inference training. Their rule-based responses in classification training were consistently higher than those in inference training, which is consistent with previous evidence (Yamauchi \& A. Markman, 1998; Hoffman \& Rehder, 2010) suggesting that adults process and represent categorical information differently. Specifically, classification learners are more likely to focus on deterministic (or rule-based) features than inference learners. However, for young children, the symmetry between classification and inference suggests that they do not treat these two training conditions differently. Second, adults tend to spontaneously detect a defining feature (Experiment 2) and classification learners tend to consistently rely on it to categorize items (Experiment 1 and 2). But there is little evidence that children rely on the deterministic feature in categorization. In contrast to adults, children tend to rely on a pattern of correlated probabilistic features, which reflects the overall similarity.
The results have implications for understanding the mechanisms underlying category learning and how these mechanisms may change in the course of development. Future research will also examine how attention is allocated in category learning by using a combination of eye tracking and behavioral paradigm.

\begin{abstract}
We study three-person groups solving a simple, two alternative forced choice task of perceptual nature. The group members provide individual answers and afterwards discuss and reach a joint decision. Different models of information sharing describe the theoretical relationship between group and individual performance. Experimental data shows that average-performing members can benefit from cooperation, but the groups do not outperform their best members. Results point to voting as the best explanation of the behavior of the groups.
\end{abstract}

Keywords: group decision making; distributed cognition; information sharing

\section*{Introduction}

Whether "two heads are better than one" is no settled question in psychology. Many studies report groups to be less proficient than their most capable members (Corfman \& Kahn, 1995), or that there is no benefit (Heaney, Foster, Gregor, O’Neill, \& Wood, 2010). Groups are often regarded as source of negative influence on individual performance, stemming from conformism (Asch, 1951) or social loafing (Allport, 1924).

There are, however, studies that report benefit from cooperation (Kerr \& Tindale, 2004; Hastie \& Kameda, 2005). In one of such studies Bahrami (B. Bahrami et al., 2010) determined that dyads can outperform their members in a simple two-choice perceptual task, provided that those members have similar individual effectiveness. This group benefit disappeared when communication was forbidden; hence free information sharing was a key factor.

This result is interesting because there is no obvious reason for group benefit to occur in such a simple task. For certain types of tasks, such as concept mastery, concept attainment or learning, group members can pool cognitive resources, or utilize complimentary skill or knowledge. Then a group can provide better solutions in terms of quality, though not necessarily efficiency (Steiner, 1966;

Hill 1982). A notable exception is brainstorming, where participating in a group has a negative impact both on quality and quantity of creative solutions (Taylor, Berry, \& Block, 1958).

If resources cannot be shared, perhaps solutions can be. For so-called "eureka-tasks" a solution can be demonstrated in objective terms, thus (at least in theory) a single participant, who finds the correct answer, can easily persuade other members, leading to a correct group solution. Hence, the chance of group solving a task grows with its size. Examples of such task are Remote Associates Test (Laughlin \& Bitz, 1975), or simply scrambled letters/anagrams.

In Bahrami's study neither of these conditions was met. The participants first performed the perceptual task on their own, without the ability to divide it into parts. Then a group decision was made, based solely on what the participants perceived individually. No reasoning or previous knowledge or was of any use and the only thing, that the participants could communicate was their subjective idea, of what they think the answer was. Still not only did the pairs perform better, than chance (which in this case means the averaged effectiveness of the two participants), but they also outperformed the better of the two members.

Bahrami tested several theoretical models of information sharing in communication, developed in the spirit of signal detection theory, and concluded, that dyad members communicate their own relative confidences, which allows the group benefit to occur.

Later these models were theoretically extended to groups of arbitrary size by Migdał (Migdał, Raczaszek-Leonardi, Denkiewicz \& Plewczynski, 2012). "Aggregation of decisions" was also considered, that is a situation when subgroups of a larger group first reach their decisions, and then try to convince one another.

The topic of this paper is an experimental attempt to verify the applicability of these theoretical models to three-
person groups, and shed light onto how these groups reach their decisions.

\section*{Decision-Making Models}

Consider the following task. On each trial a group consisting of three participants views two sets of stimuli, one after another, for a brief period ( 85 ms ). Each of the two sets consists of six Gabor patches. All patches are identical, with the exception of one (target) patch - which has higher contrast. The task is to determine which screen, the first or the second, contains the target patch. The difference in contrasts between the target patch and non-target patches determines the difficulty of the task. We use the convention, that this difference is positive, when the target is in the second set, and negative, if it's on the first.

Knowing the answers of a given a participant, we can determine the probability, that he or she chooses the second answer as a function of the contrast difference. We model this relationship with a cumulative of the normal distribution, as it provides a good fit to the experimental data (Bahrami et al., 2010).

Again, following the convention we describe this psychometric function with two parameters: slope ( \(s\) ) and bias (b). The slope is a measure of participant's performance and is of primary interest. The bias describes the tendency to give one particular answer - the task is constructed in such a way, that this parameter should be close to 0 . These parameters are related to the standard parameters of a Gaussian curve (mean \(\mu\) and standard deviation \(\sigma\) ) in the following way:
\[
\begin{align*}
& s=\frac{1}{\sqrt{2 \pi} \sigma}  \tag{1}\\
& b=-\mu \tag{2}
\end{align*}
\]

In the same way as individual decision are used to construct curves for participants, group curves can be obtained from group decisions, allowing for a comparison of group and individual slope parameters.

By making different assumptions about communication and decision making process within the group, a theoretical dependency between individual slopes \(s_{1}, s_{2}, s_{3}\) and group slope parameter \(s_{g}\) can be established, in the form of a function \(s_{g}\left(s_{1}, s_{2}, s_{3}\right)\).

If the behavior of the group actually matches the assumptions, then the empirically obtained group slopes should not differ significantly from theoretical predictions. By an information-sharing model we understand a possible set of such assumptions. We consider six such models:

Random Responder (RR) This model assumes that the communication is actually ineffective, and the final decision is randomly chosen from the individual decisions.

Best Decides (BD) It is plausible that the group will simply entrust the decision to the biggest "expert" in the task. That person's decision becomes the group decision. The model assumes that the group initially possesses the knowledge
about who is the best member. This is a somewhat simplistic assumption, yet it is feasible that the best member can be determined in the beginning, based on a small number of trials.

Voting (Vot) The group uses the majority rule to determine the group decision. It requires only the communication of individual decisions.

Weighted Confidence Sharing (WCS) Each member shares his/her own relative confidence. The participants are unable to discern their perceived contrast difference from its reliability (determined by the participant's slope).

Direct Signal Sharing (DSS) Group members communicate both their perceived contrast difference and their confidence separately. This allows for a statistically optimal decision (Sorkin \& Hays, 2001).

Truth Wins (TW) In this model each participant either knows the correct answer, or is aware of not knowing it. In other words a person cannot falsely believe that he knows the answer. This basically means, that if a single group member finds out the correct answer, the group also answers correctly.

Table 1 summarizes the mathematical relationships between group and individual performance, according to the formulas for arbitrary group sizes presented in Migdał et al., 2012.

Table 1: Group slope as a function of individual slopes according to different models.
\begin{tabular}{lc}
\hline Model & \(s_{g}\left(s_{1}, s_{2}, s_{3}\right)\) \\
\hline\(R R\) & \(\frac{s_{1}+s_{2}+s_{3}}{3}\) \\
Vot & \(\frac{s_{1}+s_{2}+s_{3}}{2}\) \\
\(B D\) & \(\max \left\{s_{1}, s_{2}, s_{3}\right\}\) \\
\(W C S\) & \(\frac{s_{1}+s_{2}+s_{3}}{\sqrt{3}}\) \\
\(D S S\) & \(\sqrt{s_{1}^{2}+s_{2}^{2}+s_{3}^{2}}\) \\
\(T W\) & \(s_{1}+s_{2}+s_{3}\) \\
\hline
\end{tabular}

All models, with the exception of the RR model, predict that group performance should exceed average individual performance of that group's members.

In Bahrami's (Bahrami et al. 2010) study of dyads, the WCS model best described the behavior of the participants.

We expected that such behavior should also be seen in three-person groups, that is the groups would outperform their best members, at least in cases of homogenous groups (in terms of performance).

\section*{Experiment}

\section*{Subjects}

Participants were recruited from general population of Warsaw, Poland, using snowball method. There were 15 three-person groups, which gives 45 participants: 30 female and 15 male. All participants were adults (mean age 38, s.d. 15.6) with normal or corrected-to-normal vision. Members of each group knew each other. Written informed consent was obtained from each participant prior to the experiment and each person was rewarded with 25 PLN (approximately 6 EUR) for completing the experiment.

\section*{Experimental setup}

The testing room contained three computer stations, each with a LCD display ( 24 inch, resolution \(=1920 \times 1280\), refresh rate \(=60 \mathrm{~Hz}\) ) and a keyboard. The stations were connected via a local network and arranged in the form of an equilateral triangle, with the displays facing outwards. Each participant saw only his/her own display, but was able to see the fellow group members' faces. To minimize distractions, during the experiment the room was nearly completely dark - the only sources of light were the monitors. However, the lighting was sufficient for the participants to see each other's faces.
Each computer was assigned a color: blue, orange or yellow, for the purpose of identification. The experiment was controlled by custom software based on the PsychoPy framework ("http://www.psychopy.org/"; Peirce, 2008).

\section*{Stimuli}

Each of the two stimuli sets consisted of six Gabor patches evenly distributed around the center of the screen, at a distance of 8 degrees. All patches were vertically oriented and had the following parameters: standard deviation of the Gaussian envelope \(=0.45\) deg. spatial frequency \(=1.5\) cycles/deg. The contrast parameter equaled \(10 \%\) for the non-target patch and \(11.5 \% 13.5 \%, 17 \%\) or \(25 \%\) for the target patch (hence, the contrast difference value was \(1.5 \%\) \(3.5 \%, 7 \%\) and \(15 \%\), respectively). The position of the target patch within its set was chosen randomly each trial.

The background was uniform and gray at all times.

\section*{Task and Procedure}

The experiment consisted of a practice block followed by three experimental blocks. After each experimental block the participants changed their places, moving one seat to the left, so that each participant spent about the same time using each computer. The experimenter was present in the testing
room during the entire experiment, to assure that the procedure was followed.
There were 288 experimental trials - three blocks of 96 trials. The practice sessions consisted of 8 trials. The number of trials with each combination of difficulty level and correct answer combination was equal within blocks. Each trial started with a black fixation cross, placed in the center of the screen, displayed for 500 ms . The two sets of stimuli followed, each visible for 85 ms , separated with a blank screen presented for 1000 ms. Finally, a white question mark appeared, indicating that the participants are to make their individual decisions. The decisions were made by pressing an appropriate key - left or right arrow indicating that the target was in the first or in the second set respectively. The keys were labeled " 1 " and " 2 ". After a button had been pressed the question mark was replaced with a message "Wait for other participants" decisions". It stayed on the screen until all individual decisions were made. So far the participants were not allowed to communicate with each other.
Next, the group decision phase followed. Individual decisions were displayed for 1.5 s , one above the other, each in the color of the respective computer. Then a message appeared asking the participants to discuss the group decision. After the group decision has been agreed upon, a single person was required to input the decision, in the same way as the individual decisions were made. This was always the person to the left of the previous decision maker.
During the group decision phase the participants [] could communicate freely, but were not allowed to leave their seats. The method they could use to arrive at a group decision was not constrained in any way, there was no predefined decision-making scheme (e.g. voting).
After the group decision had been made, feedback was displayed, containing information about the correctness of the group decision and of each individual decision. Feedback was visible for 1.5 s and after it disappeared, the next trial followed immediately.

If the individual decisions were unanimous, the group decision was automatically assumed to be the same. In such case the group decision phase was skipped and feedback was displayed.
The duration of the experimental session depended solely on the pace at which the participants completed the trials, and this was on average 44 minutes.

\section*{Results}

For each participant and each group the slope, \(s\), and bias, \(b\), parameters were estimated by fitting a probit regression model to that individuals (or that groups) decisions. Individual slopes were used to compute the theoretical values of group slope, predicted by each model, according to appropriate formula from Table 1 ( \(\left.s_{\text {model }}\right)\). These values were compared to the values obtained empirically \(\left(s_{\text {group }}\right)\). If the ratio of the empirical and theoretical value, \(s_{\text {group }} / s_{\text {model }}\), was greater than one, it means that the groups outperformed the model, if it was less than one - the groups did not reach
predicted accuracy. A one sample Student's t-test was used to determine the significance of the deviations from theoretical predictions; the quotient was compared with the value of 1 . The results are summarized in Table 2.

Table 2: Experimental results.
\begin{tabular}{llllll} 
model & \(M\) & \(S D\) & \(t(14)\) & \(p\) & \\
\hline RR & 1.42 & 0.32 & 5.16 & \(<.001\) & \(* * *\) \\
BD & 0.93 & 0.24 & -1.11 & .29 & \\
Vot & 0.95 & 0.21 & -0.94 & .36 & \\
WCS & 0.82 & 0.18 & -3.77 & .002 & \(* *\) \\
DSS & 0.71 & 0.15 & -7.19 & \(<.001\) & \(* * *\) \\
TW & 0.47 & 0.11 & -19.23 & \(<.001\) & \(* * *\) \\
\hline \multicolumn{4}{l}{ Note: \({ }^{*} p<.05 .{ }^{* *} p<.01 .{ }^{* * *} p<.001\)}
\end{tabular}

The ratio \(s_{\text {group }} / s_{\text {model }}\) was significantly greater than 1 for the RR model and significantly less than 1 in the case of WCS, DSS and TW models. In other words the actual slope parameters of the groups were significantly greater than those predicted by RR model, and significantly lower, than the predictions of the WCS, DSS, TW models.

In case of some models, namely BD, Vot and TW, a group decision on a given trial can be determined from the individual decisions. This allows for a per-trial comparison of the theoretical decisions and the decisions actually made. A group decision agrees with the BD models if it is the same, as the decision of the best group member (i.e. the one with the highest slope parameter). In case of the Vot model it is the decision made by the majority of participants. Finally, in the TW model it is the correct answer, unless all members were wrong. For each group three values were calculated, indicating the number of group decisions that were consistent with each of these tree models. A paired ttest was performed for each pair of these models. The differences in consistency between the Vot model ( \(M=\) 254.7, \(S D=21.18\) ) and both the BD model ( \(M=218.7, S D\) \(=27.6, \mathrm{p}<.001)\), and TW model, \((M=213.5, S D=19.6, \mathrm{p}\) \(<.001\) ) were significant and positive. The difference in consistency between BD model and TW model was not significant ( \(\mathrm{p}=.77\) ).

\section*{Discussion}

Analysis of individual and group slopes allows us to reject the RR, WCS, DSS and TW models, leaving Vot and BD as plausible explanations of group performance. A trial-by-trial analysis points to Vot model (majority voting) as the best explanation.

The rejection of some models does not mean that the types of behavior they describe did not occur or that they are impossible. It merely shows that they were not dominant in the course of the experiment. Indeed in a small, but not negligible number of trials (about 12\%), the group decisions corresponded neither to BD nor Vot model predictions.

\section*{Conclusions}

Results of the experiment indicate that three-person groups prefer voting as a method of reaching a joint decision, and more advanced communication is rarely employed. Groups outperformed, so to say, their average members, but best members generally made better decisions than the group. This group benefit can be attributed solely to the use of voting as a decision-making scheme.

The failure to outperform the best group members, as it was in the case of pairs in the study by Bahrami et al. (2010), can be explained in many ways. First, the requirement for cognitive resources used for communication and integration of information increase as more group members are added, leading to deterioration of information processing performance. Secondly, in groups of size three, as opposed to dyads, voting becomes possible. Since group members are not directly rewarded for accuracy, and the experimental task is somewhat tedious, employing a simple, relatively good, and socially acceptable method of reaching a group decision seems tempting.

Conformism, or caring for group's coherence, can also play a role, as it can shy away a single correct group member, from confronting the majority decision (and prolonging the decision phase). The social acceptance of voting can afterwards serve as a justification for this group member, if he or she were blamed for not insisting on the correct answer. On the other hand the responsibility for being wrong diminishes, if one is the member of a majority.

It is feasible that the impossibility of automatically resolving a tie in dyads fosters communication and, in turn, increases performance. Adding a third member provides an opportunity to use a simpler and less effective decision making system and, paradoxically, diminish performance. This shows how seemingly simple task and situations can produce non-trivial dependencies.

\begin{abstract}
Societies sometimes stick to the status quo instead of switching to superior technologies and institutions. Existing explanations often attribute this to a coordination failure due to payoff externalities: people may know that another alternative is superior but nobody has an incentive to switch unless many others do so. We show that a simple learning argument can provide an alternative explanation. When people learn about the alternatives from their own experiences but tend to adopt the behaviors of others, they will mistakenly learn to believe that a popular alternative is superior to a better, but unpopular alternative. Our model neither assumes that agents engage in motivated cognition nor that they transmit mistaken information to others. Rather, it emphasizes the role of a fundamental asymmetry in access to information about popular versus unpopular alternatives. Our model thus provides a novel, sampling-based, explanation of how conformity in behavior can lead to private acceptance.
\end{abstract}

Keywords: Social Change, Learning, Conformity, Popularity
Explaining why collective mistakes emerge and persist is central to understanding social change, immobility, and differences in welfare (e.g. Elster, 1978; North, 1990). In developing countries, people keep on using poor domestic hygiene practices even though simple changes would save many lives (Curtis, Cairncrosss \& Yonli, 2000), and farmers fail to use fertilizer despite their potential for large increases in productivity (Duflo, Kremer \& Robinson, 2009). In western countries, firms persist in making abundant use of temporary workforce despite the inefficiency of this arrangement (Pfeffer, 1998). How come large groups of people could persist in using inefficient technologies, practices or institutions when better courses of actions are available?

Prior literature has proposed two classes of explanations. The first perspective has demonstrated that such mistakes can occur when payoffs increase with the number of people taking the same action (Arthur, 1989; Elster, 1978; North, 1990). This type of explanation, which relies on network externalities, generally assumes that people know the values of the alternatives. The problem is that nobody has an incentive to switch unless many others do so. The second perspective proposes that collective mistakes can emerge because agents sometimes believe that an alternative that is in fact suboptimal is the best. Rather than emphasizing a coordination failure, such explanations rely on the fact that people may not be aware of the qualities of the alternatives. This perspective assumes that agents use popularity as a signal of quality (Banerjee, 1992; Bikhchandani, Hirshleifer \& Welch, 1992). Explanations that fall in this tradition are thus only valid when agents infer the qualities of the alternatives of the basis of the choices of others.

Here, we show that collective mistakes can still emerge and persist even if payoffs do not depend on the choices of others and people do not use popularity as a signal of quality. Instead of assuming that popularity directly affects an agent's evaluation of the available alternatives, we analyze situations where popularity only affects agents' sampling decisions: In our model, agents are more likely to try the most popular alternative, i.e., the alternative believed by most to be the superior. But agents' quality estimates are solely based on their own experiences with the alternatives. There are many situations where one might expect to see such conformity in behavior (people choose the popular alternative) but not in attitudes (their attitudes depend only on their own experience). For example, people may decide to go along with the majority and select the most popular alternative to avoid being seen as deviant (Cialdini \& Goldstein, 2004), or because of adverse reputation effects to receiving a poor outcome with an unusual alternative (Keynes, 1936; Scharfstein \& Stein, 1990). For example, it is difficult to avoid learning about the research tradition that is dominant in your department.

We show that when agents are more likely to be exposed to popular alternatives, a sampling bias emerges that leads most people to believe that the quality of popular alternatives is superior to that of unpopular alternatives. The intuition behind this result pertains to how people sample information about the available alternatives (Denrell \& Le Mens, 2007; Le Mens \& Denrell, 2011). Consider a medical doctor who has to select one of two possible treatments to cure a patient. Treatment P is popular among other doctors in her reference group and patients whereas treatment R is rarely chosen. Suppose the doctor selects R and the initial outcome is disappointing. While this might be a signal of the poor quality of R , it could also have resulted from other causes. But because patients may not want to continue a treatment with an unpopular drug with disappointing initial results, the doctor is likely to abandon R. In doing so, she will fail to discover that R might be an efficacious treatment. Compare this to what would have happened, had she selected P instead. She might have continued with \(P\), even following disappointing initial results, because patients have heard that P has been efficacious in the past. In doing so, she would have acquired additional information about P and she might have discovered that this treatment was in fact efficacious.

This stylized story illustrates an important asymmetry in opportunities for error correction: an error of underestimation of the efficacy of a popular treatment is less likely to persist than an error of underestimation the efficacy of an unpopular
treatment.
Prior research has identified a number of psychological mechanisms and biases that explain why people might come to prefer what is available or most popular even when it is not the best alternative (Bem, 1972; Festinger, 1957; Heider, 1958). These explanations assume that people adjust their evaluations of the alternatives based on what is seen as a norm. Here, we analyze a simple learning model that demonstrates that it is not necessary to invoke such intra-psychic adjustment. Our model also has novel policy implications, as it suggests that exposing initially skeptical adopters to a new practice may be sufficient to enhance its diffusion.

\section*{Model}

In our model, agents make a sequence of choices among two uncertain alternatives and learn about the qualities of the alternatives from their own experiences. Our model is an extension of standard models of the evolution of coordination (Arthur, 1989). Consider a growing population. In each period, \(t=1,2, \ldots\), one new agent enters the population. Each agent makes a choice, in every period, between two competing alternatives. Everything else equal, agents prefer to select the alternative that is chosen by the largest proportion of others in the previous period. People might care about popularity because of payoff externalities (i.e. when an alternative is more useful if widely spread) or because of adverse reputation effects to receiving a poor outcome with an unusual alternative (Keynes, 1936; Scharfstein \& Stein, 1990). An agent may forego some of the benefits of coordination, however, and choose the less popular alternative, if she believes it is of a higher quality. These assumptions are implemented in the model by the use of the following logistic choice rule. The the probability that Agent \(i\) selects Alt. 1 in period \(t+1\) is:
\[
\begin{equation*}
p C_{1}^{i}\left(\hat{q}_{1, t}^{i}, \hat{q}_{2, t}^{i}, p_{1, t}\right)=\frac{e^{a p_{1, t}+b \hat{q}_{1, t}^{i}}}{e^{a p_{1, t}+b \hat{q}_{1, t}^{i}}+e^{a\left(1-p_{1, t}\right)+b \hat{q}_{2, t}^{i}}} \tag{1}
\end{equation*}
\]
where \(a\) and \(b\) are positive constants, \(p_{k, t}\) is the share of the population choosing Alt. \(k\) in period \(t\), and \(\hat{q}_{k, t}^{i}\) is Agent \(i\) 's estimate of the quality of Alt. \(k\) at the end of period \(t\). The logistic choice rule is often used to model choice under uncertainty (Erev \& Baron, 2005; Sutton \& Barto, 2005) and provides good fit to experimental data on sequential choices (Denrell, 2005).

Whenever Agent \(i\) chooses Alt. \(k\), she can observe some information about the quality of that alternative. The observation, \(z_{k, t}^{i}\), is a random variable drawn from the underlying quality distribution, which is assumed to be normally distributed with expected value \(\mu_{k}\) and common variance \(\sigma^{2}\). We assume a simple updating rule: the revised estimate is a weighted average of the past estimate and the new observation (Busemeyer \& Myung, 1992; Denrell, 2005),
\[
\begin{equation*}
\hat{q}_{k, t}^{i}=(1-\lambda) \hat{q}_{k, t-1}^{i}+\lambda z_{k, t}^{i}, \tag{2}
\end{equation*}
\]
where \(\lambda\) is between 0 and 1 . If \(i\) does not select Alt. \(k\) in period \(t-1\), the estimate remains the same: \(\hat{q}_{k, t}^{i}=\hat{q}_{k, t-1}^{i}\). Agent \(i\) 's
initial estimate, when she enters the population, is a random variable drawn from a normal distribution with mean zero and variance \(\sigma^{2}\).

Note that this formulation assumes that agents only learn from personal experience: an agent only updates her estimate of the quality of the alternative she personally observes. Thus, in this model, agents do not infer the qualities of the alternatives based on the choices of others, nor do they learn from the observations of others.

\section*{Analysis}

It is possible to do a formal analysis of estimates and choices when the number of period becomes large. In the Appendix, we derive an explicit expression for the joint distribution of the asymptotic quality estimates \(\left(\hat{Q}_{1}, \hat{Q}_{2}\right)\) of the two alternatives (eq. 10). We then solve, numerically, for the limiting values of \(p_{1}\), the proportion of agents choosing Alt. 1. Finally, for any given value of \(p_{1}\), we compute, by numerical integration, the probability that Alt. 1 is considered superior.

The predictions of the asymptotic analysis are depicted by the solid lines on the graphs of Fig. 1; the diamonds represent simulated estimates after 500 periods. The left panel shows that when the weight of popularity in the sampling rule (parameter \(a\), see eq. 1 , is small, most agents select the first alternative, which has a higher average quality. If \(a\) is sufficiently large, however, it is possible that most agents select the second, inferior, alternative instead. The right panel shows that, in this case, most agents will also come to believe that the second alternative has a higher quality, i.e., \(P\left(\hat{Q}_{1}<\hat{Q}_{2}\right)>0.5\). In summary, our model implies that, in all cases, most agents will come to believe that the alternative chosen by most has the higher quality, even if such belief is mistaken.

More generally, the expected asymptotic quality estimate of an alternative, for a randomly chosen agent, is an increasing function of the limiting proportion of agents who choose it:
\[
\begin{equation*}
E\left[\hat{Q}_{k}\right]=\mu_{k}-\left(1-p_{k}\right) \frac{b \lambda}{(2-\lambda)} \sigma^{2} \tag{3}
\end{equation*}
\]

This equation demonstrates that the choices of other agents create a systematic externality on the quality estimates of an agent, in spite of the fact that she learns only from her own experience. More precisely, the quality of a rarely chosen alternative is systematically underestimated, and the lower the number of agents who choose it, the more severe the underestimation. The negativity bias also occurs for the popular alternative but is of much lower magnitude. In particular, when the limiting proportion of agents who select the popular alternative is close to 1 , there is almost no bias in the quality estimate of that alternative.

The probability that the process will converge to the inferior alternative, and that this alternative will be believed to have a higher quality, depends crucially on the difference in average qualities and on the variability of the observations. If the mean returns differ substantially, agents will quickly identify the best alternative. For example, suppose \(\mu_{1}=1, \mu_{2}=0\)

Figure 1: Simulated estimates (open diamonds) match the predictions of the asymptotic theory (solid line). The left panel displays the possible limiting values for the proportion of agents who select Alt. 1. These are the roots of the self-consistency equation (eq. 12). The right panel displays the limiting proportion of agents who believe that Alt. 1 is the best. When most agents choose Alt. \(1\left(p_{1}>1 / 2\right)\), most of them also believe that it is the best. And inversely, when most agents choose Alt. 2 ( \(p_{1}<1 / 2\) ), most agents believe that it is the best. Simulation results are averages based on 500 runs of 500 periods each (with \(b=1.5, \mu_{1}=0.25, \mu_{2}=0\) and \(\sigma^{2}=1\) ).
and \(\sigma^{2}=1\). It is then highly unlikely that agents will converge to Alt. 2 and believe it has higher quality. The presence of the variance of the observations in eq. 3 also shows that convergence on the inferior alternative is much more likely if alternatives are difficult to distinguish because observations are noisy. Noisy observations often happen when there is some delay between choices and observations of the corresponding outcomes which makes the association between actions and outcomes difficult. In those settings, the dynamics of experiential learning could be of particular importance.

To understand the intuition underlying these results, note that individuals accumulate biased samples of information about the qualities of the two alternatives. Negative estimates reduce the probability of further sampling, which implies that no further information is available and the quality estimate will not be updated (Denrell, 2005; Fazio, Eiser, \& Shook, 2004). This implies, in turn, that the qualities of the alternatives will tend to be underestimated, as illustrated by eq. 3 .

The magnitude of the information bias, however, is moderated by popularity. To see how, consider extreme cases. Suppose, for example, that Alt. 1 is much more popular than Alt. 2. In this case, decision makers will sample Alt. 1 almost no matter what their quality estimates are. There is thus almost no sampling bias for this alternative, the quality estimate is close to the true quality and there is almost no underestimation tendency for this alternative. When Alt. 1 is much less popular than Alt. 2, sampling will depend more strongly on quality estimates. The quality estimate will thus be subject to the systematic underestimation tendency described above.

It is important to note that our results do not require that the estimates of each individual converge toward a stable value.

In fact, the magnitude of the sampling bias is strongest when \(\lambda=1\). In this case, agents' quality estimates correspond to their last observation of the alternative, and thus the estimates are subject to potentially large changes after each observation. But the population still converges to one of the two alternatives, and the estimates for this alternative become more positive than for the other alternative. More generally, simulations show that people will still tend to evaluate popular alternatives more positively under different assumptions regarding the estimate updating rule, such as when \(\lambda\) declines with the number of observations. For example, when the quality estimate of Alt. \(k\) is the average of all prior observations of that alternative, it can still happen that most people select the inferior alternative and mistakenly believe it to be the alternative of higher quality. But the synchronization of estimates and behavior occurs for values of \(\sigma\) that tend to be larger than when \(\lambda\) is constant. This is not surprising, because in that case, estimates integrate information better (when the environment is stable) than when \(\lambda\) is constant. \({ }^{1}\)

\section*{Coordination and Synchronization of Estimates}

We motivated our assumption that people are more likely to select popular alternatives by referring to settings where people want to conform to the majority. But another reason for wanting to select a popular alternative is the desire to coordinate one's behavior with others (e.g. Hardin, 1968). For example, people might want to go to the same venues as those in the same social group, or they might want to use the same computer platform as others so as to be able to exchange files

\footnotetext{
\({ }^{1}\) This case is very close to Bayesian updating with a prior on \(\mu_{k}\) that has a \(N\left(\mu_{k}, \sigma\right)\) distribution.
}
more easily. It is possible to model such settings as follows: Suppose that there are \(N\) players who choose, in each period, one of \(M\) alternatives. The payoff of Alt. \(k\) follows a Gaussian distribution with mean \(\mu_{k}\) and variance \(\sigma^{2}\). That is, if \(o_{k, t}^{i}\) denotes the payoff Player \(i\) receives from selecting Alt. \(k\) in period \(t\), we have \(o_{k, t}^{i} \sim N\left(\mu_{k}, \sigma\right)\). In addition, there is a coordination bonus: if \(i\) selects Alt. \(k\) in period \(t\) and \(\eta_{k, t}^{-i}\) other players select Alt. \(k\) in that period, Player \(i\) receives a bonus of \(c \eta_{k, t}^{-i}\) where \(c\) is a positive parameter. Suppose there are \(T\) periods and that the goal of each player is to maximize the total payoff she receives over the \(T\) periods.

These assumptions regarding the payoff structure and the goals of the decision makers specify a coordination game (e.g. Gibbons, 1992). In this setup, people have an incentive to select a popular alternative. This formulation defines a setting where people are likely to develop quality estimates consistent with the predictions of our theory without making assumptions about the estimate updating and the choice rules. This suggests a simple way to test our theory in the laboratory: make people play a coordination game such as the one just described, measure if a majority of players believe the alternative chosen by most people to be the superior one (even in cases where it is in fact the inferior alternative) and evaluate if the pattern of estimates can be well explained by an information bias in favor of the popular alternative.

Our assumptions regarding sampling and estimate updating define a heuristic that people can use to play this coordination game. But people can also adopt other heuristics. A widely studied strategy for playing coordination games is the best-reply strategy (e.g. Young, 1998). A decision maker uses a 'best-reply' strategy when she selects the alternative that has the highest subjective expected payoff, assuming that other players will choose the same alternative as they did in the prior period (choice is randomized if more than one alternative has maximal subjective expected payoff). We ran 10,000 simulations of the game, assuming that players use the best-reply strategy, with \(N=10, \mu_{1}=1, \mu_{2}=2, \sigma=3\), \(c=0.1\) and \(\lambda=0.5\). Simulations show that the quality estimates of the players will tend to synchronize with each others, in a fashion similar to what happens in the model we have analyzed earlier in the paper. For example, after 20 periods, the correlation between the quality estimates of Player 1 for Alt. 1 and the sum of the estimates of Players 2 to 10 is 0.64 . Furthermore, the players' choices sometimes coordinate on the inferior alternative (with the above parameters, the likelihood that 6 or more players prefer Alt. 1 is about \(16 \%\) ). This is not surprising because, if \(c\) is high enough, coordination on the inferior alternative is a Nash equilibrium.

\section*{Discussion and Conclusion}

Our model illustrates a novel mechanism that explains why groups may be reluctant to switch to another practice, even when this other practice is superior. Our mechanism complements existing explanations that show how a concern for popularity can lead to lock-in. More precisely, our model
demonstrates how a concern for popularity can also influence evaluations of the qualities of the alternatives even when people learn only from their own private observations. Our theory thus provides a simple mechanism for why public conformity in behavior (a tendency to choose popular alternatives) may lead to private acceptance (the belief that the popular alternative is the best) at the individual level and to collective illusions at the level of the group.

Existing psychological explanations of this synchronization of beliefs with behavior, such as cognitive dissonance theory, or self-perception theory, attribute it to motivated cognition (Bem, 1972; Festinger, 1957; Heider, 1958). Our explanation does not challenge the experimental evidence underlying those explanations. Rather, it suggests a complementary explanation that is likely to be important in realistic settings where popularity affects choices and access to payoff information. A distinctive feature of our analysis is that it assumes that people are good processors of information, but are naïve with respect to the nature of the sample they use to form their quality estimates. This is a standard assumption of the research program on sampling explanations of judgment biases that has received broad empirical support (Fiedler, 2012; Fiedler \& Juslin, 2006; Juslin et al., 2007). We do not claim that people do not engage in motivated cognition. Instead, we point to a fundamental asymmetry regarding the information sample that people have about popular v.s. unpopular alternatives. Because cognition operates on the available sample of information, our sampling explanation operates at a different level of analysis and thus complements explanations that focus on cognitive processes.

How do our results relate to herding models (Banerjee, 1992; Bikhchandani et al., 1992), which also explain collective failures to identify the best alternative? These models also assume that people are good processors of information. But contrary to these models, we do not assume that agents use popularity as a signal of quality. Therefore, our model may be more suitable for contexts where the assumptions of herding models do not apply. In particular, our model fits contexts where people have different tastes or do not believe that others know best, but where their sampling behavior is still influenced by others (Sutton \& Barto, 1998).

Our theory also differs from explanations of collective mistakes that attribute them to a coordination failure due to network externalities (e.g. Elster, 1978; North, 1990). In fact, our theory suggests that, if network externalities affect sampling behavior, the group may not only converge to the inferior alternative but, when this happens, most agents will also come to believe that the inferior alternative is of superior quality. Thus, in a vote about whether to switch to another alternative, most people would favor sticking to the status quo even if it is actually inferior. By contrast, explanations that rely on a coordination failure predict that people will switch if a vote could be organized and switching cost were low. Despite this difference in prediction, our theory complements explanations based on payoff externalities by suggesting that
payoff externalities can have a systematic effect on quality estimates that reinforces the possibility of a lock-in.

More generally, our results point to the systematic effect of unbiased experiences on beliefs. From a policy perspective, this illustrates the potential benefits of exposing initially skeptical adopters to an unpopular practice. Agents may appear to be resistant to unpopular practices not because they are risk averse or conservative, but because their own experiences with the unpopular practice are often skewed towards failures. In this case, inducing agents to try the unpopular practice again might help its acceptance, even when persuasive campaigns are not effective.

\section*{Appendix}

\section*{Preliminaries}

In this appendix, we analyze the asymptotic behavior of the model. Let \(\hat{Q}_{1, t}\) (resp. \(\hat{Q}_{2, t}\) ) be a random variable that refers to the quality estimate for Alt. 1 (resp. Alt. 2 ) of a randomly chosen agent, at the end of period \(t\). Let \(h_{t}\left(\hat{q}_{1, t}, \hat{q}_{2, t}\right)\) be the joint density of the quality estimates in period \(t\). Let \(P_{1, t}\) denote the proportion of the population choosing alternative 1 in period \(t\). Capital letters denote random variables, and corresponding lower case letters denote realizations of the random variables.

The expected proportion of agents choosing Alt. 1 in period \(t+1\) is:
\[
\begin{equation*}
E\left[P_{1, t+1} \mid p_{1, t}\right]=\iint_{\hat{q}_{1, t}, \hat{q}_{2, t}} p C_{1}\left(\hat{q}_{1, t}, \hat{q}_{2, t}, p_{1, t}\right) h_{t}\left(\hat{q}_{1, t}, \hat{q}_{2, t}\right) d \hat{q}_{1, t} d \hat{q}_{2, t}, \tag{4}
\end{equation*}
\]

One of the difficulties in analyzing the asymptotic behavior of equation 4 is that \(P_{1, t}\) is a random variable, which varies from period to period. It is reasonable to suspect, however, that \(P_{1, t}\) will converge to a constant, as \(t \rightarrow \infty\) and the number of agents increases. Let \(p_{1}\) denote this limiting proportion. The intuition is the same as for the law of large numbers: if the number of agents is very large, the proportion choosing Alt. 1 should converge to its expected value.
Another difficulty in solving the above equation is that \(h_{t}\left(\hat{q}_{1, t}, \hat{q}_{2, t}\right)\) will change over time. Nevertheless, there is reason to believe that as \(t \rightarrow \infty, h_{t}\left(\hat{q}_{1, t}, \hat{q}_{2, t}\right)\) will converge to a stationary distribution, denoted \(h\left(\hat{q}_{1}, \hat{q}_{2}\right)\). As \(t \rightarrow \infty\), more agents are added to the system and a larger proportion of agents will have had extensive opportunities to sample the two alternatives. While a new agent, with random estimates, is added to the system in each period, the influence of such agents should become vanishly small over time.

To calculate the equilibrium the model converges to, we adopt both of these simplifying assumptions. That is, we will assume, without a rigorous proof, that \(P_{1, t}\) converges to a constant \(p_{1}\) and that \(h_{t}\left(\hat{q}_{1, t}, \hat{q}_{2, t}\right)\) converges to a stationary distribution \(h\left(\hat{q}_{1}, \hat{q}_{2}\right)\). Under these assumptions, the following self-consistency equation must hold for \(p_{1}\) :
\[
\begin{equation*}
p_{1}=\iint_{\hat{q}_{1}, \hat{q}_{2}} p C_{1}\left(\hat{q}_{1}, \hat{q}_{2}, p_{1}\right) h\left(\hat{q}_{1}, \hat{q}_{2}\right) d \hat{q}_{1} d \hat{q}_{2} . \tag{5}
\end{equation*}
\]

Moreover, for any given value of \(p_{1}\), the stationary joint density of the quality estimates, \(h\left(\hat{q}_{1}, \hat{q}_{2}\right)\), must satisfy
\[
\begin{align*}
h\left(\hat{q}_{1}, \hat{q}_{2}\right)= & \int_{r} h\left(r, \hat{q}_{2}\right) p C_{1}\left(r, \hat{q}_{2}, p_{1}\right) \tau_{1}\left(r, \hat{q}_{1}\right) d r \\
& \quad+\int_{k} h\left(\hat{q}_{1}, k\right) p C_{2}\left(\hat{q}_{1}, k, p_{1}\right) \tau_{2}\left(k, \hat{q}_{2}\right) d k . \tag{6}
\end{align*}
\]

Here, \(p C_{2}\left(\hat{q}_{1}, k, p_{1}\right)\) is the probability that an agent with quality estimates \(\hat{q}_{1}\) and \(k\) will choose Alt. 2 and \(\tau_{k}\left(r, \hat{q}_{k}\right)\) is the probability mass that the quality estimate for Alt. \(k\) transitions from \(r\) to \(\hat{q}_{k}\)
given that the agent samples Alt. \(k\). Because the new estimate equals \(\hat{q}_{k}=(1-\lambda) r+\lambda z_{k}\), where \(z_{k}\) is normally distributed with mean \(\mu_{k}\) and variance \(\sigma^{2}, \tau_{k}\left(r, \hat{q}_{k}\right)\) equals the probability mass that \(z_{k}\) is equal to \(\left(\hat{q}_{k}-(1-\lambda) r\right) / \lambda\).

To explain the above equation (eq. 6), note that the terms to the right add up to the probability that the quality estimates for alternatives 1 and 2 are \(\hat{q}_{1}\) and \(\hat{q}_{2}\), after an agent has sampled one of the alternatives. The first term on the right hand side is the probability that the quality estimates for alternatives 1 and 2 are \(\hat{q}_{1}\) and \(\hat{q}_{2}\), and that the agent sampled Alt. 1 in the previous period. This set of estimates can only emerge, after the agent samples Alt. 1 , if this agent's estimate of the quality of Alt. 2 was equal to \(\hat{q}_{2}\). Similarly, the second term on the right hand side is the probability that the quality estimates for alternatives 1 and 2 are \(\hat{q}_{1}\) and \(\hat{q}_{2}\) and that the agent sampled Alt. 2 in the previous period.

Below, we show how one can solve for \(h\left(\hat{q}_{1}, \hat{q}_{2}\right)\), for any value of \(p_{1}\). Using \(h\left(\hat{q}_{1}, \hat{q}_{2}\right)\), we can then solve for the equilibrium value of \(p_{1}\). Finally, we derive the expected quality estimates in the stationary state.

\section*{The Stationary Distribution of the quality estimates}

For a given value of \(p_{1}\), the quality estimates for a representative agent follow a discrete time markov process, with a general state space \(\mathbb{R} \times \mathbb{R}\). Because there is a positive probability, in any period, that the system could transition from any state to another, the markov process has a unique stationary distribution, which has to satisfy equation 6 . The unique joint density that satisfies this equation is
\[
\begin{equation*}
h\left(\hat{q}_{1}, \hat{q}_{2}\right)=K g_{1}\left(\hat{q}_{1}\right) g_{2}\left(\hat{q}_{2}\right)\left[e^{-a p_{1}-b \hat{q}_{1}}+e^{-a\left(1-p_{1}\right)-b \hat{q}_{2}}\right], \tag{7}
\end{equation*}
\]
where \(K\) is a normalizing constant, i.e.,
\[
\begin{equation*}
1 / K=\iint_{\hat{q}_{1}, \hat{q}_{2}} g_{1}\left(\hat{q}_{1}\right) g_{2}\left(\hat{q}_{2}\right)\left[e^{-a p_{1}-b \hat{q}_{1}}+e^{-a\left(1-p_{1}\right)-b \hat{q}_{2}}\right] d \hat{q}_{1} d \hat{q}_{2} \tag{8}
\end{equation*}
\]
and \(g_{k}(y)=\int_{r} g_{k}(r) \tau_{k}(r, y) d r\), i.e., \(g_{k}(\cdot)\) is the distribution of the random variable the estimate of Alt. \(k\) would converge to if the probability that Alt. \(k\) is selected were equal to 1 in every period. When the quality distribution of Alt. \(k\) is normally distributed with mean \(\mu_{k}\) and variance \(\sigma^{2}\), it can be shown that \(g_{k}(\cdot)\) is a normal density with mean \(\mu_{k}\) and variance \(\sigma^{2} \lambda /(2-\lambda)\).

Using appropriate algebraic manipulations, it can be easily verified that the joint density in eq. 7 satisfies the stability equation 6 . The explicit formula for the normalizing constant is:
\[
\begin{equation*}
1 / K=e^{\frac{b^{2} \sigma^{2} \lambda}{2(2-\lambda)}}\left(e^{-a p_{1}} e^{-b \mu_{1}}+e^{-a\left(1-p_{1}\right)} e^{-b \mu_{2}}\right) \tag{9}
\end{equation*}
\]

The stationary joint density of the estimates is
\[
\begin{align*}
& h\left(\hat{q}_{1}, \hat{q}_{2}\right)= \\
& \frac{\frac{1}{2 \pi \frac{\lambda}{2-\lambda} \sigma^{2}} e^{\frac{-\left(\hat{q}_{1}-\mu_{1}\right)^{2}}{2 \frac{2}{2-\lambda} \sigma^{2}}} e^{\frac{-\left(\hat{q}_{2}-\mu_{2}\right)^{2}}{22-\lambda} \sigma^{2}}\left[e^{-a p_{1}-b \hat{q}_{1}}+e^{-a\left(1-p_{1}\right)-b \hat{q}_{2}}\right]}{e^{\frac{b^{2} \sigma^{2} \lambda}{2(2 \lambda)}}\left(e^{-a p_{1}} e^{-b \mu_{1}}+e^{-a\left(1-p_{1}\right)} e^{-b \mu_{2}}\right)} . \tag{10}
\end{align*}
\]

The probability that an agent will consider Alt. 1 to have a quality higher than Alt. 2 is thus
\[
\begin{equation*}
P\left(\hat{Q}_{1}>\hat{Q}_{2}\right)=\int_{\hat{q}_{1}=-\infty}^{+\infty}\left(\int_{\hat{Q}_{2}=-\infty}^{\hat{q}_{1}} h\left(\hat{q}_{1}, \hat{q}_{2}\right) d \hat{q}_{2}\right) d \hat{q}_{1}, \tag{11}
\end{equation*}
\]
which can be computed by numerical integration.

\section*{The equilibrium value of \(p_{1}\)}

In the stationary state, the probability that Alt. 1 is selected is given by equation 5 . The appropriate substitutions and algebraic manipulations imply
\[
\begin{equation*}
p_{1}=\frac{1}{1+e^{-2 a\left(p_{1}-0.5\right)} e^{-b\left(\mu_{1}-\mu_{2}\right)}} \tag{12}
\end{equation*}
\]

The values that \(p_{1}\) could converge to are the stable roots of the selfconsistency equation (eq. 5), which can be found numerically for any value of \(a\) by using equation 12 . When the value of \(a\) is sufficiently low, such as when \(a=1\), there is only one root and this is above 0.5 . However, if \(a\) is sufficiently large, such as when \(a=3.5\), the equation has three roots, one close to zero, one close to one, and another one, between the two other roots. The intermediary root is unstable, however. That is, the derivative of right-hand-side of the stationarity equation, evaluated at the intermediary root, is higher than 1. As a result, any small disturbance will tend to move the system away from the intermediary root.

\section*{The expected quality estimates}

The marginal distribution of \(\hat{q}_{1}\), given \(p_{1}\), is given by integration of the joint distribution (eq. 10) over \(\hat{q}_{2}\). After simplifications, we get:
\[
\begin{equation*}
E\left[\hat{Q}_{1}\right]=\mu_{1}-\left(1-p_{1}\right) \frac{b \lambda}{(2-\lambda)} \sigma^{2} \tag{13}
\end{equation*}
\]
which is an increasing function of \(p_{1}\). A similar calculation gives \(E\left[\hat{Q}_{2}\right]=\mu_{2}-p_{1} \frac{b \lambda}{(2-\lambda)} \sigma^{2}\), which is a decreasing function of \(p_{1}\). Moreover,
\[
\begin{equation*}
E\left[\hat{Q}_{1}\right]-E\left[\hat{Q}_{2}\right]=\mu_{1}-\mu_{2}+\left(2 p_{1}-1\right) \frac{b \lambda}{(2-\lambda)} \sigma^{2} \tag{14}
\end{equation*}
\]
which is an increasing function of \(p_{1}\). Thus, \(E\left[\hat{Q}_{2}\right]>E\left[\hat{Q}_{1}\right]\) even if \(\mu_{2}<\mu_{1}\) whenever
\[
\begin{equation*}
\left(1-2 p_{1}\right) \frac{b \lambda}{(2-\lambda)} \sigma^{2}>\mu_{1}-\mu_{2} \tag{15}
\end{equation*}
\]

The maximum difference is obtained when \(p_{1}=0\), and
\[
\begin{equation*}
\frac{\mu_{1}-\mu_{2}}{\sigma^{2}}<\frac{b \lambda}{(2-\lambda)} \tag{16}
\end{equation*}
\]

\title{
Speed Facilitation In The Absence Of Enhanced Recognition For Target-Aligned But Irrelevant Stimuli Under Cross-modal Presentations
}

\author{

}

\begin{abstract}
An ignored stimulus is later recognized at enhanced levels if it had previously been aligned with a target from a separate task. This has been demonstrated using both visual and auditory presentations. Here we extend these findings to multisensory conditions. Participants were required to detect immediate repetitions in a sound or picture stream while ignoring superimposed words presented in the opposite modality (either written or spoken, respectively), and then underwent a surprise recognition test for these words. Contrary to the previous unisensory examples (Dewald, Sinnett, \& Doumas, in press; Dewald \& Sinnett, 2012), a significant difference between recognition rates for target-aligned and non-aligned words was not observed. However, a highly significant difference in response latency was observed, with target-aligned words being responded to much more quickly. This finding was robust and observed when the surprise test was presented in either the visual or auditory modalities, as well as across modalities.
\end{abstract}

Key words: Attention, Multimodal Presentation, Response latency, Cross-modal processing.

\section*{Introduction}

Investigations of the relationship between attention and perception have demonstrated significant learning enhancements for certain stimuli in the absence of focused attention (Seitz \& Watanabe, 2003, 2005; Watanabe, Náñez, \& Sasaki, 2001). However, in order to observer these enhancements a number of compulsory prerequisite conditions were required. These included extended exposure rates of unattended stimuli (a random dot motion display) that were presented below threshold (a subset of dots moved coherently and subliminally) and also temporally aligned with a target from an attended secondary task. Under such conditions, enhanced learning performance was observed for the unattended stimuli in later motion discrimination tasks (see, Seitz \& Watanabe, 2003, 2005; Watanabe et al., 2001). Curiously however, when presenting the same type of stimuli (coherent motion) under the same conditions, but at levels that are easily perceptible (i.e., suprathreshold), the aforementioned learning enhancements vanish (Tsushima, Sasaki, \& Watanabe, 2006; Tsushima, Seitz, \& Watanabe 2008). Thus, it appears that the relationship between whether or not learning enhancements occur for irrelevant
stimuli is dependent on whether the initial presentation is sub- or suprathreshold. It is important to note that the investigations that collectively posit this idea have exclusively used random-dot, coherent motion displays (Seitz \& Watanabe, 2003, 2005; Watanabe et al., 2001; Tsushima et al., 2006; Tsushima et al., 2008). A natural ensuing question, therefore, would be whether these findings apply to stimuli that arguably demand a higher level of processing?

Directly addressing this question, Dewald, Sinnett, and Doumas (in press) adapted Seitz and Watanabe's (2003, 2005, see also, Watanabe et al., 2001) motion detection task to include a high-level irrelevant semantic stimulus (words) in an inattentional blindness paradigm (see Rees et al., 1999 for a similar example of the paradigm). Specifically, participants were required to respond to immediate picture repetitions in a stream of serially presented line drawings, while at the same time ignore a simultaneously presented stream of superimposed words. The irrelevant word stream contained a single, unchanging word aligned with the presence of an immediate picture repetition (i.e., targetaligned) as well as seven additional words that were superimposed over the non-repeated pictures (non-aligned; i.e., analogous to exposure frequencies used by Seitz \& Watanabe, 2003). The findings demonstrated that, despite attention being directed away from the task-irrelevant items (i.e., the words), subsequent recognition of these previously irrelevant items was nevertheless enhanced. Critically, this enhancement only occurred for words that had been presented simultaneously with a task-target in the previous task (i.e., target-aligned) when compared to non-aligned irrelevant words.

Similar enhancements for target-aligned stimuli have been observed when measuring recognition performance for irrelevant pictures that had appeared with targets (geometric shapes) in a separate task (e.g., the attentional boost effect; see Swallow \& Jiang, 2010). Collectively, the findings by both Dewald et al. (in press) and Swallow and Jiang seem to paint a different picture than what was described earlier. That is, explicit presentations lead to an enhancement in recognition performance for previously target-aligned items. This is the exact opposite of the inhibited performance observed when explicit motion presentations were used as the irrelevant stimulus (see Tsushima et al., 2006; Tsushima
et al., 2008). Dewald et al. argue that the high saliency of the irrelevant stimuli (i.e., written words rather than a lower level stimulus) likely underpins the difference in findings, assuming that the previous requisite condition of simultaneous presentation is met.

Regardless of the direction of learning effects, the critical component appears to whether the irrelevant stimulus is temporally aligned with a task-relevant target in a previous task (Seitz \& Watanabe, 2003). As these investigations have largely been conducted only in the visual modality, it is important to extend these findings to other sensory modalities in order to determine whether they extend beyond the visual domain. Our recent work (Dewald \& Sinnett, 2012) recently explored this very question by presenting an analogous paradigm using spoken words and sounds (i.e., rather than pictures). A facilitation for targetaligned irrelevant stimuli was observed. Interestingly however, the enhanced performance occurred only when the surprise recognition task was presented in either the same modality as the initial presentation (audition) or across modalities (i.e., audiovisual presentations).

Despite vision being the dominant sense in humans (Chandra, Robinson, \& Sinnett, 2011; Colavita, 1974; Posner, Snyder, \& Davidson, 1980; Sinnett, Spence, \& Soto-Faraco, 2007), it is clear that the human perceptual experience is multisensory in nature. Thus, it is important to explore if the learning effects for irrelevant stimuli within the same sensory modality extend across modalities, as this will further inform how information is processed as a consequence of attentional allocation both within, and across modalities. Generally, performance improves when comparing multisensory to unisensory presentations (see for example Duncan, Martens, \& Ward, 1997; Sinnett et al., 2006; Toro, Soto-Faraco, \& Sinnett, 2005; Wickens, 1984).

The enhanced recognition performance for cross-modal presentations, when compared to unimodal presentations, can be explained by numerous findings that suggest that the capacity of the attentional system is increased if a demanding unisensory task is divided across multiple sensory modalities (i.e., multiple resources theory, see Wickens, 1984). For instance, Sinnett et al. (2006) demonstrated that under multimodal presentations, inattentional blindness for words was ameliorated (i.e., perception improved) when compared with unimodal conditions, regardless of the modality of word presentation (see also Toro et al., 2005 for a similar example involving statistical learning). These findings seem to provide support for an attentional system that is segregated, such that each sensory modality has access to individualized attentional resources (Wickens, 1984, see also Duncan et al., 1997 for an example using the attentional blink)

In the present investigation, we extend unimodal examples of learning enhancements for task irrelevant but target-aligned stimuli, to multimodal presentations. As increased performance has been observed for such presentations (see Duncan et al., 1997; Sinnett et al., 2006), we would expect an overall increase in recognition
performance for both target-aligned and non-aligned items if they are presented in a separate sensory modality from a temporally aligned task-relevant target (e.g., more attentional resources will be available for non-aligned words). Of particular interest is whether or not the comparatively higher scores for target-aligned words will persist under cross-modal presentations. Interestingly, this could possibly jettison the enhancement associated with target-alignment if performance for non-aligned words increases substantially (i.e., a ceiling effect). We presented participants with multisensory visual and auditory streams (adapted from those used in the unimodal conditions in Dewald et al., in press and Dewald \& Sinnett, 2012). This resulted in one of the streams including spoken words with distracting pictures, and the other having written words with distracting sounds. The task was to respond to repetitions in the target stream (i.e., sounds or pictures) and then to subsequently recognize as many words that had been previously presented (i.e., ignored) in the repetition detection task.

The present study also investigates the nature of the surprise recognition task. With the exception of our previous work in the auditory modality (Dewald \& Sinnett, 2012), all research involving this paradigm has presented the recognition task in the visual modality, regardless of whatever modality it was presented in during the repetition detection task. As irrelevant stimuli in the exposure portion of the experiment will be presented in either the auditory or visual sensory modalities, it is necessary to examine if subsequent recognition of these items is affected by whether presentation is in a congruent modality. Our previous work (Dewald \& Sinnett, 2012) did precisely this and systematically manipulated the modality of presentation between exposure and recognition tests. Not surprisingly, when irrelevant items were presented for recognition in the same modality as the exposure (i.e., both visually or both auditorally), learning effects were observed. However, when irrelevant stimuli were presented for recognition in an incongruent modality from their initial exposure, learning enhancements failed to surface for irrelevant items that had been temporally aligned with task-relevant targets (Dewald \& Sinnett, 2012). Lastly, cross-modal presentations lead to the greatest magnitude of enhancement for the previously aligned words in the surprise recognition test. This latter outcome dovetails with previous investigations of attentional allocation across sensory modalities in perceptual and recognition tasks, suggesting that crossmodal presentations generally lead to superior performance when compared to unimodal presentations (Dewald \& Sinnett, 2011; Duncan et al., 1997; Sinnett et al, 2006; Toro et al., 2005). Accordingly, in the present experiment we also presented the surprise recognition tests in the same or different sensory modality, or across modalities. If primary and secondary task modality congruence is a factor as it was in Dewald and Sinnett (2012), then we expect improved results for congruent matchings vs. incongruent matchings between exposure and recognition tasks, and potentially an
additional enhancement for multimodal presentations (simultaneous visual and auditory presentation of the stimulus in the recognition test) given that performance is generally enhanced for multisensory presentations (see Driver \& Spence, 2004). Note, these modality specific enhancements were only seen for target-aligned items.

\section*{Method}

Participants. Seventy-four participants \(\quad(\mathrm{n}=74)\) were recruited from the University of Hawai'i at Manoa in exchange for course credit. A total of 46 participants were assigned to the visual words and sounds condition and a total of 28 participants assigned to the auditory words and pictures condition. The uneven distribution of participants across all conditions was a consequence of convenience sampling. Participants were naïve to the experiment and had normal or corrected to normal vision and hearing. Written informed consent was obtained before participation in the experiment occurred.

Materials. The exact same stimuli and design to create streams were used here as in Dewald et al. (in press, for visual stimuli) and Dewald and Sinnett (2012, for auditory stimuli) except now with multimodal presentations (i.e., pictures presented with spoken words or sounds presented with written words).

Attending to pictures with spoken words. A total of 50 pictures were selected from the Snodgrass and Vanderwart (1980) picture database. Each of the pictures (on average 5 to 10 cm , rotated \(+/-30\) degrees from upright so as to ensure difficulty) was combined with eight one-to-two syllable, high frequency English words (average length of five letters; range 4-6) selected from the MRC psycholinguistic database (Wilson, 1988). The overall average frequency of the eight selected words was 361 per million, ranging between 135 and 782. For the auditory presentation of the words, a native English speaker's voice was recorded reading the list of selected words three times. Three blind listeners chose the best exemplar of each spoken word, with a fourth listener deciding which one was best in the event of a tie. The selected recordings were edited using sound editing software so that all items were the same presentation length ( 350 ms ) and average amplitude.

A stream of 960 picture-spoken word concatenated items was created, with repeated pictures acting as task relevanttargets. The presentation stream was broken into eight blocks of trials (120 each) in which an immediate picture repetition occurred on average one out of every eight trials, equating to 15 task-relevant target repetitions per block, for a total of 120 trials of exposure to a task-relevant target (and specific word, see below). Only eight total words were superimposed over the 960 pictures. Note then that all word types (aligned or non-aligned) were presented in equal proportions (120 times each). This was done to parallel the number of different motions used in Watanabe et al, (2001; see also Seitz \& Watanabe, 2003, 2005), so as to expose the
participants to an unchanging, single, irrelevant word, although also having seven additional irrelevant words all exposed at the same frequency. The same single word was always temporally aligned with the presentation of an immediately repeated picture target. The presentation was pseudorandomized so that on average one out of every eight trials was an immediate picture repetition (and, therefore, the presentation of the same superimposed task-irrelevant target word). Only one superimposed word was aligned with all of the immediately repeated pictures for each participant.

Attending to sounds with written words. The exact same procedure as above was employed but now with sounds, instead of pictures, serving as the task-targets, and visually presented words as the irrelevant stimuli. The sound stimuli were extracted from a database of 100 familiar sounds and were also edited to 350 ms and similar average amplitude (see Sinnett et al., 2006). All other aspects were identical to the previous condition (pictures and spoken words).

Surprise recognition task: For both conditions, a surprise recognition test for the presented words was administered after the completion of the repetition detection task. The test consisted of a total of sixteen words (i.e., half came from the previously presented words, while the other half consisted of foil words that had never been presented before, average frequency of 236 per million with a range of 165-399. The word recognition tasks were randomized and presented by DMDX software (http://www.u.arixona.edu/jforster/dmdx.htm) one at a time, in either the visual or auditory modality, or across modalities. For the visual presentation the words were written in bold, capitalized letters in Arial font at a size of 24 points, and remained on the screen until a response was made. For auditory presentations the words were spoken just as they were in the initial repetition detection task. Cross-modal presentations involved the written word on the screen with the spoken word presented simultaneously.

\section*{Procedure}

Participants were required to attend to the sound (or picture) stream (i.e., they were explicitly instructed to ignore the simultaneously presented, overlaid written/spoken words) and respond to immediate repetitions by pressing the ' \(G\) ' key on the keyboard of the computer. Each item in the sound-word (or picture-word) presentation was presented for 350 ms with a \(150-\mathrm{ms}\) inter-stimulus interval (ISI; silence) for a stimulus onset asynchrony (SOA) of 500 ms . Before the first experimental block, a training block of eight trials was given and repeated until participants were familiar and comfortable with the task. Immediately after the repetition detection task, the surprise word recognition test was administered to all participants (modality type of surprise task dependent on condition). Participants were instructed to press the "B" key if they had heard the word during the repetition detection task or, instead, the "V" key if they had not heard the word before.

\section*{Results}

Target detection accuracy in the repetition detection task. Overall performance accuracy (across all conditions) of immediate target repetition detection revealed that participants were successful at detecting target repetitions in the primary task, ( \(72 \%\) hit rate vs. \(28 \%\) miss rate, \(t(73)=\) 14.67, \(p<.001\) ).

Overall recognition accuracy. Across all conditions, participants were accurate in recognizing the unattended words (both target-aligned and non-aligned) displayed during the repetition detection task at better than chance levels \((86.1 \% S E=1.47, t(73)=17.35, p<.001)\). A threefactor mixed design ANOVA was used to analyze overall (across all conditions) recognition performance for all words. Surprise test modality (auditory, visual, or crossmodal) and exposure modality (visual words vs. auditory words) were between-subjects factors, and target alignment (target-aligned or non-aligned) was a within-subjects factor. There were no main effects for target alignment \((\mathrm{F}(1,68)=\) \(.217, \mathrm{p}=.643\) ), exposure modality in the primary task ( F \((1,68)=2.68, \mathrm{p}=.08\) ), or surprise test modality ( \(\mathrm{F}(2,68\) ) \(=.548, \mathrm{p}=.580\) ). A planed comparison further demonstrated that target-aligned and non-aligned words were recognized at statistically indistinguishable rates, across all conditions (target-aligned: 89.1.0\%, \(S E=3.06\); non-aligned: \(83.8 \%, S E=2.15, t(68)=1.30, p=.195\), Figure 1). Given these null results, no further analyses of recognition performance were conducted.

Figure 1. Recognition percentages pooled across all conditions for Target-aligned words (black bar) and NonAligned (grey bar) words.

Overall recognition speed. To explore if response latency to the words was modulated by target alignment or the modality of presentation of the surprise task, the same threefactor mixed design ANOVA was conducted as above, with surprise test modality (auditory, visual, or cross-modal) and exposure modality (visual words vs. auditory words) as between-subjects factors, and target alignment (target-
aligned or non-aligned) as a within-subjects factor. A main effect of target alignment confirmed that overall, the speed of responding to words was significantly faster for targetaligned words ( \(787.8 \mathrm{~ms}, S E=21.8\) ) when compared to non-aligned words ( \(1378.2 \mathrm{~ms}, S E=80.2\) ) ( \(\mathrm{F}(1,68)=\) \(52.44, \mathrm{p}=.001\) ) (see Figure 2). No main effects were observed for surprise test modality ( \(\mathrm{F}(1,68)=.298, \mathrm{p}=\) .587 ) or exposure modality ( \(\mathrm{F}(2,68)=1.80, \mathrm{p}=.173\) ), nor were any interactions significant except for the three-way interaction ( \(\mathrm{F}(2,68\) ) \(=3.58, \mathrm{p}=.03\) ). To further explore this interaction, further ANOVAs of response speed for each condition were conducted.

Figure 2. Response latencies pooled across all conditions for Target-Aligned (black bar) and Non-Aligned (grey bar) words.

Attending to sounds with written words. A two factor mixed design ANOVA was conducted for response latencies with surprise test modality as a between subjects factor and target-alignment as a within-subjects factor. A main effect of target alignment \((\mathrm{F}(1,43)=34.97, \mathrm{p}<.001)\) was observed, demonstrating that participants responded more quickly to target aligned ( \(812.2 \mathrm{~ms}, S E=29.3\) ) when compared with non-aligned words ( \(1371 \mathrm{~ms}, S E=93.8\) ). There was no main effect for surprise test modality ( \(\mathrm{F}(2,43\) ) \(=.237, \mathrm{p}=.790\) ) nor was there a significant interaction \((\mathrm{F}(2\), 43) \(=1.28, \mathrm{p}=.286\). Planned comparisons also confirmed that when examining response latency in the surprise word recognition task, target-aligned words were responded to significantly faster than non-aligned words in all conditions (Visual Presentation: Target-aligned: \(789.2 \mathrm{~ms}, S E=38.4\) vs. Non-aligned: 1293.7, \(S E=217.4, t(16)=2.92, \mathrm{p}=.02\); Auditory Presentation: Target-aligned: \(717.8 \mathrm{~ms}, S E=63.4\), vs. Non-aligned: \(1519.2 \mathrm{~ms}, S E=38.4, t(11)=5.31, \mathrm{p}=\) .001; Multimodal Presentation: Target-aligned: 901.9 ms , \(S E=46.1\) vs. \(1320 \mathrm{~ms}, S E=72.7,(t(16)=4.86, \mathrm{p}=.001)\). Further confirming the non-significant interaction, there were no significant differences in performance between conditions (all p>.58).

Attending to pictures with spoken words. The same two factor mixed design ANOVA was conducted for response
latencies with surprise test modality as a between subjects factor, and target-alignment as a within-subjects factor. Again, a main effect for target alignment \((\mathrm{F}(1,25)=19.57\), \(\mathrm{p}<.001\) ) was observed, demonstrating once more that participants responded more quickly to target aligned (747.8 \(\mathrm{ms}, S E=30.9\) ) when compared with non-aligned words ( \(1404.5 \mathrm{~ms}, S E=147.2\) ). while no main effect was observed for the modality of the recognition test \((\mathrm{F}(2,25)=1.51, \mathrm{p}=\) .239). The interaction also failed to reach levels of significance \((\mathrm{F}(2,25)=2.81, \mathrm{p}=.079)\). Planned comparisons also confirmed this in each modality presentation in the surprise recognition task (Visual Presentation: Target-aligned: \(659.7 \mathrm{~ms}, S E=67.8\) vs. Nonaligned: 1833.9, \(S E=368.9, t(8)=2.84, \mathrm{p}=.02\); Auditory Presentation: Target-aligned: \(819.8 \mathrm{~ms}, S E=44.5 \mathrm{vs}\). Nonaligned: \(1159.4 \mathrm{~ms}, S E=116.5, t(9)=3.10, \mathrm{p}=.01\); Multimodal Presentation: Target-aligned: \(755.9 \mathrm{~ms}, S E=\) 35.5 vs. \(1247.3 \mathrm{~ms}, S E=200.9, t(8)=2.42, \mathrm{p}=.04)\). Despite the marginal interaction, there were no significant differences in performance between conditions (all p>.05)..

\section*{Discussion}

There are a number of outcomes that necessitate discussion, as the present findings strengthen the understanding of how unattended information is processed when it appears simultaneously with an attended target, especially when considering the multimodal exposures used here. Specifically, the findings exhibit that both presentation types (pictures with auditory words, or sounds with visually presented words) lead to learning effects, exemplified by high recognition rates in the surprise task, despite attention not being directed to the words. This is similar to analogous paradigms using only unimodal visual (Dewald et al, in press) or auditory (Dewald \& Sinnett, 2012) presentations. However, both of these unimodal studies indicated enhanced recognition rates for target-aligned words when compared with non-aligned words. This was not the case with cross-modal presentations, as observed here. That is, although the recognition rates for the unattended stimuli were high, there was no difference between target-aligned and non-aligned items.

The lack of a significant difference in recognition rates based on target alignment is likely due to the cross-modal presentations used here. It is possible that the division of the task could have permitted additional attentional resources to focus on processing all of the words, as shown by the high recognition rates for non-aligned words here (overall 84\%). While it is difficult to statistically compare this rate to our previous studies (already published), it is worth noting that, in analogous but unimodal paradigms, performance for nonaligned words was much lower in either the visual ( \(68 \%\), Dewald et al., in press) or auditory modality (59\%, Dewald \& Sinnett, 2012). Thus, it appears that by presenting the repetition detection task across modalities, additional resources were available that potentially enabled the processing of irrelevant stimuli, resulting in arguably near
ceiling recognition rates for both aligned and non-aligned words. This dovetails well with other research demonstrating enhanced performance under multimodal conditions (Duncan et al., 1997; Sinnett et al., 2006), possibly indicating a segregation of attentional resources across modalities (Wickens, 1984).

Despite the lack of a recognition difference between target-aligned and non-aligned items, the former were responded to significantly faster, regardless of the modality of presentation (target-aligned: 787.8 ms vs. non-aligned: 1378.2 ms ), suggesting alignment did play a role. That is, it is possible that there was improved learning of words that were temporally aligned with a task-relevant target, indicated by response latencies to target-aligned words being faster in all three recognition conditions (visual, auditory, audiovisual). This is an intriguing finding as it indicates a conceivable enhancement for target-aligned material without explicit awareness, as there were no differences in recognition performance. Although, it should be acknowledged that recognition performance might have been at ceiling levels and therefore masked any possible improvement for target-aligned words. Regardless, this finding warrants discussion, as well as further research. Indeed, of the many studies published on this topic (see, Dewald et al, in press, Dewald et al., 2011; Dewald \& Sinnett, 2012; Rees et al, 1999; Sinnett et al, 2006; Swallow \& Jiang, 2010; Tipper \& Driver, 1988) the present experiment is the first to use response latency as a potential measure of enhancement for target-aligned material.

Also of key interest here, is that we did not observe an interaction in performance between target-alignment and the modality of the surprise test, as was observed by Dewald and Sinnett (2012). Across all conditions, regardless of the congruency between presentation and recognition task, there was no significant difference between target-aligned and non-aligned words. Accordingly, this suggests that, at least in the present case, under multimodal presentation, the modality of presentation does not need to match exposure and test conditions. This could be a byproduct of the overall enhanced recognition performance seen after cross-modal presentations. A more systematic approach manipulating presentation (unimodal vs. cross-modal) and surprise test (congruent, incongruent, cross-modal) is required before ruling out that this factor is unnecessary.

Collectively, the present findings provide insight into how irrelevant information is processed when it is presented simultaneously with an attended target across sensory modalities. If certain prerequisite conditions are met, unattended stimuli can be perceived and affect behavior, perhaps even below levels of conscious awareness. Additionally, although a significant difference was not observed here, future research should consider the congruency of modality presentation in both exposure and testing conditions.

\begin{abstract}
This paper proposes a model giving Theory of Mind (ToM) capabilities to artificial agents to allow them to carry out deceptive behaviours. It describes a model supporting an N -level Theory of Mind and reports a study to assess whether equipping agents with a two-level ToM results in them being perceived as more socially intelligent than agents with a singlelevel ToM. A deception game being developed for intercultural training of children, used for this study, is described. Finally, we report results from this study consistent with the hypothesis that a two-level Theory of Mind better supports agents in deceptive behaviour.
\end{abstract}

Keywords: Virtual Agents; Theory of Mind; Deception

\section*{Introduction}

The work reported in this paper arises from the use of synthetic graphical characters interacting in rich virtual worlds. These may be required for interactive drama applications (Mateas \& Stern, 2003), or for story-based education and training applications (Paiva et al., 2004) (Swartout et al., 2006). A key criterion for success is that such agents be believable, that is lead a user, or viewer, to feel that they have an inner life of their own, with goals, motivations and emotions, and are in some sense 'alive' (Bates, 1994). Thus interaction between such characters must display features related to human-human interaction; whether the actions they carry out, their emotional expressions, ability to exhibit empathy, or non-verbal as well as verbal communications. Such features must be contextually appropriate, and in order to achieve this, characters may be driven by an architecture uniting cognitive and affective models, for example using a cognitive appraisal approach (Dias \& Paiva, 2005) (Marsella \& Gratch, 2009).

Computationally implemented cognitive appraisal models are often naive, assuming entirely open behaviour, sometimes referred to as meeting the sincerity condition (Searle, 1976). However, this is unusual in everyday human-human communication where deception often occurs. This may be as simple as masking anger in front of a social superior or fear in front of a child on a dark night (Rosis, Pelachaud, Poggi, Carofiglio, \& Carolis, 2003), (Prendinger \& Ishizuka, 2001), or as complex as deliberately misleading or lying to another person in order to gain an advantage. Deceptive behaviour includes not only the generation of false beliefs in others but also the claiming of desired identities, the exchange of non-existent emotions, and the communication of false preferences or opinions (Wyer \& Epstein, 1996). Thus decep-
tion can be seen as a human-like characteristic that would enhance the believability of synthetic characters portrayed in real world social situations.

A Theory of Mind (ToM) process allows an agent to attribute an artificial mental state to another agent and reason about it. In a single-level ToM, agent A can represent only its belief about what an agent \(B\) is thinking; an agent \(C\) that can not only model what B is thinking but can also model what agent \(B\) thinks about \(C\) has a two-level ToM. In this paper we investigate the hypothesis that an agent with a single-level ToM will be less successful in believable deception then an agent with a two-level ToM. Deception cannot be investigated in abstract but requires a concrete scenario. Our work uses an interactive game played by and with autonomous graphical characters. This is based on the popular game Mafia, or Werewolf, described below, in which deception is fundamental to successful play. The characters are implemented with a cognitive appraisal-based architecture (Dias \& Paiva, 2005) that includes a deliberative mechanism and has been extended to support an N -level ToM mechanism.

\section*{Background and Related Work}

We define a "lie" as a direct communicative act that an agent performs to deceive another agent. We consider deception through verbal mechanisms - speech acts - though deception may also be achieved through non-verbal mechanisms. Deception has been widely studied in AI, though usually with disembodied software agents.

GOLEM (Castelfranchi \& deRosis, 1998) is based on the blocks world of AI planning research. Goals conflict, since agents aim to build different structures from the same available blocks. Agents can achieve goals through their own actions or by asking for "help" from others. Agents have task delegation and adoption preferences and different capabilities, used to plan their actions based on their knowledge of other agents. Deception is instrumental, resulting only from goal conflicts, though it extends to deception about capabilities, goals or personality. However, agents in GOLEM can only produce lies within this limited scope. They cannot for example lie about the requests they have made or plan to make. This would require second order reasoning about the reasoning of other agents, which is not present here.

De Rosis and Carofiglio (deRosis, F; Carofiglio, V; Grassano \& Castelfranchi, 2003) focus on the communicative per-
spective of a deceptive action. In their scenario, a Sender agent tries to convince a Receiver agent that some fact X is not true, where the Sender can lie or use other deceptive strategies. Their system, "Mouth of Truth" implements reasoning models as belief networks (Neapolitan, 1990; Pearl, 1997), where nodes represent belief and probabilities across links to other node represent uncertainty. This allows the Sender to lie not about the belief they want to manipulate, but about one connected to it. Thus uncertainty can be increased for the belief "it rained" if the Sender claims "the floor outside is dry". However, the Sender needs a model of the Receiver's beliefs to be able to do this and so acts as if its own set of beliefs and reasoning rules is replicated in the Receiver. This can then be used to influence the decision making process of the Sender.

The work so far discussed did not ground deception in an explicit model of other agents. Theory of Mind is a term coined by (Premack \& Woodruff, 1978) who define it as the ability to infer the full range of epistemic mental states of others, i.e. beliefs, desires, intentions and knowledge. This is a mechanism that helps to make sense of the behaviour of others in specific contexts and to predict their next action.

Recent work (Harbers \& Meyer, 2009) focuses on a computational implementation of ToM, giving agents the capacity to interact in a believable way with trainees, and to explain their actions and decisions after the training is over. The agents model a trainee's mind and give feedback either through simple action decisions, or by an explanation at the end. Meyer et al. here combined two prominent but conceptually different approaches to the human theory of mind: the Theory-Theory approach (TT) and the Simulation-Theory approach (ST).

In TT, the mental state we attribute to others is not observable, but is knowable through intuition and insight. Implementationally, this is achieved by using inference rules to reason about the beliefs of others. On the other hand, ST claims that each person simulates being another while trying to reason about their epistemic state, using the same structures and processes as those updating their own beliefs and knowledge (Aylett \& Louchart, 2008). Meyer et al. showed that the main difference lay in ease of implementation rather than in outcome, as ST models are better in terms of code re-usability and modularity. Moreover, the TT approach can only deal with BDI (Beliefs Desires Intentions) models (Rao \& Georgeff, 1995) due to a rigid representation of the mental state of other agents in terms of beliefs, limiting it to a specific symbolic representation.

PsychSim (Pynadath \& Marsella, 2005) is a multi-agent based simulation tool for modeling interactions using a decision-theoretic approach. Unlike most such frameworks, where agents select actions maximizing rewards using their own beliefs, PsychSim agents also take into account their beliefs about other agent's beliefs. These recursively- "nested beliefs" may include subjective views of the agent itself. Agents update their beliefs according to the changes in the
world and their subjective interpretations of world dynamics. In particular, messages are implicit ways through which one agent may influence the beliefs of another.

Wagner and Arkin developed algorithms to give an an intelligent robot the ability to deceive (Wagner \& Arkin, 2010). The Deceiver seeks to induce a false belief in another agent, the Target, who is modeled as an action model and utility functions with associated outcomes matrix for a specific situation. This involves performing some action in the environment transmitting a false communication to the Target, so that it will behave in a way benefiting the Deceiver. This modifies the outcome matrix for the Target, the induced outcome matrix. Wagner and Arkin showed that knowledge of the Target affected the success of a deceit attempt. However this work did not explore the implications of different levels of ToM. Although there are systems that implemented a Theory of Mind in agents, and interesting projects on deception, we believe this is the first generic model that combines the two in a way that is flexible enough to be featured in a game. Further, we also show a study that compares different levels of abstraction in the way agents are perceived in terms of lying.

\section*{A Mindreading Agent Model}

Our agent ToM is based on the Mindreading model of (BaronCohen, 1995), and follows the ST approach of Meyer et al.see Figure 1. A central Knowledge Base (KB) stores the agent's beliefs and world knowledge and is the foundation for the agent's behaviour given that its actions are based on its knowledge.

Figure 1: Proposed model for a Mindreading Agent
The ToM has three components, following Baron-Cohen \({ }^{1}\) : the EDD (Eye Direction Detector), SAM (Shared Attention Model), and ToMM (Theory of Mind Mechanism). EDD determines who sees what, while SAM constructs higher level relations between entities (John sees that Luke sees the book). The ToMM represents and stores the mental states of other agents and is used to influence or deceive another agent. However, a deceiving agent must also be able to plan and reason about the consequences of its own actions. Thus our model includes a Deliberation component giving planning capabilities using knowledge from the KB and the ToMM to select the best actions for the agent to perform to meet its current goals.

\footnotetext{
\({ }^{1}\) There is an additional component, the Intentionality Detector but to simplify our model it was not included
}

\section*{Representing Models of Others}

Each Model of Other in the ToMM represents the beliefs of a specific Other the agent knows. A single-level theory of mind allows us to represent an agents's beliefs about another agent's beliefs. However, human adults are able to model more than one level (e.g. beliefs about another's beliefs about another's beliefs). Children start to develop a second level of ToM at around the age of six. Thus agents intended to function believably at the level of older children - as in the Werewolf game used as a study - require a model with more than one level of ToM.

A specific Model of Other contains its own ToMM also containing Models of Others, creating a recursive hierarchical tree-like structure - see Figure 2.

Figure 2: ToMM Hierarchy: 3 agents and 2 levels
Thus three agents, A, B, and C, each with a two-level ToM modeling ability, need six models each. If agents include a three-level ToM, this rises to fourteen models, and with four levels, to thirty models. The more complex the tree structure for the model hierarchy, the more effort is required for each update cycle. We will focus on a two-level ToM, bearing in mind that in the human case, applying more than two levels also causes a substantial overhead. More levels could be used in exchange for a slower reasoning cycle.

The ST approach represents others by simulating ones own processes in that same situation. Hence a ToMM Model of Other corresponds to a simplified version of the Agent Model depicted in Fig. 1, including both data structures and processes. A Model of Other can therefore be updated with a given percept through the same process used to update the agent's own model.

\section*{Updating Models of Others}

When a given percept is received (e.g. a property has changed, or an action was performed), the agent updates its KB and its Models of Others. This is done through the EDD and SAM components.

The EDD determines what entities, objects, and events are perceived by other agents. It first checks whether a target agent is within a certain radius or in the same location as the agent, and if so, asserts that it also receives the percept.However this does not deal with more complex percepts such as a whisper into an ear, where only the specific receiving agent will know what was said. Hence the EDD may also include domain-specific rules about actions with particular restrictions on the perceptual mechanism. A rule specifies information about the action (such as subject, action name,
target, parameters) and associates it with a list of effects. Two main types of effects are used in these rules:
- Global effect - effect of an action assumed to be perceived and shared by everyone (who is close enough). E.g. *:Werewolf(Rob) represents that everyone can perceive Werewolf(Rob).
- Local effect - an effect perceived only by a particular agent. E.g. John:Werewolf \((\) Rob \()\) represents that only John will perceive Werewolf(Rob).

When EDD receives percept \(P\), it determines two lists, perceptionVisibilities and agentVisibilities. The perceptionVisibilities list contains all pairs \(A g: P\), such that agent \(A g\) perceives proposition \(P\), while the agentsVisibilities list contains all pairs of form \(A g: A g\), stating which agents see which other agents. SAM uses this to update Models of Others. It traverses the tree hierarchy, establishing whether a Model \(M\) should perceive \(P\) applying the following test:

\section*{1. Test if Model \(M\) is contained in perceptionVisibilities.}
2. Test if the pair Predecessor \((M): M\) is contained in the agentVisibilities list. Predecessor \((M)\) returns the predecessor of model \(M\) in the tree hierarchy.
3. If both tests are verified, then model \(M\) can perceive \(P\), otherwise the algorithm stops following the remaining subtree and continues the recursive process.

For example, suppose three agents, A, B and C. When A receives a percept \(P\), it will update its own \(K B\) with \(P\), but will also process P in its ToM to update models for B and C . Further, suppose that \(A\) knows that both \(B\) and \(C\) perceived \(P\), and also knows that B does not see C (so it will not see that C perceives P). In this situation A's Model of \(B\) will be updated with P but A's model of B's Model of C (second level) will not be updated.

\section*{Using the ToMM Information}

Agents have two reasoning mechanisms, one forwards (from data to conclusions) using inference rules, and one backwards (from goals to actions needed to achieve them) used to create plans that achieve the agent's goals. An inference rule is a tuple \(\langle R, P, E\rangle\) where \(R\) is the name of the rule, \(P\) (Preconditions) is a list of propositions that need to be verified for the rule to be applied, and \(E\) (Effects) a list of propositions that will be added to or removed from the KB when the rule is applied. Whenever new knowledge is added to the KB, the deliberation component will test the preconditions of the existing Inference rules. If any rule is fired (i.e. its preconditions are verified) the deliberation component will automatically update the KB with the effects in its effects list. If this process adds a new proposition to the KB , the inference process will be repeated until no more changes are verified.

The second mechanism involves goals, plans and actions. A goal is a tuple \(\langle G, P, S\rangle\) where \(G\) is the Goal's name, \(P\) a list of propositions that correspond to the goal's preconditions, and \(S\) a list of propositions that correspond to the goal's
success conditions (i.e. the desired goal state). The deliberation component is constantly checking to see if any goal becomes active by testing its preconditions. Once a goal becomes active, the planner tries to build a plan of actions to achieve the goal's success conditions. The actions used by the planner are defined using a STRIPS-like (Fikes \& Nilsson, 1971) formalism and correspond to a tuple \(<A g, A, P, E>\) where \(A g\) is the agent who performs the action, \(A\) is the action's name, while \(P\) and \(E\) correspond to a list of preconditions and effects. Given the similar representations, Inference Rules can also be used by the planner to build plans of actions; the difference is that when an Inference Rule is selected for execution (when the agent is executing the plan) it is not returned as an action to be performed in the environment. For more details about these mechanisms, please refer to (Aylett, Dias, \& Paiva, 2006).

The first step in making the ToM information available to the deliberation component is to allow the specification of preconditions that are not tested against the agent's own KB but using a particular Model of Other. This is done by specifying explicitly the Model of Other to be tested by representing preconditions as a list of colon separated agents followed by a proposition \(A g_{1}: \ldots: A g_{n}: P\). When the deliberative component finds such a precondition it starts by traversing the tree hierarchy of Models of Others using the list of colon separated agents, and selecting the corresponding Model Of Other. Then the proposition P is tested using the selected Model of Other's KB. As example, \(A: B: \operatorname{Suspects}(A)\) is true if Suspects \((A)\) is true in the Model of \(B\) that is stored in the agent's Model of \(A\) (intuitively representing "I think that A thinks that B suspects him to be the Werewolf"'). If a proposition \(P\) does not specify a Model of Other it will be tested against the agent's own model, in other words, its own KB.

Using preconditions this way allows us to specify goals and inference rules triggered according to beliefs of others. It would be even more useful to model higher-level goals and inference rules, i.e. explicit goals and rules to change the mental states of others. To do so, we use the same mechanism used to specify local and global effects as described previously. An effect is specified as \(A g_{1}: \ldots: A g_{n}: P\), where \(A g_{i}\) is an an agent's name, or the symbol "'*", and represents that only the Models of Others obtained by the list \(A g_{1} \ldots: A g_{n}\) will have the proposition \(P\) added to its KB. The symbol "**" represents that all Models of Others at that particular level will be selected. The planner was extended to be able to handle matching and detection of conflicts between preconditions and local/global effects. In planning terms, a precondition is matched or threatened by a local effect only if their agents lists are compatible and if they refer to the same proposition \(P\). In its simplest version, two agents lists are compatible if they have the same size and the agents are unifiable (the symbol "**" unifies with everything). As examples, the effect \(A: B\) :Suspects \((C)\) matches the precondition \(A: B: \operatorname{Suspects}(C)\), but does not match the precondition \(B: A: \operatorname{Suspects}(C)\), whilst \(A: *: \operatorname{Suspects}(C)\) matches
both \(A: B: \operatorname{Suspects}(C)\) and \(A: D: S u s p e c t s(C)\).
When an inference rule has an effect specified with an agents list (e.g \(A g: P\) ), instead of updating its own KB , the deliberation component will traverse the tree hierarchy in order to update the corresponding Models of Others. Moreover, the ST approach means that the Model of Other corresponds to a version of an Agent Model with its own inference mechanism. When creating a Model of Other, the agent assumes that others will use the same inference rules as its own. Therefore, every update cycle, the inference mechanism will also be executed recursively for each Model of Other. In other words, the agent will simulate other's inference processes, and update the corresponding models. This process is applied even if the effects of the inference rule specify an agent's list. For instance, if the Model of Other of John at level 1, applies an inference rule that results in the effect Rob:Suspects(John), it will update John's Model about Rob's Model at level 2.

Due to its greater complexity, we did not include goal selection/planning, and thus simplified the version of the Agent used as a Model of Other. The agent is therefore not capable of simulating the planning process of others.

\section*{Case Study}

The model above was used to build NPCs that deceive in a system for intercultural training, MIXER (Hall et al., 2011). This is aimed at children aged \(9-11\) and conflict between groups (an in- and out-group scenario) is presented through a social game. Rules act as cultural expectation and if they are varied, conflict will occur. Older children usually define rules before starting to play, but late primary children generally only discover the difference in rules when the conflict occurs, often with game abandonment and shouts of "'it's not fair"" and "'I don't want to play any more". The user acts as an invisible (out-of-game) friend to a character thrust into this situation with the pedagogic aim of showing that the existence of different rules is not the same thing as 'cheating'. MIXER uses variations of the game Werewolf, or Mafia \({ }^{2}\).

A simplified version of the game involves five players, the Villagers, who are divided into two groups, one Werewolf and four potential Victims. Victims have limited information, since they do not know who the Werewolf is (they are 'killed' at night). Characters can be human players or NPCs (Non Playable Characters) running the architecture supporting deception. The goal is to discover who is the Werewolf: the character who is lying.. The Werewolf must lie purposefully: its objective is to remain hidden until no longer outnumbered by Victims. Thus it tries to eliminate Victims while concealing its true identity.

The game has been implemented in turn-based rounds. In each round every character performs the Accuse action in order, naming another character as the Werewolf (see Figure3 ). The Werewolf deceptively accuses one of the victims, knowing they are not in fact the Werewolf. At the end of each turn,

\footnotetext{
\({ }^{2}\) http://en.wikipedia.org/wiki/Mafia_(party_game)
}
the agreed werewolf is excluded from the game and informs the other agents about its true identity. This is used to infer new information about past accusations. The real Werewolf wins if it reaches the last turn alive, when there is only one victim left. At this stage the Werewolf announces its identity. Victims win if they manage to discover who the Werewolf is before the last turn.

Figure 3: An agent performing the Accuse action

The following inference rules allow the victims to reason about past actions, trying to determine possible werewolf suspects:
- I suspect those that were accused by someone I don't suspect
- I stop suspecting someone who accuses a target I suspect
- I suspect those who accused a victim that was eliminated the previous round
- Someone who accuses a target suspects that they are a werewolf
- Someone that is accused will suspect the accuser

\section*{Modeling the Werewolf}

Two versions of the Werewolf agent were implemented. One has a single-level ToM, able to represent what victims believe, but not what victims think it or the other victims believe. The second has a two-level ToM, able to represent what victims think about what it knows and in general, what victims think about the suspicions of others. Both versions also have the inference rules above, used by victims to determine suspects.

The single-level Werewolf has two main strategies compatible with its single-level ToM: eliminate victims that suspect it, and make a victim suspect another victim who has not been accused yet. The second goal corresponds to changing the victim's beliefs, and can be modeled by the success condition \(\left[v_{1}\right]:\) Suspects \(\left(\left[v_{2}\right]\right)\), where \(\left[v_{1}\right]\) is a variable representing a victim and \(\left[v_{2}\right]\) is a variable representing another victim. These variables will be instantiated by the goal activation process, and the agent will then try to make \(\left[v_{1}\right]\) suspect \(\left[v_{2}\right]\).

The two-level Werewolf agent has a strategy commonly used by human players in this game. The agent will "'Lay low"', by avoiding suspicious actions, trying to make victims believe that it thinks the same way they do. This is modeled with the following second level success condition \([v]: S E L F: S u s p e c t s([\) target \(])\), where \([v]\) is a victim, [target \(]\) is another villager that \([v]\) suspects to be the Werewolf, and

SELF represents the Werewolf agent itself. Thus the twolevel ToM Werewolf will accuse villagers that are already being accused by other victims.

\section*{Tests and Evaluation}

Two tests were run comparing these two versions. A first simulation test assessed how well the two types of ToMs performed in the game. In order to test the hypothesis that an agent with a single-level ToM is less successful in believable deception then an agent with a two-level ToM, a second evaluation was conducted with users, assessing their perception of the single-level and two-level ToM Werewolves.

As an autonomous agent architecture is being used, scenarios are unscripted and do not run identically. To avoid different outcomes biasing user responses, a video of a particular run was used for the second test. The simulation test allowed us to select this video.

In the first test, two versions of the system were generated. The first was parameterized so that the Werewolf used the single-level ToM (ToM1 condition), and in the second it used the two-level ToM (ToM2 condition). The victims used a single level ToM in both conditions. With five players, the maximum number of possible rounds is 4 . Both versions ran ten times, from the beginning until the Werewolf was caught or won the game. The number of turns the Werewolf managed in each run was recorded. The video of the best scoring run for each version was used for the second test.

In the TOM1 condition, the Werewolf never lasted four rounds, and so did not win a single game. The ToM2 Werewolf won in two out of ten runs and on average lasted 0.6 more turns than the ToM1 version.

\section*{User Perception of the Lying Agents}

The second test evaluated user-perceptions of the two Werewolf versions' believability. An online questionnaire was used with the two videos selected from the first test. Sixty participants ( \(34 \mathrm{M}, 26 \mathrm{~F}\) ), of which 55 were aged 19-25, were recruited online, and randomly assigned to one of the two versions. They were asked to pay special attention to agents' actions and to try to work out who was lying. They watched the game and then rated affirmations using a Likert scale (ranged from -2 meaning totally disagree, to 2 meaning totally agree) in four sections: (1) affirmations about the game itself; (2) affirmations about all players; (3) the same affirmations as (2) but only for the the liar; (4) affirmations focused on deceptive behaviour. Data was analyzed using a non-parametric Mann-Whitney statistical test to compare conditions ToM1 and ToM2.

Participants perceived the ToM2 condition as more interesting according to A1: "'The game is interesting", ( \(p<\) \(0.05, r=-0.263\) ) and would play this version of the game more "'A2: I would play a game like this"'( \(p<0.05, r=\) -0.292). ToM2 scores were significantly lower ( \(p<0.05\) ) for A3: "'It is easy to win while playing as a Victim"' and significantly higher \((p<0.5)\) for A4: "It is easy to win while playing as a Werewolf"'. We conclude that participants
thought the liar did a more competent job in the ToM2 version.

Answers to A8: "'Players behaved in a predictable way", were also significantly different in the ToM2 condition ( \(p<\) \(0.001,|r|=0.5\) ): player characters were seen as less predictable in ToM1 than ToM2. This is seen as a surrogate for believability given the answers to A10: "'Players are easily deceived"' gave significantly lower values in ToM1 than in ToM2 ( \(p<0.001, r=-0.478\) ), reflecting the more believable performance of the Werewolf in ToM2.

Finally, two additional measures: "how well did the liar play" and its "intelligence" also lead to statistically significant differences between the two conditions ( \(p<0.001\) ) supported by a large effect size \((|r|=0.5)\). We conclude that the liar in ToM2 is perceived as more intelligent than in ToM1. Also statistically significant ( \(p<0.001, r=-0.467\) ) were answers to A15: The liar is affected by others' actions indicating that the Werewolf was seen as more responsive to the play of others in ToM2. Finally, the higher results in ToM2 for A21: The liar managed to deceive the other players ( \(p<0.001, r=-0.524\) ) confirm those for A10 above.

\section*{Conclusions}

This paper advances a model for virtual agents that are able to deceive, embedding a ToM mechanism inspired by work on the human ToM. The model can produce N -level ToM behaviour using a simulation approach, where the agent runs its own mechanisms, reasoning about the beliefs and actions of others as if it was in their shoes. Parametrization allows the number of levels of ToM to be easily varied.

Evaluation was carried out using a social game, MIXER, for intercultural training of children aged 9-11. This game includes one character, the Werewolf, that must lie in order to play successfully. The first test showed that when a Werewolf was given a two-level rather than single-level ToM and played against Villagers with a single-level ToM, the Werewolf's game performance improved. The user testing with 60 subjects showed that participants clearly perceived the ToM2 version Werewolf as better at deceiving the other agents, and, furthermore, saw this as more intelligent behaviour. These results support the hypothesis that an agent with a single-level ToM will be less successful in believable deception then an agent with a two-level ToM.

As future work, it would be interesting to compare different combinations of the scenarios (e.g. one-level werewolf against two-level victims), and to include the simulation of other's planning processes in order to make it posible to reason about other agent's goals and plans. Another interesting extension to this work would be to apply the model to a different type of deception than verbal lies, for example to deceptive display of affective states (Rosis et al., 2003).

\begin{abstract}
One of the challenges in developing multi-agent systems is the creation of agents able to exhibit human-like behaviours in complex social situations. In order to do so, agents need to be socially aware of their environment and perceive other agents not only as individuals but also as social group members. Following Social Identity and Self-Categorization theories, we developed the Dynamic Identity Model for Agents that provides agents with the ability to adapt their identity and behaviour to the social context. We then implemented it in a social dilemma scenario where different situations were explored.
\end{abstract}

Keywords: Identity; Social Identity; Social Dilemmas; Context-Situated Agents.

\section*{Introduction}

With virtual worlds' increasing complexity, where agents and players are exposed to different scenarios and social contexts, it has become even more important to develop agents whose identity does not remain unaffected, and in turn reacts to its environment in a believable way.

Although some works have been done on agent's identity adaptability, either through the agent's personality (Tan \& Cheng, 2007) or by their culture's background (De Rosis, Pelachaud, \& Poggi, 2004; Mascarenhas, Dias, Afonso, Enz, \& Paiva, 2009), these are adaptations to the player's traits, and does not address the influence of the social context. Moreover, each approach alone did not encompass both individual and social concepts of identity working together and dynamically.

In real life a person's identity is not static and free of influences (Turner, Oakes, Haslam, \& McGarty, 1994; Hogg \& Williams, 2000; Smith \& Mackie, 2000). Instead, several social context factors (Smith \& Mackie, 2000) are known to have an impact on an individual's identity and behaviour, with one of the most studied factors being the presence of in-group or out-group members. In fact, Social Identity (Tajfel, 1972) and Self-Categorization (Turner, Hogg, Oakes, Reicher, \& Wetherell, 1987; Turner et al., 1994) theories explained this process postulating that one's identity can both be personal and social. When in the presence of members of a person's in-group, the individual's behaviour is going to be determined
by its personal identity, and one will relate to others in an interpersonal manner, dependent on his or her personality traits and close personal relationships with others. However, when in the presence of an out-group, a social identity becomes salient, and the perception as group member strengthens, as a person tends to focus his or her perception on the shared features with other in-group members. Consequently, there is a shift of a person's own motives and values from self-interest to group interests (Brewer, 1991). When a social identity emerges, people are more likely to see themselves and others as interchangeable components of a larger social unit rather than unique individuals.

According to (Tajfel, 1972; Turner et al., 1987, 1994), this psychological process of social identification constitutes the basis for in-group cooperation. Because in-group members share the same attributes, they become part of a person's identity and due to this, a person will want to treat all in-group members as he or she would like to be treated. In fact, several studies have already demonstrated that social identity has a positive effect in in-group cooperation and negative effect in out-group cooperation (Goette, Huffman, \& Meier, 2006; McLeish \& Oxoby, 2007), but more specifically that it has an important role in eliciting cooperative behaviour in social dilemmas (Wit \& Wilke, 1992; Kollock, 1998; Weber, Kopelman, \& Messick, 2004). Social dilemmas are, in broad terms, social situations of individual rationality conflict where group interests are at odds with individual ones (Dawes, 1974), and thus making them an interesting application for agents with social identities.

Nonetheless, while some authors have already been modelling the concept of social identity and used it on simulations of crowd behaviour (Fridman \& Kaminka, 2009) or opinion dynamics, such political views (Grier, Skarin, Lubyansky, \& Wolpert, 2008; Lustick, 2002; Salzarulo, 2006), they still did not handle the dynamics of identity, nor have worked on its impact in social dilemmas situations. As such, we developed the Dynamic Identity Model for Agents (Dimas \& Prada, 2013) and implemented it in a social dilemma scenario in order to evaluate it in a game environment.

The paper is organized as follows. Next section we introduce the model, followed by the description of the model's implementation and the platform used to demonstrate the example scenarios we present on the following section. Finally we present some conclusions and future work.

\section*{Dynamic Identity Model for Agents}

The Dynamic Identity Model for Agents (DIMA) aims at providing agents with a dynamic identity that is determined by the social context.

\section*{Agent's Identity}

In DIMA, the agent's identity is not fixed, instead the agent features a sub-set of characteristics that represents the part of the identity that is currently salient on the agent. So in the model each agent has a salient identity that will filter the characteristics that will determine the agent's decision, and also a set of social groups that are known by the agent.
- Salient Identity: representation of the agent's active identity that is going to influence the agent's decision making;
- Social Groups’ Knowledge Base: representation of the agent's known social groups (aggregation of agents that share the same characteristics) and its prototypical characteristics (characteristics that represent the typical agent of that group).
While personal identity is the part of the self-concept defined in terms of idiosyncrasies derived from the intra-group differentiation (Tajfel, 1972), social identity refers to the aspects of a person's self-concept that are derived from the knowledge and feelings about his or her in-group (Tajfel, 1972). As such, the agent is not only going to be able to express its individual identity, but also, for each social group it belongs, the agent will hold a social identity that can be expressed if the situation leads it. In DIMA, an agent's salient identity can have two different levels. It can be social, if an agent's group membership becomes salient trough intergroup differentiation, or it can be personal when no social identity is salient. Thus, the agent's salient identity can be:
- Social: a set of characteristics that the agent shares with the other members of the in-group;
- Personal: a set of characteristics that distinguishes the agent from it's in-group.
In order to represent these two levels, both social and personal identities are defined by:
- Characteristics: representation of the agent's attributes or features that are going to be taken into consideration on the agent's decision making, defined by a name and value.
When an agent's salient identity is personal, the agent's decision will be determined by its personal identity characteristics values, but when the salient identity is social, i.e., then the agent's expressed characteristics' values are going to shift towards the values of the prototypical characteristics of that specific social group.

\section*{Characteristics}

Each characteristic is defined in DIMA by a name and a value:
- Type: a label used to identify the characteristic;
- Value: measurable attribute or feature.

Characteristics can be one of the two types: explicit or implicit. Whereas explicit characteristics can be easily observed and obtained by other agents (e.g. skin or clothes colour, symbols, skills and gender), implicit characteristic are gleaned indirectly by observing the agent's behaviour and expressions, requiring agents with inferring mechanisms. Implicit characteristics can be social values, norms, interests or goals (Hofstede \& Hofstede, 2001; Schwartz, 1992)

\section*{Social Context}

The social context the agent is in will have a great influence on how the agent will perceive itself and others. It will increase the likelihood of the agent behave according to its personal identity or to its social identity, and will also determine which type of identity is going to be salient and influencing the agent's behaviour.

In DIMA, two aspects from the social context are represented:
- Agents Present: agents that share the same space and agents that are not in the space but are referenced in a conversation or by an event.
- Theme: set of characteristics that are relevant in the context, and can be manifested by a place, a talk or an event;

When a specific theme is introduced on the social context, either by a place (e.g. a university), by a topic of a conversation (e.g. a talk about politics), by an event (e.g. travelling outside), or by a task (e.g. cleaning the classroom), the theme will bring out the characteristics that are relevant in that specific social context, and then this set of relevant characteristics is going to be processed by the agent.

It is while looking at each other agents' characteristics that the theme defines as relevant to the current situation, that the agent calculates and perceives if it is in the presence of members with which it shares the same social group (in-group) or not (out-group). If the agent perceives itself as in the presence of only in-group members, its identity is going to be determined by its personal identity. But if the agent is in the presence of out-group members, its identity can be determined by a social identity, according to a formula that we will see next.

\section*{Identity Salience}

Fundamentally, the identity that the agent is going to take in account when processing its decision-making and to generate its behaviour, is going to be determined by the presence or not of the the out-group (Brewer, 1979) but also by several other aspects inherent to the social identity itself. These factors are going to have an impact on the social identity salience
strength, and the more salient a social identity is, more is its influence on the agent's behaviour.

According to Social Identity and Self-Categorization theories (Tajfel, 1972; Turner, 1985; Turner et al., 1987), the salience of a particular social identity is determined by the interaction between how accessible in memory that social identity is to an individual (accessibility), as well as how well it fits the social context (fit) (Turner et al., 1987, 1994). Following (Oakes, 1987), in this model a social identity salience is the product of fit and accessibility (see equation 1 ).
\[
\begin{equation*}
\text { Salience }_{(\text {Social Identity })}=\text { Fit } * \text { Accessibility } \tag{1}
\end{equation*}
\]

Fit between a social identity and the context where the agent is situated is composed by two aspects: comparative fit and normative fit. Comparative fit is defined by the principles of the Meta-Contrast theory (Turner et al., 1987), which states that:
"any collection of people will tend to be categorized into distinct groups to the degree that intra-group differences are perceived as smaller, on average, than inter group differences within the relevant comparative context", p.455, (Turner et al., 1994)
Normative fit refers to the content of that categorization and how well does it match with the characteristics of a social group from the agent's knowledge base.

In order to determine the fit of a social identity with DIMA, first the agent needs to define the social groups present in the context given the actual theme.

All agents present in the social context are going to be clustered into categories, according to the relevant characteristics given by the theme. For this to be possible, all characteristics must have a numeric comparative function which returns the distance between two vectors ranging from 0 to 100 , where 0 means the absence of that characteristic and 100 means that it highly represents the agent.

According to the clustering algorithm results, the agent might perceive as being in the presence of one or more social groups. If the number of clusters is one, that means that the agent is in the presence of one social group. In this case, because of the absence of an out-group the salience of a social identity does not apply, and the agent will use its personal identity. Only in the presence of two or more groups, the agent proceeds in calculating the fit.

In this situation, through normative fit, the agent will be able to determine if it is in the presence of a social group that it already knows and had experience with. So for all social groups in the agent's knowledge base that has those relevant characteristics, the fit is computed by comparing them to all the clusters resulted from the previous clustering process. If no match is found, its because the agent is in the presence of ad-hoc groups (groups who the agent does not have previous knowledge or past experiences with). In those situations the prototypical member, or centroid ( \(C t\) ), of each social group that is going to be used later by the fit is going to be determined by the prototypical member of the present clusters. If
there is actually a match between the social groups found by the clustering algorithm, the agent will use the centroid from the normative social groups that it already knows. The process for computing the value of the normative fit is similar to the comparative fit described bellow.

Calculating the comparative fit of a social identity \(\left(S I_{i}\right)\) is going to be done according to the equation 2 where the distance between the agent's in-group \(\left(S G_{i}\right)\) and any other group \(\left(S G_{o}\right)\) is going to be calculated (inter group differences), and the dispersion of its own social group is measured (intragroup differences). Alfa ( \(\alpha\) ) and Beta \((\beta)\) are weighting values for both distance and dispersion, and since we want to attribute more weight to the distance than to the social group's dispersion, we set the default of \(\alpha\) as 0.8 and \(\beta\) as 0.2 .
\[
\begin{equation*}
\text { ComparativeFit }_{\left(S I_{i}\right)}=\alpha\left(\operatorname{distance}_{\left(S G_{i}, S G_{o}\right)}\right)+\beta\left(1-\operatorname{dispersion}_{\left(S G_{i}\right)}\right) \tag{2}
\end{equation*}
\]

The distance between the agent's group and another group present in the social context is going to be measured by calculating the difference between the out-group centroids \(\left(C t_{\left(S G_{o}\right)}\right)\), that represent the group's prototypical members, and the in-group centroids \(\left(C t_{\left(S G_{i}\right)}\right)\) (see equation 3). If the agent recognizes the groups through the normative fit process then the group's centroids used will be the prototypical members' characteristics from the social groups from the agent's social group's knowledge base, if not, it will be the prototypical members' characteristics of the clusters found trough the clustering algorithm.
\[
\begin{equation*}
\operatorname{distance}_{\left(S G_{i}, S G_{o}\right)}=\frac{\left|C t_{\left(S G_{o}\right)}-C t_{\left(S G_{i}\right)}\right|}{K m d} \tag{3}
\end{equation*}
\]

The dispersion of the agent's social group is measured by calculating the average of absolute differences (MD) of all its members from the prototypical member of the social group (see 4).
\[
\begin{equation*}
\operatorname{dispersion}_{\left(S G_{i}\right)}=\frac{M D_{\left(S G_{i}\right)}}{K m c w} \tag{4}
\end{equation*}
\]

Both distance and dispersion are normalized, using the constants Kmd and Kmcw, where:
- Kmd: is the maximum distance two clusters can hold, and can be calculated according to the equation 5 , where \(N\) is the number of characteristics used for clustering and MAX is the maximum value a characteristic can have;
- Kmcw: is the maximum distance between the centroid member and another member for it to be considered as member of that group. It is a parametrizable value, which is currently set to 50 .
\[
\begin{equation*}
K m d_{S G_{i}, S G_{o}}=\sqrt{N} * M A X \tag{5}
\end{equation*}
\]

Social groups with higher fit are the ones with less clustering dispersion and higher distance from the other social groups.

Accessibility of a particular social group, reflects a person's past experience with that group (Turner et al., 1994). Identities have higher or lower accessibility depending on how accessible is that specific categorization in a person's memory. Identities that have been used more times and displace more emotional valence are more accessible.

The accessibility from new social identities, as the ones from ad-hoc social groups, is implied by the distance between the agent values ( \(<c_{1}, \ldots, c_{n}>_{A g}\) ) and the centroid from its in-group. As such, agents that are closer to the centroid have higher accessibility while agents further from it have lower accessibility, translating this way the connection strength between a agent and that ad-hoc social group (see equation 6).
\[
\begin{equation*}
\operatorname{Acc}(S I)_{t=0}=1-\frac{\left|<c_{1}, \ldots, c_{n}>_{A g}-C t_{\left(S G_{i}\right)}\right|}{K m d} \tag{6}
\end{equation*}
\]

In the presence of normative groups the agent's social identity can have an accessibility value determined by the emotional memory and the easiness of bringing that social identity into the agent's mind (Turner et al., 1994). The emotional valence of a memory is defined by the emotional impact of the actions taken by the agent supported by that identity.

For every time a social identity is salient its accessibility is updated according to the equation 7. The sum of all agent's identities is normalized so when one identity accessibility increases all the others suffer a decay.
\[
\begin{equation*}
\text { Acc }(S I)_{t+1}=\operatorname{Acc}(S I)_{t}+\text { Salience }(S I)_{t} * \text { EmotionalValence }(S I)_{t} \tag{7}
\end{equation*}
\]

The salience of a social identity will be highest if both accessibility and fit are high. The higher a social identity, more impact that will have on the agent's behaviour.

\section*{Implementing DIMA}

For the purposes of experimentation and analysis, DIMA was implemented. The agent behaviour generation system consists of three components: The Characteristic Archetype, The Clustering Algorithm, The Social Identity Calculation.

The Characteristic Archetype consists of an abstract class, which allows the representation of multiple types of characteristics within the system.

In order to calculate the comparative fit and accessibility we used as a clustering algorithm the K-Means algorithm with a few modifications. The clustering algorithm takes into consideration all of the players characteristics values. First it will kick start itself with one K cluster, if there is at least one point who's distance is farther from the distance constraint X , the algorithm will increment K adding one more cluster, forcing the optimization process to restart. The algorithm finishes when the distance constraint heuristic is satisfied.

Figure 1 represents the program pipeline, which starts by assembling a list of the other players known by the agent and their characteristics. Using this list the agent will create a K-Means cluster containing a list with centroids and points. The number of centroids will be a direct representation of the

Figure 1: The Salience Calculation Pipeline.
number of clusters in the agent's K-Means algorithm. The comparative fit and accessibility are then calculated using this K-Means as an input parameter. Finally the salience is obtained through both the comparative fit and the accessibility value.

\section*{Platform}

To explore the above, we used a multi-player game within the Project INVITE \({ }^{1}\) (social Identity and partNership in VIrTual Environments) (Prada et al., 2012) where both humans and virtual agents can participate. The game begins with players stranded on an island due to a plane crash, where an active volcano threatens their lives at any moment. Each player's personal objective is to obtain the largest amount of gold, while at the same time help their campsite members collect wood to build a raft (the team objective) so as to get off the island. The players are faced with the dilemma of either helping their team by collecting wood or gathering gold and thus become rich when saved. If everyone collects mainly gold then the raft will not be built in time and everyone will loose when the volcano erupts. The player who can get off the island with the most gold is the winner.

Although this project aims at exploring the role of social identity and social dilemmas in mixed motive tasks, this platform is fully parametrized and allows the exploration of different scenarios and case studies. Some of the parametrizable variables are: the number of turns until the volcano erupts (end-game condition); number of campsites or teams; number of players per team (that could be a mix of humans and agents); visual characteristics for each player; total wood necessary to finish the raft; number of resources (wood and gold) each player can collect; among others.

\section*{Example Scenarios}

For experimentation purposes a simulation of the game was created. In our scenario the game was limited to 1 turn, 2 teams and 4 players for each of the both campsites, A and B. Players were controlled by virtually intelligent agents. Since different uniform colour has been known to prime differences

\footnotetext{
\({ }^{1}\) http://project-invite.eu/
}
in social group perceptions (Frank, Gilovich, et al., 1988; Peña, Hancock, \& Merola, 2009), it was used a form of differentiation of the two teams, in form of characteristics. In that order players were characterized by a shirt characteristic with the values 0 (red) or 100 (blue), and a campsite characteristic (A and B). Because this work's intentions is the study of the effects of an out-group, each player's K-Means algorithm was limited to a maximum of 2 clusters (i.e. the player's in-group and out-group). Due to the theme of the problem, the campsite will be the most influential characteristic of the clustering algorithm.

The total wood collected by agents is obtained by multiplying the salience value by the total carrying weight, which is 10 . The gold is the difference of the obtained wood value by the total weight. It is expected that agents with a higher salience identity with the campsite (common coloured shirt), will cooperate with more wood.

\section*{Red versus Blue}

In this scenario all campsite A members wear blue shirts while all campsite B members wear red shirts. Because both campsites have members with identical characteristics (i.e. no dispersion) the salience value will be 1 , it's maximum value (see table 1).

Table 1: Red versus Blue Scenario - Campsite A
\begin{tabular}{lccccc}
\hline \hline & Agent 1 & Agent 2 & Agent 3 & Agent4 & Total \\
\hline Colour & Blue & Blue & Blue & Blue & \\
\hline Accessib. & 1 & 1 & 1 & 1 & \\
Comp. Fit & 1 & 1 & 1 & 1 & \\
Salience & 1 & 1 & 1 & 1 & \\
\hline Wood & 10 & 10 & 10 & 10 & 50 \\
Gold & 0 & 0 & 0 & 0 & 0 \\
\hline
\end{tabular}

\section*{Unbalanced Teams}

In this scenario, campsite A has one member wearing a red shirt while the others wear blue shirts, as opposed to campsite B , where one member wears a blue shirt and the others wear red shirts. Although both campsites are similar in their shirt colour distribution, in the perspective of campsite A, the presence of the out-group (campsite B) will be weaker for the red shirt member than for the rest of its members (and vice versa for campsite B). Still, because three of the other members are similar, their salience identity values are strong enough to bias their behaviour to help their team (see table 2).

Table 2: Unbalanced Teams Scenario - Campsite A
\begin{tabular}{lccccc}
\hline \hline & Agent 1 & Agent 2 & Agent 3 & Agent4 & Total \\
\hline Colour & Blue & Blue & Blue & Red & \\
\hline Accessib. & 0.82 & 0.82 & 0.82 & 0.47 & \\
Comp. Fit & 0.68 & 0.68 & 0.68 & 0.68 & \\
Salience & 0.56 & 0.56 & 0.56 & 0.32 & \\
\hline Wood & 6 & 6 & 6 & 3 & 21 \\
Gold & 4 & 4 & 4 & 7 & 19 \\
\hline
\end{tabular}

\section*{Equal Mixed Teams}

In this scenario all campsite A and B members are equally divided between red and blue shirts (i.e. two blue and two red). From the perspective of one campsite, the presence of the out-group will be particularly weak, resulting in a low social identity salience. As such all members are going to behave a little more greedily than in the previous scenarios (see table 3).

Table 3: Equal Mixed Teams Scenario - Campsite A
\begin{tabular}{lccccc}
\hline \hline & Agent 1 & Agent 2 & Agent 3 & Agent4 & Total \\
\hline Colour & Blue & Blue & Red & Red & \\
\hline Accessib. & 0.65 & 0.65 & 0.65 & 0.65 & \\
Comp. Fit & 0.57 & 0.57 & 0.57 & 0.57 & \\
Salience & 0.37 & 0.37 & 0.37 & 0.37 & \\
\hline Wood & 4 & 4 & 4 & 4 & 16 \\
Gold & 6 & 6 & 6 & 6 & 24 \\
\hline
\end{tabular}

\section*{One Team Only}

In this scenario there is only one campsite as such all four agents are in the presence of in-group members. In this situation all agents share the same coloured shirt. Because there is no presence of an out-group, the social identity salience value is 0 , and all members behave accordingly to their personal identity (see table 4).

Table 4: One Team Only Scenario - Campsite A
\begin{tabular}{lccccr}
\hline \hline & Agent 1 & Agent 2 & Agent 3 & Agent4 & Total \\
\hline Colour & Blue & Blue & Blue & Blue & \\
\hline \hline Wood & 0 & 0 & 0 & 0 & 0 \\
Gold & 10 & 10 & 10 & 10 & 40 \\
\hline
\end{tabular}

\section*{Conclusion and Future Work}

Because social identity has a great impact in a wide range of fields and settings such as group formation, cohesiveness, prejudice, conformity, social influence and crowd behaviour (Turner et al. 1994; Hogg, 2003), we believe the study of this other phenomena could also benefit from DIMA.

Running the simulation we found that, as expected, agents whose t-shirt colour matches the majority of their campsite, expressed higher salience identity, cooperating with more wood, while the opposite situation had reverse results. However, in the extreme situations such as Red versus Blue Scenario, or One Team Only Scenario, it was quite evident that agents did not act rationally and presented extreme behaviour (collecting all wood or all gold). In these situations, it looked like they did not care about winning or surviving, respectively, as it would happen in a real situation with humans. As such, for future work, we intent to introduce rational thinking on agent's decision-making in which the influence of social identity salience will work upon. We are also, currently extending DIMA to calculate social identity salience in situations where three or more groups are present, as well as introducing the dynamics of the salience of multiple identities and relations among themselves.

\begin{abstract}
It has been repeatedly debated which strategies people rely on in inference. These debates have been difficult to resolve, partially because hypotheses about the decision processes assumed by these strategies have typically been formulated qualitatively, making it hard to test precise quantitative predictions about response times and other behavioral data. One way to increase the precision of strategies is to implement them in cognitive architectures such as ACT-R. Often, however, a given strategy can be implemented in several ways, with each implementation yielding different behavioral predictions. We present and report a study with an experimental paradigm that can help to identify the correct implementations of classic compensatory and noncompensatory strategies such as the take-the-best and tallying heuristics, and the weighted-linear model.
\end{abstract}

Keywords: Take-the-best, tallying, weighted-linear model, process models, ACT-R

\section*{Introduction}

One important characteristic of well-developed scientific theories is precision. In psychology, theoretical precision can be achieved by complementing verbally formulated theories with formal models. Typically, formal models are specified in terms of mathematical equations or computer code. The goals, level of detail, and level of description of such models vary as a function of the psychological subdiscipline, research questions being asked, or the available technology, to name only a few factors. Computational models have become both increasingly popular and powerful, and have aided cognitive scientists in their endeavor to shed light into the behaviorist's black box. Computer models allow one to specify, on an algorithmic level, the cognitive processes psychological mechanisms are assumed to draw on.

Such process models predict not only what decision a person will make, but also how the information used to make the decision will be processed. The predictions made by these models can thus be tested not only on outcome data (e.g., what item is chosen) but also on process data, including on patterns of information search, response times, or neural activation. Such predictions can eventually differentiate among competing theories that make identical outcome predictions. In particular in the cognitive and decision sciences, describing cognitive processes represents a central goal of theorizing on its own. In fact, the past decades have seen repeated calls to develop process models.

Yet, surprisingly there are relatively few theories of decision making that yield detailed quantitative predictions about process data. Instead, typically qualitative predictions about response times and other process data are tested in experiments. This theoretical and methodological weakness contributes to fuelling important scholarly debates about which decisional processes describe behavior best: simple non-compensatory ones, for which decisions based on some predictors cannot be overturned by others, or complex compensatory integration processes, for which various predictors can neutralize each-other's influence (cf. Bröder \& Schiffer, 2003; Glöckner \& Betsch, 2008; Marewski et al., 2010).

One way to increase the precision of theories of decision making is to implement them in detailed cognitive architectures such as the ACT-R theory of cognition (e.g., Anderson, 2007). ACT-R is a quantitative framework that applies to a broad array of behaviors and tasks, formally integrating theories of memory, perception, action, and other aspects of cognition. ACT-R also allows modeling decision processes. When models of decision making are implemented in ACT-R, quantitative predictions about response time distributions at the millisecond level and other process data can be made and compared to experimental studies. Marewski and Mehlhorn (2011), for instance, implemented several compensatory and noncompensatory decision strategies in ACT-R. In doing so, they modeled for each of the strategies how decisional processes interplay with memory, perceptual, and motor processes, which, in turn, allowed them to quantitatively predict the response time distributions associated with using each strategy in a simple two-alternative forced choice decision task.

While the architectural approach can thus help remedying the aforementioned theoretical and methodological weakness, this approach does not come without its complications. Specifically, often a given strategy can be implemented in numerous different ways in ACT-R (or other cognitive architectures), with each implementation yielding different response time and other process predictions. Part of the problem is that many decision strategies are-in the worst case-only formulated verbally or-in the best case-specified mathematically or algorithmically, without spelling out the strategies' assumptions about lower-level cognitive processes. This specification problem (see Lewandowsky, 1993), namely
how to translate an underspecified theory or strategy into a detailed cognitive model, poses a paramount modeling challenge to the researcher who sets out to find out which implementation is the most adequate one. To illustrate this point, Marewski and Mehlhorn (2011) actually ended up implementing over thirty ACT-R models of similar decision strategies without being able to make strong conclusions about which model most likely represented the correct one.

In this paper, we present and report a study with an experimental paradigm that can help to build and identify the correct implementations of decision strategies. In what we call the train-to-constrain-paradigm, participants are instructed in a detailed step-by-step procedure how to apply specific strategies in a decision task. Since the experimenter thus knows which strategies participants have relied on in the experiment, the resulting response times lend themselves to constraining ACT-R implementations of these strategies. Specifically, as an initial step, here we focus on a variant of that paradigm in which participants are instructed to apply three classic compensatory and non-compensatory strategies, namely the take-the-best (henceforth: TTB) and tallying heuristics, and the weighted-linear model (henceforth: WLM).

The remainder of this paper is structured as follows. First, we will explain in more detail the three decision strategies. Second, we will present the train-to-constrain-paradigm and, in doing so, report a study that we ran using that paradigm. Third, we will report the results of this study, and, fourth, briefly illustrate how these results can be used to build and constrain ACT-R implementations of the three strategies.

\section*{Decision Strategies}

Tallying and WLM have been formulated in different ways (and at times also been given different names); here we use Gigerenzer and Goldstein's (1996) definitions as well as their TTB heuristic. Gigerenzer and Goldstein specified these strategies as models of inductive inference about unknown quantities or future events in simple twoalternative forced choice tasks. In such tasks, a person has to infer which of two alternatives (e.g., cities) has a larger value on a given criterion (e.g., population). One variant of this task that has received considerable attention during the past years is the memory-based decision task illustrated in Figure 1. In this task, a person has to make inferences by relying exclusively on the contents of their memory. The experimental paradigm for identifying correct ACT-R implementations of TTB, tallying, and the WLM that we propose here extends this memory-based task.

Take-the-best. The simple TTB heuristic stands in the tradition of Tversky's (1972) classic elimination by aspects model. TTB bases inferences on the attributes of the alternatives (e.g., whether a city has an airport), which it uses as cues. A cue can have a positive (e.g., a city has an airport, coded as " 1 "), negative (has no airport, coded as "1 "), or an unknown (coded as " 0 ") value. The vector of cue values that define a person's knowledge about a specific
alternative is called the alternative's cue profile. TTB bases inferences on just one good cue. Specifically, TTB orders the cues \(i\) unconditionally according to their validity \(v_{i}\), with \(v_{i}=c_{i} /\left(c_{i}+w_{i}\right), c_{i}\) being the number of correct inferences based on cue \(i\) given that it discriminates between two alternatives (i.e., cue values are \(1 \& 0\), respectively, or \(1 \&-\) 1 , respectively), and \(w_{i}\) the number of incorrect inferences. TTB's rules for searching cues, stopping search, and making a decision can be summarized as follows:

Search: Search through cues in the order of their validity. Stopping: Stop as soon as a cue is found that discriminates between the alternatives.
Decision: Infer that the alternative with the positive cue value has the higher value on the criterion of interest.
As can be seen, TTB is a non-compensatory strategy, which uses solely the first discriminating cue. Translated into a process prediction this implies, for example, that the time it takes to make decisions with TTB should depend on how many cues have been considered before a discriminating cue is found.

Figure 1: Illustration of the memory-based decision task
Tallying. In contrast to TTB and other non-compensatory strategies, many decision models posit that people evaluate alternatives by integrating knowledge about multiple cues. One such heuristic is tallying. This representative of classic unit-weight linear integration models (e.g., Dawes, 1979) simplifies decisions by treating all cues equally. For each alternative, tallying simply counts the cues with positive values and infers that alternatives with the larger number of positive cue values score higher on the criterion of interest. As a consequence, the various cues can neutralize each other's influence on the final decision, thus making tallying a compensatory model. Tallying's search, stopping, and decision rules read as follows:

Search: Search through cues in any order.
Stopping: Stop search after \(m\) out of a total of \(M\) cues (with \(1<m<M\) ) have been accessed.
Decision: Decide for the alternative that is favored by more positive cue values. If the number of positive cue values is the same for both alternatives, guess.

Weighted-linear model. The WLM is similar to tallying in that it integrates all the information available when choosing an alternative. In the WLM, cue values are coded like in TTB. As suggested by its name however, it integrates all cue information by multiplying the cue values by their validities and summing them over for each city, thus
computing the weighted sum of the cues for each city. The WLM's rules can be summarized as follows:

Search: Search through cues in any order.
Stopping: Stop search after \(m\) out of a total of \(M\) cues (with \(1<m<M\) ) have been accessed. Multiply each cue value with its validity and compute the weighted sum of cues for each alternative.
Decision: Decide for the alternative that is favored by the larger weighted sum. If the weighted sum is the same for both alternatives, guess.
The WLM has a long tradition in the cognitive and decision sciences and beyond. For instance, variants of this model have been viewed as optimal rules for preferential choice and are often considered to define rational behavior (cf. Payne, Bettman, \& Johnson, 1993).

\section*{Experimental Paradigm}

The train-to-constrain-paradigm builds on several earlier studies on TTB, tallying, and the WLM (e.g., Bröder \& Gaissmaier, 2007; Bröder \& Schiffer, 2003; Mata, Schooler \& Rieskamp, 2007) and on approaches that teach subjects to rely on specific decision strategies (e.g., Khader et al., 2011; Marewski \& Schooler, 2011).

In our study, we implemented the training portion of our paradigm in a computerized experiment, in which subjects were told that they would participate in a quiz show. In that show, they first learned fictitious facts about how British cities would look like in the future, namely whether these cities would have an international airport, a train station, a university, and/or a premier league soccer team in the year 2100 (such facts are typically judged as useful for inferring city size; cf. Pachur, Bröder, \& Marewski, 2008). In a second step, subjects learned how to employ a strategy that uses these facts as cues to make decisions. During the actual quiz show, they then saw pairs of cities on the computer screen and were instructed to always use the strategy to infer which of the two cities would be larger in the year 2100. Subjects were paid according to the degree to which their decisions agreed with predictions of the respective decision strategy.

Subjects and design. A total of 141 subjects participated in the experiment ( 89 male, \(\mathrm{M}_{\text {age }}=25.3\) ), of which 120 finished it successfully. Subjects were randomly assigned to one of three between-subjects conditions. The conditions differed in terms of the strategy participants learned to use. In the first condition subjects learned TTB, in the other two conditions they learned tallying and the WLM, respectively.

Materials. Sixteen well-known British cities were used as alternatives. These cities correspond to those that most subjects in Pachur et al.'s (2008) pre-study 1 recognized. A pre-study suggested that subjects' familiarity with these cities' names aids them to learn a large number of facts about these cities. Since the degree of familiarity was roughly the same for all cities in both Pachur et al.'s prestudies, no interference effects of familiarity were expected,
and, indeed, also none found. These 16 cities were combined with 8 cue profiles, illustrated in Table 1. In doing so, each of the 8 cue profiles was used twice-albeit with different city names.

Table 1: Cue profiles used
\begin{tabular}{|c|c|c|c|c|c|c|c|c|}
\hline & City1 & City2 & City3 & City4 & City5 & City6 & City7 & City8 \\
\hline Airport & + & + & - & - & + & + & - & - \\
\hline Soccer team & - & - & - & - & - & - & + & + \\
\hline University & - & - & + & + & + & + & + & + \\
\hline Train station & + & - & + & - & + & - & + & - \\
\hline
\end{tabular}

Learning task. The experiment started with a learning task (cf. Bröder \& Schiffer, 2003), in which subjects were taught the 4 cues about the 16 British cities, corresponding to a total of \(4 \times 16=64\) facts. Specifically, during learning, cities and cues were presented repeatedly in a random order until subjects correctly recalled at least 14 of the 16 cities' cue profiles perfectly. Cue profiles were assigned at random to specific cities.

Strategy learning task. After having learned all cues, in each of the three between-subjects conditions, subjects were trained how to use one of three decision strategies. The strategy learning procedure required subjects to go through a stepwise explanation of the decision process assumed by each strategy as well as to apply that strategy correctly on several practice trials that mimic the actual decision task. During practice, subjects received feedback about whether they had applied the strategy correctly, and the strategy was practiced until subjects' decisions concurred to \(100 \%\) with the strategy's predictions. During the strategy learning task, subjects also memorized additional information that is necessary for applying the strategy, such as the cue validities in the case of TTB and WLM. The instructions on how to use each strategy were crafted such that they reflect the strategy descriptions from the literature.

Repetition of learning task. To make sure participants still remembered the 64 facts correctly, one round of the learning task was repeated upon completion of the strategy learning task.

Decision task. In a decision task, 72 pairs of the previously learned British cities were presented (one city on the left side of the computer screen, the other one on the right; see Figure 1). To avoid inducing frequency effects, the pairs were constructed such that each city name appears equally often. Subjects were instructed to always apply the strategy to decide which of the cities will be larger in the year 2100. For each correct application of the strategy, subjects received a bonus payment of 0.5 Euros (0.68 US\$). Each decision inconsistent with the strategy's prediction resulted in a penalty of 0.5 Euros (no feedback was given).

Cue-memory task. In a cue-memory task, subjects had to reproduce the cue values they learned for the cities. The purpose of this task was to collect data about how well subjects remembered the cue values they were taught. This data will be used in future projects to populate the declarative memory of the ACT-R models.

\section*{Experimental Results}

Figure 2 shows the mean of the \(25^{\text {th }}, 50^{\text {th }}\) and \(75^{\text {th }}\) response time percentiles for the three experimental conditions as a function of the number of cues that have to be retrieved from memory prior to finding the most valid discriminating one (henceforth: most valid discriminating cue). Several important observations can be made. First, tallying participants made the fastest decisions. Their response time varied from under 3 s for the \(25^{\text {th }}\) percentile to almost 6 s for the \(75^{\text {th }}\) percentile. This is much faster than previous decision making experiments have reported. For example, Bröder and Gaissmaier (2007) reported mean response times between 6.5 s and 8 s in their first, and between 11 s and 15 s in their second experiment. It should be noted that those experiments did not instruct subjects to rely on specific strategies, but that instead used participants’ decisions to infer, post hoc, by means of strategy classification procedures which strategies subjects have used.

Figure 2: Participants’ aggregate response time percentiles as a function of most valid discriminating cue. Error bars are standard errors of the mean computed across all participants in the respective experimental condition.

Second, the response times of TTB participants fall in the response time range of those reported in these previous experiments. However, this resulted in participants in the TTB condition being slower than tallying participants, which also is a finding that stands in contrast to previous studies, in which post hoc strategy classification procedures were used (e.g., Bröder \& Gaismaier, 2007).

Third, WLM participants are the slowest, which is a result that is consistent with Bröder and Gaissmaier's (2007) earlier studies. Bröder and Gaissmaier reported mean response times between 10s and 11s in their first and between 15 s and 23 s in their second experiment, which fall close to the time range of our participants.

Fourth, as can be seen in Figure 2a, TTB participants' response times increase as a function of most valid discriminating cue. In contrast, Figures 2b and 2c show that for tallying and the WLM the response times do not exhibit such an increase when they are analyzed in the same way as for TTB participants. This result is to a large extent consistent with earlier work: in Bröder and Gaissmaier's (2007) experiments, participants who were inferred to have relied on TTB exhibited strong increases in mean response times as a function of the most valid discriminating cue, while those who were classified as likely users of tallying or the WLM did not exhibit increases that were as strong.

\section*{Implementing Strategies in ACT-R}

In the constraining portion of our paradigm, the observed response times will be used to build and constrain ACT-R implementations of the three decision strategies. Specifically, each individual participant's responses in the memory task can be used to model the contents of that subject's declarative memory after having gone through the training phase. These declarative memory contents can then be used to model the retrieval processes associated with using each of the three decision strategies (cf. Marewski \& Mehlhorn 2011, for this approach). Together with perceptual, motor, and other cognitive processes-all of which can be modeled in ACT-R-these retrieval processes will contribute to the response times predicted by the corresponding ACT-R models of the decision task.

\section*{Overview of ACT-R}

ACT-R describes cognition as a set of modules that interact through a production system. The production system consists of production rules (i.e., if-then rules) whose conditions (i.e., the "if" parts) are matched against the contents of the modules. If a rule's conditions are met, then the production rule can fire and the specified action is carried out. Each module implements different cognitive processes. The declarative module, for instance, enables information storage in and retrieval from memory, the intentional module keeps track of a person's goals, while the imaginal module holds information necessary to perform the current task. A visual module for visual perception and a manual module for motor actions (e.g., typing on a keyboard) simulate interactions with the world. In coordinating the modules, the production rules can only act on information that is available in buffers, which can be thought of as processing bottlenecks, linking the modules' contents to the production rules. For instance, the production rules cannot access all contents of the declarative module, but only these that are currently available in the retrieval buffer. ACT-R distinguishes between a symbolic

Figure 3: Processing stream of the weighted-linear model for the first and last seconds of the decision process. Production rules on the right hand side are stylized representations of the actual ACT-R productions for this model. Note that the model's decision time predictions can vary across different decision trials, for instance, as a function of perceptual and motor processes, or cue activation. Also note that the same production rules fire more than once during the process.
and a subsymbolic system. The symbolic system is composed of the productions rules as well as of the modules and buffers. Access to the information stored in the modules and buffers is determined by the subsymbolic system. This system is cast as a set of equations and determines, for instance, the timing of memory retrieval.

Figure 4: ACT-R predictions of response time percentiles of a tallying and weighted-linear model implementation. Error bars are standard errors of the mean, computed across 30 simulation runs of the ACT-R model.

\section*{Illustrating our ACT-R models}

Figures 4a, 4b and 4c present our preliminary ACT-R models, developed prior to running the experiment as a source of rough predictions of participants' eventual behavior. All of these three models are, perhaps, the most naïve implementations which follow the above mentioned strategy definitions and experimental instructions. In developing these models, no parameters were fitted, but
those from Marewski and Mehlhorn (2011) were used.
All models perform the same task as our experimental subjects: The models "read" two city names off a computer screen, process them, decide for one of them, and enter a response by "pressing" a key. To illustrate this, Figure 3 shows the first and last seconds of an 18 -seconds-long processing stream of our preliminary ACT-R implementation of the WLM. The various decisional, memorial, perceptual and motor processes assumed by the model are coordinated by production rules.

Specifically, by first "reading" the names of both cities, the model tries to retrieve a memory trace of the city names called a chunk. Chunks are facts like "York is a city" or "York has an airport" which model people's familiarity with city names and their cue knowledge about these cities, respectively. For each cue, the model retrieves its validity. If the cue value is positive, the model adds the validity of this cue to the weighted sum of the city, initiating a summation procedure. If the cue value is negative, the model subtracts the validity of the corresponding cue from the weighted sum of that city, initiating a subtraction procedure. Finally, the model compares the total weighted sums of the two cities and chooses the one with the larger total weighted sum by pressing a key. As Figure 4c shows, the predicted response time percentiles of 30 simulation runs of this WLM ACT-R implementation lie close to the \(75^{\text {th }}\) percentile range observed in participants' data (Figure 2c), suggesting that this implementation is not an implausible model, but also that other processes which boost participants' response times, such as memorizing the weighted sum, are present in participants. Our preliminary tallying model (Figure 2b) predicts response times within experimental data, while the TTB model (Figure 2a) is faster. These three models have to be adapted to successfully capture participants' behavior, a more successful example of which is the tallying model presented on Figure 4d, which was built after the experiment. While the former tallying model did not include
memorization of the number of positive cue values of already seen cities, the latter model did, which produced a response time distribution close to participants' response times. Exact modeling of each participant's cue knowledge is the next modeling step to be made. Naturally, after identifying the most promising implementations of all strategies, all models would then have to be tested in new experiments, this way ensuring that they can also account for behavior in tasks for which they were not developed.

\section*{Discussion and Conclusion}

While it goes beyond the scope of this short proceedings paper to present more ACT-R implementations-that is part of a larger research paper-one legitimate question one may raise is what the methodological advantages of our approach over earlier experimental work is. As mentioned above, in earlier studies including Marewski and Mehlhorn's (2011) ACT-R modeling efforts and Bröder and Gaissmaier's (2007) response time analyses for TTB and other heuristics, participants' decisions had to be used to infer, post hoc, by means of strategy-classification and/or other model selection procedures which strategies participants relied upon in an experiment. As a result, the conclusions that could be drawn from analyses of response times crucially hinged on the accuracy of the strategy classification and/or model selection procedure. Our train-to-constrain approach, in contrast, allows identifying the response time patterns associated with a strategy without the need to use potentially inaccurate strategy classification. To illustrate this point, the deviations observed between Bröder and Gaissmaier's and our findings could, besides being a product of differences in the stimuli and materials used, also be a result from the strategy classification method used by these authors. More studies with our paradigm, including experiments that make use of Bröder and Gaissmaier's stimuli and materials, are warranted to decide between these and other competing explanations.

To conclude, response times such as the ones observed in our experimental paradigm can be used to find out which ACT-R implementation best mirrors classic decision strategies used by trained subjects. Once identified, these implementations can, hopefully, be used to model behavior both in previously published studies as well as in new studies in which subjects' decision strategies are unconstrained by training.

\begin{abstract}
The executive functions have been studied separately in the fields of neuropsychology and of motor control. However, it is not clear whether across fields one is referring to similar cognitive functions. In the present study, we compared the performance scores obtained in a motor spatial-tapping task with those scores obtained in a battery of three neuropsychological tasks which assess respectively the executive functions of updating ( N -back task), inhibiting (GonoGo task) and switching (Letter-number task). Multiple regression analyses revealed significant and specific effects between the motor task and the classical neuropsychological tasks: the timing error measured at slow tempi in the tapping task predicted the scores observed in the updating task only; the spatial error at faster tempi predicted the scores obtained in the switching task only; the contact times at intermediate tempi predicted the scores obtained in the inhibiting task only. Hence, we introduce this easy-to-use non-verbal task as a novel paradigm to assess executive functioning.
\end{abstract}

\section*{Introduction}

\section*{Neuropsychological approach of Planning}

Research on the executive functions has historical roots in the study of patients with frontal lobe damage. These patients were the first to demonstrate disruptions to control and organize daily activities independent of any language or memory disorders (Damasio, 1994; Harlow, 1868). The socalled 'frontal' or 'executive' tasks were specifically developed to assess how the main functional deficit encountered by frontal patients, i.e. the planning of daily activities, was affected following brain injury. For example, the Tower of London (Shallice, 1982), a task inspired by a logical reasoning game (the Tower of Hanoi) was proposed to evaluate the ability to inhibit a routine schema - that consisted in producing each move in an isolated and impulsive fashion in response to the true visual configuration of the Tower - in order to define and adopt a cognitive plan to achieve the puzzle in fewer moves (see the model of SAS/GOC, Shallice, 1988). The Wisconsin Card Sorting Test (WCST, Grant \& Berg, 1948), on the other hand, was proposed to target individuals' inability to switch efficiently from an ongoing plan to a novel one. In this task, perseverating errors were measured and used as indicators of cognitive flexibility (Milner, 1963). Finally, working memory tasks, e.g., the n-back task, were developed to
target a person's ability to maintain a cognitive plan active and to update between relevant parts of the plan in function of a given situation. Hence, the executive functions are here directly related to the abilities to inhibit a routine schema in order to adopt and adapt a novel more cognitive plan, to maintain and update parts of a given plan across time and/or to switch flexibly from one plan to another. In the last decade, these cognitive abilities have been referred to in the literature as the inhibiting, the updating, and the switching executive functions (Miyake \& Friedman, 2012; Miyake et al., 2000) and it is common today to use a multiple-test battery to assess the well functioning of the executive functions related to planning abilities.

However, it is the case that the neuropsychological tasks that are classically used to assess the executive functions suffer from a number of validity problems that limits severely the possibility to compare the functions between them. Indeed, the tasks are known to have impurity issues because of the presence of non-executive demands specifically related to the various contents that are used in the tasks (e.g., language, limb displacements, object identification, etc., Burgess, 1997; Phillips, 1997). Second, they present a lack of test-retest reliability, i.e. people can adopt different executive strategies to perform the same task across sessions (Rabbitt, 1997). For example, although the WCST has been designed to reveal a lack of cognitive flexibility, subjects may perform the task by inhibiting certain responses that are no longer appropriate (Miyake et al., 2000). Thus, scores in different sessions may reflect different cognitive strategies, with participants who are sometimes switching between rules and at other times using inhibition to solve the task. The difficulty to characterize the possible relationships between the executive functions is in itself a motivator to consider today a different approach to the evaluation of executive functioning.

\section*{Planning in the Motor Control domain}

A major interest in the field of motor control is to understand how actions are coordinated to enable the execution of complex sequential motor activities, e.g. playing a musical instrument or dancing in rhythm. This question has been particularly studied in the context of sensorimotor synchronization (for a review on SMS, see Repp, 2005). Even if synchronized behaviors require motor coordination both through space and time, research has focused historically on the timing aspects of motor planning and experimental findings have led to the acceptance today
of the existence of two distinct timing modes related to the control and execution of rhythmical action sequences (Robertson et al., 1999; Zelaznik, Spencer, \& Ivry, 2002). The event-based timing mode is primarily involved in tasks that have a clear temporal goal, e.g. trying to keep the beat of a metronome, and is assumed to require an explicit internal representation or memory of the referential temporal interval to produce (Wing \& Kristofferson, 1973). By contrast, emergent timing is assumed to arise implicitly, i.e. from the extraction of temporal regularities emerging naturally from the dynamics of movement control when actions are repeated in smooth oscillatory cycles (Ivry, Spencer, Zelaznik, \& Diedrichsen, 2002; Turvey, 1977). For example I can infer that "I will be late given the speed of my successive footsteps". While finger tapping is the prevailing paradigm to reveal event-based timing, circle drawing has been proposed as the exemplar task to reveal emergent timing (Zelaznik et al., 2002). In terms of statistics, negative lag-1 autocorrelation values are typically observed in fingertapping tasks suggesting that motor responses are controlled through an internal timekeeper (Vorberg \& Wing, 1996; Wing \& Kristofferson, 1973). In contrast, positive or near-to-zero AC-1 values are classically reported in circle drawing tasks suggesting that other mechanisms of control enter into play and enable the implicit emergence of a certain sense of rhythmicity (Lemoine \& Delignières, 2009; Torre \& Delignières, 2008; Zelaznik et al., 2002). Anchoring has been described as a possible mechanism that could explain how timing emerges when movements are continuous rather than discrete. This phenomenon, commonly observed in cyclical movements, consists in a local reduction in spatial and/or temporal errors at a specific location along the trajectory path and is often observed around reversal points, i.e. at points of transition between flexion/extension movements (Beek, Turvey, \& Schmidt, 1992; Roerdink, Ophoff, Peper, \& Beek, 2008). This specific point of transition could be used as a referential to infer timing regularities in the case of continuous movements (Repp \& Steinman, 2010).

In a recent study (Dione \& Delevoye-Turrell, unpublished) the use of a unique task designed as a hybrid of finger tapping and circle drawing was suggested to reveal, assess and compare the two modes of timing between them. In this 'spatial-tapping' task, a picture composed of six discrete visual targets (disposed around a virtual circle) was displayed on a tactile screen. Participants were asked to produce discrete taps on each target, one after the other and to follow the circular trajectory with the arm at the regular pace of a metronome (from 1100 to 300 ms of inter-tone intervals, ITI). The motor actions were assumed to be discrete at slower tempi with the need of cognitive control to maintain long timing intervals through timekeeping at slow tempi; motor actions were proposed to be continuous at faster tempi through the capacity to anticipate only the point of transition between flexion/extension movements when the tempi were too fast. Autocorrelation values were measured up to ten lags to
reveal event-based timing at slow tempi (negative AC-1) and emergent timing at faster tempi (positive AC-6). Furthermore, a detailed spatial analysis was conducted on the spatial endpoint distributions to assess whether the cognitive strategy was turned towards the need to anticipate the point of transition between flexion and extension movement at faster tempi. Spatial ellipses were first measured for each target. The mean area and the angular orientation of each ellipse were then computed. An orientation error was finally calculated as the angular difference between the orientation of the ellipse and the tangent to the circle measured at each target. Performance results revealed first that both the timing ( \(\%\) of \(\mathrm{IRI}_{\text {error }}\) ) and the spatial accuracy (mean spatial area) were perfectly maintained at slowest tempi (from 1100 to 900 ms ). A first small but significant decrease in the performance arose at 800 ms and was maintained until 600 ms . For tempi that were faster than 500 ms the performance was the worst with rather large spatial and timing errors. As predicted for the timing strategies, significant negative autocorrelation values emerged at lag-1 at slow tempi only (from 1100 to 700 ms ) and significant positive AC emerged at lag-6 at faster tempi only (from 500 to 300 ms ). In order to assess whether the actions were controlled or not through an internal timekeeper (event-based timing), the motor delays were measured for each tempo and both lags according to the WK model. Results revealed that the motor delays increased in function of tempi at lag-1 only, suggesting that the timing was event-based at slow tempi only in this spatial-tapping task and that other mechanisms entered into play to explain the correlation factors observed at lag-6. Finally, the spatial analysis confirmed that the endpoint distributions were more oriented in relation to the tangent to the circle at faster tempi, with the emergence of an anchor point at the point of maximal extension in the fastest tempi only.

Overall, these results suggested that in the spatial-tapping task, the timing mode was changed from event-based timing at slow tempi towards emergent timing at faster tempi. Consequently, it is possible to presume that in this motor task the cognitive demands depended on different behavioral strategies in function of the cognitive needs to actively maintain a referential timing interval in working memory (from 1100 to 900 ms ), and to anticipate the spatial point of transition between the two movements of flexion vs. extension involved in the sequence (from 500 to 300 ms ). An intermediate phase was here observed for those tempi between 800 to 600 ms in which the performance was decreased in space and time but in which at the same time the event-based timing strategy was efficiently maintained for \(2 / 3\) of the trials. It is thus possible that in this phase motor inhibition was used in order to avoid a too fast transition from discrete to continuous movement by making an effort to maintain attention on each discrete action in spite of the increase in temporal pressure.

\section*{From neuropsychology to motor control}

In the present study, we suggest that the spatial-tapping task, a task in which several motor actions need to be planned and executed both in space and time could be an interesting method to assess the so-called executive functions. Indeed, the spatial-tapping task requires: (1) working-memory at slow tempi in order to produce discrete tapping actions in reference to memorized timing intervals, (2) the active reduction of a switching cost related to the motor switching between the two biomechanically distinct movements of flexion and extension that compose the movement sequence with the idea that bad switching will lead to poor spatial control of movement trajectory, (3) and finally inhibition of a too fast transition from discrete to continuous actions at intermediate tempi, with finger contact times that are too short to maintain high timing levels of performance.

In order to test this hypothesis performance scores were measured both in a spatial-tapping task and in a battery of neuropsychological tests assessing the three main executive functions. Multiple regression analyses were then computed to explore and reveal specific relationships between the functions.

\section*{Methods}

\section*{Participants}

Twenty-six right-handed students between 18 to 21 years of age and recruited from the University of Lille3 participated voluntarily in the study. All participants received an information letter and provided written informed consent. All participants performed the task with their right hand and reported having normal or corrected-to-normal vision. The protocol received approval of the ethics committee in human sciences of the University of Lille3.

\section*{The spatial-tapping task}

Material \& Stimuli. A picture composed of 6 black targets was displayed on a touch screen Elo Touch 19'' 1915L. The targets ( 10 mm of diameter, distanced of 100 mm ) were placed around a virtual circle of 100 mm of radius. The participants were invited to stand in front of the screen that was placed upon a table and titled at 90 degrees of angle.

Procedure. The subjects' task was to touch each visual target one after the other, starting from the bottom right target, and moving counter-clockwise using the right index finger (fist closed). Participants were instructed to synchronize each pointing action to a series of regular auditory tones (beep duration \(=100 \mathrm{~ms}\) ) that was played through classic computer speakers. Participants were encouraged to maintain their left arm relaxed along the body side. They were clearly instructed of the goal of the task that was to be at best synchronized with the metronome. Each subject performed a total of ten trials. The initial tempo was an inter-tone interval (ITI) of 1200 ms . The temporal
interval was increased by 100 ms between each trial with the fastest one being at an ITI of 300 ms . Participants were required to produce sixty taps for each trial. The total duration of the session was 10 minutes, approximately.

\section*{Performance measures.}

Timing performance. Inter-response intervals (IRIs) were measured as the time interval between the start of two successive taps. Long intervals ( \(>2 *\) ITI) were omitted from all calculations. The \(\mathrm{IRI}_{\text {error }}\) was then computed as the percentage of absolute difference between each IRI and the reference ITI of a given trial. This measure served as an indicator of the magnitude of the timing error.

Spatial performance. The endpoint distributions of the pointing actions were plotted in function of each visual target position. All taps were used (ten data points per ellipse). Through vector calculations, spatial ellipses were then calculated. The mean area of the spatial ellipses was finally measured in \(\mathrm{mm}^{2}\) as an indicator of the magnitude of the spatial error (SE).

Motor Fluency. The Contact time (CT) was defined as the time of finger contact with the touch screen. This measure (in ms ) was used to assess the level of control of the motor response output, with shorter CTs being related to a more fluent gesture.

\section*{Planning indicators.}

Event-based vs. emergent timing. After having suppressed the first six IRIs of each trial, autocorrelation (AC) values were calculated at lag-1 and lag-6 (for details, see Vorberg \& Wing, 1996). These measures served as an indicator of the timing mode that was used to guide the pointing actions with event-based timing being revealed through negative AC-1 values, and emergent timing through positive AC-6 values.

Statistical Analyses. Performance measures and planning indicators were first calculated for individual trials and then averaged across participants. Second, analyses of variances (ANOVA) were conducted with ITI as a repeated measure on measures and indicators. Fisher LSD post hoc tests were used when required and the alpha level was set to 0.05 . The performance measures were then averaged within three phases for each subject according to the moment of change in planning strategy: slow or updating phase, intermediate or inhibiting phase, fast or switching phase.

\section*{Neuropsychological tasks}

Material \& Stimuli. The tasks were all selected from a French version of the TAP computerized battery of tests (Zimmermann \& Fimm, 1994). Participants were seated in front of the computer. The experimenter provided instructions orally. The same instructions were then displayed on the screen. A familiarization trial was performed before each task. One or two response keys were used, in function of task requirements. When only one response key was presented, subjects were asked to respond
with their right hand only. When two response keys were required, participants were asked to respond with their right hand on the right key, and their left hand on the left key. For each task, participants were asked to respond as rapidly as possible while maintaining a low error-rate.

\section*{Tasks procedures.}

Updating \& \(N\)-back task. A series of one-digit numbers were presented one after the other, in the centre of the screen ( 100 items that 15 target items). The subjects' task was to press the response key as fast as possible when the item on the screen was the same as the item presented two times before. Subjects were scored according to the median of their reaction times (RT).

Inhibiting \& Go-noGo task. A straight or a diagonal cross ('+' or ' \(x\) ') appeared briefly in the centre of the screen, for a total sequence length of 40 items. The participant's task was to press a response key as fast as possible for the diagonal cross ('x') only. The target item was present \(50 \%\) of the time. Participants were scored according to the number of false responses.

Switching \& The Letter-number task. A letter and a number were simultaneously presented on the computer screen, for a total sequence of 100 items. Two control conditions and one alternation condition were performed. Two response-keys were used. In the first control or pure block condition, the participants' task was to press the response key that was in the same hemi-field than the letter (for example, if the letter was presented on the left side of the screen, subjects had to press the left response key). In the second control condition, participants had to press the response key that was in the same hemi-field than the number. In the alternation condition, the participants were instructed to alternate a response to a letter, and a response to a number, from trial-to-trial, by pressing the response key that was located in the corresponding hemi-field. Participants were scored according to a switching cost that was measured as the difference in reaction time between the pure blocks (that were pooled together) and the alternation condition.

Statistical Analyses. Performance scores were calculated for each individual in each task and then averaged across participants. Descriptive results (mean, standard, deviation, \(\min \& \max\) values) were then computed. \(\chi 2\) tests were then performed to ensure that performance scores were normally distributed across tasks.

\section*{Multiple regression analyses: ST vs. classical tasks}

Standard multiple regression analyses were conducted to evaluate how well each performance scores ( \(\mathrm{IRI}_{\text {error }}\), CTs, area) obtained in each phase of the spatial-tapping task (regressors) could predict the scores obtained in each of the neuropsychological tasks (dependent variables). The alpha value was set at 0.05 . Following our hypotheses, (1) the timing accuracy in the slow phase of the spatial-tapping task (IRIerror) should require WM abilities (n-back task); (2)
control of the motor response (CTs) as required in the intermediate phase of the spatial-tapping task should be an indicator of inhibition abilities (go-no-go); (3) decrease in the spatial error in the faster phase of the spatial-tapping task (area) should be an indicator of the switching abilities (letter-number task).

\section*{Results}

\section*{The Spatial Tapping task}

\section*{Performance results.}

Timing performances. Results revealed that all participants closely followed the tempo even at fast tempi, with a maximum mean error of \(8 \%\) across the ITI spectrum. As an example, the greatest errors were observed in the fastest tempo of ITI= 300 ms , with IRIs contained between 276 and 324 ms . ANOVA on the \(\mathrm{IRI}_{\text {error }}\) revealed nevertheless that the timing errors were significantly different in function of ITI \((\mathrm{F}(9 ; 225)=7.685 ; \mathrm{p}<0.001)\). Post hoc tests revealed that timing errors were larger at faster tempi, i.e. for \(\mathrm{ITI}=400\) to \(300 \mathrm{~ms}(\) Mean \(=7.6 \% ; \mathrm{SD}=2.8 \%)\) and these values were significantly different from that measured at slower tempi (Mean \(=5.9 \%\); SD \(=1.7 \%\) ).

Spatial performance. ANOVA conducted on the spatial area revealed an increase in the spatial errors at faster tempi \((F(9 ; 225)=83.678 ; p<0.001)\). More specifically, the mean area of the endpoint ellipses were the smallest at slower tempi, i.e., at ITI \(=1100\) to \(800 \mathrm{~ms}\left(\right.\) Mean \(=42.9 \mathrm{~mm}^{2}\); SD \(=\) \(23.7 \mathrm{~mm}^{2}\) ), with all other tempi being characterised by significantly larger errors. Spatial areas were the largest at faster tempi (from \(\mathrm{ITI}=500\) to 300 ms ) and these results were significantly different from all other ITIs (Mean = \(126.8 \mathrm{~mm}^{2} ; \mathrm{SD}=73.96 \mathrm{~mm}^{2}\) ).

Motor fluency. ANOVA conducted on the mean contact times revealed that the CTs were shorter with increasing tempi \((\mathrm{F}(9 ; 225)=31.14 ; \mathrm{p}<0.001)\). Post Hoc tests revealed that the decrease in CT was linear with increasing tempi, with significant differences between the \(\mathrm{n}^{\text {th }}\) trial and the trial \((\mathrm{n}+2)\). Nevertheless, no differences between neighbouring ITIs emerged at the slower tempi, i.e. between ITIs \(=1200\) to 1000 ms for which the largest contact times were measured.

Overall, motor actions were precise in space and time at the slowest tempi ( \(\geq 800 \mathrm{~ms}\) ), less accurate in space but more fluent at intermediate tempi (at 700 and 600 ms of ITI), less precise in both space and time but much more fluent at faster tempi (from 500 to 300 ms of ITI).

\section*{Planning indicators.}

Event-based timing. To note first is the fact that all AC-1 values were negative. Repeated ANOVAs on the AC-1 values showed that these values were significantly different in function of ITI \((\mathrm{F}(9 ; 225)=5.933 ; \mathrm{p}<0.001)\). Post Hoc tests confirmed that the AC-1 values were the largest at slower tempi, i.e. for ITI=1100 to 900 ms of ITI (Mean = \(0.28 ; \mathrm{SD}=0.15\) ) and significantly smaller with increasing tempi, i.e. from \(\mathrm{ITI}=800\) to 400 ms (Mean \(=-0.17, \mathrm{SD}=\) 0.18 ). The AC-1 value was finally the smallest at the fastest

ITI of 300 ms (Mean \(=-0.02, \mathrm{SD}=0.21\) ). These results suggest that the timing mode was event-based for slow tempi ( 1200 to 900 ms ) in this task.

Emergent timing. To note first that all AC-6 values were positive. Repeated ANOVAs on the AC-6 values revealed that these values were significantly different in functions of ITI \((\mathrm{F}(9,225)=8.524 ; \mathrm{p}<0.001)\). Post Hoc tests revealed that the AC-6 values were the smallest at slower tempi, i.e. for \(\mathrm{ITI}=1200\) to \(900 \mathrm{~ms}(\) Mean \(=0.08 ; \mathrm{SD}=0.15)\). At faster tempi (ITI \(=500 \mathrm{~ms}\) to 300 ms ), the positive AC-6 values were the largest (Mean \(=0.31, \mathrm{SD}=0.20\) ) and not significantly different between each other. At intermediate tempi (from 800 to 600 ms ), the AC-6 values were all significantly smaller than at least one of the faster ITIs and larger than at least one of the slower ITI. These results indicate that the timing mode became emergent at fast tempi of 500 to 300 ms of ITI.

Overall, these results suggests that the timing was eventbased at slowest tempi (from 1200 to 900 ms ), emergent at fastest tempi ( 500 to 300 ms ) and in a transition phase at intermediate tempi (from 800 to 600 ms ).

\section*{Neuropsychological tasks}

Performance scores observed in the neuropsychological tasks are presented in table 1. \(\chi^{2}\) tests revealed that performance scores were normally distributed across tasks.

\section*{Multiple Regression Analyses: ST vs. classical tasks}

Beta coefficients and corresponding p-values are presented in table 2 for each regressor in function of each dependent variable. Results confirm our hypotheses: (1) small timing errors in the slow phase of the ST task predict short reaction times in the WM task, (2) short contact times in the ST-task predict larger number of inhibition error in the go-no-go task, (3) smaller are in the fast phase of the ST-task predict smaller switching cost in the letter-number task.

\section*{Discussion}

In this study, we asked whether a simple motor sequencing task could be used to assess the executive functions of planning described in the neuropsychological literature. This motor task was assumed to involve updating in working memory at slowest tempi, inhibiting at intermediate tempi, and switching at faster tempi. This hypothesis was tested by comparing performance scores in the spatial-tapping task to those scores obtained in three neuropsychological tasks selected to target each specific executive function. The findings reported here confirmed our working hypothesis. Indeed, in the slow phase of the spatial tapping task, results suggested that the motor actions were triggered through an internal representation of time intervals, with larger negative auto-correlations at slow tempi (from 900 to 1200 ms ). To perform the task adequately, subjects were required to maintain actively in working memory the target time interval to produce, across the entire duration of the trial.

\end{tabular}

Regression analyses confirmed furthermore the existence of a relationship between these motor results and those performances obtained in a cognitive WM task, suggesting similar WM functions in the cognitive and in the motor domains. In the faster phase of the spatial-tapping task (from 500 to 300 ms ), with actions becoming more circular, it was suggested that the action sequence was divided in two biomechanically distinct movements that compose the sequence, i.e., flexion vs. extension movement patterns. The cognitive goal in this case was then geared towards the need to coordinate smoothly the distinct movements composing the sequence towards a more global trajectory pattern that binds them together, here a circle. In circle drawing, this phenomena is actually measurable through the emergence of an anchor point that is a kinematic reduction in the timing and/or spatial variability at the point of transition between flexion/extension movements (Beek et al., 1992). It has been shown that the anchor point is effectively reduced through explicit anticipatory processes. Indeed, orienting the gaze in advance towards the anchor point significantly reduces the spatial variability observed at this point. In the same vain, flexing and extending the wrist in an anticipatory rhythmic fashion significantly reduces both the spatial and temporal errors respectively at the points of maximum flexion vs. extension related to the movement pathway (Roerdink et al., 2008). In the present results, we observed an anchor point within our circular trajectory at the point of maximal extension (upper left target); point in space at which smaller spatial variability was measured but only in the faster phase of the task, which confirms the role of emergent timing at fast tempi. In reference to the cognitive tests, our results revealed furthermore that the performances at fast tempi in the spatial tapping task were effectively related to smaller switching cost in a classical switching task, suggesting that
switching between two biomechanical movements may be in fact controlled by those similar functions used for cognitive switching. Finally, in the intermediate phase of the spatial-tapping task, it was suggested that motor inhibition of a too fast transition from discrete to continuous actions entered into play to maintain high levels of spatial and timing accuracy in spite of the increase in temporal pressure. This hypothesis was confirmed here with longer contact times in the intermediate phase of the spatialtapping task being significantly related with the ability to inhibit impulsive response in a classical go-no-go task.

In conclusion, we propose the spatial-tapping as a novel paradigm (1) to assess the executive functions in an easy and non-verbal context, (2) to gain a better understanding of the relationships between the distinct executive functions. This approach may be a promising way to reconsider cognitive strategy in broader context and offers a starting point for the study of the functional relationships between motor and cognitive control.

\begin{abstract}
Spatial congruity effects have often been interpreted as evidence for metaphorical thinking, but an alternative markedness-based account challenges this view. In two experiments, we directly compared metaphor and markedness explanations for spatial congruity effects, using musical pitch as a testbed. English speakers who talk about pitch in terms of spatial height were tested in speeded space-pitch compatibility tasks. To determine whether space-pitch congruency effects could be elicited by any marked spatial continuum, participants were asked to classify high- and low-frequency pitches as 'high' and 'low' or as 'front' and 'back' (both pairs of terms constitute cases of marked continuums). We found congruency effects in high/low conditions but not in front/back conditions, indicating that markedness is not sufficient to account for congruity effects (Experiment 1). A second experiment showed that congruency effects were specific to spatial words that cued a vertical schema (tall/short), and that congruity effects were not an artifact of polysemy (e.g., 'high' referring both to space and pitch). Together, these results suggest that congruency effects reveal metaphorical uses of spatial schemas, not markedness effects.
\end{abstract}

Keywords: metaphor, polarity correspondence, markedness, musical pitch, space

\section*{Introduction}

Are high hopes somewhere in the air? Or what about rising prices? And where exactly are you when you are feeling down? Spatial metaphors like these are very common in language. Moreover, according to conceptual metaphor theory, people not only talk in terms of space but they also think metaphorically (i.e. spatially) (Lakoff \& Johnson, 1980). Whereas arguments in favor of this claim were initially based on linguistic data (and thus circular in nature), psychological experiments have now shown that spatial representations importantly contribute to people's understanding of domains like time (Casasanto \& Boroditsky, 2008), social dominance (Schubert, 2005), or valence (Meier \& Robinson, 2004).
Many of these psychological studies base their findings on binary compatibility tasks. In one experiment, for instance, participants were asked to classify dimensions in a metaphoric target domain (i.e., valence: judge the positive or negative valence of a word), while, at the same time aspects of the spatial source domain (i.e, location; up and down) were varied. In line with "GOOD is UP" metaphors, people were faster to evaluate positive words when they
appeared in a high spatial location compared to a low location (and vice versa for negatively valenced words) (Meier \& Robinson, 2004). Similarly, participants made faster judgments about social power when words for powerful people are at the top of a display and powerless people at the bottom (e.g., 'king' above 'slave', rather than vice versa; Schubert, 2005). These "metaphoric congruency effects" (Lakens, 2012), with faster performance for congruent compared to incongruent trials, have been taken as evidence that metaphoric target domains automatically activate congruent spatial information, supporting claims of conceptual metaphor theory (e.g. Meier \& Robinson, 2004; Schubert, 2005).

On an alternative account, however, it has been argued that congruency effects may be better explained as polarity alignment effects, also called markedness effects \({ }^{1}\) (Lakens, 2012). Like many other continuums in language and mind, metaphoric source and target domains (e.g. height or happiness) are considered to be bipolar. That is, they consist of an unmarked or +polar endpoint (e.g. high, happy), and an opposing marked or -polar endpoint (low, sad). Unmarked endpoints (+polar) are commonly defined as the default, evaluatively positive or broader dimension as opposed to the marked (-polar) ones (see e.g., Lehrer, 1985; Proctor \& Cho, 2006; for a critical approach see Haspelmath, 2006). Moreover, there is evidence that polarity differences affect cognitive processing. Participants show faster reaction times for unmarked (+polar) dimensions as compared to marked (-polar) ones (Clark, 1969; Seymour, 1974). Reaction time benefits for congruent metaphoric dimensions (like happy and up) could thus alternatively be explained by an additive processing advantage for + polar endpoints (e.g. happy +polar, up +polar): Across many studies, perceptual and linguistic judgments are faster when the poles of marked continuums are aligned (e.g., 'good' matched with 'up') than when they are misaligned (e.g., 'good' matched with 'down'; Clark, 1969; Lakens, 2012; Proctor \& Cho, 2006). The existence of markedness effects in binary response compatibility tasks raises a question: Does polarity alignment offer an alternative, non-metaphorical explanation for "metaphor congruency effects" like those reported by Meier \& Robinson (2004) and Schubert (2005), which rely on

\footnotetext{
1 Here, the terms "markedness" and "polarity" will be used interchangeably.
}
dimensional compatibility in binary speeded response tasks? And if so, what would this mean for theories of metaphorical mental representation?
Crucially, not all of the evidence for metaphoric thinking comes from (binary) congruency effects. Rather, it has been shown that people's metaphoric representations of domains like time or musical pitch map onto space in a continuous analog fashion (Casasanto, 2010; Dolscheid, Shayan, Majid, \& Casasanto, 2013). English speakers, for instance, who talk about musical pitch in terms of spatial height (high vs. low pitch; see e.g. Stumpf, 2006) also associate higher pitches with higher positions in space in nonlinguistic psychophysical tasks. In one study, participants were asked to reproduce musical pitches while watching lines varying in spatial height. Since lines were presented at multiple positions (i.e., 9 levels of height) in a random order, effects of space on pitch could not be attributed to (binary) polarity. Rather, participants' pitch reproductions were affected by the spatial information in a continuous way; tones accompanied by higher lines were reproduced at a higher frequency on average than the same tones accompanied by lower lines, resulting in a linear influence of height on pitch (Dolscheid et al., 2013). In this study, responses were not speeded, and the metaphor-congruity effects did not rely on the kind of binary stimulus-response compatibility that is believed to give rise to polarity alignment effects (Proctor \& Cho, 2006).
Furthermore, some mappings between space and musical pitch go against markedness. Whereas speakers of many languages (including English) refer to pitch in terms of spatial height, other languages like Farsi or Turkish encode pitch in terms of spatial thickness (Shayan, Ozturk, \& Sicoli, 2011). These thickness-pitch metaphors follow a reversed polarity alignment. Thick (+polar) refers to a low frequency pitch (-polar), whereas thin (-polar) refers to a high frequency pitch (+polar). Since Farsi speakers implicitly represent pitch in terms of thickness (Dolscheid et al., 2013), spatial schemas appear to be more important than polarity alignment.

Although experiments like Dolscheid et al.'s (2013) provide evidence for metaphorical mental representation that cannot be explained by markedness, the role of markedness in binary compatibility tasks remains controversial. Do source-target congruity effects merely show polarity alignment? Or do they reveal metaphoric associations? While metaphors and polarity are often indistinguishable in compatibility tasks (see also Lakens, 2012), we predict that when markedness and metaphor are juxtaposed, congruity effects will support metaphoric thinking, not markedness. What should matter is whether the words that participants have to classify in binary compatibility tasks activate the appropriate spatial schema (e.g., in the case of space-pitch mappings for English speakers, it should be a vertical spatial schema). That is, schema-appropriateness should be necessary, and markedness may not be sufficient to produce congruity effects.

In Experiment 1, we tested compatibility in height-pitch metaphors for 2 pairs of spatial terms, both paradigm cases of marked continuums (Clark, 1973). One pair corresponds to the poles of the correct spatial continuum (high-low), the other to the poles of an incorrect spatial continuum (frontback). High and front both constitute the unmarked or +polar endpoint, whereas low and back represent the marked or -polar endpoint (see e.g., Clark, 1973; Landsberg, 1995). Participants were asked to make binary speeded judgments on high-frequency and low-frequency pitches, classifying pitches either in a polarity-congruent way (e.g. high pitches as high or front), or in a polarityincongruent way (e.g. high pitches as low or back). If polarity alignment drives space-pitch congruity effects, then similar effects should be found when pitch is mapped to any marked linear spatial continuum, regardless of its orientation: High/low and front/back should both produce pitch-congruity effects. Alternatively, if activating a particular spatial schema for pitch is critical (i.e., the schema that is encoded in the participants' language), then high/low should result in a congruency effect, but front/back should not.

\section*{Experiment 1}

\section*{Methods}

Participants Twenty-four English speakers with no reported hearing problems participated for payment ( \(5 \$\) per 30 minutes). Four participants were excluded from analyses for not following instructions (i.e. they responded according to the wrong response mapping throughout at least one condition). They were replaced by a new sample of 4 participants who had not previously participated in the task.

Materials and Procedure Participants were asked to classify tones (one high and one low pitch) as quickly and accurately as possible by pressing buttons on the QWERTY keyboard (Q and P-keys). Stimuli were presented on an Apple iMac using Vision Egg 2.6 (Straw, 2008). Sounds were generated by Audacity software (http://audacity.sourceforge.net/) and comprised two pure tones (frequency: 262 and 440 hertz). Each tone lasted 400 ms . Participants listened to one tone at a time, via sealed headphones. Immediately following the offset of each tone, two response options (e.g., high, low) appeared, one on the bottom left and the other on the bottom right of the screen. Participants were instructed to classify the sound by pressing the button located under the corresponding word (e.g., high or low) as fast and accurately as possible. The left-right locations of the spatial terms varied randomly from trial to trial so that participants could not predict the location of the correct word in advance.

Spatial terms (high-low vs. front-back) were presented in 2 blocks, a high-low block and a front-back block. Within each block, spatial terms were crossed with 2 mappings (congruent, incongruent). The order of blocks was counterbalanced across participants. The order of congruity was counterbalanced within each block. Across blocks,
incongruent and congruent conditions were always presented in alternation. Before each condition, participants received 6 practice trials with feedback. Participants were also given an example illustrating the respective mapping before the practice trials.

Each condition consisted of 24 trials, 96 trials in total. In half of the trials a high pitch was presented, in the other half a low pitch. In the high-low congruent condition, the high pitch had to be classified as high and the low pitch as low. In the high-low incongruent condition, the high pitch had to be categorized as low and the low pitch as high. In the frontback congruent condition the high pitch had to be categorized as front and the low pitch as back (according to patterns of polarity/markedness). In the front-back incongruent condition the low pitch had to be categorized as front and the high pitch as back.

\section*{Results}

All data were analyzed using R (version 2.14.2; http://www.r-project.org/) and the R packages lme4 (Bates \& Maechler, 2009) and languageR (Baayen, 2009; cf. Baayen, 2008). We carried out linear mixed-effects regression models of Space (high-low versus front-back) and Congruency (congruent, incongruent) on accuracy and RTs. Using the principle of backward selection, we started out with a full (conservative) model which took into consideration not only the random intercept but also the random slopes of subject whenever it was appropriate (i.e., when the factor was a within-subject factor). Random intercepts and slopes of items were not included in the analysis due to the small number of items (4 words: high/low, front/back). To interpret the significance, we adopted the criterion that a given cosine was significant if the absolute value of the \(t\)-statistic (or \(z\)-statistic) exceeded 2 (Baayen, 2008).

Accuracy The mean accuracy for all target trials was 92.4\% ( \(S D=8.1\) ). For high/low conditions, accuracy was \(92.4 \%\) ( \(S D=9.7\) ), and for front/back conditions, accuracy was \(92.5 \%(S D=11.3)\). For congruent conditions, accuracy was \(95.9 \%\) ( \(S D=4.5\) ) and for incongruent conditions it was \(88.9 \%(S D=15.5)\). Analyzing accuracy by using a logistic mixed effects model on binary accuracy data yielded no main effects or interaction of Space (high/low, front/back) and Congruency (congruent, incongruent), (Space: \(z=|1.3|\); Congruency: \(z=|0.2|\); Space by Congruency: \(z=|1.2|\) ).

Reaction times Reaction times of the button presses were analyzed by linear mixed effects models. Only correct trials were considered which resulted in the exclusion of \(7 \%\) of the data. Responses greater or less than \(\pm 2\) SDs away from each participant's average RTs were also excluded, which resulted in the removal of \(6 \%\) of the accurate trials.

There was no significant main effect of Space \((t=|0.3|)\). The model yielded a significant main effect of Congruency ( \(t=|3.5|\) ) and a significant interaction of Congruency by Space ( \(t=|3.3|\) ). A linear mixed effect model of Congruency
on reaction times restricted to the level of high/low, yielded a significant effect of Congruency ( \(t=|4.5|\) ), demonstrating a congruity effect of high/low conditions. Restricting the model to the level of front-back yielded no significant effect of Congruency ( \(t=|0.2|\) ) (see Figure 1).

Figure 1: The influence of Space (high-low; front-back) and Congruency (congruent; incongruent) on pitch categorization (plotted in milliseconds).

\section*{Discussion}

In Experiment 1 we find congruency effects for high/low but not for front/back conditions, suggesting that activating the appropriate spatial schema (i.e., spatial height) is what is relevant in such binary response compatibility tasks. Words that activate a different (irrelevant) spatial schema (frontback), however, do not result in a congruity effect. This finding indicates that congruity effects cannot be attributed to markedness (polarity alignment), since 'front' and 'back' also name the unmarked and marked ends of a (sagittally oriented) linear spatial continuum.

\section*{Experiment 2}

Whereas high/low terminology is conventional for pitch in English, front/back is not. Maybe we only find a congruency effect in the case that is lexicalized, but not in the other case (front/back)? This skeptical interpretation would not change the fact that markedness is not sufficient to elicit congruency effects, but it would call into question our claim about activating the right spatial schema. Do we find congruency effects only because participants were using the polysemous words high/low, which can refer to "height" in both space and pitch?
To rule out this alternative explanation, in Experiment 2, we compared congruity effects in two pairs of spatial terms: tall/short and big/small. Neither pair of spatial expressions can be used in conventional English to describe the height of musical pitches (i.e., their frequency). If high/low congruency effects were driven by polysemy, then neither of these pairs of spatial terms should produce a congruity effect. However, if space-pitch congruity effects result from using words that activate a vertical spatial schema, then "tall" and "short" should produce a congruity effect because they are schematically appropriate (even though they are
lexically inappropriate). By contrast, "big" and "small" should not produce any space-pitch congruity effect, because these terms refer to 3 -dimensional size, and should not activate the appropriate 1 -dimensional vertical spatial schema (Dirven \& Taylor, 1988; Taylor, 2002).
In addition to testing whether the height-pitch congruity effect in Experiment 1 depended on the polysemy of "high" and "low," Experiment 2 also provides a second test of the sufficiency of markedness to produce space-pitch congruity effects. "Big" is the unmarked (positive) end and "small" the marked (negative) end of the big-small continuum. Therefore, markedness predicts that judgments should be faster when "big" is matched with "high" than when "small" is matched with "high."

\section*{Methods}

Participants Twenty-four English speakers with no reported hearing problems participated for payment ( \(5 \$\) per 30 minutes). One participant was excluded from analyses for not following instructions (i.e. the participant responded according to the wrong response mapping throughout one condition). He was replaced by a new participant who had not previously participated in the task.

Materials and Procedure The same procedure as in Experiment 1 was used, with the following exceptions. Rather than classifying pitches as high-low or front-back, participants classified them as tall-short for one block and big-small for the other.

In the tall-short congruent condition the high pitch had to be categorized as tall and the low pitch as short. In the tallshort incongruent condition the low pitch had to be categorized as tall and the high pitch as short. In the bigsmall congruent condition the high pitch had to be categorized as big and the low pitch as small (according to patterns of markedness). In the big-small incongruent condition the low pitch had to be categorized as big and the high pitch as small.

\section*{Results}

All data were analyzed using R (version 2.14.2; http://www.r-project.org/) and the R packages lme4 (Bates \& Maechler, 2009) and languageR (Baayen, 2009; cf. Baayen, 2008). We carried out linear mixed-effects regression models of Space (tall-short versus big-small) and Congruency (congruent, incongruent) on accuracy and RTs. Using the principle of backward selection, we again started out with a full (conservative) model which took into consideration not only the random intercept but also the random slopes of subject whenever it was appropriate (i.e., when the factor was a within-subject factor). Random intercepts and slopes of items were not included in the analysis due to the small number of items (4 words: tall/short, big/small). To interpret the significance, we adopted the criterion that a given cosine was significant if the absolute value of the \(t\)-statistic (or \(z\)-statistic) exceeded 2 (Baayen, 2008).

Accuracy The mean accuracy for all target trials was 94.8\% ( \(S D=11.4\) ). For tall/short conditions, accuracy was \(94.6 \%\) ( \(S D=13.1\) ), and for big/small conditions, accuracy was \(94.9 \%(S D=10.1)\). For congruent conditions, accuracy was \(96.2 \%\) ( \(S D=6.7\) ) and for incongruent conditions it was \(93.3 \%(S D=17.1)\). Analyzing accuracy by using a logistic mixed effects model on binary accuracy data yielded no main effects or interaction of Space (tall/short, big/small) and Congruency (congruent, incongruent), (Space: \(z=|1.0|\); Congruency: \(z=|1.0|\); Space by Congruency: \(z=|1.0|\) ).

Reaction times Reaction times of the button presses were analyzed by linear mixed effects models. Only correct trials were considered which resulted in the exclusion of \(4 \%\) of the data. Responses greater or less than \(\pm 2\) SDs away from each participant's average RTs were also excluded, which resulted in the removal of \(4 \%\) of the accurate trials.

There was no significant main effect of Congruency \((t=|0.9|)\). The model yielded a significant main effect of Space ( \(t=|2.3|\) ) and a significant interaction of Congruency by Space \((t=|3.2|)\). A linear mixed effect model of Congruency on reaction times restricted to the level of tall/short, yielded a significant effect of Congruency ( \(t=|3.0|\) ), demonstrating a congruity effect of tall/short conditions. Restricting the model to the level of big-small yielded no significant effect of Congruency ( \(t=|1.5|\) ) (see Figure 2).

Figure 2: The influence of Space (tall-short; big-small) and Congruency (congruent; incongruent) on pitch categorization (plotted in milliseconds).

\section*{Discussion}

In Experiment 2 we find a congruency effect in tall/short but not in big/small conditions. Therefore, congruity effects cannot be attributed to polysemy or markedness. Rather, space-pitch compatibility is based on activating the appropriate spatial schema, which serves as the source domain for English speakers' mental representations of musical pitch.

\section*{General Discussion}

In two experiments, we show binary response-time congruity effects attributable to metaphorical thinking, but not to markedness. Classifying pitches with vertical spatial terms elicited space-pitch congruity effects, but no comparable effects are found when people were asked to classify pitches with terms that name the poles of other marked spatial continuums (front vs. back; big vs. small). Polarity alignment (a.k.a. markedness), therefore, is not sufficient to produce space-pitch congruency effects. Rather, schema-appropriateness is necessary, supporting theories of metaphorical mental representation.
Moreover, congruity effects are not restricted to polysemous words like "high" and "low," which can be used for both space and pitch. Rather, congruity effects can also be found for words like "tall" and "short," which have no musical senses, but which activate a vertical spatial schema: the "active ingredient" in the observed space-pitch congruity effects.
In most cases, the polarities of metaphorical source and target domains are aligned (e.g. Lakens, 2012; Lakoff \& Johnson, 1980). For instance, happy, powerful, good, and high in pitch are all UP (the positive end of this spatial continuum), whereas their antonyms are DOWN (the negative end of the continuum). This relationship between metaphor and markedness makes it hard to determine the cause of many response compatibility effects. However, the polarities of metaphorical source and target domains are not always aligned. Musical pitch provides one domain, in which the marked end of the source domain (space) can be matched to the unmarked end of the target domain (pitch). Farsi speakers, for instance, represent pitch in terms of thickness. In Farsi speakers' language and thought, the unmarked pole of the spatial continuum (thick) is aligned with the marked pole of the pitch continuum (low frequency). Thus, metaphors and markedness can dissociate in Farsi - at least to the extent that markedness can be established in a principled way.

Making psychological predictions on the basis of markedness is problematic because researchers may disagree on how markedness is defined, and even on which end of a given continuum is marked. Whereas Schubert (2005) describes "powerful" as the marked and "powerless" as the unmarked endpoint of the "power" continuum, others have suggested the reverse (e.g. Lakens, 2012). In addition to these inconsistencies, it is not always clear what markedness actually means. By definition, quite a number of attributes like frequency, familiarity, or fluency, seem to be subsumed under the umbrella term markedness (see Haspelmath, 2006). In one experiment, for instance, Lakens (2012) manipulated polarity by adjusting the frequency of the 'marked' endpoint. While usually marked attributes like bad or down (-polar) occur less frequently, this was no longer the case for a group of Laken's participants. Critically, these participants also no longer showed a congruency effect, which was taken as evidence for a polarity account. However, in line with Haspelmath (2006),
it is questionable why one should talk about polarity when actually frequency is driving the effects. Unlike markedness, which is a notoriously ambiguous construct (e.g., Haspelmath, 2006, enumerates 12 distinct usages of this term in cognitive science), metaphors in language are more widely agreed upon. Expressions like "a high soprano" and "a low bass" make clear predictions about the spatial mappings that people should be activating for pitch, and therefore what congruity effects should be found: Linguistic metaphors tell us which end is "up."

Here we find an impact of spatial schemas on sourcetarget congruity as predicted by metaphors in language. Our results suggest an automatic, Stroop-like interference effect of metaphorical associations, converging with other findings of height-pitch congruity effects. In one task, for instance, participants made judgments about musical timbre while spatial height information was varied on a computer screen. Although pitch was irrelevant to the task, people's judgments were affected by the alignment of tonal and spatial height (Evans \& Treisman, 2010), suggesting a highly automatic source-target mapping (see also Rusconi, Kwan, Giordano, Umiltà, \& Butterworth, 2006; for limits of automaticity see Brookshire, Ivry, \& Casasanto, 2010).

Unlike previous experiments, here the spatial source domain was not manipulated physically but rather via linguistic stimuli (i.e., we presented words like high/low; tall/short etc.). This allowed us to directly assess effects of polysemy. In Experiment 2, height-pitch congruity effects could not simply be attributed to lexical overlap (high/low for space and pitch). Rather, we found that words activating a similar vertical schema (tall/short) were sufficient to trigger space-pitch congruity effects even if the words were lexically inappropriate. One could argue, however, that congruity effects in tall/short conditions were still indirectly driven by polysemy. Participants may have activated high/low terminology when classifying pitches, which then in turn led to semantic priming from high to tall, and low to short. However, although we cannot entirely rule out such priming effects, this explanation is unlikely to account for our results, for several reasons. According to Latent Semantic Analysis (LSA; http://lsa.colorado.edu/), 'tall' is more strongly related to 'short' (LSA cosine: .48) than to 'high' (LSA cosine: .31). Moreover, 'short' is about equally strongly related to 'high' (LSA cosine: .30) as to 'low' (LSA cosine: .31). Since activation is expected to spread between the most strongly related items (Collins \& Loftus, 1975), simple spreading activation would have wiped out a tall-short congruity effect rather than producing it. Moreover, although big is more closely related to high than to low (LSA cosine: . 18 versus .12) congruity effects remain absent in big/small conditions. The non-significant big/small effect even points into the opposite direction (see Figure 2), suggesting that semantic priming is unlikely to drive the observed patterns of results. \({ }^{2}\) Thus, while spatial

\footnotetext{
\({ }^{2}\) The trend toward a big-low congruity effect could be driven by underlying associations between size and pitch (e.g., see Evans \& Treisman, 2009) - but not by markendess or semantic priming.
}
terms like high/tall/big may be semantically related and overlap in markedness, we find that activating the appropriate vertical spatial schema is critical for producing space-pitch congruity effects.

\section*{Conclusions}

Metaphor congruency effects have been challenged by a polarity account, claiming that binary response compatibility effects may be better explained by markedness than by metaphorical thinking (Lakens, 2012). Indeed, metaphor and polarity are often hard to distinguish. However, here we show that when polarity and metaphor are juxtaposed, congruity effects support metaphorical thinking, not polarity.

Furthermore, these results show that it is not necessary to use polysemous words to produce source-target congruity effects (i.e., words that can refer to both the metaphorical source and target domains). Words that activate a vertical schema (e.g., tall/short) produce a space-pitch congruity effect despite being lexically inappropriate. Words that activate a different spatial schema (e.g., front/back, \(\mathrm{big} / \mathrm{small})\) do not produce any space-pitch congruity effect, despite naming the poles of other marked spatial continuums.
Together, these results indicate that activating the appropriate spatial schema is the "active ingredient" in space-pitch congruity effects - not polysemy or markedness - supporting theories of metaphorical mental representation.

\title{
A Two Process Account of the Memory Improvement Due to Choosing
}

\author{

}

\begin{abstract}
Previous accounts of the mechanism which generates improvement in memory when people freely choose items, compared to other methods of item assignment, conflict and lack integration. I examine facial recognition performance of 40 participants asked to choose either the most or least attractive face from a series of pairs, and find that recognition of chosen faces is greater than recognition of unchosen, while no effect is found for the valence of faces. Considering these results in tandem with prior results and theories, I argue that a two process account of memory improvements due to choice is necessary, with one deliberative process occurring across all options available to choose from, and the other selective process focused on the actual chosen item. I detail the delineation of these processes, and describe and test the current best accounts of each - the multiple-cue hypothesis, and the self-reference effect for memory.
\end{abstract}

Keywords: Self; incidental memory; choice; self-choice effect; multiple cuing; learning and memory;

\section*{Introduction}

Why did you choose that brand at the supermarket, or that politician to vote for? Choices are everywhere, with ramifications from insignificant to major. A form of decision-making, choice more specifically involves a selection from a set of options. Substantial research has addressed the influence of various factors influencing our choices, but comparatively little has examined the direct cognitive impact of actually making a choice. One important cognitive impact is our memory of the choice, both because simply remembering them can be crucial, but also because the memory of previously choosing something has been shown to positively influence us in regards to that choice in future - even when that memory is incorrect. This positive influence occurs during both recall and encoding (Benney \& Henkel, 2006),via an influence on preferences (Bernstein \& Loftus, 2009), further decisions (Chen \& Zhang, 2003), as well as the attributes we associate with items (Benney \& Henkel, 2006; Henkel \& Mather, 2007). A better understanding of the way choices are remembered may thus help us to mitigate some of these arbitrary biases, improve our decision making in general, and inform our broader understanding of both memory and choice.

\section*{Memory improvements due to choice}

Freely choosing items has long been recognized to facilitate memory compared to other methods of item assignment (e.g. random assignment), but current accounts of the mechanisms driving this improvement focus on only
one possible mechanism, and conflict with each other. Early work in the field noted improvements in associative learning performance when participants chose their own learning materials (Perlmuter, Monty, \& Kimble, 1971). It was argued that increased motivation arising from having freely chosen either the stimulus or response increased performance. Later work by Takahashi (1991) examined recall and recognition performance for freely-chosen versus experimenter-assigned options, and found an improvement in memory for freely-chosen items that they termed the selfchoice effect. Takahashi posed a meta-memory interpretation for this effect, suggesting that while choice enhances memory, it does so because participants can select more easily remembered options, and not because freely choosing items increases motivation.

\section*{The multiple-cue hypothesis}

Watanabe (2001) critiqued both Takahashi and Perlmuter's explanations (though further endorsed the selfchoice effect) by demonstrating that the effect was maintained in a constrained choice condition. Watanabe asked participants a series of questions, and provided a number of answers to select from for each, although only one was correct. Participants had to process the various options and make a selection - just as with free choices but only one of the options answered the question appropriately. Because the self-choice effect was maintained when participants went through the process of choosing, yet could not simply choose their favored or more easily remembered options, Watanabe rejected both motivational and meta-memory explanations. Instead, Watanabe proposed a parallel between the self-choice effect, and the generation effect. When participants generate responses to a question, they are generally remembered better than when they are assigned responses (Slamecka \& Graf, 1978). This generation effect also accords with Craik and Lockhart's (1972) levels-of-processing framework, which suggests that the more substantively we think about an item, the better we remember it. The premise for the generation effect is that responding to a question typically involves generating multiple candidate responses, comparing and deliberating between them, then selecting the best response. Watanabe suggests that in order to compare responses, positive and negative attributes of each must be generated. They then argue that while choosing between presented options does not involve the generation of candidate responses themselves, it does involve the generation of attributes for each candidate, and then a
comparison between these generated attributes. They call this the multiple-cue hypothesis, and suggest it is responsible for the improved memory in both generation and self-choice effects; the item attributes that are generated in both cases provide additional cues to facilitate memory of the item. The generative process encourages the encoding of item-specific information (i.e. detailed information about the item), while the comparative process encodes relational information (i.e. how the item connects to other items and concepts in memory).

\section*{The Self-reference effect}

An entirely separate stream of research into choice suggests that rather than improvements in memory being driven by the generative and comparative processes of deliberation, they instead arise because the feeling of freely choosing something causes us to associate it with our selves (Cloutier \& Macrae, 2008). This is suggested as arising because self-reference is encouraged by the sense of personal responsibility in selection. The self-reference effect for memory was proposed by Rogers, Kuiper and Kirker (1977) after many observations that we remember items such as traits, nouns, prose, mental imagery, etc. better when we consider how the items relate to ourselves than to others. Symons and Johnson conducted an extensive meta-analysis of theories and findings for the self-reference effect (1997), and suggest that items encoded in relation to our self construct benefit from the highly developed memory structure (i.e., well organised, richly detailed and massively connected), already in place regarding our self. This self-referential encoding facilitates recognition and recall, as more connections exist to other memory traces. As with the self-choice effect, Symons and Johnson argue that self-reference encourages both item-specific and relational information encoding (i.e., increases encoding of both detail regarding the specific item, and associated connections with other memory traces). Additionally, Symons and Johnson suggest that we use our self-concept as a default source of retrieval cues. This default means that in the absence of other sources of cues, we look to memory traces associated with our self. As such, self-referentially encoded items are also likely to be recalled with reference to the self. Such compatibility of encoding and retrieval conditions - transfer-appropriate-processing (Morris, Bransford, \& Franks, 1977) - leads to improved memory for the items (Wells, Hoffman, \& Enzle, 1984).

When Cloutier and Macrae (2008) extended self-reference to the domain of choices, they examined whether selfreference could improve memory when participants were not explicitly directed to think in terms of the self. They theorized that when someone feels personally responsible for the assignment of an item to their self (i.e. free choice), greater self-reference should be elicited, improving memory for the item. While this is similar to work on the self-choice effect, this study allows a critical delineation between the
act of selecting an item and the process of deliberating between items, by removing the latter. Cloutier and Macrae paired 44 participants, and had each member of the pair take turns to pass slips of paper to the experimenter from either a central bowl (free choice condition), or a participantspecific bowl (assigned condition). The experimenter then read out loud a number printed on the slip, and indicated a positive trait that corresponded to that number from a hidden list - removing any possible influence of deliberation between choices on memory. Even though a choice from the central bowl resulted in just as random and arbitrary a selection as an initial assignment of items to individual bowls, recall and recognition performance of the traits that participants chose themselves via the central bowl was significantly better than both traits chosen by the other participant, and traits when participants chose from the selfspecific bowl. While the explanation that this memory improvement occurs due to increased self-reference needs further examination and testing, this work does show that the mere act of selecting an item can enhance memory for it, so long as a sense of choosing is maintained - even in situations where the choice is arbitrary and no processing of the options is involved.

\section*{Two mechanisms for memory improvement?}

The multiple-cue hypothesis and self-reference accounts pose very different mechanisms for memory improvements due to choosing. Watanabe's (2001) examination of the self-choice effect and multiple-cue hypothesis suggested that deliberation between options drives memory improvements when choosing items, but Cloutier and Macrae's (2008) work on choice and self-reference demonstrated that the sense of freely choosing an item, devoid of deliberation, is sufficient to elicit better memory for it. This latter sense alone could be sufficient to account for the full extent of memory improvement due to choosing, with no need for the multiple-cue hypothesis. However, the effect that the sense of freely choosing has on memory for unchosen items is unknown, whereas Watanabe showed that memory improvements also occurred for deliberated and compared, but unchosen, items. For the sense of freely choosing to sufficiently account for all memory improvements due to choice, it must endow unchosen items with comparable memory improvements to chosen items. That is, chosen and unchosen options that have been deliberated between should exhibit comparable memory performance. This requires a direct comparison between unchosen and chosen item memory performance, which prior works have not pursued (Watanabe compared both to different assignment methods). So, while prior works posit different, but singular, processes for the memory improvement due to choice, a direct comparison between unchosen and chosen can show whether one is sufficient, or that multiple processes are necessary.

\section*{Is self-reference relevant?}

Beyond the question of one or two (or more) processes, is the question of why the sense of freely choosing an item is important for memory - how does it cause the improvement. Cloutier and Macrae (2008) argued that it is the self-referentiality caused by the sense of choosing which drives memory improvements. However, because participants in their studies only chose their own items, and were not asked to choose items from the central bowl for the other participant, it is unclear whether it is the sense of choosing an item to suit oneself, or the mere sense of choosing at all that is driving the effect. Were the latter found to be the case, self-reference would either need to be construed very differently in regards to choice, or a new explanation developed. Cloutier and Macrae acknowledge a further limitation, in that they only provided positive traits in each condition - would the act of selection have improved memory for neutral or negative traits in the same manner as for positive? Items which were deemed less favorable, less in line with personal preferences and desires, should elicit fewer connections in memory with the self. Although far from a complete test of the theory, examining this can enlighten us as to whether the theoretical background of self-reference is a strong basis for this observed effect of freely choosing on memory.

\section*{Outline of the experiment}

To determine whether freely choosing between a pair of options causes differences in memory of unchosen and chosen items, and thus whether one or two processes are necessary to account for memory improvements due to choice, I will examine whether our memory for chosen items is better than our memory for unchosen. Support for this would demonstrate that the sense of freely choosing is insufficient on its own to account for memory improvements due to choosing. Such a finding would then lend support to a two process account, whereby improvement across both chosen and unchosen items arises due to deliberation between the items, while further improvement in memory for only the chosen item arises due to the sense of having personally selected it.

Further to determing whether a one or two process account is necessary, I will also examine the mechanism of the memory improvements due to the sense of freely choosing. I examine this aspect because while I do not debate the existence of the effect, it is very unclear that selfreference is the mechanism. To assess this I will ask whether when we choose options we favor, we will exhibit more improvement in memory than when we choose unfavorable options. Such a finding would lend support to the notion that self-reference is behind the memory improvement associated with the sense of freely choosing.

To examine these questions I will present participants a series of choices between two facial images. Half will be asked to choose the most attractive face, and half the least
attractive. The faces will then be presented one at a time, interspersed with unfamiliar faces, and recognition for the faces will be assessed.

\section*{Method}

\section*{Participants}

Forty undergraduate psychology students (Six male) of mean age 19.57 years \((S D=2.64)\) participated in this study for course credit.

\section*{Materials}

Participants completed a computer-based choice and subsequent memory task. Colour images of female faces were used for the choices offered to participants, the same as in Tangen, Murphy and Thompson (2011). Originally from a Slovakian database of 200 faces (SmartNet IBC, n.d.), the faces were eye-aligned using PsychoMorph (Tiddeman, Burt, \& Perrett, 2001), and clearly identifying extraneous features such as piercings were digitally removed as necessary. An example face pairing is shown in Figure 1.

Figure 1: Example of facial image pairings

\section*{Procedure}

Participants were initially told they would be completing a task in which they had to select faces based on attractiveness, followed by a range of cognitive testing. They were given basic demographic questions followed by a series of 18 choices. Each choice was between a pair of female face images as shown above in Figure 1. The order of pair presentation was randomized for each participant. Half of the participants were asked to "please choose the face you find most attractive", while the other half were asked to choose least attractive. Participants then performed a word unscrambling distracter task for two minutes, after which a surprise memory test commenced. During the memory task, the 18 chosen faces, 18 unchosen faces, as well as 36 new faces, were presented serially in randomized order. Participants were told that they would be presented both old and new faces, but were not informed of the proportion, or of how long the test would last.

\section*{Design}

A 2 (choice type: most attractive, least attractive) \(\times 2\) (memory stimulus: chosen, unchosen) mixed factorial design was used, where choice type was randomly assigned and varied between-participants. Memory stimulus varied within-participants in a randomized order. Recognition was gauged by asking participants "Did you see this face in the earlier sequence of pairs", with a forced-choice response of yes or no. The percentage of recognition responses to each type of memory stimulus was calculated for each participant.

\section*{Results}

Initial examination of the data in Table 1 suggests that chosen faces are recognized more often than unchosen, while both are recognized more often than new faces. Participants appear to be more accurate in their recognition judgment when presented with a new face than either a chosen or unchosen, in that they make the correct judgment \(84 \%\) of the time. However this simply suggests that people are more likely to not recognize a previously seen face than they are to mistakenly recognize a new face.

Table 1: Recognition rates based on choice type.
\begin{tabular}{lccccc}
\hline & \multicolumn{2}{c}{\begin{tabular}{c} 
Choose most \\
Memory \\
attractive \((\mathrm{n}=20)\)
\end{tabular}} & & \multicolumn{2}{c}{\begin{tabular}{c} 
Choose least \\
attractive \((\mathrm{n}=20)\)
\end{tabular}} \\
\cline { 2 - 3 } \cline { 5 - 6 } & M & SD & & M & SD \\
\hline Chosen face & .71 & .14 & & .71 & .12 \\
Unchosen face & .62 & .15 & & .65 & .14 \\
New face & .16 & .8 & & .16 & .9 \\
\hline
\end{tabular}

Recognition rates were assessed with a mixed betweenwithin subjects \(2 \times 2\) (choice type [most, least] \(\times\) memory stimulus [chosen, unchosen]) analysis of variance. There was no main effect of choice type on recognition, \(F(1,38)=\) \(0.12, p=.731\). This lack of main effect of choice type indicates that the type of choice participants were asked to make - choosing either the most or least attractive - did not influence overall recognition rates. There was a significant main effect of stimulus type, \(F(1,38)=12.48, p=.001\). This main effect of stimuli type indicates that previously chosen faces were recognized significantly more often than faces that were shown and participants deliberated over, but left unchosen. No significant interaction between choice type and memory stimuli was observed, \(F(1,38)=0.47, p=\) .490. This absence of interaction indicates that the observed effect of memory stimuli on recognition was not influenced by choice type; the improvement in recognition for chosen compared to unchosen faces was the same whether people were asked to choose the most, or the least, attractive face.

\section*{General Discussion}

When asked to choose between pairs of faces, participants later recognized faces they had chosen more frequently than the faces they did not choose - deliberating between two items and then selecting one led to improved memory for the chosen item compared to the unchosen. This lends support to my proposal that two processes are necessary to account for memory improvements due to choosing. Previous accounts of this memory improvement include the multiple-cue hypothesis (Watanabe, 2001) and the selfreference effect (Cloutier \& Macrae, 2008). My results show that neither explanation alone is sufficient to account for the range of results seen across research in the area, but that in combination they may provide an effective account.

The multiple-cue hypothesis (Watanabe, 2001) suggests that deliberating between items generates additional attributes (which can function as cues) associated with each item, thereby improving recognition and recall of the items. This was based on observations that any items that were part of a selection process (both chosen and unchosen) were better remembered than items that were merely assigned to participants. However, Cloutier and Macrae (2008) showed that even in the absence of deliberation between items, a sense of involvement in the selection process is sufficient to improve memory for items. This sense of involvement could thus have potentially accounted for the full extent of memory gains that people exhibit when choosing between items. However, because personal involvement in the decision is comparable for both chosen and unchosen items, and my results show that participants' recognition of chosen items is greater than unchosen, the sense of involvement is insufficient to explain Watanabe's earlier findings of improved memory for unchosen items compared to items assigned by an experimenter. As such, it appears that at least two processes are necessary to account for memory improvements due to choosing. Some portion of improvement likely occurs as a function of the process of deliberating between options, which improves memory for all items involved in the decision process, while another process related to the act of selecting one option improves memory primarily (or only) for the selected option.

\section*{Multiple-cues and the deliberative process}

Although insufficient to explain the entirety of improvements in memory due to choosing, the multiple-cue hypothesis (Watanabe, 2001) is presently the best explanation for the memory improvement arising from the process of deliberating between items, and is thus responsible for improvements observed for unchosen items involved in a deliberative process compared to unchosen items not involved in a deliberative process. Further understanding of the influence of this deliberative process on memory could be gained by varying the number of options selected between while constraining the time available to choose. I expect that the inclusion of additional
options would reduce the influence of deliberation, while maintaining a similar effect of selection. That is, if choosing between five options instead of two, differences in memory between chosen and unchosen options should be greater, because any quickly rejected options will benefit less from deliberative processes, while chosen options should still benefit similarly from the sense of freely choosing. Note though that it was important in this work to limit the options in choices to two, to avoid confounding an effect of choosing with an effect of rejecting early. This is because if three options are presented, one could be rejected as inappropriate early in the choice process, leading to reduced memory for it, unrelated to the actual act of selection. If this effect were apparent, it would mean that any examination of differences between unchosen and chosen when more than two options are presented is likely to be confounded by attentional differences due to early rejecting. However, now having confirmed the influence of both deliberative and selective processes on memory, choices with more than two options may be able to both further test the two mechanisms, and highlight the relative effects of each.

\section*{Self-reference and the act of selection}

Memory improvements due merely to the act of selection (as distinct from the deliberation between items) have only recently been noted, with the frequently observed but somewhat narrowly specified self-reference effect (Rogers et al., 1977) posed by Cloutier and Macrae (2008) as the only explanation so far. Typically regarded as the phenomenon whereby participants remember items assessed in terms of their relation to their self better than items assessed in relation to others (Symons \& Johnson, 1997), it is generally elicited by explicitly asking participants to think of an item in relation to their self or another. When stepping outside this paradigm, it is difficult to determine a priori the types of items or actions likely to elicit selfreferential processing. Nevertheless, Cloutier and Macrae posed self-referential processing as responsible for participants improved memories of items they felt they chose themselves, compared to memories of items they felt others had chosen. In their case however, rather than varying whether the item was assessed in relation to the self or other, they varied the sense of who was responsible for selecting the item.

To test support for Cloutier and Macrae's proposed selfreference explanation, half of my participants were asked to choose items they found most attractive, while half chose items they found least attractive. Items which more closely represent a participants preferences and desires were expected to be more likely to induce associations with their self (Cloutier \& Macrae, 2008), however, no difference in recognition performance between more and less attractive faces was found, and participants performed no differently when choosing either the most or least attractive faces.

While this result raises questions as to the applicability of self-reference as an explanation for memory improvements due to choice, further research is needed to assess whether this null result is: an artifact of the type of stimuli used; an indication that an items' self-referentiality does not vary based on the strength of accord with personal preferences; or an indication that the observed memory improvement due to the sense of personally choosing is not due to selfreference. These multiple possibilities highlight what I think is a weakness in the application of self-reference based theories - unless directly and overtly introduced, greater self-reference must be assumed in order for self-reference to function as an explanatory mechanism for observed improvements in memory. An alternative approach to this question would be to repeat my experiment, but ask some participants to make choices based on their own preferences, and others to make choices for a friend. This would more closely match the typical approach to eliciting selfreference, such that choosing for a friend should result in less self-reference. Should such an experiment also yield a null result, the predictive usefulness of self-reference as an explanation for the observed effect would seem very questionable.

\section*{Delineating between the two processes}

I have demonstrated that memory improvements due to choosing are likely best described by two distinct processes, as opposed to the singular process accounts described in the literature until now, which I have shown to be inadequate. These two processes are delineated as the initial deliberation between multiple options, or latter act of selecting one specific option. The best accounts of the individual processes at present are the multiple-cue hypothesis (Watanabe, 2001) as driving that portion of improvements due to deliberation, and a self-reference effect (Cloutier \& Macrae, 2008) further improving memory only for those items which are felt to be personally selected. The multiplecue hypothesis was developed in response to a series of works in the area of memory for choices, and allows for relatively clear predictions and testing. Results here neither confirm nor disconfirm the theory, but the further testing I propose involving more choice candidates will go some way towards this. While my results clearly show an effect related only to selection, there are weaknesses with selfreference as an explanation for this effect. My results failed to demonstrate one possible prediction of self-reference, that the valence of items should influence the level of selfreference - yet the weaknesses of self-reference (in current guise) as a theory for memory of choices is seen in that alternative explanations can be given for my observed results which maintain a causal role for self-reference. One such explanation could be that self-reference occurs whenever we judge an item for ourselves, and we do not in fact more closely associate positive items and features with ourselves. My proposal of adhering more closely to the
original self-reference paradigm will be one informative step for this issue.

While I have proposed a number of specific extensions to this line of research, I also suggest that a critical feature of my work - the direct comparison between chosen and unchosen options - is crucial to further investigations related to choice. This distinction allows a clear delineation of the process of deliberating between items, from the act of selecting a single item. That is, the process of deliberating involves cognitive processes that occur across all options, selecting one option rather than another results in differential cognitive effects - direct comparisons between chosen and unchosen options allow these to be examined.

\section*{Towards a reduction of biases}

A final, more general direction this research could fruitfully be extended, is the influence of memories for choosing, and not choosing, on preferences and future decisions. How do the arbitrary biases in memory (Benney \& Henkel, 2006; Henkel \& Mather, 2007; Mather, Shafir, \& Johnson, 2000), and resulting preferences (Bernstein \& Loftus, 2009), that choosing causes vary under different conditions of choice? Could we enhance or minimize this post-choice polarization between options? My results suggest this may be possible: while the choice posed to participants (which face they found more, or less, attractive) varied, the information gained did not - regardless of choice type, we come to know both the face they found most attractive, and the face they found least attractive. Therefore varying the direction of the original choice, manipulating how well the different options and the decision are remembered, may be a very simple way to alter the extent of bias people show towards items after making a choice between them. The earlier suggestion of testing with more than two options could also be explored here. If the multiple-cue hypothesis is adequate, more choices may further reduce our memories for unchosen items, and in turn reduce any biases towards the unchosen options which arise from a memory of not choosing them.

\section*{Acknowledgements}

I thank Jason Tangen for his support across all aspects of the project, and Mike Humphreys and Giulia Paparo for their comments on various portions. The School of Psychology at University of Queensland provided the participant pool.

\begin{abstract}
In contrast to symbolic models of language understanding, embodied models of language comprehension suggest that language is closely connected with visual and motor processing. In the current study we show that motion words, such as rise or fall, are processed faster if displayed against a background of compatible motion (e.g., upward vs. downward random dot motion with \(60 \%\) motion coherence). However, this interaction between semantic processing and visual processing only occurred if the word and the motion display were presented simultaneously. If the visual motion display was short-lived and occurred 100 or 200 ms after word-onset, no interactions between language and visual motion were found. We suggest that only in situations that do not allow ignoring or strategically suppressing the visual motion display, supra-threshold visual motion can affect language comprehension.
\end{abstract}

Keywords: Language processing; motion verbs; vision; visual motion processing; embodiment; grounding.

\section*{Introduction}

Embodied models of language understanding propose a close connection between language and perceptuomotor processes in the brain (e.g., Barsalou, 1999). Recently, compelling evidence supported the close association between language and other cognitive functions (e.g., Zwaan, Stanfield \& Yaxley, 2002). In the motor domain converging evidence suggests that language facilitates compatible motor actions (e.g., Glenberg \& Kaschak, 2002) and that language comprehension involves cortical motor areas that are also involved in performing the described actions (e.g., Hauk, Jonsrude, \& Pulvermüller, 2004). For example, Glenberg and Kaschak showed that processing sentences such as "Close the drawer" can interfere with motoric responses incompatible with the motion implied in the sentence (e.g., arm movement towards my body). Similar effects have been reported in studies using motion verbs (e.g., rise, climb) or nouns implicitly implying a location (e.g., bird vs. shoe), whereby upward verbs and nouns facilitate upward arm movements (Dudschig, Lachmair, de la Vega, De Filippis, \& Kaup, 2012a;

Lachmair, Dudschig, De Filippis, de la Vega \& Kaup, 2011). In contrast to the effects of language on motor processing, in the perceptual domain there is rather mixed evidence regarding the relation between language and visual processing. In particular, evidence regarding the influence of non-linguistic factors on language processing is rare. This direction of cause is particularly important, as these findings would suggest that mechanisms underlying non-linguistic processes are required and recruited during language processing.

Studies in the visual domain typically investigate the influence of language on perceptual detection or discrimination tasks. For example, it has been shown that words referring to entities with a typical location (e.g., hat vs. shoe) can influence visual target perception in upper or lower screen locations (e.g., Dudschig, Lachmair, de la Vega, De Filippis, \& Kaup, 2012b; Estes, Verges \& Barsalou, 2008). Similar results have been reported for valence words (e.g., Meier \& Robinson, 2004) and religious concepts (e.g., Chasteen, Burdzy \& Pratt, 2010). Additionally, there have been studies demonstrating that visual simulation can also occur during sentence processing and subsequently affect visual discrimination performance (Bergen, Lindsay, Matlock \& Narayanan, 2007). Recently, it has been shown that not only visual discrimination performance but also eye-movements can be affected by words referring to entities in the upper or lower field of vision (Dudschig, Souman, Lachmair, de la Vega, \& Kaup, 2013). More specifically, upward saccades are faster following words referring to entities in the upper visual field (e.g., bird) and in contrast, downward saccades are faster following words referring to entities in the lower visual field (e.g., shoe). Importantly, the relation between language and visual processing was also reported in the other causal direction: Perceiving visual motion patterns can affect language processing. For example, Kaschak, Madden, Therriault, Yaxley, Aveyard, Blanchard and Zwaan (2005) first reported the effects of visual motion perception on language comprehension. In their study, participants viewed visual motion patterns (e.g., upward vs. downward moving
horizontal stripes on a screen) and at the same time had to listen to sentences and perform a sensibility judgment task. The results showed that reading times were slower when the visual motion (e.g., upwards pattern) matched the motion direction implied by the sentence (e.g., "The rocket blasted off'). The authors concluded that language processing demands access to visual processing resources. If these visual processing resources are engaged by the processing of motion patterns, sentence understanding can be impaired.

Interestingly, studies investigating the effect of visual motion percepts on single word comprehension reported opposing results. Meteyard, Zokaei, Bahrami and Vigliocco (2008) analyzed how the understanding of motion verbs (e.g., rise vs. fall) is influenced by activation of motionresponsive visual brain areas. In their study, motion verbs were presented on a screen together with a short-lived ( 200 ms ) visual motion pattern, whereby the visual motion pattern was noisy to a greater or lesser extent. In the nearthreshold condition, the motion display was presented at a coherence level that made it difficult for the participants to detect the motion direction of the motion pattern. In the above-threshold condition, motion coherence was set to a level that clearly allowed classification of the motion direction (upward vs. downward moving pattern). Participants had to perform a lexical decision task. The results showed that near-threshold motion patterns facilitated processing of words implying compatible motions (e.g., rise was faster processed if presented together with a near-threshold upward motion). In the other experiments where the visual motion was set to abovethreshold levels no effect of visual motion perception on language processing was observed. The authors suggested that visual motion activates motion-responsive areas in the brain ( \(\mathrm{MT}+\) ). However, this activation can be suppressed by top-down control mechanisms in the case of abovethreshold motion coherence only. Thus, only in nearthreshold motion patterns the motion information resulted in interactions with semantic language processing. In contrast, in the case of above-threshold visual motion pattern topdown control was recruited and suppressed this visual activation. Importantly, in the study by Meteyard et al. the visual motion patterns were presented very briefly ( 200 ms ) in contrast to 35 sec visual motion percepts in the study of Kaschak et al. (2005). Taken together there is mixed evidence regarding the influence of visual motion perception on language processing. On the one side, abovethreshold and long-lasting visual motion can influence sentences processing (Kaschak et al., 2005), on the other side, only near-threshold visual-motion patterns affected lexical access to single words (Meteyard et al., 2008). Thus, it remains open whether above-threshold visual motion can interact with semantic language processing on a word-level.

In the current study we investigate whether single-word processing can be affected by above-threshold visual motion if visual motion patterns are presented from word onset until response. Such findings would be important for the embodied model of language understanding, as they would
suggest convergence in the empirical evidence in favor of the model, and suggest that both word and sentence processing are influenced similarly by co-occurring visual motion. In order to test this we adapted the visual motion displays used by Meteyard et al. (2008) and created abovethreshold random dot motion displays, that clearly allowed classification of the motion as an upward or downward directed motion. Additionally, we manipulated the stimulus onset asynchrony (SOA) between the word display and the visual motion display. In the 0 ms SOA condition the word and visual motion were displayed simultaneously. In the 100 ms SOA condition first the word was displayed and after 100 ms delay the visual motion pattern appeared. Similarly, in the 200 ms SOA condition, the visual motion pattern followed the word display by 200 ms . Importantly, only in the 0 ms SOA condition word and motion display fully overlapped. Thus, in this condition the simultaneous presentation of word and motion display minimizes the possibility of the participants to ignore the visual motion display. We expected that in conditions were participants were constantly exposed to visual motion during the lexical decision task, visual motion will most strongly influence semantic language processing.

\section*{Method}

\section*{Participants}

Eighteen right-handed psychology students from the University of Tübingen took part in this experiment ( \(M_{\text {age }}=\) \(24.39,16\) female) for monetary reward or course credit.

Figure 1: Trial examples for Go-Trials (word) and NoGo Trials (non-words). Visual motion was either compatible to the motion implied by the verb (top-left display) or incompatible (bottom-left display). Arrows illustrate visual motion direction and were not displayed in the actual experimental setup.

\section*{Stimuli \& Apparatus}

The experiment took place in a sound-attenuated booth. Participants viewed the screen from a 60 cm viewing distance. Experimental procedure was implemented in MATLAB R2010a, Psychtoolbox, 3.0.8.

Words Twenty-four German verbs \({ }^{1}\) referring to upwards motion and 24 verbs referring to a downwards motion were used as experimental stimuli. Upwards and downwards motion verbs did not differ in length ( \(M_{\text {up }}=8.74\) ( \(S D=\) \(\left.1.18), M_{\text {down }}=8.35(S D=2.01), t(44)=.69, p=.49\right)\). Word frequency was retrieved from the Leipziger Wortschatzportal, upwards and downwards motion verbs did not differ in word frequency ( \(M_{\text {up }}=1886.17\) ( \(S D=\) \(3545.31), M_{\text {down }}=1667.70(S D=3134.64), t(44)=.22, p=\) .83. Additionally, 48 pronounceable non-words were constructed. Therefore we used a different set of German verbs and permuted and exchanged various letters.

Visual Motion Patterns Visual motion patterns were adapted from Meteyard et al. (2008) with some adjustments, in order to make the motion clearly visible to the participants. 1000 moving dots were included in each display moving at a speed of \(20^{\circ} / \mathrm{s}\). Dot size was \(0.1^{\circ}\). Dots were presented within an aperture of approximately 15 cm diameter. Figure 1 shows examples of compatible and incompatible visual motion trials.

\section*{Procedure \& Design}

Each experimental trial started with the presentation of a fixation cross in the middle of the screen for the duration of 500 ms (size: 20 pixels). Then, either a word or a non-word replaced the fixation cross. Words were presented in Arial font with a size of \(0.5^{\circ} \times 2.5^{\circ}\) visual angle. In the 0 ms SOA condition, the visual motion pattern was presented together with the word. In the 100 ms and 200 ms SOA conditions, the visual motion pattern followed word onset by 100 or 200 ms , respectively. Words and visual motion were presented until response. Participants had to press the space bar if they decided that the displayed stimulus is a word and withhold response in case of non-word trials. If no response was recorded within 1500 ms the next trial started automatically. The inter-trial-interval was 500 ms . 20 Practice trials were conducted using a separate set of verbal stimuli. The experiment consisted of 576 Go-Trials (word trials) and 576 NoGo-Trials (non-word trials). Each of the 48 words was presented four times in each SOA condition (twice with an upward motion pattern and twice with a downward motion pattern). The experimental design was a within-subject design, with the factors \(\operatorname{SOA}(0,100,200 \mathrm{~ms})\), visual motion

\footnotetext{
\({ }^{1}\) Exemplary German verbs denoting to upwards motion: steigen to rise), erhöhen (to increase), klettern (to climb), wachsen (to grow), hissen (to hoist), erheben (to lift) etc.. Exemplary German verbs denoting to downwards motion: fallen (to fall), sinken (to sink), tauchen (to dive), tropfen (to drip), landen (to land), schütten (to pour), einstürzen (to collapse) etc.
}
(upward, downward) and word direction (upward, downward).

\section*{Results}

All NoGo-Trials and erroneous trials were excluded from analysis. Error exclusion reduced the dataset by 1.40 \%. Additionally, outliers were excluded from reaction time (RT) analysis, with a criterion of 4 SD reducing the dataset by less than \(0.43 \%\). The lexical decision times were analyzed in two repeated measures ANOVAs. In the first ANOVA participant was the random-factor ( \(F_{1}\) : byparticipant analysis) and in an additional ANOVA the stimulus word served as random-factor ( \(F_{2}\) : by-item analysis).

Reaction time results are displayed in Figure 2. There was a main effect of word direction in the by-participant analysis only, \(F_{1}(1,17)=13.06, M S E=834, p<.01, F_{2}(1,46)=1.56\), \(M S E=11520, p=.22\), with responses to downwards word ( 624 ms ) being faster than to upwards words ( 639 ms ). There was no effect of visual motion, \(F_{1}(1,17)=0.12, M S E\) \(=652.8, p=.74, F_{2}(1,46)=0.27, M S E=731.4, p=.60\), nor of \(\mathrm{SOA}, F_{1}(2,34)=0.59, M S E=721.2, p=.56, F_{2}(2,92)=\) 2.53, \(M S E=896.2, p=.09\). There was no interaction between visual motion and SOA, \(F_{1}(2,34)=0.54, M S E=\) \(454.5, p=.59, F_{2}(2,92)=0.64, M S E=901.3, p=.53\). There was no interaction between word direction and SOA, \(F_{1}(2,34)=2.56, M S E=486.4, p=.09, F_{2}(2,92)=0.34\), \(M S E=896.2, p=.71\). There was no interaction between word direction and visual motion direction, \(F_{1}(1,17)=3.15\), \(M S E=573.8, p=.09, F_{2}(1,46)=0.62, M S E=731.4, p=\) .44. Importantly, there was a significant three-wayinteraction between word direction, visual motion and SOA, \(F_{1}(2,34)=3.56, M S E=456.7, p<.05, F_{2}(2,92)=3.03\), \(M S E=901.3, p=.05\). Separate analysis of the SOA conditions showed, that the three way interaction was due to the interaction between word direction and visual motion being significant for the 0 ms SOA condition only, \(F_{1}(1,17)\) \(=8.64, M S E=585, p<.01, F_{2}(1,46)=6.43, M S E=790, p\) \(<.05\) and not for the \(100 \mathrm{~ms} \mathrm{SOA}, F_{1}(1,17)=0.01, M S E=\) \(483.4, p=.94, F_{2}(1,46)=0.96, M S E=839.9, p<.033\) or the \(200 \mathrm{~ms} \mathrm{SOA}, F_{1}(1,17)=0.00, M S E=491.1, p=.97\), \(F_{2}(1,46)=0.04, M S E=904.3, p<.84\). In summary, visual motion direction did interact with lexical processing. However, this was only in trials were word and visual motion display fully overlapped ( 0 ms SOA condition). Posthoc tests showed that this effect was due to faster classification of words referring to upward motion (e.g., rise, climb) if presented on the background of an upward motion in contrast to a downward motion, \(t_{1}(17)=-2.27, p<\) \(.05, t_{2}(23)=-2.40, p<.05\). In contrast word referring to a downward motion (e.g., fall, drip) were faster classified if presented on the background of a downward motion, this was reflected in a trend in the by-subject analysis, \(t_{1}(17)=\) \(1.93, p=.07, t_{2}(23)=1.24, p=.22\).

Figure 2: Reaction time results for the lexical decision task, separately for the three SOA conditions, the word direction and the visual motion direction. Error bars represent confidence intervals for within-subject designs according to Loftus and Masson (1994).

\section*{Discussion}

Converging evidence suggests that language processing is closely related to other cognitive functions and can affect visual and motor processing. Interestingly, some studies also report an effect of motor processes (e.g., Glenberg, Sato, \& Cattaneo, 2008) or visual processing (e.g., Kaschak et al., 2005; Meteyard et al., 2008) on language comprehension, suggesting direct involvement of visual and
motor processes during language understanding. Kaschak et al. (2005) reported that visual motion perception (e.g., downwards motion) interferes with understanding of sentences that imply compatible motions (e.g., "The confetti fell on the parade"). In contrast, Meteyard et al. showed that near-threshold visual motion facilitates lexical access to words that imply compatible motion directions. In the current experiment, we addressed the question whether above-threshold visual motion can affect lexical processing of motion verbs if the participants have no possibility to strategically ignore the visual information. Indeed, our results showed that in conditions where word display and visual motion display occurred simultaneously ( 0 ms SOA ) and persisted throughout the trial, visual motion patterns did interact with lexical processing of the motion verbs. More specifically, we found that upward motion words (e.g., rise) are processed faster if displayed against the background of an upward motion than against downward motion, and the opposite holds for downward motion verbs.

To our knowledge, these findings are the first that show an effect of above-threshold visual motion on single-word processing. But why do we not find interference effects as reported by Kaschak et al. (2005)? First of all, single-word processing might differ regarding the mechanisms how visual processing resources are activated during reading, thus language-vision interactions might occur at different time-points or processing stages. Indeed, previous studies showed that timing can play a crucial role and may determine whether facilitation or interference effects are found (e.g., Boulengner, Roy, Paulignan, Deprez, Jeannerod \& Nazir, 2006). Additionally, in our study we used motion patterns that were very different from Kaschak et al. (moving dot patterns vs. moving bars) and our moving dot patterns were only displayed during each trial. In contrast, Kaschak et al. (2005) displayed motion for as long as 35 s and motion display extended between trials. Moreover, sentences were presented auditory in Kaschak et al.'s study. Thus, differences in task parameters and language material might results in facilitation effects in our study. Indeed, we adapted our visual motion patterns from the study of Meteyard et al. who also reported facilitation effects in case of single-word processing and lexical decision tasks.

This directly leads to the next question: Why do we find a facilitation effect despite using above-threshold motion patterns that can be clearly classified as upward or downward moving motion pattern? In the study of Meteyard et al. these influences of visual motion on language understanding were only observed for near-threshold motion patterns. Previously it has been suggested that the influence of task-irrelevant sub-threshold motion patterns on task performance is stronger than the influence of suprathreshold motion patterns (Tsushima, Sasaki, \& Watanabe, 2006). The authors suggested that sub-threshold motion patterns are processed in the visual cortex similar to suprathreshold motion patterns; however in contrast to suprathreshold motion patterns sub-threshold motion patterns do not automatically result in recruitment of inhibitory control
from the lateral prefrontal cortex (LFPC) in order to inhibit the visual cortex activation (in MT+ ) and thus reduce the influence of the motion percept on responding. The fact that we do find an influence of supra-threshold visual motion patterns on lexical decision task might have several implications. First, as our motion display occurred throughout the whole trial participants might fail to recruit sufficient top-down control mechanisms in order to fully suppress the influence of the visual motion on performance. Additionally, if language processing and visual processing are directly related, small activation in the visual cortex might also be sufficient to influence language processes. Thus, due to top-down control inhibitory control from the LPFC that suppressed visual motion activation, the effects in our study might be rather small. Additionally, in the 100 ms and the 200 ms SOA condition, the LPFC suppression mechanisms on the MT+ activation might be stronger, as it might be easier to suppress the influence of a visual motion display that is delayed in onset to the critical stimulus. Further studies will be required to fully understand the interplay between the language and the visual system and the critical time intervals during language processing, where this interaction occurs.

In summary, our findings have several implications. First, our results suggest that visual motion can also affect language processing if visual motion is presented abovethreshold. Second, these findings pose a challenge to some findings in the motor domain. Typically, in motor tasks participants can see their arm or hand motion. Thus, if participants are instructed to perform a lexical decision task, decision times might be faster in compatible directions, because the visual input from the moving arm or hand will interact with lexical processing. Thus, given that our findings show that word processing interacts with visual motion perception, some findings in the motor domain might also be explained by perception of actual arm or hand movements. In future studies interactions between motor action and language need to be considered carefully, as potentially also being influenced by visual motion perception. In summary, our findings show that language processing and visual processing are closely interrelated. In paradigms, where participants cannot ignore or actively avoid motion perception, language processing can be facilitated by compatible visual motion.

\title{
Using Music as a Turn in Conversation in a Lesson
}

\author{
Sam Duffy (s.duffy@eecs.qmul.ac.uk) \\ Patrick G. T. Healey (ph@eecs.qmul.ac.uk) \\ Cognitive Science Research Group \\ School of Electronic Engineering and Computer Science \\ Queen Mary University of London \\ London, E1 4NS, United Kingdom

\begin{abstract}
Music is sometimes compared to language as a system of communication, however this comparison is usually at a generic formal, cultural or social level. This paper explores this analogy at the detailed level of interaction: to what extent can musical contributions act as conversational turns? We explore this question through an ethnographic study of music lessons. We describe a new transcription notation designed to capture the interactional details of musical contributions. Using this notation we show that although the ultimate objective of a lesson is development of musical performance, the detailed structure of the musical contributions depends on their interactional organisation. We show that musical contributions display interactional structure at the turn and sub-turn level and are closely integrated with other verbal and non-verbal cues as part of the unfolding conversation.
\end{abstract}

Keywords: music tuition; conversational turn; interaction; repair

\section*{Introduction}

Comparisons of music and speech are well documented, for example Feld and Fox (1994) critically review a broad interdisciplinary collection of anthropological work on the relationship of music to language. Besson, Chobert, and Marie (2011) take a cognitive approach, considering evidence for the bidirectional influence of musical expertise on speech processing and of linguistic expertise on the processing of harmonic sounds. Zatorre, Belin, and Penhune (2002) show that whilst each auditory cortex, in the left and right hemispheres of the brain, has been shown to favour processing of either music or speech, this complimentary specialisation should "be seen as arising from a single underlying principle rather than being unrelated phenomena".

In this paper we look at the relationship between music and speech in social interaction through the study of instrumental music lessons. We describe a new transcription notation designed to capture the interactional details of musical contributions. This is used to investigate the extent to which musical utterances produced during a lesson act as conversational turns. Initially we will summarise some of the characteristics and rules which govern turn taking in conversation. We will then look at the different, context-dependant roles that music can play in different types of interaction. We will use an ethnographic study of clarinet lessons to provide examples of the interplay between music and speech in a pedagogical setting

\section*{What is a Turn?}

In conversation, the participants manage their exchange of units of speech. Sacks, Schegloff, and Jefferson (1974) set out
rules describing the mechanics of how this is achieved, identifying dialogue as a turn organised activity. In order to investigate any turn taking system, be it playing a game of cards or managing a queue, there is a need to define what constitutes a turn. In conversation analysis, the building block for turns is the turn construction unit (TCU), which can be formed from a single word or utterance, a sentence, or a phrase. As one speaker approaches the possible completion of a TCU, another speaker may recognise this as a transition-relevance place (TRP) where they can take the floor. However this is an opportunity rather than an obligation. It may be that the current speaker starts a new TCU and continues with their turn. Since it is possible to predict when turns are heading towards completion, the next speaker can often start their turn without a perceivable gap in the conversation, or even start before the current speaker has finished, causing a brief overlap. Whilst we do not usually talk at the same time as someone else for prolonged periods, brief overlaps like this at transition points are frequent. To investigate these rules in action, a set of notations was proposed for use in conversation analysis transcripts (for example see Figure 1).
```

// The point in the current speaker's speech where overlap
y the other starts
The point where overlap finishes
= latching (no interval between two pieces of talk
() elapsed time in tenths of seconds, used to denote
pauses and silence
Prior syllable is prolonged
empty parenthesis indicate an utterance which could not
be clearly heard
double parenthesis indicate features other than
verbalisation

```

Figure 1: Conversation analysis notation (Sacks et al., 1974)

\section*{Non-verbal interaction}

The gestures which accompany speech are an important scaffold to conversation as well as an integral part of interaction. Bavelas, Chovil, Lawrie, and Wade (1992) explain that conversation is not made up of alternating monologues but is an interactive social system, and show that interactive gestures are essential in maintaining conversation. Cassell and Thorisson (1999) describe the importance of envelope feedback, non-verbal accompaniments to speech such as beat gestures, gaze and head turns. Engle (1998) demonstrate that when gesture and speech are consistent with respect to the underlying referent, they are understood as composite signals rather than separate channels. Clark and Krych (2004) show the im-
portance of visual modality to collaborative work with shared objects, gesturing in relation to an object whilst another is speaking effectively reducing the number of turns required for task completion. Non-verbal interactions can also function as a turn in themselves, the expected response to a verbal turn taking the form of physical activity rather than speech. For example, a request at the family dinner table during a busy multi-party conversation to pass the butter can be actioned without any reference in the continuing conversation (E. A. Schegloff, 2007, pp. 10 Chicken Dinner).

In the same way that gestures act as a scaffold to to speech, non-verbal interaction is vital to the co-ordination of musical sound production. In jazz, a solo may be scored as for a prescribed number of bars with a chord structure, but it may also be open, thrown around the group for others to take a turn or even choose to play against each other, so non-verbal communication with fellow performers is important to manage improvisation. Observing a group of musicians engaged in free improvisation sessions, Healey, Leach, and Bryan-Kinns (2005) found that the musicians used the patterns of body position and orientation, or f-formations (Kendon, 1990) typical of face-to-face conversation to organise the timing of their musical contributions. Moran (2011) observes a group of North Indian musicians whose vocal and bodily responses to musical ideas could be interpreted as comparable to the function of back channelling in everyday conversation. Even in the performance of a predetermined composed score, an ensemble must synchronise entrances and exits, and changes in dynamics and tempo and this is usually achieved by gestures, head and body movement and gaze. In an analysis of co-ordination between members of a string quartet, Davidson and Good (2002) wrote "The nature of the interaction and coordination in conversation are, we believe, analogous to that in small group music-making contexts."

\section*{Turn breakdown and self repair}

An important part of maintaining conversation is dealing with turn-taking errors or rule violations such as a misunderstandings, interruptions, gaps and overlaps. These are frequent in natural dialogue and we manage these breakdowns through repair. Self-repair occurs when the current speaker manages an error within the same turn in which it was made. To do this, the speaker must be able to self-monitor and detect a problem in what they are saying, or see some outward sign of the listener's confusion. Correction is made promptly once the problem has been detected, a neutral holding term such as 'uh' often being used to communicate error detection to the listener and so hold the turn for the self-repair to be made (Levelt, 1983). Self-repair occurs much more frequently than other-initiated repair in natural speech. However even if the other speaker initiates repair, they are much more likely to encourage the original speaker to correct themselves, rather than make a direct correction (E. Schegloff, Jefferson, \& Sacks, 1977).

\section*{The Role of Music in a Pedagogical Context}

There are many different types of interaction involving the production of music. From an ethnomethodological perspective, the social norms which govern how members of a group understand their world and so behave in it (Garfinkel, 1964) are relevant to any interaction, whatever the mode of communication. The context of a musical interaction is therefore important in determining the roles of the participants and the communication content of the music produced. Players in an ensemble rehearsal will use verbal interaction to analyse, discuss and shape their approach to a piece. During a performance, they cannot use the same level of verbal interaction unless they want to share their inner workings with the audience. A soloist is not generally expecting to enter into a dialogue with the audience, however they may engage in extensive non-verbal interaction with fellow performers and the conductor, as part of co-ordinating their performance with an orchestra.

In a pedagogical context, such as an instrumental lesson, both student and tutor produce music but it is subject to immediate scrutiny, their musical utterances being produced with the expectation of immediate feedback. The tutor is not listening to the performance from the perspective of an audience member, but as an expert critic and must be able to immediately verbalise their assessment of the student's performance. In order to prepare a complete piece or movement, they will focus on a small part of it each week, building up the work gradually. Small fragments of music, perhaps only a few bars, are worked on at a time. The student plays them, receives feedback, then plays them again for the tutor to assess if they have incorporated the feedback, and so on in an iterative process.

\section*{Representing Music in a transcript}

It is surprising how few authors looking at interaction in a musical context attempt to represent the musical sounds produced. When they do, one approach is to use musical notation to locate activity on a musical timeline, for example Figure 2 (Holck, 2002). However this presentation is less meaningful for those who do not read music.

In applying the rules of conversation analysis to musical utterances, our notation needs to be comprehensible to those who are used to working with transcripts, whilst being able to capture the interactionally relevant aspects of music production. A system has been devised with two main aims: to make representation of the music understandable for both musicians and non-musicians, and make it possible for a written transcript to convey the full interaction whether utterances are verbal or musical. The starting point was established notation for conversational analysis as shown in Figure 1. This was adapted to produce notation for musical sounds as shown in Figure 3.

Figure 2: Extract from a transcript using musical notation. English translation used with permission Holck (2007, pp 33)
\begin{tabular}{|c|c|}
\hline (1.4) & Long single note and duration \\
\hline - - _ - \({ }^{(2.3)}\) & Short notes in a musical phrase (duration optional) \\
\hline \(\uparrow_{\sim}\) _ _ (1.2) & Rising passage of notes \\
\hline \(\downarrow_{\sim}\) _ _ (2.1) & Falling passage of notes \\
\hline , , , (1.2) & Breath in and duration \\
\hline _//__(1.5) & Interrupted long note \\
\hline [ & Beginning of overlap (verbal or musical) \\
\hline ] & End of overlap \\
\hline \{first octave\} & Additional information for music notation \\
\hline ((smiles)) & Features other than verbalisation e.g.gestures \\
\hline
\end{tabular}

Figure 3: Notation devised to represent musical sounds.

\section*{Applying Musical Notation to Data}

We have observed clarinet lessons with four students and two tutors at two music schools in London which prepare young adults for the study of performance at an undergraduate level. For explanatory purposes we focus on the turn-like organisation of musical contributions in one lesson however, we have found that these phenomena recur across the sample. The student is a male clarinet player studying for his grade eight exam. Throughout, we will indicate the areas of interest which are to be the subject of further work using the broader dataset which has been collected.

\section*{Non-verbal interaction as a scaffold for musical utterances}

The student is being tested on playing scales from memory. The tutor holds a small book containing the syllabus in her hands, at chest height. The student is holding his clarinet in front of his body with both hands and they are facing each other. The tutor has asked him to play a three octave scale. There are eight notes in an octave, the last note and the first note are the same, the last note being an octave higher in pitch. To simplify our transcript, we can represent this as numbers rather than notes \(12345678(1)\), where 8 represents the top of the scale. To play a scale over several octaves you would play seven notes, then start the next octave so a three octave scale could be represented as 1234567123

456712345678 . The instances of octaves are shown separately on the transcript below for clarity. The student (S) is expected to play all three octaves ascending and then descending in one smooth phrase. He commences the ascending scale, flicking his eyes up to the tutor (T) occasionally, but makes an unpleasant squeak at the start of note 7 of the third octave. He elongates this note and then briefly stops playing (Figure 4).
```

T: OK great (0.33) Ah let's have (0.44) F sharp major
((T moves head up from book to look at student))
(0.82) tongued
((S brings clarinet up to mouth))
so by tongued I mean legato [tongued you know
[yeah
((T looks back down to her book))
S: ' ' '(0.82)
=\uparrow1_2_3_4_[5]_6]_7_ {first octave}
[S glances briefly up at tutor]
=\uparrow1_[2]_3_4_5_6_7_ {second octave}
[S glances briefly up at tutor]
=\uparrow 1_2_3_4_5_6_ {third octave}
={squeak} 7

```
\(\qquad\)
``` (0.75)
    pause (0.16)
    =\uparrow [8__] (0.75)
    [S looks up at tutor and raises eyebrows]
S: the[re? ((speaks with clarinet still in mouth))
    [because you want E sharp here
```

Figure 4: The student seeks guidance musically and verbally.

The tutor does not change her position or gaze, or seek to interrupt in this brief pause, and the student continues with the next note in the scale (note 8) again elongating it, looking up at the tutor as he plays and raising his eyebrows. This is a possible parallel with Levelt's word-completion hypothesis (Levelt, 1983) in which it is suggested that speakers have a tendency to complete words after detection of trouble. Musicians may exhibit a similar tendency to finish a musical idea, although this does not always happen, since examples of the student restarting mid-phrase after a mistake have also been found. The circumstances around whether the student finishes a phrase or restarts mid-phrase is a potential area of further investigation. The tutor still does not visibly react. Rather than continue with the scale (which would now be the three octave descent), the student stops and verbally seeks guidance 'there?' with the clarinet still in his mouth (Figure 5). Finally she responds, verbally indicating that the error was with the note that played by not referring to the squeak.

The tutor puts her book down on the music stand, turns away and picks up her clarinet from its resting place on the piano. She then twists her body back to look up and meet the student's gaze as he retries the top of the scale tentatively (Figure 6). They continue to make frequent brief direct eye contact and the tutor nods and encourages him verbally 'yeah' as he starts the descent. He continues down the scale, picking

Figure 5: The student seeks verbal guidance "There?"
up speed to finish with a confident long final note. The tutor continues to hold her clarinet close to her mouth but does not play, letting him finish before giving verbal feedback on the rest of the scale.

```
S: _ _ _ _ `7_8_ {resumes third ascending octave}
S: =
    tentatively}
    [yeah
    [((T nods several times at S))
T holds clarinet in front of her, gaze resting on S
playing, mouthpiece remains several inches below her
mouth
S: +4_3_2_1 {continues third octave, resumes tempo
    and fluidity}
    =\downarrow7_6_5_4_3_2_1{second octave}
    =\downarrow7_6_5_4_3_2_{first octave} =1____{last note}
```

Figure 6: The student continues after encouragement

In this short vignette we see the student's use of gaze to seek feedback whilst playing. When this is unacknowledged, it is escalated to a verbal utterance. When gaze is used to seek a response again but encouragement is received, the student continues to play without seeking feedback verbally. We then see how the student uses tempo to express confidence in the descent, holding the turn long enough to complete the scale. Speeding up talk has been shown to be a way to hold on to a turn (Button, 1993).

## Delayed interruption

We have previously noted that in a music lesson, where a verbal request by the tutor is usually followed by a musical response, it is reasonable to assume that this musical phrase is analogous to a conversational turn, and we should therefore be able to see the characteristics of turn management (Duffy \& Healey, 2012). The tutor will often interrupt the student's playing once a problem has been detected. However rather than stop them as soon as the error has occurred, the end of a musical phrase is preferred by the tutor as a TRP to take the turn, even if they have detected the problem earlier. During the short period of time between detection and interruption, the tutor's non-verbal behaviour reveals their intention to interrupt, such as moving in closer to the music, raising their
arms from their listening pose or picking up a pencil (to write an instruction on the score). If the tutor decides to demonstrate the fragment, they start to pick up their instrument, or bring it closer to a playing position, whilst the student finishes the phrase. Student and tutor will not deliberately play at the same time during this part of the lesson, however we will see later that brief overlap does occur.

We will now examine this in more detail using the notation devised. In this extract, student and tutor have been working on an exam piece together for several weeks (Clarinet Sonata in Eb Major Op. 167 Mvmt IV Molto Allegro by Saint-Saens). It includes passages of ascending and descending scales and arpeggios which are challenging to play fluidly. The tutor suggests that they pick up where they left off the previous week. The student starts by playing the phrase shown in Figure 7 however he plays a wrong note from a different scale which changes the tonality of the passage. The tutor indicates that she has noticed the error by adjusting her gaze and listening position but does not interrupt the student yet. He restarts mid-phrase, from just before the error (Figure 7). This may be for the benefit of the tutor, who has to solve a continuation problem, i.e., how to relate the repair to the original utterance (Levelt, 1983) or for his own benefit in ease of correction. The choice of where to start a musical self-repair is another area worthy of further investigation.

Figure 7: Bars 118-120 Clarinet Sonata in Eb Major Mvmt IV Publisher Durand, 1921. Plate D. \& F. 10,063, Paris.

The tutor moves closer to the score with her pencil and as the student reaches the long note at the end of the phrase, she talks over it and moves the pencil towards the score (Figure 8). We see that rather than interrupt mid-phrase, she lets the student attempt self-repair, only taking over the turn at the TRP presented by the long note at the end of the phrase.
: ${ }^{\uparrow}-----{ }^{\downarrow}--------{ }^{*}$ \{*error, wrong note\} T turns head up from music to the student, moves in from her listening position but does not say anything.
$S$ blows into the clarinet and restarts from just before the error, playing more slowly.
S: [\downarrow- -- - - - `_] [ [\downarrow- - - - ] S: [\downarrow- -- - - - `_] [ [\downarrow- - - - ]
[T pícks`\mp@code{up pencil] [T moves into score with pencil]}     [T pícks`\mp@code{up pencil] [T moves into score with pencil]}
//_(1.37) {final note of phrase}
//_(1.37) {final note of phrase}
T: //ok so make sure that it's A major not E major.
T: //ok so make sure that it's A major not E major.

Figure 8: The tutor delays interruption

## Using 'readiness to play' to signal the intent to interrupt

Here we will see how the tutor uses the position of her clarinet to indicate her 'readiness to play', effectively taking the floor through playing. The student has become stuck on a particular section and the tutor has decided that they will practice it together. She picks up her clarinet and demonstrates the phrase in full at a steady pace, as they both read from the student's score (Figure 9). The tutor bounces her clarinet bell to emphasis the rhythm of the phrase and briefly glances at the student, who is still looking at the score. He starts to nod in time with her clarinet bell, signalling his attention to the demonstration in response to the tutor's checking glance.

```
T plays the phrase in full, at steady pace.
T: }\mp@subsup{\uparrow}{\uparrow}{+
    ((*)
T: Just ((T points to the score))
    //that section (0.2) OK?
S://There?
S brings arm up and points to the score
S: What, just there?=
T: =((nods)) Just do what I've just played
```

Figure 9: The tutor plays the phrase to be worked on in full

The student then tries the phrase himself as directed. He makes several undesirable squeaking sounds in place of the expected notes (Figure10) and as he exhales loudly, the tutor turns towards him.

```
S: ' ' \(\quad(0.6)^{\uparrow}---\{\) squeak \} \{squeak\}
: ((exhales audibiy))
```

Figure 10: The student makes undesirable squeaking sounds

She brings her left hand up to clasp the barrel of her instrument, which she had been holding in her right hand. By moving from holding her clarinet in just one hand, to both hands, the tutor is signalling an intention to interrupt through demonstration. However the student restarts the phrase and the tutor brings her right hand back down to her side. Now she is holding her clarinet in just one hand again, using the change in state of readiness to play to signal that he should keep the turn and continue playing.
This time he manages a substantial part of the phrase without any mistakes however he plays an incorrect note on starting the final scale descent. As he restarts and makes a further mistake, the tutor moves her clarinet back to playing position in three stages, first by bringing her left hand back to the instrument body, then raising the clarinet vertically in her hands so that they are closer the the keys, and then bringing the mouthpiece towards her mouth. Each time she brings the
clarinet closer to the playing position, she is escalating the likelihood of interruption (Figure 11). The student lowers his mouthpiece as soon as he finishes his last note, even though on this final attempt he has played the last part of the phrase correctly. The tutor takes over straight away and plays the end of the phrase that the he has been struggling with.

```
((T moves hands on clarinet closer to keys))
S: &_ _ [_]* {*last two notes are incorrect}
        [T raises clarinet closer to lips]
S: \downarrow_ _ _ **
{**last two notes incorrect, last note distorted}
S: \downarrow_ - - - [___]
        [T places clarinet in mouth]
```

Figure 11: Escalation of visible intention to interrupt

## Self-repair and overlap

Continuing straight on from the last extract we now see the pair negotiate moving into a period of exchanging musical turns. The student takes the floor again in order to try the phrase himself. They now enter a period of alternating turns with brief overlaps, repeating the same phrase again and again, small corrections to the phrasing and rhythm being made by the tutor on each round (Figure 12). The tutor keeps her clarinet in her mouth during the student's turns, resting on her bottom lip, only lifting her top lip to take in breath between playing. The student briefly lowers his clarinet from his mouth during the tutor's turns, indication perhaps that the tutor is going to continue until the phrase is right whilst the student would like to move on.

Figure 12: Student and tutor alternate the same phrase

Then the tutor elongates the phrase, adding in more notes at the beginning and the student copies her, again overlapping with her last note. He manages to play this longer extract, but the tutor repeats it, implying there is still something that needs correction. On his second attempt, the student stumbles after just two notes. He then exhales noisily and continues, restarting twice at mistakes. The tutor keeps her clarinet in her mouth and small head movements indicate that she is preparing to take the floor from the student, however she does let him get to the end of the phrase (Figure 13).

The tutor allows a brief pause before playing the full phrase at a much faster tempo than previously. The student tries to match her but soon stumbles, however the tutor has removed her clarinet from her mouth now and she lets him self repair (Figure 14).

Figure 13: The tutor elongates the phrase

```
T: \
    \uparrow------------------- 
    ((pause (1.33) restarts from error))
S: \downarrow_ _ _ _ _ _ _ _ _ _ _ \uparrow _ _ \downarrow_ _ _
```

Figure 14: The tutor allows the student to self-repair

## A Final Note

It is worth noting that some findings around turn taking mechanisms cannot be so easily applied to the production of music. The phrases played by a clarinetist are defined by the structure of the music - both in terms of notes and phrasing, complete bars, tempo and breathing. Hence some of the recognised ways to manage and hold turns are not available to the player. With a woodwind instrument, holding a turn through an in-breath (Button, 1993) is not always possible since sound production relies on breathing out. It is also difficult to use speed to hold a turn when control of tempo (either consistent speed or dictated rallentando or accelerando) is a goal. Whilst we saw this device used during the part of the lesson devoted to scales, it is less likely to be employed when the student is performing a piece of music for the tutor.

## Acknowledgments

The authors would like to thank the students and tutors who participated in these studies. This work is supported by the Media and Arts Technology programme, EPSRC Doctoral Training Centre EP/G03723X/1.

# Object-based Saliency as a Predictor of Attention in Visual Tasks 

Michal Dziemianko (m.dziemianko@sms.ed.ac.uk) Alasdair Clarke (a.clarke@ed.ac.uk) Frank Keller (keller@inf.ed.ac.uk)<br>Institute for Language, Cognition and Computation<br>School of Informatics, University of Edinburgh<br>10 Crichton Street, Edinburgh EH8 9AB, UK

#### Abstract

The top-down guidance of visual attention is an important factor allowing humans to effectively process incoming visual information. Our understanding of the processes governing attention is not complete, with growing evidence for attention selection based on cognitive relevance. In this paper, we investigate whether models for salient object detection from computer vision can be used to predict attentional shifts in visual tasks. Our results show that the object-based interpretation of saliency provided by these models is a substantially better predictor of fixation locations than traditional pixel-based saliency.

Keywords: eye-tacking; saliency; visual attention.

## Introduction

Virtually every human activity occurs within a visual context and many tasks require visual attention in order of be successfully accomplished (Land \& Hayhoe, 2001). When processing a visual scene, humans have to localize objects, identify them, and establish their spatial relations. The eyemovements involved in this process provide important information about the cognitive processes that unfold during scene comprehension.

A number of models have been proposed to predict eyemovements during scene processing and they can be broadly divided into two categories. The first category consists of bottom-up models that exploit low-level visual features to predict areas likely to be fixated. A number of studies have shown that certain features and their statistical unexpectedness attract human attention (e.g., Bruce \& Tsotsos, 2006). Moreover, low-level features are believed to contribute to the selection of fixated areas, especially when the visual input does not provide useful high-level information (Peters et al., 2005). These experimental results are captured by models that detect salient areas in the visual input and use them to predict attention. The best-known example is the model of Itti et al. (1998), which builds a pixel-based saliency map using color, orientation, and scale filters inspired by neurobiological results.

The second group of models assumes that top-down supervision of attention contributes to the selection of fixation targets (e.g., Torralba et al., 2006). Various types of such supervision have been observed experimentally. Humans show the ability to learn general statistics of the appearance, position, size, spatial arrangement of objects, and their relationships (e.g., Zelinsky, 2008). They also exploit visual memory during scene comprehension tasks (e.g., Shore \& Klein, 2000). Moreover, studies such as those of Chun \& Jiang
(1998) show that participants benefit from learning spatial arrangement of the objects in consecutive searches. Theoretically, such results can be accommodated by the Cognitive Relevance Framework (Henderson et al., 2009), which assumes that attention is allocated to locations that are cognitively relevant for the task performed.

Cognitive relevance predicts that objects should have a privileged status in visual processing, which is in line with experimental evidence suggesting that the allocation of attention is object-based rather than pixel-based. For example, Henderson et al. (2007) argue that saliency does not account for fixated areas in visual search, while Nuthmann \& Henderson (2010) show that the preferred fixation point or landing position is the center of an object: fixations are distributed normally around an object's center of mass, where the spread might be explained by oculomotor errors. Consistent with this, Einhauser et al. (2008) show that the position of objects is a better predictor of fixations than early saliency in tasks such as artistic evaluation, analysis of content, and search.

An alternative view on saliency comes from the computer vision literature, which deals with task of salient object detection: the objects that are perceived by humans as visually most interesting have to be separated from the background. Typically this involves image segmentation and the calculation of visual features in order to select pixels belonging to salient objects. In this context, saliency is a feature of an object, rather than an early pixel-based attractor of attention.

In this paper, we investigate the extent to which methods proposed for salient object detection can be applied to the prediction of fixations. We are not concerned with the prediction of salient image patches, but rather with the selection of objects that are likely to be fixated. This approach allows us to develop computational models of attentional selection based on cognitive relevance defined over objects (Henderson et al., 2007, 2009). We compare the performance of this approach to traditional models which predict fixation locations using pixel-based saliency maps.

## Background

As discussed above, there is experimental evidence for the object-based allocation of attention. Additionally, some objects seem to inherently attract more attention than others, a fact that has been conceptualized using proto-objects: pre-recognition entities that draw attention (Rensink, 2000). Proto-objects have been incorporated into saliency-based models (Walther \& Koch, 2006) and have also been applied

Figure 1: Example of proto-objects extracted from an image using the model of Walther \& Koch (2006). From left to right: original image, saliency map computed according to Itti et al. (1998), proto-object mask. The salient patches, and hence the proto-objects, do not necessarily correspond to the real objects in the scene.
in robotics to create attentional systems for virtual and physical agents (see e.g., Yu et al., 2010). These models perform image segmentation to identify proto-objects: the image is divided into a collection of regions that correspond to areas enclosed by constant, high saliency values. Figure 1 shows an example of such proto-objects extracted from an image using the model of Walther \& Koch (2006).

While Walther and Koch's model is conceptually interesting, its cognitive status is questionable, as there is evidence that it does not predict fixation locations well (Nuthmann \& Henderson, 2010). Alternative models of attention selection based on objects rather than proto-objects have been proposed in computer vision. For example, the work of Liu et al. (2011) focuses on detecting objects annotated by people as salient. These models use machine learning techniques to compute which arrangements of visual features such as center-surround histograms, orientation, scale are perceived as salient. However, in a computer vision context, attentional selection is regarded merely as an engineering task: the aim is to identify areas matching pre-annotated training data, rather than to gain a greater understanding of human behavior.

## Models

We implemented and evaluated three models for salient object detection. Throughout our work we assume that the images are fully annotated with object boundaries, therefore the problem of segmentation and separation of objects from the background does not need to be solved within the models. This assumption makes it possible to evaluate object-based saliency models separately from image segmentation algorithms, which can vary widely in their performance.

## A. Conversion of Standard Saliency

Standard, pixel-based saliency is the baseline against which we evaluate object-based models. The baseline model we use is Torralba et al.'s (2006), which approximates saliency as the probability of the local images feature $L$ in a given location based on the global distribution of these features:

$$
\begin{equation*}
p(L) \propto e^{-\frac{1}{2}\left[(L-\mu)^{T} \Sigma^{-1}(L-\mu)\right]} \tag{1}
\end{equation*}
$$

Here, $\mu$ is the mean vector and $\Sigma$ the covariance matrix of the Gaussian distribution of local features estimated over the
currently processed image. The local features are computed as a set of Steerable pyramid responses computed over three color channels for six orientations and four scales, totaling 72 values at each position.

Based Torralba et al.'s model, we can define a group of models which convert pixel-based saliency values to objectbased salience scores. Such a conversion can be performed by computing functions such as the maximum, mean, median, or mode of the pixels that make up an object. Examples for the use of this method exist in the literature (e.g., Spain \& Perona, 2011), with maximum and mean being common. These models will be referred to as converted in this paper.

## B. Liu et al. Features

Liu et al. (2011) describes a system for salient object detection based on conditional random fields, which simultaneously segments pixels into areas corresponding to objects and computes the pixel's salience. The model is based on three feature channels - contrast, center-surround histograms and spatial color - which are described below. The salience of a pixel is defined to be the a weighted sum of these three feature maps, while the salience of an object is defined as the sum over all pixels within the object's boundary. The full specification of our implementation of Liu's model can be found in Dziemianko (2013). Examples of the feature channels are given in Figure 3.

Multiscale Contrast Contrast is one of the most commonly used features in saliency models and is implemented over a multiscale Gaussian pyramid. In each layer of the pyramid, the contrast at pixel $(x, y)$ is defined to be the mean squared difference of the intensity of pixel at $(x, y)$ and its adjacent neighbors. The multiscale contrast for $I(x, y)$ is then taken to be the sum over the layers of the corresponding pyramid. This has the effect of approximating human receptive field by highlighting high-contrast boundaries while omitting homogeneous regions within objects.

Center-Surround Histograms One of the weaknesses of previous measures of visual salience is that, due to their reliance on high-contrast center-surround features, they tend to emphasis the boundaries of objects while giving very low scores to pixels within an object's boundary (see Figure 2). To tackle this issue, Liu et al. (2011) propose to use region-based features in addition to the center-surrounds described above. These are computed by considering the histogram of colors within an object's bounding box, and comparing it with a surrounding region of equal area (see Figure 2). The $\chi^{2}$ metric is used to measure the distance between histograms and the full details on how these regions are constructed can be found in Liu et al. (2011).
Color Spatial Distribution The last feature used by Liu et al. (2011) is the spatial color distribution, motivated by the observation that salient objects are less likely to contain colors that are distributed widely throughout the image. A simple method for quantifying this is to compute the spatial vari-

Figure 2: An example of high saliency values being assigned to object boundaries due to its reliance on high-contrast features. From left to right: original image, traditional saliency, an object (red) and its surrounding area (green).

Figure 3: Examples of features from Liu et al. (2011). From left to right: original image, multiscale contrast, centersurround histogram, color spatial distribution (image from Liu et al. (2011) with modifications).
ance of color. This involves representing the distribution of colors contained in the image by a Gaussian mixture model. We then carry out soft assignment: for each of these Gaussians, $c$, we then calculate $p(c \mid I(x, y))$, the probability of assigning pixel $I(x, y)$ to the Gaussian $\mathcal{N}\left(\mu_{c}, \Sigma_{c}\right)$. Using these we can calculate the weighted mean and variance for each color component along the horizontal axis:

$$
\begin{align*}
M_{h}(c) & =\frac{1}{|X|_{c}} \sum_{x} p(c \mid I(x, y)) \cdot x  \tag{2}\\
V_{h}(c) & =\frac{1}{|X|_{c}} \sum_{x} p(c \mid I(x, y)) \cdot\left|x-M_{h}(c)\right|^{2} \tag{3}
\end{align*}
$$

where $|X|_{c}=\sum_{x} p\left(c \mid I_{x}\right)$. The vertical spatial variance, $V_{v}$, is computed in the same way, and $V(c)$, the spatial variance of each color component, is then simply defined as:

$$
\begin{equation*}
V(c)=V_{h}(c)+V_{v}(c) \tag{4}
\end{equation*}
$$

Finally, the feature function $f_{s}(x, y)$ is defined as:

$$
\begin{equation*}
f_{s}(x, y) \propto \sum_{c} p(c \mid I(x, y)) \cdot(1-V(c)) \tag{5}
\end{equation*}
$$

## C. Color-component Histograms

In addition to the models described above, we have implemented our own model based on a simplified factored shapes and appearances representation (Eslami \& Williams, 2011). This model shares some characteristics with the spatial color distribution described above, as it assumes that the pixels corresponding to each object have been generated by a number of Gaussians in a feature space (we found Lab-space to be

Figure 4: Examples of scenes used in the visual counting experiment. Targets on the images on the left and in center are man, while for the image on the right it is goggle.
the most effective). However, it performs a comparison of histograms of color cluster assignments within the object and its surrounding area.

In the first phase, the means $\mu$ and covariances $\Sigma$ of these Gaussians are extracted by fitting a Gaussian mixture model (GMM) with $W$ components over all pixels in the image. Similar to Eslami \& Williams (2011), we use $W=15$ Gaussians. At this stage object boundaries and locations are ignored. In the subsequent step, pixels are clustered into $W$ clusters according to the associated GMM components by selecting a component, $\hat{w}$, that maximizes the probability of a pixel being drawn from the Gaussian distribution. The final step of the first phase consists of computing global histograms $H$ of the pixel assignments $\hat{w}$ representing the proportion of pixels belonging to each cluster.

The saliency scores are computed in the second phase. At this stage, the model assumes that the image is fully annotated (i.e., boundaries for each object within the scene are provided). For each object in the scene, we calculate the histogram of pixel assignments over the pixels within the object's boundary. We then define an interestingness value for each object as the Kullback-Leibler (KL) divergence between the local (object) pixel distribution and the global distribution $H$. Intuitively, I represents how different the object is from its surroundings and thus interesting.

## Evaluation

## Method

We evaluate the performance of the models discussed on eyetracking data collected in a visual counting and an object naming task. In the visual counting task, 25 participants were asked to count the number of occurrences of a cued target object, which was either animate (e.g., man) or inanimate (e.g., goggle). The data set consisted of 72 fully objectannotated photo-realistic scenes (both indoor and outdoor), with total of 1809 polygons with mean of $25.12 \pm 11$ and a median of 25 polygons per image, containing zero to three instances of the target object. The data was collected using an Eyelink II head-mounted eye-tracker with a sampling rate of 500 Hz . The images were displayed with a resolution of $1024 \times 768$ pixels, subtending a visual field of approximately $34 \times 30$ degrees. The data set consists of 54,029 fixations. Figure 4 presents examples of scenes used in the experiment.

The object naming dataset (Clarke et al., under revision) contains data collected during an object naming experiment.

Figure 5: Examples of stimuli used in the object naming experiment. Typical responses are: cars, crossing, person for the left, bench, man for the center, and barbecue, charcoal, chimney for the right image.

The stimuli consists 132 fully object-annotated images with a total of 2,858 polygons with mean of $14.2 \pm 5$ and a median of 26 polygons per image. The images were presented to 24 participants after the task was explained using written instructions. Before each trial, participants were asked to fixate a central cross. The image was then displayed for 5000 ms , followed by a beep, after which the participants named objects present in the scene. The image was displayed until the participant finished the trial. Image presentation and apparatus were the same as in the visual counting data set. A total of 2,904 usable trials were collected, resulting in 88,371 fixations. Examples of images used as stimuli are shown in Figure 5.

## Analysis

As well as the models described above, we test two baselines that do not use saliency in any form. The first one weights objects by their Euclidean distance from the center of the image, normalized by object area. This approach is inspired by experimental evidence of center bias in scene viewing (e.g. Tatler, 2007), and will be referred to as center bias.

Secondly, based on the findings of Nuthmann \& Henderson (2010), we also include a baseline that predicts fixations by selecting object centers. In this case, a map is built as a sum of Gaussians centered on the bounding boxes of the object in the image. The covariances of the Gaussians are dependent on object's size, with a factor fitted using 10-fold cross-validation to avoid overfitting the datasets. This baseline is referred to as object overlay.

In the Results and Discussion section below, we show how the different models perform by using receiver operating characteristic (ROC) plots, which indicate the sensitivity (i.e., true positive rate vs. false positive rate) of a classifier as its discrimination threshold varies. Moreover, in order to statistically compare model performance, we calculate the area under the ROC curve (AUC) of each participant. The AUC measures the probability that a classifier will rank a randomly chosen positive instance higher than a randomly chosen negative one. ${ }^{1}$ We submit the AUC means to an ANOVA analysis to compare the performance of the different models pairwise, e.g., saliency against converted (mean). For standard pixelbased saliency, the ROC curve is constructed by thresholding

[^255]| Model | Obj. counting | Obj. naming |
| :--- | :---: | :---: |
| Saliency | 61.66 | 55.87 |
| Object overlay | 63.60 | 59.78 |
| Center bias | 68.02 | 69.17 |
| Converted (max) | 55.27 | 64.66 |
| Converted (mean) | 70.44 | 68.65 |
| Liu et al. 2011 features | 66.67 | 67.42 |
| Color-component hist. | 66.73 | 67.40 |

Table 1: Estimated percentage areas under the ROC curves presented in Figure 6.
the saliency values to select the desired proportion of pixels. The ROC plots for object-based models can not be constructed this method as it would not ensure that entire objects are selected. Instead, an increasing number of objects with the highest saliency values is iteratively selected, and their total area is plotted in the ROC curve. The ROC curves constructed this way are incomplete, representing only selection of up to about $50 \%$ of the image area. Constructing ROC plot for larger selections would result in significant discontinuities due to the fact of all small objects being already selected and essentially only large objects corresponding to surfaces such as floor, sky, or wall being left.

## Results and Discussion

The results are presented in Figure 6. The ROC curves show that selection based on object overlay is better than saliency for thresholds smaller than $40 \%$. Object-based saliency models in turn outperform object overlay. Center bias turns out to be a very competitive baseline, which is only matched by converted (mean).

An analysis of the areas under the ROCs, summarized in Table 1, confirm these observations. The ANOVAs reveal that for both datasets, object position overlay is significantly better than saliency with $F(1,24)=9.27, p<0.005$ for object counting, and $F(1,23)=9,84, p<0.005$ for object naming.

The calculation of area under ROC curve for object-based models is not trivial due to the discontinuity of the plot. We estimated the AUC by interpolating the missing values. ${ }^{2}$ The analysis of the interpolated curves shows that for both datasets, object-based selection is superior to traditional saliency, and to object overlay. These differences are statistically significant, for example converted (mean) is better than saliency with $F(1,24)=165.60, p<0.001$ for counting and $F(1,23)=279.30, p<0.001$ for naming; for color histogram the values are $F(1,24)=34.67, p<0.001$ and $F(1,24)=227.40, p<0.001$ respectively.

The pattern for Converted (max) is more complicated. On the naming data, it is significantly better than saliency $(F(1,24)=132.10, p<0.001)$, but not as good as any of the other methods. On the counting data, it is significantly weaker than standard saliency $(F(1,23)=245.70, p<$

[^256]

Figure 6: Performance of object-based selection of fixation locations on the Visual Count (top) and Object Naming (bottom) datasets. Note that traditional saliency and object-based models cannot be compared directly due to differences in the selection method, see text for details.
0.001 ), operating around chance level. This can be explained by the fact that saliency is sensitive to high contrast edges, usually corresponding to object boundaries. As such, the highest saliency values corresponding to the object might not
fall within the object, but rather belong to its neighbors.
A surprising results is that object-based selection does not outperform selection based on center bias. However, closer investigation of the object rankings based on center bias and

Converted (mean) reveals that the average correlation coefficient between the respective rankings is only 0.50 for the naming and 0.43 for the counting data. This indicates that different sets of objects are selected by the two model for a given threshold, accounting for different subsets of fixations. A combined model would be a promising next step.

## Conclusion

In this paper, we discussed the issue of objectness and its relation to the allocation of visual attention. We demonstrated that it is possible to develop object-based version of saliency. Object-based saliency is not calculated as a value for each of the image pixels (or coordinates), but rather over an area within the boundaries of an object. In this approach, saliency is treated as a feature of an object, similar to other features such as position. This approach is compatible with theories assuming an object-based allocation of attention, such as the Cognitive Relevance Framework (Henderson et al., 2009).

The evaluation we presented used an object counting and an object naming data set. In spite of both of these tasks being object-centric by definition, we believe that our results generalize to other experimental tasks. Such tasks are often either object-centric as well (e.g., visual search), or evidence exists that attentional access is object-based even if the task defined in terms of objects (e.g., in aesthetic judgment or interestingness judgment, see Nuthmann \& Henderson 2010; Einhauser et al. 2008). Indeed it was shown that visual attention is object-based during everyday interaction with the surrounding world (Land et al., 1999). Finally, it has been suggested that free viewing does not mean that viewers look at images without any task constraints, but rather with constraints to which experimenters do not have access (see Tatler et al., 2011, for further discussion).

Even though the intuition that salience is a property of objects has been utilized before, we are not aware of any extensive experimental study aiming to investigate whether objectbased saliency and techniques used to detect salient objects in computer vision can reliably predict human fixations. We showed that the prediction of fixations based on objects and their visual features is not only possible, but superior to standard saliency. However, using the maximum value of saliency within an object was not confirmed as a reliable predictor of whether object is going to be fixated, which is a important result considering the popularity of this feature in previous modeling studies.

# Verbal and Nonverbal Cues Activate Concepts Differently, at Different Times 

Pierce Edmiston (pedmiston@wisc.edu)<br>Department of Psychology, 1202 W. Johnson Street<br>Madison, WI 53706 USA<br>Gary Lupyan (lupyan@wisc.edu)<br>Department of Psychology, 1202 W. Johnson Street<br>Madison, WI 53706 USA

#### Abstract

Although the word "dog" and an unambiguous barking sound may point to the same concept DOG, verbal labels and nonverbal cues appear to activate conceptual information in systematically different ways (Lupyan \& Thompson-Schill, 2012). Here we investigate these differences in more detail. We replicate the finding that labels activate a more prototypical representation than do sounds, and find that sounds activate exemplars consistent with the source of the sound, such that after hearing a barking sound, people are faster to recognize a dog with an open-mouth than a closed mouth, but critically, only when the sound and picture are presented simultaneously. The results are consistent with perceptual cues indexing their source while labels activating a more decontextualized representation of the target category.

Keywords: categorization, concepts, sounds, recognition, cross-modal effects, language

## Introduction

Most concepts are multimodal and can be activated in a variety of ways (Hoffman \& Ralph, 2013). For example, the concept DOG can be activated by seeing a wagging tail, hearing a bark, or petting its furry coat. However, the concept DOG can also be activated by hearing the word 'dog'-without seeing, hearing, or touching an actual dog. This raises the question of how concepts activated by nonverbal sensory cues compare to those activated by verbal category labels.

In the experiments reported here we compare how verbal and nonverbal cues activate representations of purportedly the same concepts. In particular, we focus on visual aspects of familiar animals and artifacts as cued by natural sounds: auditory events with a distinct source (e.g., cat meowing, chainsaw revving), and how these same concepts are activated by verbal labels (words like "cat" and "chainsaw").

The mechanisms underlying recognition of nonverbal sounds and of speech appear to be quite similar. Recognition of both words and natural sounds varies as a function of familiarity, frequency, and context (Ballas, 1993; Stuart \& Jones, 1995). Perception of both natural sounds and speech is influenced by signal ambiguity and noise in similar ways (Aramaki, Marie, Kronland-Martinet, Ystad, \& Besson, 2010; Gygi, Kidd, \& Watson, 2004). Both labels and natural sounds elicit similar N400 event-related potentials-a coarse index of semantic processing (Cummings et al., 2006; Van Petten \& Rheinfelder, 1995)-
even when the identification of the natural sound is incidental to task demands (Orgs, Lange, Dombrowski, \& Heil, 2008). Functional imaging during similar sequential processing tasks reveals largely overlapping cortical areas recruited in processing labels and natural sounds (Dick et al., 2007). Lastly, patterns of naming deficits in patients with aphasia suggest the labeling of everyday objects and the visual recognition of natural sound sources rely on similar cognitive resources (Goll et al., 2010; Saygin, Dick, Wilson, Dronkers, \& Bates, 2003).

The perception of meaningful nonverbal sounds and of words is thus dependent on many of the same properties and activate largely the same semantic networks. Although it may seem that verbal and nonverbal cues are in important respects equivalent, there are critical differences. One such difference is that natural sounds, unlike labels, have a causal relationship with a specific physical source (Ballas, 1993). Recognizing these relationships requires learning, but the relationship between a referent and its natural sound is not arbitrary. We call these relationships "motivated": that is, they are determined by physics (e.g., thunder) or driven by biology (e.g., large dogs-and agitated dogs-have deeper barks). Auditory perceivers are able to exploit such "motivated" relationships and surmise features of a hidden physical source, such as the size of a barking dog (Taylor, Reby, \& McComb, 2008), the shape of resonating plates (Kunkler-Peck \& Turvey, 2000), or the hardness of percussion mallets (Freed, 1990). The perception of these auditory sources is surprisingly accurate, reflecting the lawful relationships between signals and sources in the environment (Fowler, 1990). Importantly, sounds covary lawfully within as well as between categories. For example, a barking sound informs us not only that its source is a dog, but can inform us of the approximate size of the dog.

In contrast, the relationship between labels and their referents is "unmotivated." By this term we do not simply mean that words are arbitrary, i.e., that "dog" refers to dogs by convention (cf. Hockett, 1966), but that there exists a word "dog" that denotes the entire category of dogs rather than a particular type or instance (dachshund, German shepherd, dog-on the left, dog-far away, etc.). In short, barks index specific occurrences of dogs. Even though we can interpret natural sounds at a more categorical level, the surface properties of a specific bark still indexes a particular dog. Verbal labels, on the other hand, abstract over these specifics. When we say "dog" we can leave all
that information unspecified. On this view, labels may activate concepts in a more categorical way. This prediction has been supported by a variety of findings (Lupyan, 2012). For example, Lupyan \& Thompson-Schill (2012) found that label cues resulted in faster visual processing over equally predictive nonverbal cues. This advantage persisted across a number of cue-to-image delay periods and extended to artificially created objects with novel labels and "natural" sounds, suggesting that labels do not activate conceptual representations faster but differently than nonverbal cues. In our view, labels activate representations that emphasize the differences between categories, and thus play a facilitative role in category learning (Lupyan, Rakison, \& McClelland, 2007). These categorical representations enable faster recognition of category-typical objects (Lupyan \& Swingley, 2012), but blur within-category differences reflected in biased exemplar memory (Lupyan, 2008).

However, what is not clear from these previous results is how "unmotivated" and "motivated" cues differ in activating different instances of purportedly the same concept. If "unmotivated" verbal cues activate more categorical representations, then what do "motivated" nonverbal cues activate? Given the inherent causal link between a natural sound and its particular physical source, we predicted that natural sound cues would lead to faster processing of images depicting the production of the auditory cue. The results ended up being more interesting.

Figure 1: Sample stimuli from Experiment 1. Does hearing the sound of a revving chainsaw activate a representation of a chainsaw in action?

## Experiment 1

Hearing a sound characteristic of an animal or artifact may automatically activate particular instances of that category. Consider the kind of chainsaw one might expect upon hearing a chainsaw sound (Fig. 1). Here, we asked whether verbal and nonverbal cues lead to different expectations about subsequent visual information. In Experiment 1 we investigated if label and natural sound cues influence visual processing differently based on the action depicted in target images. In line with previous research, we predicted that when presented a label cue, participants would respond faster to category-typical images. Conversely, we predicted that when presented a natural sound cue, participants would respond faster to sound-matched images.

## Methods

Participants 14 University of Wisconsin-Madison undergraduates participated for course credit.
Materials Auditory cues were spoken labels and natural sounds for 12 target categories of familiar animals and artifacts used in Lupyan \& Thompson-Schill (2012). ${ }^{1}$ Visual images were 4 color photographs for each category: 2 category-typical images and 2 sound-producing images. The images were normed, ensuring unambiguous identification. In addition, participants in a separate image rating study evaluated each picture on one of two dimensions (category typicality and sound match) using a 5-point Likert scale. For category typicality, participants viewed e.g., a dog, and were asked: "How typical is this dog of dogs in general?" For sound match ratings, participants listened to e.g., a bird chirping, saw a picture of a bird, and were asked: "How well does that sound go with this picture?" Each participant performed either category-typicality or sound-matching judgments. As expected, the canonical images were rated higher on category typicality $(M=4.57)$ than on sound match ( $M=3.49$ ), while sound-producing images were rated higher on sound match ( $M=4.37$ ) than on category typicality $(M=4.05)$. These ratings were standardized ( $z$-score) and used as predictors in subsequent analyses.
Procedure Participants completed a category verification task in which an auditory cue-either a spoken category label (e.g., 'cat') or a natural sound (e.g., <meow>)preceded a visual image. Participants determined if each cue-image pair matched on a category level by pressing 'Yes' or 'No' using a labeled gaming controller. For example, if they heard a chainsaw revving or the spoken word "chainsaw" and then saw a picture of a chainsaw, they would press the 'Yes' button. The picture disappeared after each response, and performance feedback was given. Cue type (label, natural sound) and picture exemplar (4 per category) varied randomly within-subjects. There were a total of 576 trials per subject ( $50 \%$ cue-image category match). Each trial began with a 250 msec fixation cross followed by the auditory cue. The target image appeared 1 sec after auditory cue offset. This long delay ensured that participants had ample time to process sounds and labels (see Lupyan \& Thompson-Schill, 2012). The experiment took 30 minutes to complete.

## Results and Discussion ${ }^{2}$

Overall accuracy was high (96\%). Only correct response times (RTs) on matching trials were included. RTs less than 250 msec or greater than 1500 msec were excluded ( $<4 \%$ of correct trials). We fit the data with linear mixed regression (Bates, Maechler, \& Bolker, 2012) to predict response times (RTs) from the interaction between cue type (label, natural sound) and image rating (category-typicality or sound-

[^257]

Figure 2: Significant interaction between cue type and category typicality, but not between cue type and sound match when the target picture lagged auditory cue offset by 1000 msec . Confidence bands denote $\pm 1$ standard error of linear mixed regression point estimates (Mazerolle, 2012). Error bars denote $\pm 1$ standard error of main effect of cue type.
match) with random subject and item effects (target category). As expected (Lupyan \& Thompson-Schill, 2012), responses to label cues ( $M=609 \mathrm{msec}$ ) were reliably faster than responses to natural sound cues ( $M=639 \mathrm{msec}$ ), $F(1,13)=22.03, \quad p<0.001 .^{3}$ The effect of cue type was moderated by category-typicality, $F(1,13)=10.45, p=0.002$ (Fig. 2, left), but not by sound-match, $F(1,13)=0.001$, $p=0.98$ (Fig. 2, right).

To summarize, labels, but not natural sounds, resulted in faster processing of category-typical images, but neither cue resulted in faster processing of sound-matched images. These results replicate previous findings that labels facilitate visual processing more effectively than nonverbal cues (Lupyan \& Thompson-Schill, 2012) and that labels improve recognition of category-typical exemplars (Lupyan \& Swingley, 2012). The results clearly show that labels and natural sounds activate familiar concepts differently and that labels appear to activate a representation that is more categorical/typical. Unexpectedly, natural sounds did not selectively facilitate recognition of pictures that were better matches to the sound-cues. This finding is investigated further in Experiment 2.

[^258]
## Experiment 2

Our second experiment extends the first in two important ways. First, we compiled a more extensive set of stimuli by sampling from the 2-dimensional space of category typical and sound-matched category exemplars (Fig. 3). Second, we varied the cue-to-image delay. We did this because natural sounds, unlike labels, index the animals and objects that produce them. While labels often occur in the absence of the referent (we talk about things not presently in view), sounds are temporally contingent on the presence of the referent. If we hear a bark, chances are a dog is in the vicinity.

In Experiment 2, we investigated if label and natural sound cues influence recognition speed based on the fit between an auditory cue and an image, and on the delay between the cue and the image. In line with the results of Experiment 1, we predicted a label cue would improve processing of category-typical images. We also predicted that a natural sound would improve processing of a fuller set of sound-matched images-that is, where the image depicted an animal or object that was the likely source of the natural sound-and that this effect would be greater when the cue and image were temporally coupled-that is, presented simultaneously.

## Methods

Participants 56 University of Wisconsin-Madison undergraduates participated for course credit.
Materials Auditory cues comprised spoken labels and natural sounds for 10 of the 12 target categories used in Experiment 1 (categories river and toilet were excluded; all sounds edited to 600 msec ). Image ratings (categorytypicality and sound-match) for an augmented set of images were collected via Amazon's Mechanical Turk (mTurk). mTurk workers $(N=42)$ heard either 10 spoken labels or 10 natural sounds to be used in Experiment 2, and were

Figure 3: Sample stimuli from Experiment 2. Categorytypicality was measured independently of sound-match.
presented 8 to 10 pictures for each category with the following instructions: "Please listen to the following audio clip and report how well each image fits with the audio file." Ratings were given on a 5-point Likert scale. From these data, we selected 4 images for each category corresponding to the quadrants depicted in Fig. 3. There was a positive correlation between category-typicality and sound-match (Pearson's $r=0.27$ ). These ratings were standardized ( $z$-score) and used as predictors in subsequent analyses.
Procedure The procedure was the same as in Experiment 1. Cue type (Label, Natural Sound), picture exemplar (4 per category), and image delay (Simultaneous or Delayed 400 msec ) varied randomly within-subject for a total of 427 trials per subject ( $75 \%$ cue-image category match ${ }^{4}$ ). Each trial began with a 250 msec fixation cross. On a random half of the trials, the auditory cue and picture were presented simultaneously; on the remaining trials the picture was presented 400 msec after the offset of the auditory cue. The experiment took 30 minutes to complete.

## Results and Discussion

Overall accuracy was high ( $M=97 \%$ ), except trials in which pictures of scissors were cued by a sound of scissors cutting paper ( $M=91 \%, S D=1.8$ ). Participants also reported difficulties with these trials during debriefing ( 24 out of 56 participants; next most frequent was 5 for bee), and these trials were removed from subsequent analyses ( $<5 \%$ ). ${ }^{5} \mathrm{We}$ excluded trials using the same exclusion criteria as in Experiment 1 ( $<2 \%$ of correct trials removed). Again, we fit the data with linear mixed regression to predict response times from cue type (label, natural sound), delay (simultaneous, delayed), and image rating (category typicality or sound typicality) allowing random subject and item effects (picture category).
Delay and Cue Type We first report how the effect of cue type varied by image delay. As in Experiment 1, responses to label cues were reliably faster than responses to natural sound cues, $F(1,41)=30.14, p<0.0001$. The effect of cue type was moderated by delay, $F(1,41)=6.86, p=0.009$. The RT advantage of labels over natural sounds was greater on simultaneous trials than it was on delayed trials (Fig. 4).
Category Typicality We next report how image ratings of category typicality influenced RTs differently by cue type and by image delay. Category typicality was a reliable

[^259]predictor of RTs, $F(1,41)=10.30, p=0.001$. Importantly, this effect remained constant across both cue types and both image delays. That is, the RT advantage for more categorytypical images over less category-typical images was equivalent for label and natural sound cues, on both simultaneous and delayed trials (Fig. 4, left column). Responses following natural sound cues were predicted by category-typicality of the image during simultaneous and 400 msec delayed trials, an effect not found at the longer delay in Experiment 1.
Sound Match We now report how image ratings of soundmatch influenced response times differently by cue type and

Figure 4: Label and natural sound auditory cues affect response latencies differently by cue-image delay (rows) and by image rating (columns). Confidence bands denote $\pm 1$ standard error of linear mixed regression point estimates (Mazerolle, 2012). Error bars denote $\pm 1$ standard error of main effect of cue type.
by image delay. There was a reliable three-way interaction between sound-match, cue type, and image delay, $F(1,46)=$ 4.67, $p=0.03$. On simultaneous presentation trials, RTs following natural sound cues decreased as the sound-match of the image increased, while RTs following label cues did not vary by sound-match, $t(46)=-3.47, p<0.001$, (Fig. 4, upper right). However, there was no such cue type $\times$ soundmatch interaction at the 400 msec delay, $t(46)=-0.44, p=0.66$ (Fig. 4, lower right). That is, sound-match predicted RTs following natural sounds and not labels when the delay was simultaneous, but not with a 400 msec delay.

To summarize: the image ratings for category-typicality and sound-match correlated with response times based on the cue and the cue-image delay. First, when presented with a spoken label, RTs were predicted by category-typicality of the image, and this effect held across both cue-to-image delay periods. Second, when presented with a natural sound, the sound-match of the image correlated with the response time to that image, but only when the cue-image pair was presented simultaneously. That is, hearing a natural sound improved processing of a particular kind of visual image: a picture depicting an object that could have made the sound at the moment the sound was detected. These results show that the ways in which an auditory cue influences recognition of visual images depends on both the fit of the image to the auditory cue and the time course of the presentation.

## General Discussion

In two experiments we demonstrated that verbal and nonverbal cues systematically differ in how they activate conceptual information, as tested by the speed of visual recognition of category exemplars. Experiment 1 revealed more category-typical exemplars were recognized faster following a spoken label cue but not a natural sound. In addition, Experiment 1 revealed that exemplars that were more sound producing were not recognized faster following either auditory cue. Importantly, responses following natural sound cues did not vary as a function of category-typicality while those following labels did, suggesting that verbal and nonverbal cues are indeed operating on different gradients. Experiment 2 added to these results with a fuller stimulus set and varying image delays. In Experiment 2, but not in Experiment 1, responses following natural sounds did vary with category-typicality. We believe this result to be due to the shorter delays used in Experiment 2 (see Lupyan \& Thompson-Schill, 2012 for differences between labels and natural sounds at longer delays). In Experiment 2, but not in Experiment 1, responses to natural sounds varied as a function of the match between the sound and image, but the relationship was time sensitive. In particular, high soundmatched exemplars were recognized faster following a natural sound only during simultaneous presentation, and sound-match did not predict RTs following verbal cues.

Together, the two experiments reported here highlight the role of multisensory integration as a feature of what we have called "motivated" cues. We associate barking with dogs,
but the bark informs us about the particular dog that made it-a deeper bark is likely to come from a larger dog, and hearing a bark usually temporally coincides with seeing the actual animal. Such contingencies result in audiovisual integration of simultaneous auditory and visual cues that improves detection (Laurienti, Kraft, Maldjian, Burdette, \& Wallace, 2004). For example, Chen \& Spence (2011) reported increased visual detection of masked pictures when presented with a congruent natural sound cue, and that the effectiveness of an auditory cue varied by cue-image delay. The present results support the time sensitivity in cross modal priming of natural sounds and pictures, and measure the strength of this relationship through a "motivated" sound-to-image match.

In contrast, word-to-referent mappings are "unmotivated" (cf. Hockett, 1966). Saying "dog" in a deeper voice does not systematically imply a larger or angrier dog. ${ }^{6}$ So, even though both "dog" and a dog-bark may be unambiguously associated with dogs, the dog-bark indexes a specific dog with a specific size, location, and temperament. The word "dog", while varying systematically with aspects of the speaker (e.g., the lower the pitch, the more likely the speaker is to be male), does not systematically vary with the referent. We can talk about particular dogs, of course, but the word "dog" can and often does remain categorical, abstract.

In addition, these findings establish a heretofore underappreciated relationship between an auditory cue and a sound-matched image in similar cognitive processing tasks. Future attempts to compare semantic and conceptual processing of labels to that of natural sounds may benefit from operationalizing what we have termed the soundmatch between a natural sound and its purported referent (e.g., Saygin, Dick, \& Bates, 2005).

Conclusion We found verbal and nonverbal cues activate different conceptual representations evident in patterns of response latencies to recognize and verify different category exemplars. In a replication of previous findings, verbal cues facilitated recognition of category-typical images. We extended these findings to discern the specifics of conceptual representations activated via natural sound cues: Natural sounds facilitated visual processing of images that fit with the presented sound, but only if the sound and image were presented simultaneously. Critically, these effects were mediated by time, with natural sound cues improving responses to sound-matched images only during simultaneous presentation.

#### Abstract

We investigate the effect of linguistic complexity on cognitive load in a dual-task scenario, namely simultaneous driving and language use. To this end, we designed an experiment where participants use a driving simulator while listening to spoken stimuli and answering comprehension questions. Online physiological measures of cognitive load, including the recently established Index of Cognitive Activity, as well as measures of performance in both tasks have been collected with high temporal resolution. The resulting aligned data streams can be used to test a vast array of different hypotheses about the relationship between performance, difficulty, and cognitive load in dual tasks at various levels of temporal resolution and linguistic structure. We present results of the data analysis, including evidence that different linguistic structures may cause measurable changes in cognitive workload on a very fine temporal scale in cases of increased primary task difficulty.

Keywords: relative clause; dual task; cognitive load; pupillometry; skin conductance; tracking task; driving; multitasking

## Introduction

Is there a relationship between psycholinguistic measures of language complexity and quantified cognitive workload in dual-task environments? To answer this question, we experimentally evaluate these measures of language processing in an environment where one task is language-related and the other not. Such language complexity measures have been shown in single-task studies to account for processing difficulty. This work represents a first step in which we investigate the effect of a grammatical structure (German locally ambiguous subject vs. object relative clauses) on a simplified, well-controlled non-linguistic task, a driving task.

Dual tasks are ubiquitous in everyday life, often in situations where attention and performance in the primary task is critical. An example is driving while engaging in dialogue, be it with a passenger, a dialogue-controlled interface, or remotely via mobile phone. Engaging in dialogue generally affects driving performance and safety (Just, Keller, \& Cynkar, 2008; Young, Regan, \& Hammer, 2007).

We manipulated the driving task difficulty and the structural complexity of the linguistic items. We also collected measurements of performance in both tasks and fine-grained physiological indicators of cognitive load, namely skin conductance levels and pupil sizes. We computed values from pupil size for the recent Index of Cognitive Activity (ICA). To our knowledge, this is the first study using the ICA measure in a setting with a language task.

## Background and Related Work

There is a rich literature on language use while driving a car, largely showing that speaking on the telephone has a negative effect on driving performance (Just et al., 2008; Kubose et al., 2006). Further studies found that this is specific to conversations with remote speakers (independent of whether one uses a hand-held device or free speaking), but that conversations with an in-car passenger are less problematic (Strayer, Drews, \& Johnston, 2003; Drews, Pasupathi, \& Strayer, 2004). It appears that passengers adapt their conversation to the traffic situation, leaving the driver more resources to deal with demands of the driving task when driving becomes difficult (Drews, Pasupathi, \& Strayer, 2008; Crundall, Bains, Chapman, \& Underwood, 2005; Villing, 2009). By contrast, remote conversational partners cannot adapt their speech, so that the driver may reach the point of cognitive overload more easily and thus commit driving errors. However, these lines of research have not taken into account how the fine-grained details of linguistic complexity affect cognitive load and driving task performance.

On the other hand, there is a very rich literature on linguistic processing difficulty in single tasks using brain imaging, ERPs, and reading time studies, as well as a number of dual task experiments generally showing that performance on the linguistic task deteriorates with increased complexity of the other task, see for example King and Just (1991). Finally, multiple models explain the effect of cognitive load in one task on performance in another (Baddeley, 2003; Wickens, 2008; Just, Carpenter, \& Miyake, 2003).

We see, however, unbroken ground in relating the effect of linguistic complexity on a realistic task (e.g., driving) and the size of the interference of linguistic processing with driving performance. This study takes a step in this direction in testing different methods for assessing cognitive load and the effect of one particular linguistic structure-incrementally ambiguous relative clauses-on driving performance in a simplified but controllable and continuous driving task.

## The dual-task experiment

## The ConTRe task

Our primary task was a tracking task (Jagacinski \& Flach, 2003) presented as a car driving scenario and called the "Continuous Tracking and Reaction" (ConTRe) task (Mahr, Feld,

Figure 1: A screenshot of the ConTRe steering task.

Moniri, \& Math, 2012). In this task, participants see a simulated 3-D road moving at a constant speed, intended to simulate a moving vehicle. Additionally, two bars of different color appear approximately 20 m in front of the simulated vehicle. The two bars represent the vehicle's position and the target (reference) position. They move laterally across the screen. The reference bar's movement is pseudo-randomly generated by an algorithm, while the "vehicle" bar is controllable by the participant by means of a gaming steering wheel. Participants were instructed to track the reference bar's movements with the controllable bar as closely as possible. To reduce noise in our data, we removed all other elements of the original ConTRe environment (e.g., buildings along the side of the road, and traffic lights), except for the road and the moving bars. A screenshot of the simulated environment can be seen in fig. 1.

This task is a useful abstraction of driving, since it allows a precise and continuous performance measure for steering, essential to driving. We manipulated the difficulty of the ConTRe task by changing the speed of the reference and vehicle bars in order to create a "difficult driving" condition and an "easy driving" condition ${ }^{1}$.

## Language comprehension task

The spoken comprehension task consists in listening to a sentence containing a relative clause followed by two thematically related 'filler' sentences and a yes/no comprehension question. Questions were related to the relative clause (50\% of the stimuli) or to the filler sentences. All sentences and questions are in German, inspired by Bader and Meng (1999). The stimuli are designed in pairs in such a way that the items in each pair are identical except for the form of the auxiliary of the relative clause (RC), which determines whether it is an object RC (ORC) or a subject RC (SRC). An example of such a relative clause pair is the following:

> Die Lehrerin, die einige Eltern wegen einer solchen Kleinigkeit angerufen [haben / hat], hat nun eine Elternversammlung einberufen.
> "The teacher ${ }_{\text {FEM }}$ [who called some parents / whom

[^261]some parents called] because of such a trivial issue, has now called a parents' meeting."

The sentence is locally ambiguous between ORC and SRC until reaching the auxiliary; in previous experiments, increased reaction times in a speeded judgment task (Bader \& Meng, 1999) have been observed when subjects read "haben" (ORC) compared to "hat" (SRC). This is evidence for an interpretive bias toward SRC. All items were synthesized prior to the experiment using MARY TTS (Schröder, Charfuelan, Pammi, \& Türk, 2008) and pauses manipulated so that the critical region duration (hat / haben) is always identical.

## Experimental setup

Each experiment is divided into 4 recording phases, each lasting about 6 minutes, with short pauses in-between. Each phase is composed of a driving-only phase of 2 minutes followed by a driving-with-language phase of approximately 4 minutes, during which 10 blocks, consisting each of one relative clause, two fillers and one question. Participants answer the question verbally and their response is coded by the experimenter. In the first and the third phase, the driving difficulty is set to "easy", while in the second and fourth phase it is set to "difficult". The order of presented items in the language condition was randomized, and we ensured that each person only saw one condition of each item.

## Measures of cognitive workload

We have two principal sources of quantified cognitive workload data: physiological and task dependent. Our physiological measures are further divided into two subtypes: pupil area-based (pupillometry) and skin conductance-based, both of which have been widely used in cognitive workload studies, although principally on non-linguistic tasks. Our study is an opportunity to evaluate the relative efficacy of these data sources on linguistic tasks. We also take the opportunity to evaluate a novel form of pupillometric data processing: the Index of Cognitive Activity (ICA). To the best of our knowledge, ours is the first study to investigate the potential of the ICA as a measure of linguistically-induced cognitive load in a dual-task scenario.

Our task-dependent measure is driving performance in our simulated environment, which serves to confirm the "realworld" effect of variations in cognitive workload.

The Index of Cognitive Activity (ICA) Research in pupillometry (Just et al., 2003; Engelhardt, Ferreira, \& Patsenko, 2010; Palinko, Kun, Shyrokov, \& Heeman, 2010) has found that cognition-related changes in pupil size typically amount to a difference of $20 \%$ relative to the typical pupil size (Laeng, Sirois, \& Gredebäck, 2010). However, light conditions also affect pupil sizes, with brightness-induced changes being much larger than cognitively induced ones (up to $120 \%$ of typical pupil size).

The Index of Cognitive Activity (ICA; Marshall (2002)) is a patented measure which applies signal processing techniques to filter out slow, large light-induced changes and identify
the occurrence of short, abrupt changes in pupil size, held to be caused by cognitive load. The ICA measure is argued to be robust with respect to changes in light conditions and eye movement. It relates the frequency of rapid small changes in pupil size (also known as pupillary hippus) to cognitive load. The ICA measure has been used for measuring cognitive load in driving simulation tasks (Schwalm, Keinath, \& Zimmer, 2008), simulated driving and visual search (Marshall, 2007), detecting different levels of surgical skill (Richstone et al., 2010), and for measuring linguistically induced cognitive load (Demberg, Kiagia, \& Sayeed, 2013) among other uses. Demberg (2013) provides a more detailed analysis of the ICA measure in the dual task setting presented here.

ICA measurements have been shown to be relatively stable across several commonly used eye tracker models and sample rates ranging from 60 to 300 Hz (Bartels \& Marshall, 2012). We used a head-mounted Eyelink II and sampled at 250 Hz .
Skin conductance response Our second physiological proxy for measuring cognitive load is skin conductance response (SCR), which we calculate from skin conductance level (SCL). Changes in the electrical conductance of the skin are due to activity of the sweat glands, which are in turn controlled by the sympathetic nervous system. Skin conductance amplitude usually changes with respect to its "neutral" (tonic) level in response to unexpected, significant, or aversive stimuli. SCL has been previously used as a measure of cognitive load (Shi, Ruiz, Taib, Choi, \& Chen, 2007). In a dual task experiment with simulated driving and a secondary cognitive task, B. Mehler, Reimer, Coughlin, and Dusek (2009) found that skin conductance levels peaked in cases of mental overload caused by incrementally increasing secondary task difficulty, which was followed by a deterioration in the performance of the primary task. Son and Park (2011) found skin conductance levels along with steering wheel reversals (used as a measure of task performance) to be good input features for an artificial neural network built to predict task difficulty.

We used the Ledalab software (Benedek \& Kaernbach, 2010) to separate our raw skin conductance measurements into an estimate of the tonic component and the phasic component. The software also allows to calculate the number of skin conductance response events. SCR events are the "peaks" of the phasic component of skin conductance; both the number of such events per time unit and the amplitude of the peaks are used in the analysis below.

Driving performance We use performance on the ConTRe task as an additional measure of cognitive load. The task lets us define several measures of task success, including the distance between the reference bar and the controllable bar at each point in time and the speed and acceleration of the controllable bar.

## Results

We ran our experiment with 24 German native speakers aged 20-34, with the total duration of the recorded samples sum-
ming up to about 12 hours. We performed our data analysis in R using linear mixed effects (LME) modeling with lme4 (Baayen, Davidson, \& Bates, 2008) and mgcv (Wood, 2001).

## Correlation between physiological measures

The first question we explored was whether our physiological measures are correlated with one another. While there is no significant correlation between the raw skin conductance levels and the ICA, we do find a significant positive correlation between the number of skin conductance events and the ICA (using Spearman's $\rho$; left ICA: $\rho=0.06 ; p<0.0001$; right ICA: $\rho=0.09 ; p<0.0001$ ). One important aspect to keep in mind is also possibly different latencies of the two measures in reaction to a stimulus.

We find a strong correlation between the ICA of the left and right eye (cor $=0.74 ; p>0.001$, Pearson's product-moment correlation coefficient).

## Response to experimental phases

Driving performance The next hypothesis we tested was whether our task performance measure in the driving task, i.e., the steering deviation, is sensitive not only to the driving task difficulty, but also to the presence of language. In figure 2 , we have plotted the mean deviation for each of the difficulty settings (easy and difficult driving), with and without the secondary linguistic task. Using linear mixed effects models with a random intercept and random slopes by subject, we found a large significant main effect of driving difficulty (coef $=0.3 ; t=20.33 ; p<0.001$ ), showing that steering was less accurate when driving was more difficult. We also found a significant positive main effect of whether we are in a language phase (coef $=-0.05 ; t=-5.00 ; p<0.001$; steering is worse when people are listening to language, see also figure 3 ), as well as a significant interaction between driving difficulty and the language phase, indicating that the effect of language was more burdensome in the difficult driving condition (coef $=-0.024 ; t=-6.98 ; p<0.001$ ). To confirm whether the effect of language is significant in both driving conditions, we also split the data into two subsets, easy driving and difficult driving, and found that the effect of language was significant in both linear mixed effects models.

This figure illustrates an obvious difference between steering deviation in the easy and difficult driving conditions.

Figure 2: Driving condition/language vs. steering deviation.

Table 1: ICA estimates for the driving plus language phases.

|  | right ICA |  |  |  | left ICA |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | :---: |
|  | coef | t-value | sign | coef | t value | sign |  |
| (Intercept) | 0.8116 | 123.40 | $* * *$ | 0.7965 | 135.63 | $* * *$ |  |
| sound playing | 0.0198 | 10.88 | $* * *$ | 0.0186 | 10.10 | $* * *$ |  |
| easy driving | -0.0057 | -2.44 | $*$ | -0.0004 | -0.21 |  |  |

Table 2: \# of SCR events reduced during easy driving. (Random slope of driving condition by subject included.)

|  | Estimate | t value | signif. |
| :--- | ---: | ---: | :---: |
| (Intercept) | 0.68626 | 12.550 | $* * *$ |
| difficulty=easy | -0.06495 | -4.274 | $* * *$ |

Pupillometry For the ICA, we find a main effect of driving difficulty in the ICA of the right eye, but not in the left eye (Table 1). Furthermore, we find significantly more blinks during the phases when language was playing. In-depth analysis of the pupillometric data reveals that overall dilation was larger when people were listening to language stimuli, but the number of ICA events was lower (Figure 3). If we look into the language phase, however, the ICA of both eyes went down significantly whenever language wasn't playing (e.g., between stimuli; Table 1: we factored out the effect of blinks or partial blinks on both the pupil area calculations and the ICA). This effect can also be seen in Figure 3, where the 10 ICA spikes in the language region coincide with our 10 blocks of language stimuli.

Skin conductance For skin conductance, we cannot easily compare the easy vs. difficult driving settings, as the skin conductance measuring device was removed between phases, and comparison of absolute values between phases is thus impossible. A measure that can be compared between driving conditions is however the number of skin conductance events. When running a linear mixed effects regression model with this measure as a response variable, we find that more such skin conductance events happened, as expected, in the difficult driving condition, see Table 2.

We do however not find any significant effect of the language vs. no language condition on this measure. Unexpectedly, we find that tonic skin conductance is lower in the driving plus language condition, see Figure 3.

## Cognitive load and language processing difficulty

To this point, we find that the measures largely behave as expected. Thus we come to our main question: can they detect the effect of fine-grained language complexity? To this end, we analysed the data to see whether we can find a) a correlate for higher processing difficulty in the ambiguous region or right after the disambiguation at hat/haben, and b) whether ORCs lead to less cognitive load than SRCs.

Disambiguating region Detailed analysis of the ambiguous region of the relative clause shows that the Index of Cognitive Activity is high during the ambiguous region of the

Figure 3: Spline plots ( 120 knots; with 0.95 conf intervals) showing the effect of language on physiological measures during an experimental phase ( 2 min driving only followed by 4 min of driving plus language).

relative clause (during the time span of -2000 msec to 0 msec ), and that the ICA sharply falls right after disambiguation (see Table 4 which shows a significant reduction in ICA of both eyes following disambiguation, encoded as time wrt. onset). These effects hold over and above effects of the steering task, which have been mathematically accounted for by including the task difficulty as a factor in the model. These results indicate that subjects encounter processing difficulty due to the ambiguity. (This is possibly also something they learn during the experiment.)

For skin conductance, we know that effects can be expected 2-4 seconds after the stimulus. Figure 4 shows a significant rise in skin conductance during the five seconds after

Table 3: Mixed effects regression analysis with steering deviation as response variable, for region of 2 s before the onset till 2 s after end of the critical region.

|  | Estimate | t -value |  |
| :--- | :--- | ---: | :--- |
| (Intercept) | $3.562 \mathrm{e}-01$ | 17.07 | $* * *$ |
| phase time | $8.459 \mathrm{e}-08$ | 3.44 | $* * *$ |

Table 4: Mixed effects regression analysis with left and right ICA as response variable, $100-1800 \mathrm{msec}$ after critical region onset. (Critical region duration: $0-600 \mathrm{msec}$ )

|  | left ICA |  | right ICA |  |
| :--- | :--- | :--- | :--- | :--- |
|  | Estimate | t-value | Estimate | t-value |
| (Intercept) | 0.7504 | $35.71 * * *$ | 0.736 | $37.82 * * *$ |
| subject RC | -0.0354 | -2.12 | $*$ |  |
| phase time | $-1.16 \times 10^{-7}$ | -2.59 | $*$ |  |
| time wrt. onset | $-2.78 \times 10^{-5}$ | $-6.38 * * *$ |  |  |
| steering veloc | 0.0257 | $5.37 * * *$ |  |  |
| steering accel | 0.0108 | 2.00 | $*$ |  |
| SRC:phase time | $1.34 \times 10^{-7}$ | 2.12 | $*$ |  |
|  |  |  | $4.36 * * *$ |  |
|  |  |  |  |  |
|  |  |  |  |  |

the critical region, which would be consistent with an interpretation that the ambiguity causes higher cognitive load.

But can we see any effect of our linguistic stimuli on the driving performance? We compared steering accuracy at the time of the disambiguating region with steering accuracy during the two seconds before and after, and indeed found that deviation of the controllable bar from the reference bar was significantly larger during the disambiguating region than before or after; see the positive coefficient (Table 3) for the binary variable "critical region".

Subject vs. object relative clauses Finally, we test whether the ICA is sensitive to fine-grained linguistic complexity effects. We isolated the subset of the data which fell within the 1800 msec following the onset of the critical region hat / haben. The duration of this critical region at hat / haben is 650 ms in both conditions, which we imposed by manipulating the duration of the phrase boundary pause during synthesis. On this subset of the data, we built two LME models (one for each eye) with the ICA measure as the response variable and the relative clause type as the fixed effect, while also introducing a random effect per participant.

The results of this analysis are shown in Table 4. We can see that there is a negative effect for the SRC type in both cases, although only the result for the right eye is significant. The interpretation of the coefficient is that SRCs tend to occur with smaller values of ICA than ORCs.

We did not find any significant effects of relative clause condition on skin conductance, overall pupil dilation or steering performance.

Table 5: LME model for answer accuracy.

|  | Estimate | t-value | Sig |
| :--- | ---: | ---: | :---: |
| INTERCEPT | 2.663 | 5.72 | $* * *$ |
| RC-TYPE (OBJ) | 0.445 | 1.17 |  |
| VOICE (PASSIVE) | -1.802 | -3.11 | $* *$ |
| DRIVINGDIFFICULTY (EASY) | -0.222 | -1.18 |  |

## Performance in the language task

A last link that we wanted to investigate was the one between performance in the linguistic task (i.e., answer accuracy) and the difficulty of the driving and language tasks. We built a binomial LME model with the answer accuracy as the response factor and driving task difficulty, relative clause type, and the voice (passive vs. active) of the question as fixed effects with a random intercept per participant and subject and a random slope for relative clause type by item ${ }^{2}$. The resulting coefficients are presented in Table 5. While answer accuracy was lower for object relative clauses (74\%) than for subject relative clauses ( $78 \%$ ), and lower in difficult driving ( $75 \%$ ) than in easy driving (77\%), these differences did not reach significance. (NB: questions related to relative clauses were only asked after half of the items; i.e., this analysis is based on relatively little data.) The only significant negative effect on answer accuracy was found for passive voice questions, which means that there are significantly more wrong answers to passive voice questions than to active voice ones (this is not unexpected, as it has long been known that passives are more difficult to process than actives (J. Mehler, 1963)).

## Discussion and conclusions

We designed the tasks in our experiment to require continuous attention. The language task clearly affects performance on the primary steering task: we see the effect of the secondary task in all of our measures. Furthermore, we find effects of linguistic ambiguity and complexity in our measures of cognitive load: during the ambiguous region in our stimuli, we see evidence for higher cognitive load in our pupillometric measure, which is also reflected in a slightly later galvanic skin response. During the disambiguating region, we observe significantly higher steering deviation, which indicates that people are allocating more mental resources to the linguistic task, hence impeding steering performance. We also found evidence for a measurable effect of linguistic complexity in our pupillometric measure ICA: the ICA was significantly higher during the disambiguating region and the following second for the ORC condition compared to SRC. This experiment provides early support for the ICA as a useful measure to assess language-induced cognitive load.

# Math and Metacognition: Resolving the Paradox 

Shanna Erickson (serickson@ucmerced.edu) Evan Heit (eheit@ucmerced.edu)<br>Cognitive and Information Sciences, University of California, Merced<br>Merced, CA 95343 USA

#### Abstract

Metacognition plays a fundamental role in forming selfjudgments of ability and knowledge. Is metacognition domain and gender specific? Metacognitive judgments and performance were measured across biology, literature, and math content. Undergraduates took three shortened SAT II Subject Tests, and provided estimates of their performance both before and after taking each test. The results were that judgments differed across domain and gender. Overconfidence was evident in all domains, although estimates of ability were more accurate after taking a test. Males tended to be more overconfident, while females were less confident yet more accurately calibrated when estimating ability. Students were over-confident in math, bringing into question the existence of math phobia. Improvement in calibration and gender difference in calibration were most noticeable in math.

Keywords: metacognition, math anxiety, gender differences, mathematics education.

## Introduction

Metacognition, a form of higher-order thinking, plays an important role in cognitive processing. It impacts several areas within cognitive science, such as attention, memory, perception, comprehension, and problem solving (Kitchener, 1983; Metcalfe \& Shimamura, 1994). Metacognition aids intellectual endeavors requiring complex thought processes (Schoenfeld, 1983) and also affects social behavior (Jaccard, Dodge \& Guilamo-Ramos, 2005) and decision making (Cohen, Freeman, \& Thompson, 1998).

Two components of metacognition are of particular importance in education: the ability to monitor what you know, which acts as a basis for predicting retention, and the control processes that are used to enact study activities (Nelson \& Dunlosky, 1991). Students need to use metacognitive control in gauging what they know and deciding what study methods to use (Thiede, Anderson, \& Therriault, 2003; Metcalfe, 2009). This process is constantly changing, as students adapt their behaviors in monitoring a learning goal. Self-regulation is necessary for this process (Kornell \& Bjork, 2007), thus students must select from a variety of strategies, enacting these strategies in goal-directed activities, and monitoring their progress in using these strategies.

Success of metacognition affects students' academic performance (Hattie, Biggs, \& Purdie, 1996; Paris \& Paris, 2001, Coutinho, 2008), as well as their ability to communicate what they know about a particular problem. Being able to communicate their level of understanding to instructors is crucial to the learning process. It guides how classroom and self-study materials are constructed, and can
affect what strategies students are taught for study and examination.

Metacognition has been shown to play a crucial role in gauging one's own knowledge (Sperling, Howard, Stanley \& DuBois, 2004; Schunk \& Ertmer, 2000), including specific academic domains such as reading comprehension (Pressley, 2002), math (Pugalee, 2001), science (Schraw, Crippen, \& Hartley, 2006), and writing (Pugalee, 2001). Any improvements in metacognition would allow students to better judge what they know and how well they will be able to recall information. This holds much promise for improving student academic performance.

Despite the importance of metacognition, people commonly display glaring overconfidence in their selfperception of their own knowledge and various abilities (Kruger \& Dunning, 1999; Dunning, Johnson, Ehrlinger, \& Kruger, 2003). Furthermore, people with lower abilities show an even more exaggerated overconfidence. Students in particular often self-report confidence judgments that are unrelated to their actual performance on assessments (Schraw, 1996). Compounding this is students' inability to allocate study times effectively. Methods of self-guided study often result in non-optimal allocation of study time (Son \& Sethi, 2010). Improved methods are available, but students generally do not employ them, even though it has been shown that it is possible to use metacognitive control. There is potential for optimal study (Son \& Sethi, 2006), but students instead use uninformed metacognitive decisions to structure their study time.

A possible exception to the overconfidence phenomenon is the occurrence of math anxiety (Meece, Wigfield, \& Eccles, 1990; Furner \& Berman, 2003). Math anxiety (or math phobia) is a fear of math that leads to math avoidance or lower math performance (Ashcraft, 2002; Ashcraft \& Krause, 2007) and has been observed in children and adults alike (Wigfield \& Meece, 1988). This sometimes extreme anxiety is harmful in educational and workplace settings (Meece et al., 1990; Furner \& Berman, 2003), undermining national and worldwide priorities to emphasize science, technology, engineering, and math (STEM) achievement. Indeed, a recent national report predicts increased demand for STEM professionals in the US as well as an inadequate supply of prepared graduates (STEMconnector, 2013). Performing math tasks in stressful situations, such as during tests, only compounds math anxiety (Beilock, 2008). Mathphobic attitudes of teachers can also be detrimental to students' math achievement, particularly for female teachers and students (Beilock, 2010).

This fear of math implies that there should be a corresponding underconfidence in self-evaluation of
mathematical ability. The consistent and persisting documentation of widespread math phobia contradicts the finding that people are generally overconfident. How then can we resolve this paradox? We wish to determine if students are as overconfident in math as they are in other academic domains, or if is math an exception to an otherwise global overconfidence.

Past findings indicate that females generally lag behind their male counterparts on standardized test performance in math (Brown \& Josephs, 1999). This is particularly true among high school and college students (Hyde et al., 2006). This gap does appear to have narrowed in recent years (Else-Quest, Hyde, Shibley, Marcia, 2010). However, attitudes toward math between genders still follow differing patterns, and females are more likely to feel intimidated by math than are males (Jakobsson, 2012; Brown \& Josephs, 1999). This lack of confidence often leads to a selffulfilling lag in performance (Brown \& Josephs, 1999; Kiefer \& Sekaquaptewa, 2007) that can lead to gaps in performance between genders.

We wish to explore is if overconfidence generalizes to all domains of academic knowledge and ability, or if it is domain specific. If there exist confidence differences among various academic subjects, this suggests that overconfidence is domain specific and not a general phenomenon that is implied by the findings of Kruger \& Dunning (1999) and Dunning et al. (2003). If overconfidence is a global phenomenon, we would expect to see overconfidence in students' ratings across various academic domains. If metacognition is instead domain specific, we would then expect to find differences in overconfidence among academic domains. In the light of math phobia, we would expect to see underconfidence rather than overconfidence in math tasks, in contrast to other domains.

We also seek to determine if metacognitive ability differs over gender as well, keeping in mind that female students show greater math phobia than males. Finally, we compared metacognitive judgments before and after an intervention, namely taking a test, to determine if students are able to improve their metacognitive judgments. We expected to see improvements, as people could re-evaluate their metacognitive estimates after being exposed to more information in the intervention. This would be consistent with Bayesian accounts of cognition, in that people would be updating their hypothesis of ability based on new observations (Jones \& Love, 2011; Heit \& Erickson, 2011).

## Experiment

We considered test performance, confidence, and calibration in predicted scores. Three comparisons will be highlighted. The first is the comparison among the three different SAT II Subject Tests to assess if overconfidence is a domain specific or general phenomenon. While predictions (estimates before taking an assessment) provide a measure of general confidence within a subject, postdictions (estimates after taking an assessment) provide a more
accurate and comparable measure of metacognitive ability to evaluate knowledge. The use of SAT II Subject Test sample questions gave participants a reference for difficulty level of the assessment before they take it. However, it might have been some years since the participants have taken these, and some participants may have chosen to take a different selection of subject tests than the ones presented in this experiment. Use of retrieval fluency and recognition heuristics would negatively affect metacognition, both for past experience and future performance (Benjamin, Bjork, \& Hirshman, 1998). The use of postdictions brings all participants to a more equitable level of familiarity with the test material before making a judgment of ability. As such, calibration was determined by comparing postdicted estimates of performance with actual scores of performance. If overconfidence is domain specific, we then expect that metacognitive performance would differ among different domains, and that there would be a higher rate of underconfidence within math. If metacognition is domain general, then a similar level of overconfidence should be observed across all three assessments.

The second comparison will be one made between genders. Males were expected to show higher confidence ratings in math than females. Third is the comparison between predictions and postdictions for performance on a task. This allows us to determine if participants improved their metacognitive judgments after completing a task. We expect that postdictions for performance on a task will be more accurately calibrated than predictions for the same task, and results reflected this.

## Method

Participants There were 31 participants in this experiment: 17 female and 14 male. All were UC Merced undergraduates (mean age $=19.03, \mathrm{SD}=0.98$ ) who took the experiment as a form of extra credit in one of their introductory Psychology or Cognitive Science classes.

Tasks and Materials Participants took three tests: a biology, literature, and math test, each consisting of 15 questions. Participants were told before the experiment that they would be taking tests based on SAT II Subject Tests content. Before each test, participants were asked to provide a predicted score (out of 15) for how well they would do. After taking each test, participants provided a postdicted score for how well they thought they performed. They were not told their actual scores on tests.

## Results

Key descriptive results for all participants are shown in Figure 1. The leftmost bar for each category represents average predicted score, the middle bar represents average actual test score, and the rightmost bar represents average postdicted score. Average performance across all tests was $40 \%$. Participants showed general overconfidence in predicted scores before each test. Overconfidence generally persisted in postdicted scores, although drastic reductions in
residual magnitudes show that participants were better able to assess their ability after each test, providing evidence for improvement in metacognitive judgment of ability ( $t=3.30$, $d f=60, p<0.0001$ ). The only test in which participants showed slight underconfidence was biology.

Notably, participants showed high overconfidence in math. The residual for average predicted math score was $35 \%$. This was higher than the residuals for both biology (2.6\%) and literature (19\%).

Results by gender are shown in Figures 2 and 3. Notable was the difference in calibration between genders. Overall, females were more accurate in self-estimates of ability. Differences between their predictions and scores averaged $11 \%$, compared to $29 \%$ for males. Similarly for postdictions, females misestimated their performance by an average of $5 \%$ while males misestimated by an average of $14 \%$. Males were generally overconfident both before and after taking each assessment. Overall, females had lower measures of overconfidence. Within literature and math, females began with overestimates of their ability, but their postdictions were more calibrated. Within biology, females actually started underconfident and became even more so after taking this assessment.

Both genders show little trace of math phobia, as shown by their predominant overestimates of performance. Average prediction and postdiction residuals in math were $27 \%$ (overconfident) and $-5 \%$ (underconfident) for females and were $42 \%$ and $15 \%$ for males. Though participants were generally overconfident with their predictions, they were able to improve their metacognitive judgment accuracy significantly in this domain. Males showed the most marked improvement in calibration in math, and females actually changed their judgments from being overconfident to predominantly underconfident.

In a three-way, predicted versus actual score $\times$ academic subject (biology or literature or math) $\times$ gender (male or female) ANOVA, there was a main effect of gender $F(1,29)$ $=4.48, M S E=13.69, \eta^{2}=0.08, p<0.05$. There was also a significant main effect of predicted ( mean $=59.00$ ) versus actual $($ mean $=40.22)$ score, $F(1,29)=36.61, M S E=10.1$, $\eta^{2}=0.50, p<0.0001$, indicating overconfidence in predictions. There was also a significant main effect of academic subject, $F(2,116)=6.59, M S E=5.33, \eta^{2}=0.08$, $p<0.01$. Notice that scores were lowest overall in math. There was a significant interaction between these two variables, $F(2,116)=16.80, M S E=5.33, \eta^{2}=0.20, p<$ 0.0001 , indicating that degree of overconfidence depended on academic subject. Overconfidence was greatest in math (predicted score $=62.15$, actual score $=27.53$ ). We are careful not to over-interpret the interaction, as actual scores also varied by academic subject. There was also a significant interaction between gender and predicted versus actual score, $F(1,29)=8.19, M S E=10.1, \eta^{2}=0.11, p<$ 0.01 , providing further evidence that overconfidence depended on gender. The remaining main effects and interactions were not significant.

Figure 1: Overall results by test.

Figure 2: Overall results for females.

Figure 3: Overall results for males.
We also conducted a similar analysis on postdicted scores $($ mean $=43.44)$ and actual scores. This ANOVA revealed a main effect of academic subject, $F(2,116)=36.28, M S E=$ 4.85, $\eta^{2}=0.37, p<0.0001$, as well as a main effect of gender $F(1,29)=4.48, M S E=15.49, \eta^{2}=0.09, p<0.05$. There was also a significant interaction between gender and postdicted versus actual scores, $F(1,106.27)=17.55, M S E$ $=6.05, \eta^{2}=0.37, p<0.001$, again showing gender differences in overconfidence. Remaining main effects and interactions were not significant.

Note that although scores were lowest for math, this assessment was not designed to be more difficult than the
other subject tests. In fact, it had the lowest difficulty level. During pilot experiments, test questions were chosen using difficulty ratings provided by College Board. Although we originally chose a variety of easy, medium, and difficult questions for each subject test, performance on this balanced math test was so poor that we substituted easier questions in place of all medium and difficult questions. Thus, the severe overconfidence observed in math is not a result of higher test difficulty level compared to other academic subjects.

Figures 4 and 5 show calibration slopes by domain. The dashed line represents the equation $y=x$ (predicted score $=$ actual score) is used to convey perfect calibration. The closer a line is to this dashed line, the better the calibration. For the predicted scores, there are apparent subject differences, e.g., the slope is highest for math, indicating the highest level of sensitivity to actual performance, and the slope is actually slightly negative for biology. Each domain slope more closely follows the calibration line $y=x$ for postdicted scores, showing that that participants were better able to judge their ability after taking each assessment. Each of models also crosses $y=x$, switching from overconfidence to underconfidence as test performance increases. In addition, correlations between actual scores and residuals calculated from estimated scores $(r=-0.63$ for both predicted and postdicted residuals) reveal that

Figure 4: Overall results for postdicted scores.

Figure 5: Overall results for females.
higher scores are associated with lower residuals. These findings support the previous work by Kruger \& Dunning (1999), Dunning et al. (2003) and Schraw (1996) and show that people with low test scores generally exhibit overconfidence, while people with high test scores are better able to judge their ability. Thus higher performing students tend to be better judges of their ability than are lower performers.

Gender differences were most striking within math. Figure 6 and 7 show calibration models by gender for both predictions and postdictions. Males made predictions with almost no calibration ( $r=0.02$ ), and females were overconfident overall with the predictions. Despite this, both genders were able to make much more accurate postdictions. In fact, these postdiction models were the best of any of the observed estimates of ability in this experiment when compared to other subjects.

## Discussion

The results of this study support past findings that people are generally overconfident in their abilities, although overconfidence does not appear to be exactly the same across domains. This was shown in the varying judgments of ability across academic domains. While both males and females are generally overconfident, females tend to be better calibrated in judging their domain knowledge.

Figure 6: Overall results for females.

Figure 7: Overall results for females.

Postdictions were significantly lower than predictions, showing that people are able to recalibrate their metacognitive judgments towards more accurate judgments after attempting an assessment.

In addressing the paradox of general overconfidence alongside the seeming exception of math phobia, we saw that overconfidence was particularly high in predicted scores for math assessment. This led us to question whether math phobia was present.

Although there was a higher incidence of overconfidence in mathematics, participants showed the greatest beneficial adjustment of metacognitive judgment miscalibration for mathematical ability. All participants were successfully able to recalibrate their estimates towards more accurate judgments of domain knowledge after an assessment.

We have replicated this severe overconfidence in math in other experiments, although gender no longer reached the level of statistical significance. Thus high math overconfidence is not specific to college-level students: In a subsequent experiment $(n=40)$, this result was replicated at a local high school using the same experimental design. In another experiment with college students $(n=46)$, we extended our findings by using the same experiment presented here, but also including Likert scale measures of confidence for each domain, as well as an adapted math Anxiety Rating Scale (MARS) survey (Alexander \& Martray, 1989). Initial results indicate that there does exist math phobia, as we observed MARS ratings similar to other college populations identified as math anxious. We expected higher anxiety ratings to be linked with underestimates of ability. We did not observe this. Instead, math phobia moderated overestimates of ability to be less extreme, although overconfidence still persisted. This is a possible explanation for the coexistence of math phobia and overconfidence in mathematical ability. Further plans include the replication of studies within actual classroom settings in which participants must judge their ability on class assessments.

Does a higher confidence in one subject over another really indicate domain specificity rather than generality? If so, this suggests we may be using different metacognitive methods for different domains such as sciences versus the humanities. Alternatively, we might be using one overarching metacognitive ability that uses different cues and leads to different results across domains.

Our results are relevant for applications in cognitive science, particularly for studying and improving education. We have seen that students are overconfident in math, yet there is evidence that these same students are math phobic. These views pose two strong deterrents for students to seek practice and improvement in math. If students are overconfident in their mathematical abilities and have anxiety about mathematical tasks, they have little incentive to study the subject. This reluctance likely carries over to other science, technology, and engineering subjects that require a significant amount of math background.

We also know that our use of metacognition does not always lead to calibrated self-views of ability. There are optimal models for allocation of study time, but student behaviors do not conform to these (Son \& Sethi, 2006; 2010). Judgments of improvement and learning rate that students use to make time allocation decision are often inaccurate as well (Townsend \& Heit, 2010; 2011). Math phobia has come to be so expected that it has started to influence curriculum design. Already changes have been made in computer science programs to deemphasize math (Tucker, 2001) even though math content is fundamental to this area. The spread of this trend to other science, technology and engineering programs would seriously undermine students' foundational math knowledge. Therefore it will be important to develop techniques that improve students' metacognitive calibration for mathematics and other subjects.

# Candle-Candle-Candle-Candy: Continuous Attraction Toward Previously Seen Phonological Competitors 

Jesse Falke (jfalke@ucmerced.edu)<br>Bodo Winter (bodo@bodowinter.com)<br>Michael J. Spivey (spivey@ucmerced.edu)<br>Cognitive and Information Sciences, 5200 North Lake Road, Merced, CA 95343 USA

#### Abstract

Mouse-tracking provides rich information about temporally sensitive mental processing. In two experiments, we applied this methodology to a phonological cohort task that can be interpreted as a version of the A-not-B task. In the first experiment, participants had to click a word such as "candle" three times in a row on the same side of the computer screen. They then had to click a phonological competitor ("candy") on the other side during the critical trial. This was contrasted with a condition in which the word to be clicked three times in a row was phonologically unrelated to the word at the critical trial. We found that the phonological priming increased attraction toward the competitor. In the second experiment, mouse movements revealed attraction towards the competitor as a function of the number of previous presentations. The results demonstrate that phonological competitors can exert graded influence on motor responses even if the competitors are not simultaneously presented. These results are predicted by and provide evidence for the dynamic field theory of movement preparation and execution. These results can furthermore be interpreted as evidence for continuity underlying the A-not-B task.

Keywords: A-not-B error; deictic pointers; dynamical systems; mouse-tracking

## Introduction

The A-not-B error has been investigated with children for over half of a century (Piaget, 1954). In the standard version of the task, the researcher presents an object to the child and hides it in one location (" A "). When this process is repeated multiple times, the child will often reach for the object in " A " even if it was moved in front of the child's eyes to another location, "B". Eight to ten month old children reliably commit this error (cf., Marcovitch \& Zelazo, 1999).

Smith and Thelen (2003) and Thelen, Schöner, Scheier and Smith (2001) conceptualize the A-not-B task in terms of dynamic field theory (Erlhagen \& Schöner, 2002), where the decision to perform a movement towards either A or B develops in a continuous fashion. The theory views the A-not-B error as the result of changes to an activation field, where both $A$ and $B$ are represented as points on a plane. If the researcher hides a toy under A , the point for A increases in activation and sends inhibitory activation to B . The child reaches for A if a threshold of activation is crossed. Crucially, the memory of this reaching "pre-shapes" the field for the next trial. Over multiple trials, the A region of the field becomes stronger and increasingly exerts inhibitory
influence on the B region of the field, ultimately resulting in the A-not-B error.

Dynamic field theory accurately predicts that if posture is changed between A and B trials (Smith, Thelen, Titzer, \& McLin, 1999), the child does not commit an A-not-B error as often. This follows from the assumption that changes in posture on $A$ and $B$ trials decrease the similarity of preceding memories to the current trials, thus lessening the strength of the pre-shaping of the field.

This account is also compatible with another area of research, deictic pointers (Ballard, Hayhoe, Pook \& Rao, 1997; Chun \& Nakayama, 2000; Richardson \& Spivey, 2000). By associating content and locations with a deictic pointer, a cognitive agent can reference necessary information and use it to aid action without having to build up a detailed model of the world. We will argue that the formation of dynamic fields can be viewed as the formation of deictic pointers.

In this paper, we explore how previously seen stimuli affect perseveration in a mouse-tracking experiment. Mouse-tracking provides a real-time stream of $x, y$ coordinates during movement that has been used to reveal the continuous dynamics underlying a diverse set of cognitive processes, including phonological competition in lexical access (Spivey, Grosjean, \& Knoblich, 2005), the comprehension of sentence negation (Dale \& Duran, 2011), the categorization of typical and atypical objects (Dale, Kehoe, \& Spivey, 2007), and the categorization of faces (Freeman, Ambady, Rule, \& Johnson, 2008), among many others (for a review, see Freeman, Dale, \& Farmer, 2011).

In Spivey et al. (2005), participants saw two objects in opposite corners of the computer screen, e.g. a candy and a candle. They then heard a target word referencing one of the objects, such as "candy", while they executed the movement to click it. When the two objects were phonologically related, the mouse gravitated more toward the competitor object than when they were phonologically unrelated.

Here, we extend the task used by Spivey et al. (2005) to show the graded influence of phonological competitors that are not simultaneously present on the critical trial. Similar to the A-not-B task, we present an object such as "candy" multiple times on one side, and then on the next trial we present "candle" on the opposite side. Dynamic field theory predicts that multiple memory traces of "candy" on one side should exert graded inhibition when seeing the phonologically related "candle" at a different spatial
location. While adults may not commit the full A-not-B error by accidentally clicking on the wrong object, their mouse movements might still reveal continuous attraction towards previously seen competitors.

## Experiment 1

In the first experiment, we presented each participant with phonologically related and phonologically unrelated stimuli. Mouse movements were recorded during each trial to investigate the effects of repeated movements to phonological and non-phonological competitors.

## Methods

Participants Thirty-three undergraduates at UC Merced volunteered to participate to receive partial course credit. All participants were right-handed native speakers of English. 3 stimuli were excluded because of computer lag (0.24 \%).

Stimuli and Procedure The procedure was run using MouseTracker (Freeman \& Ambady, 2010). On each trial, two 200 pixel-wide pictures were presented in the top corners of the screen. Using headphones, we presented a target word for which the corresponding object had to be clicked (e.g., "pickle", "pepper"). Each pair of objects was always phonologically unrelated (e.g., "candle" vs. "lobster"). However, there were 16 critical trials that were preceded either by three trials to the same side without a phonological competitor (lighting-left, pepper-left, speakerleft, candy-right) or three trials to the same side with a phonological competitor (candle-left, candle-left, candleleft, candy-right). These two conditions are called "motor-3" and "phonological-3" respectively. The prime was always the target item. So, for example, a participant might have had to click "candy" three times on the left side and then, on the critical trial, "candle" had to be clicked on the right side (see Fig. 1). Across participants, we balanced the position (left vs. right) in which the target and the primes occurred, and we also balanced which of the competitors occurred as prime, and which as target (i.e., "candy-candy-candycandle" vs. "candle-candle-candle-candy"). In total, there were 8 "motor-3" items and 8 "phonological-3" items (16 critical stimuli)..

There were also 24 filler trials that occurred between critical trials and subsequent priming trials. In the analyses below, we count these filler trials as control trials, as they represent mouse movements toward target objects for which there is no previous prime and no phonological competition. There were thus 88 trials in total. These were preceded by 12 practice trials.
We instructed participants to initialize mouse movements before they heard the sound file. To encourage this, the gain was slowed down to 2 (MouseTracker setting), and the sound file played the target word after a 500 ms delay.

Figure 1: Schematic depiction of experimental trials. Note that on the critical trial, the competitor is not present.

All stimuli were spoken by a native speaker of English. For the prime-3 condition, we recorded three different utterances of the same word by the same speaker to reduce the possibility of selective adaptation effects. Mouse coordinate data was sampled at 60 Hz and was recorded with screen display information, movement durations and final response.

Analyses We inverted the $x$ coordinates of left-going responses so that left- and right-going responses had comparable spatial metrics. We then normalized all responses to have a common origin at ( 0,0 ). Mouse-tracking provides a large set of potential dependent measures. We focused on the Euclidian distance of each measured point from the diagonal line that is defined by the origin in the center of the screen and the corner response box. All analyses we present were time-normalized to 101 time steps per trial.
We analyzed our data in two ways. First, we used the R package lme4 (Bates, Maechler \& Bolker, 2012) to perform growth curve modeling (Mirman, Dixon \& Magnuson, 2008). Time step ( 1 to 101) entered the analysis as a fourth order orthogonal polynomial fixed effect (including lowerorder polynomials), and the crucial effect of interest was the interaction of condition (prime-1, prime-3, control) with time. In the by-subjects-analysis, we included random intercepts for subjects, as well as subject random slopes for time and condition (following Mirman et al., 2008). In the by-items-analysis, we did the same for items. P-values were derived separately for each coefficient based on normal approximated t -values.
Growth curve analysis allows modeling the precise trajectory; however, for comparability with other mouse tracking studies and to get the exact time points of where trajectories differ, we present an alternative analysis following Dale, Kehoe and Spivey (2007), who have shown by means of simulated random trajectories that 8 consecutive t-tests may count as a significant result at $\alpha=$ 0.01 .

With mouse-tracking data, there is always the possibility that average differences between conditions are not due to genuine gradedness in the response, but due to averaging over trials that head straight to a target and trials where participants correct a categorical choice midflight. To assess whether this could explain our results, we computed the bimodality coefficient $b$ (see Freeman \& Ambady, 2010) on the $z$-scored (by subjects and by condition) maximum deviation from the diagonal line and the area under the curve (measures are described in Freeman \& Ambady, 2010: 229). $b$ values over 0.555 are interpreted as evidence for bimodality.

## Results

There were 9 errors in total ( $0.72 \%$ of all trials), all in the control condition. Therefore, there was no indication of a categorical A-not-B error. All subsequent analyses are performed on correct trials only.

Fig. 2 shows the evolution of the Euclidian distances from the diagonal line over time. For the growth curve analysis, likelihood ratio tests revealed a significant difference between the phonological and the pure motor condition by items ( $p=0.025$ ), and a marginally significant difference by subjects ( $p=0.079$ ). In both cases, there were significant interaction effects of condition for the cubic and quadratic components of the model (cubic by subjects, $\mathrm{p}=0.0054$, by items, $p=0.02$; quadratic by subjects, $p=0.024$, by items, $\mathrm{p}=0.021$ ).

The phonological competition condition was significantly different from control by subjects and by items ( $p=0.009$, $\mathrm{p}=0.0065$ ). In both cases, the intercept was higher for phonological competition than for control (by subjects: $\mathrm{p}=0.016$, by items: $\mathrm{p}=0.027$ ), indicating overall larger Euclidian distances for this condition. In the subjects analysis, there were additionally significant effects for interactions between condition and the linear ( $\mathrm{p}=0.003$ ), cubic ( $\mathrm{p}=0.01$ ) and quadratic ( $\mathrm{p}=0.0034$ ) components of the model. The motor priming condition was significantly different from control only by subjects ( $p=0.008$ ) and not by items ( $p=0.175$ ). In both cases there were individual effects for the intercept (higher in motor priming than in control, by subjects: $p=0.01$; by items: $p=0.048$ ), but no effects for higher-order polynomials.

The alternative analysis, following Dale et al. (2007), revealed no consecutive significant differences between phonological and motor priming that passed the 8 t-test criterion. There were 36 significant differences between phonological priming and the control condition in the subjects analysis (time points 59 to 94), and 50 in the items analysis (time points 3 to 25 and 59 to 85). The region that is significant in both analyses is shaded in Fig. 3. There were 29 significant differences ( 73 to 101) between control and motor priming by subjects, as well as 30 by items ( 3 to 32). Interestingly, in this case, these regions were not overlapping.

Figure 2: Euclidian distance as a function of time. Gray area indicates significant differences between phonological competition and control (by subjects and items).

Bimodality analyses revealed no subject with $b>0.555$ for the crucial phonological competition condition, neither for the measure "maximum deviation from the diagonal", nor for the measure "area under the curve". For the motor priming condition, 1 participant had $\mathrm{b}>0.555$ for maximum deviation ( $\sim 3 \%$ ), and 4 participants for area under the curve ( $\sim 12 \%$ ). Again, this shows that the results are fairly unimodal across the board.

## Discussion

The results for the motor-3 and phonological-3 conditions were interesting. In the growth curve analysis, it was surprising that there were significant differences between the two conditions for items, but only marginally significant differences for subjects. This is surprising because the items-based analyses use a smaller sample than the subjects based analyses ( $\mathrm{N}=33$ in the subjects analysis and $\mathrm{N}=16$ in the items analysis). More data will need to be collected to explain this.

Another way to look at the data is to see when and how long the two conditions differed from the control condition in the analysis proposed by Dale and colleagues (2007). While both conditions displayed significant differences from the control by subjects and items, only the phonological priming condition displayed significant differences by both subjects and items simultaneously. In addition, the phonological condition resulted in more total significant differences from the control than the motor priming condition ( 86 vs. 59). If we take the number of significant simultaneous consecutive differences as a measure of strength of the difference (cf., Dale et al., 2007), then the prime-3 condition showed more gravitation away from the diagonal line (towards previously seen competitors) than the prime- 1 condition.

While this experiment has revealed that attraction toward a previously displayed stimulus is modulated by said stimulus being a phonological competitor, there is more to
dynamic field theory. Experiment 2 was designed to further investigate how well dynamic field theory could be applied to these results by varying the number of phonological primes before the critical trial.

## Experiment 2

In this experiment, we modified Experiment 1 slightly. Rather than presenting three motor primes or three phonological primes, the two critical conditions now both used phonological primes. One condition used three primes ("prime-3"), while the other condition used just one prime before the critical trial ("prime-1").

## Methods

Participants Thirty-two undergraduates at UC Merced volunteered to participate and received partial course credit. All participants were right-handed native speakers of English. 9 trials were excluded because of computer lag (0.8\%).

Stimuli and Procedure This experiment had a similar setup to Experiment 1 and made use of the same stimuli. The prime-3 condition was identical to the phonological-3 condition in Experiment 1. There were 18 filler items.

## Results

There were 9 errors in total ( $0.8 \%$ of all trials), 8 in the control condition ("fillers") and 1 in the prime- 3 condition. Crucially, this means that there were no noteworthy differences between the prime-3 and prime-1 error rates, indicating that no categorical A-not-B-like error was committed. Subsequent analyses will be performed on correct trials only.

Fig. 3 shows the evolution of the Euclidian distances from the diagonal line over time. There was a significant interaction between the prime-3 and the prime- 1 condition for the linear component of the growth curve model in the items analysis ( $\mathrm{p}<0.02$ ), and a nearly significant interaction in the subjects analysis ( $p=0.053$ ). This linear component indicates a steeper rise for the trajectory of the prime-3 condition than of the prime-1 condition. However, a likelihood ratio test comparing the full model with the factor "condition" against the model without indicates an only marginally significant overall effect of "prime-3 vs. prime1 " (subjects: $p=0.066$, items: $p=0.09$ ).

There were, however, significant differences between prime-3 and control both by subjects ( $\mathrm{p}=0.0008$ ) and by items ( $p=0.015$ ). This difference seems to stem from the linear component of the model (subjects: $\mathrm{p}=0.0018$, items: $\mathrm{p}=0.026$ ), and for the subjects analysis, there also was a significant difference in intercept ( $\mathrm{p}=0.0049$ ), reflecting overall larger Euclidian distances for the prime-3 condition than for trials without phonological competition and without previous movements towards the competitor. Finally, there was no significant difference of the overall model between prime -1 and the control condition (all p's $>0.1$ ). Comparing this to the effect of the prime-3 condition, this suggests that
the prime-3 trials did in fact deviate more strongly from control trials.

In terms of Dale et al. (2007)'s approach, there were 12 consecutive significant differences between prime-3 and prime-1 (time points 90 to 101) by subjects and none by items. There were 48 consecutive differences for prime-3 versus control (time points 54 to 101) by subjects, and 28 (74 to 101) by items. In contrast, there were 41 consecutive differences for prime-1 versus control (time points 20 to 34, and 64 to 101) by subjects and none by items. The shaded gray area in Fig. 2 shows the portions of prime-3 versus control that are significant in both the subjects and the items analysis.

By-subject bimodality coefficients for maximum deviation of the prime- 1 and prime-3 conditions were all below 0.555 for maximum deviations, indicating that the present results are unlikely due to averaging over bimodal responses. Bimodality coefficients for the area under the curve were above 0.555 for only three participants ( $\sim 9 \%$ ) in the 3-prime condition and for 4 participants (12.5\%) in the prime-1 condition.

Figure 3: Euclidian distance as a function of time. The shaded gray area indicates where prime-3 and control are significantly different from each other by subjects and items.

## General Discussion

In Experiment 1, we found a difference between a purely motor priming condition and a condition that had both a motor priming and a phonological priming aspect. This difference seems to lie within the higher-order polynomials of the curve fit, suggesting that complex details in the shape of the trajectories are of importance in characterizing the difference between the two conditions.. Experiment 2 further established that previous exposure to critical stimuli did affect the trajectory of upcoming trials, and there was indication that the strength of this effect was modulated by the number of previous priming trials.

In both experiments in comparison to the control condition, only the phonological-3 condition produced a
significant deviation in both the subjects and the items analysis simultaneously (shaded area Figs. 2 and 3). This was regardless of the two analysis approaches that we used above.

These results fall straightforwardly out of a dynamic field theory account of how the brain treats memory traces of objects and locations in general (Erlhagen \& Schöner, 2002; Spencer, Barich, Goldberg, \& Perone, 2012), and the A-notB error in particular (Smith \& Thelen, 2003; Thelen et al, 2001). However, in contrast to children, repeatedly clicking on a location ("A") did not lead to a categorical error (there were no significant differences in error rates between the conditions). Instead, there was evidence for a continuous, graded attraction toward the competitor.

Figure 4: Schematic activation patterns of the movement layer in a hypothetical dynamic field simulation of repeated left-moving trials (towards "A").

A similar type of finding comes from Diamond and Kirkham's (2005) adaptation of Zelazo, Frye and Rapus's (1996) Dimensional-Change Card Sort task, typically used with children. After doing multiple trials with one cardsorting rule, Diamond and Kirkham's participants were then told explicitly that the sorting rule has changed for the next block of trials. Children routinely make sorting errors on the first trial of the new block. Adults do not make categorical errors, but they do produce significantly longer reaction times on the first trial with the new sorting rule. Hindy and Spivey (2008) extended this finding by showing that adults also curve their mouse movements significantly toward the old rule's response option.

These results can also readily be interpreted from the theoretical perspective of deictic pointers or visual indices (Ballard et al., 1997) - such that peaks in the dynamic field may function as the pointers. Chun and Nakayama (2000) state that "...memory traces interact with attentional mechanisms to guide eye movements, cognition, and action." In the case of our experiment, these memory traces are built up from preceding trials, similar to the "preshaping" done by the previous trials in the A-not-B task. Fig. 4 provides a visual illustration of these cognitive processes. A peak on one trial builds a memory trace in the field that increases the activation of subsequent trials in that
location ("A"). In addition, inhibitory connections between A and B suppress the activation of the other ("B") location, making these peaks progressively smaller.
The observed difference between the motor priming condition and the phonological priming condition also provides clues as to how semantic tags get associated with deictic pointers. In the motor condition, the only information that is repeatedly associated with the spatial location is the movement. In contrast, the phonological condition had repeated phonological information and visual content in addition to the movement. These richer associations may help account for the greater spatial attraction in these trials.

## Conclusions

In Experiment 1, we showed that presentations of phonological cohort stimuli result in increased spatial attraction toward the competitor's location, even though the cohort is not simultaneously present on the critical trial. There was evidence that this spatial attraction increased due to a genuine effect of phonological competition. In Experiment 2, we modified the conditions to test the dynamic field theory prediction that multiple presentations of similar stimuli result in greater competition. We found evidence that the prime-3 condition resulted in increased spatial attraction toward the competitor in comparison to the prime-1. This can be interpreted as showing that phonological similarity and repeated presentations influence the landscape of the dynamic field. Dynamic field theory as applied to the A-not-B task readily predicts the observed results. For Experiment 1, phonological similarity should influence spatial attraction because the memory traces developed during the repeated trials are stronger than those without phonological similarity. In regards to Experiment 2, repeated presentations should also increase the strength of the memory trace (represented as a pre-shaped field), and cause increased spatial attraction.

Overall, this study and its results add to the literature by providing a indication of how dynamic field theory may be able to account for the data of an A-not-B like task in adults, as well as a novel way of investigating the formation of deictic pointers. The various processes of visual cognition and language in our experiment are spread out in time in such a way that each experimental trial is not independent of previous trials. The landscape of the dynamic field itself is an important theoretical construct for understanding these temporal dynamics. Taken together, these results are powerful support for the value of dynamic field theory modeling and the mouse-tracking experimental methodology. In the future, we intend to conduct additional control experiments within this research program as well as model human data explicitly with dynamic field theory simulations.

## Acknowledgments

We thank Teenie Matlock for making lab space available to us. We thank Robert Räder for helping out with figures.

# Communication and Categorization: New Insights into the Relation Between Speech, Labels and Concepts for Infants 

Brock Ferguson (brock@u.northwestern.edu)<br>Sandra R. Waxman (s-waxman@northwestern.edu)<br>Department of Psychology, Northwestern University, 2029 Sheridan Rd.<br>Evanston, IL 60208 USA

#### Abstract

Almost two decades of research has demonstrated that labels facilitate infants' categorization of novel objects. Some interpret this as evidence of an early link between infants' linguistic and conceptual systems. Others suggest that these effects stem exclusively from lower-level processing mechanisms in cross-modal perception, and that words promote categorization only because they are more familiar to infants than non-linguistic acoustic stimuli and therefore easier to process. Here we address these discrepant interpretations using a novel approach. We expose infants to unfamiliar non-linguistic stimuli (sine-wave tone sequences), manipulating the exposure conditions. For 6-month-olds, if the novel acoustic stimuli were embedded within a communicative episode, they subsequently facilitated categorization (Experiment 1), but if they were presented in a non-communicative episode, they had no such effect (Experiment 2). We propose a developmental model that takes infants' burgeoning perceptual and conceptual capacities into account in identifying how communication and words are linked to concepts.

Keywords: language development; words; concepts; categorization; auditory overshadowing; infancy

## Introduction

The nature of word learning has been the focus of a noteworthy debate in recent years. At stake is the relationship between words and concepts: Are words merely associated with objects by infants, as any percept might be associated with another (e.g., Sloutsky \& Fisher, 2012)? Or might even the youngest word learners appreciate words as symbols that refer to concepts (e.g., Waxman \& Gelman, 2009)? Further, if there is a privileged link between words and concepts in infancy, how is it established?

Evidence for this latter position, positing an early and unique link between words and concepts, comes from numerous studies demonstrating that infants integrate domain-specific knowledge about words when they map novel words to objects (Fennell \& Waxman, 2010; Namy \& Waxman, 2000; Woodward \& Hoyne, 1999), generalize words to object concepts (Booth \& Waxman, 2009; Booth, Waxman, \& Huang, 2005), make inferences about hidden properties of named objects (Diesendruck \& Graham, 2010; Gelman \& Heyman, 1999; Graham, Booth, \& Waxman, 2012), and individuate named objects (Dewar \& Xu, 2007; 2009).

There is also evidence for a developmental cascade underlying infants' establishment of a link between words and concepts. Initially, infants appear to hold a broad expectation that words refer to commonalities amongst objects (Waxman, 2003). With development, they refine this broad expectation to link particular types of words (e.g., nouns, adjectives) to particular types of categories (e.g., object categories, property categories) (Booth \& Waxman, 2009). This increasingly precise relation between words and concepts can be observed over the first year in object categorization tasks. Infants hearing human language successfully form categories, but other matched acoustic stimuli (e.g., sine-wave tone sequences) do not (Balaban \& Waxman, 1997; Fulkerson \& Haaf, 2003; Fulkerson \& Waxman, 2007; Waxman \& Markow, 1995). More recent evidence reveals that infants as young as 3- and 4-months (who do not yet segment distinct words from fluent speech) form object categories in the context of human speech, but not in the context of sine-wave tones (Ferry, Hespos \& Waxman, 2010). Thus over the first year, infants' response to words may be a refinement of a broader and earlier response to communicative signals.

Some researchers have argued that the influence of language in these studies reflects cross-modal perceptual processing alone (Robinson \& Sloutsky, 2007; Sloutsky \& Robinson, 2008). Their claims are clear: (1) object categorization tasks with paired acoustic stimuli recruit infants' cross-modal processing abilities, (2) unfamiliar auditory stimuli impede visual processing through "auditory overshadowing", and (3) verbal labels are more familiar to infants than the acoustic stimuli (e.g., tone sequences) to which they are typically compared (Sloutsky \& Robinson, 2008). On this account, words benefit category formation only insofar as they are acoustically familiar.

Here we take a novel empirical approach to tease apart these two accounts. In each experiment, infants participated in a standard object categorization task. But instead of pitting human language against unfamiliar sounds, all infants heard the same unfamiliar sounds: sine-wave tone sequences. Crucially, we introduced infants to these novel sounds in a video before they were presented within an object categorization task. This gave us full control over infants' prior exposure to these novel stimuli, which in turn permits us to ascertain the precise exposure conditions that enable an auditory stimulus to facilitate visual categorization. In Experiment 1, we ask whether embedding
tone sequences in a communicative episode will allow them to subsequently facilitate object categorization. In Experiment 2, we document that this effect cannot be accounted for by appealing to familiarity alone.

## Experiment 1

We introduced 6- and 12-month-old infants to novel acoustic stimuli (sine-wave tone sequences), embedding it in a clearly communicative episode. Next, we presented new tone sequences, this time within the context of the standard object categorization task. We asked whether tone sequences would now (like speech) facilitate categorization. If infants interpreted the novel tone sequences presented in the video as communicative, then tones may now promote categorization in the standard task. However, if infants do not privilege this novel signal with communicative status, or if they resist relating it to object categories, they should not form object categories in the standard task.

We expected the consequences of our manipulation to differ as a function of infants' age. At 6 months, we expected that embedding tones in a rich communicative episode would be sufficient to facilitate categorization but that, by 12 months, infants would require more specific evidence that the signal is referential. This is consistent with evidence that by 12 months, infants distinguish referential from non-referential communicative utterances and only interpret the former as referring to object categories (Fennell \& Waxman, 2010; Hollich, Hirsh-Pasek, \& Golinkoff, 2000; Waxman \& Braun, 2005).

## Methods

Participants Twenty-four healthy, full-term infants participated. Participants included twelve 6-month-olds (6 males, $M=5.94$ months) and twelve 12-month-olds ( 6 males, $M=12.08$ months). Another 13 infants (seven 6-month-olds, six 12 -month-olds) were excluded due to looking for less than $25 \%$ of the familiarization or test phases (8), fussiness (3), or parental interference (2).

Stimuli The design included three phases: exposure, familiarization, and test (see Figure 1). In the exposure phase, infants saw a 2-minute video of two undergraduate women sitting next to each other engaged in a communicative exchange. The "beeper" appeared to produce sine wave tones that had been dubbed over her mouth movements. The "speaker" responded in infantdirected English. Both interlocutors alternated between looking and speaking towards each other and the infant.

In the familiarization phase, infants saw 8 images of members of a single object category (either dinosaurs or fish, counterbalanced). Each image was presented for 20s with 4 s between images. Images were line-drawn and filled with unique solid colours. Each image was paired with a single sine-wave tone sequence, presented at image onset and 10 s post-onset. This sequence ( 2.2 s ), which differed in pitch from the sequences presented in the dialogue, was matched
for pause-length and duration to the labeling phrases used in previous studies (e.g., Ferry et al., 2010).

In the test phase, infants saw two new images in silence for 20s. One image was another member of the familiar category (e.g., another fish), and the other a member of a novel category (e.g., a dinosaur). The left/right position of the novel image was counterbalanced.

Procedure Infants sat on their caregivers' laps approximately 110 cm from the centre of a screen. Auditory stimuli were played through two speakers placed 85 cm apart beneath the screen.

Coding Infants' left-right eye gaze directions were coded frame-by-frame by trained coders blind to the hypotheses. A second coder re-coded the videos to assess reliability (Pearson's $r=.97, p<.0001$ ).

Analyses We analyzed the first 10s of looking to either

| EXPOSURE PHASE |  |
| :---: | :---: |
| Experiment 1 | Experiment 2 |
| Sine wave tones and speech (coordinated with conversation) | Sine wave tones and speech (uncoupled from video) |
| FAMILIARIZATION PHASE (Experiments $1 \& 2$ ) |  |
| 8 images, each paired with the same sine wave tone sequence |  |
| TEST PHASE (Experiments 1 \& 2) |  |
|  |  |

Figure 1: Experimental design of Experiments 1 and 2. Procedure for Exposure, Familiarization and Test Phases, with a sample of representative stimuli.
object in the test phase, as in prior research. (An analysis of the complete test trial yielded the same pattern of results in both experiments.) For each infant, a novelty preference score was calculated as the proportion of looking towards the novel category member. All analyses used arcsin-root transformed proportions.

## Results

As predicted, 6-month-olds $(M=.61, S D=.15)$ had significantly higher novelty preference scores than 12-month-olds $(M=.49, S D=.19), t(22)=1.72$, one-tailed $p$ $<.05$. Planned comparisons to chance showed a clear novelty preference (evidence of categorization) for the 6-month-olds $(t(11)=2.51, p<.03)$ but not the 12-month-olds $(t(11)=-.19, n . s$.$) .$

There were no age differences in looking towards the familiarization images ( $M_{6 \text {-months }}=.43, S D=.15 ; M_{12 \text {-months }}$ $=.53, S D=.13), t(22)=1.71, p=.10$, and no effects of familiarized category, novel object side at test, familiarization looking time, or gender on novelty preference scores (all p's $>.3$ ). All analyses collapsed across these factors.

## Discussion

When infants were introduced to sine-wave tones during a brief communicative episode (dialogue phase), tone sequences then facilitated object categorization (test phase) for 6-month-olds, but not 12-month-olds.

This age difference is striking. We suggest that at both 6and 12 -months, infants flexibly identify the candidate communicative signals in their environment. At 6 months, infants hold a broad expectation linking communicative signals to object categories. But by 12 months, infants recognize the distinct functions of different communicative signals (e.g., speech versus gesture; Martin, Onishi, \& Vouloumanos, 2012; and naming an object versus merely indicating it (e.g., "wow"); Fennell \& Werker, 2003; Namy \& Waxman, 2000). Therefore, at 12 -months, evidence of communicative status alone is insufficient: Infants require more precise evidence that a novel signal is one that refers to objects and object categories.

But could an appeal to signal familiarity alone account for these results? There are two hints that it cannot. First, the particular pattern/pitch of the tones paired with each category member at test were novel (i.e., not presented during the dialogue phase). Second, although 6- and 12-month-olds' exposure to tone sequences was identical, only the 6-month-olds showed evidence of categorization, as we predicted

However, to further tease apart the two accounts, in Experiment 2 we pursue this issue with another group of 6-month-olds.

## Experiment 2

In this experiment, we exposed infants to the very same sine-wave tone sequences (exposure phase) as in Experiment 1, but this time uncoupled them from the
communicative context. During the exposure phase, infants listened to the same auditory signals as in Experiment 1, and saw a video with the same two women, but this time the women cooperated in a joint task in silence. Crucially, infants' exposure to the tones was held constant across both experiments, but in Experiment 2, there was no indication that the tones were part of a communicative interchange. If 6-month-olds' successful categorization in Experiment 1 reflects nothing more than their familiarity with tone sequences, then infants in Experiment 2 should also categorize successfully.

## Methods

Participants Twelve healthy, full-term, 6-month-old infants participated ( $M=5.87$ months). Another 4 infants were tested but excluded due to looking for less than $25 \%$ of the familiarization or test phases.

Stimuli The new exposure video showed two women silently engaged in a cooperative task (mixing ingredients and pouring them, as if making brownies together). They smiled to each other and the infant (as in Experiment 1), but did not communicate verbally. The audio stream included exactly the same "utterances" (tone sequences, English speech) as in Experiment 1, but these were randomly shuffled. (The goal was to remove the prosodic pattern of turn-taking in the spoken utterances that might lead infants to infer that the tone sequences were part of a conversation and therefore communicative). Familiarization and test stimuli were identical to Experiment 1.

## Procedure, Coding \& Analyses Identical to Experiment 1.

## Results

As predicted, 6-month-olds performed differently here than in Experiment $1(t(22)=2.16, p<.05)$. In contrast to Experiment 1, where 6-month-olds averaged a .61 novelty preference at test, those in Experiment 2 performed at the chance level ( $M=.48, t(11)=-0.45$, n.s. $)$.

There were no effects of familiarized category, novel object side at test, familiarization looking time, or gender on novelty preference scores (all $p$ 's > .4). All analyses collapsed across these factors.

## Discussion

These results reveal that mere familiarity with sine-wave tone sequences cannot account for their facilitative effect on object categorization in Experiment 1. Six-month-olds who received the same exposure to these sequences, uncoupled from the communicative episode, show no evidence of categorization.

## General Discussion

In these experiments, we introduce a novel approach for investigating classic questions about the nature of word learning: Are words perceptual features associated with
objects? Or is there a more nuanced link between words and concepts? And, if so, how is it established?

Waxman and colleagues (Balaban \& Waxman, 1997; Booth \& Waxman, 2003; Fulkerson \& Waxman, 2007; Waxman, 2003; Waxman \& Markow, 1995) have long argued for the latter position, and cite evidence that providing a consistent name for distinct members of an object category highlights the commonalities among them and promotes object categorization. On this account, language exerts its influence because infants link language to core conceptual capacities, including object categorization. In contrast, others have suggested that language facilitates categorization only insofar as it is a familiar acoustic stimulus (Robinson \& Sloutsky, 2007a; Sloutsky \& Robinson, 2008). On this account, any adequately familiar stimulus should show facilitative effects: the facilitative effect of an acoustic signal will vary as a function of its familiarity.

In Experiment 1, we asked whether an otherwise inert acoustic stimulus (sine wave tones), introduced within the context of a communicative episode, might facilitate categorization. Six-month-olds showed evidence of categorization, while 12-month-olds did not. In Experiment 2, we asked whether the 6-month-olds' successful categorization could be attributed to their mere exposure to the tone sequences. We provided the same amount of exposure to the sine wave tones, but uncoupled them from the communicative episode. The results were straightforward: infants in Experiment 2 revealed no evidence of categorization in the subsequent task. Stimulus familiarity alone cannot capture these results.

## Auditory overshadowing

Auditory overshadowing is a precise claim about low-level cross-modal processing, and it is relevant to many studies in infant cognitive development including object categorization (Robinson \& Sloutsky, 2007a) and individuation (Robinson \& Sloutsky, 2008). The general processing model invoked is uncontroversial: infants have limited cognitive resources and any stimulus that exhausts these resources will have consequences on subsequent processing.

Thus we do not ask whether auditory overshadowing could, in principle, influence infants' learning (about categories or otherwise), but whether it alone can account for infants' clear patterns of behaviour. The results here join a host of others in demonstrating that in addition to perceptual underpinnings, there are conceptual and socialcommunicative factors that determine whether a paired acoustic stimulus can facilitate object categorization.

Consider, for example, infants' developing knowledge of grammatical categories and its influence on categorization. By 14 months, novel nouns highlight object categories, but adjectives do not (Booth \& Waxman, 2009; Waxman \& Booth, 2001). Adopting an auditory overshadowing interpretation, Sloutsky and colleagues (Robinson \& Sloutsky, 2007a, 2008) argue that nouns are a more familiar
stimulus than adjectives, and thus interfere less with visual processing (Sloutsky \& Fisher, 2012). However, this explanation cannot account for the performance of younger infants ( 9 to 12 months), whose categorization improves when both adjectives and nouns are paired with category exemplars (Waxman \& Booth, 2003; Waxman \& Markow, 1995). Familiarity alone can neither explain this developmental change nor the results of the present studies.

## Communication, cognition, and "natural pedagogy"

Previous claims about the influence of language on categorization have focused primarily on the effect of words presented as labels for object categories (Waxman, 2003). More recent evidence suggests that, for younger infants, human speech more generally can facilitate categorization (Ferry et al., 2010). Three- and 4-month-olds show an increased ability to categorize in the context of human speech despite their inability to reliably segment the speech stream into discrete words (Jusczyk \& Aslin, 1995). The present results go further to suggest that for young infants, speech may be just one of a number of communicative signals that facilitate categorization. Infants in the present studies had no prior exposure to the sine wave tone sequences we presented, and yet merely introducing them as a human communicative signal had a powerful effect on their contribution to infants' subsequent categorization.

Why might communicative signals link to concepts? One recent proposal is that ostensive human communication is "naturally pedagogical" for infants, biasing them to interpret new information as category-relevant and generalizable (Csibra \& Gergely, 2009; Gergely \& Csibra, 2012). A recent study by Yoon, Johnson, and Csibra (2008) demonstrated the effect of communicative signals on cognition in 9-month-olds: in the context of a communicative gesture (pointing), infants most accurately encoded the shape of the object. In a non-communicative (grasping) context, infants most accurately encoded its location. Another study with 9 -month-olds reported object categorization benefits from eye gaze (Wu, Gopnik, Richardson, \& Kirkham, 2010). There is also evidence that communicative object labels enhance object recognition by augmenting core visual processes during encoding (Gliga, Volein, \& Csibra, 2010).

If one posits that the sine wave tone sequences in Experiment 1 were part of an ostensive communicative exchange with the infant (see Csibra, 2010, for a discussion of how infants recognize ostensive signals), the 6-montholds' results align with the theory of natural pedagogy: the presence of the communicative signal facilitated the discovery of category-relevant information.

## Tuning the perceptual and conceptual systems

Natural pedagogy cannot, however, explain the full developmental picture. For example, it cannot account for the results of the 12 -month-olds in Experiment 1. Neither can it explain why, for example, young infants accept gestural labels (like words) to refer to object categories but
older hearing infants do not (Namy \& Waxman, 1998; Suanda \& Namy, 2012), or why young infants map both nouns and adjectives to object categories but older infants are more precise, mapping nouns, and not adjectives, to object categories (Booth \& Waxman, 2009). We therefore suggest a more detailed developmental account. .

Our account builds on a substantial literature suggesting that infants begin life with broad perceptual sensitivities in a variety of social domains (e.g., faces, speech sounds, and hand gestures) but rapidly tune these to make functionally relevant distinctions (Grossmann, Missana, Friederici, \& Ghazanfar, 2012; Palmer, Fais, Golinkoff, \& Werker, 2012; Vouloumanos, Hauser, Werker, \& Martin, 2010; Werker \& Tees, 1984). In language development, this process of perceptual tuning is a critical step, for example, in focusing infants' attention on the signals that are potentially communicative (e.g., human speech) and tuning out those that are not (e.g., non-human primate vocalizations).

We suggest that infants also engage in a process of referential tuning in which they tease apart the particular functions of distinct communicative signals. For example, 12-month-olds expect that human speech, but not noncommunicative vocalizations (e.g., coughing) can refer (Martin et al., 2012). And within human speech, infants gradually distinguish between distinct types of words (nouns and adjectives) and map them accordingly to distinct types of meaning (e.g., to object categories and properties, respectively) (Waxman \& Booth, 2009; Waxman \& Gelman, 2009). In this ongoing, constructive process, infants recruit several knowledge systems (social, linguistic, and conceptual) to infer the intended reference and meaning of communicative signals. When a communicative signal is interpreted as intending to refer to an object category, it can serve to highlight that category and facilitate learning in young infants.

One prediction of the present account is that 12 -montholds' object categorization abilities should benefit from a novel communicative signal if they are given sufficient cues (i.e., beyond mere communicativeness) that the signal is meant to refer to an object or object category. We are currently testing this prediction.

Several other questions remain to be explored. First, this account posits an early expectation that communicative signals in general will relate to meaning in the world. This is consistent with natural pedagogy (Csibra \& Gergely, 2009). However, whether this expectation is innate or acquired prior to 6 months is presently unclear. Second, other studies that explore the influence of social cues in learning do not find a consistent benefit for social cues over non-social cues (e.g., Moore, Angelopoulos, Bennett, 1999; Theuring, Gredebäck, \& Hauf, 2007). Unlike the present experiments, these studies pit social cues against non-social cues in tasks with distractor and target events. Thus their failure to show benefits from social cues may reflect younger infants' limited capacities for inhibitory control and attention deployment. Future research in complex environments can examine this hypothesis and the constraints of learning in
communicative contexts. Finally, it is important to explore the range of conditions under which infants interpret a novel stimulus as communicative.

The present research integrates social, conceptual, and linguistic development for a rich description of infants' early communicative development. We suggest with others (e.g., Noles \& Gelman, 2012; Waxman \& Gelman, 2009) that words are not merely perceptual features that associate with objects, but are communicative symbols, and the products of early perceptual and conceptual tuning.

# Stopping Rule Selection (SRS) Theory Applied to Deferred Decision Making 

Mario Fifić (fificm@gvsu.edu)<br>Department of Psychology, Grand Valley State University<br>Allendale, MI 49501 USA<br>Marcus Buckmann (buckmann@ gmx.net)<br>Max Planck Institute for Human Development, Center for Adaptive Behavior and Cognition, Berlin Germany

#### Abstract

The critical step facing every decision maker is when to stop collecting evidence and proceed with the decision act. This is known as the stopping rule. Over the years, several unconnected explanations have been proposed that suggest nonoptimal approaches can account for some of the observable violations of the optimal stopping rule. The current research proposes a unifying explanation for these violations based on a new stopping rule selection (SRS) theory. The main innovation here is the assumption that a decision maker draws from a large set of different kinds of stopping rules and is not limited to using a single one. The SRS theory hypothesizes that there is a storage area for stopping rules-the so-called decision operative space (DOS)and a retrieval mechanism that is used to select stopping rules from the DOS. The SRS theory has shown good fit to challenging data published in the relevant literature.

Keywords: Stopping rule, deferred decision task, optimal, nonoptimal, decision making.

One of the most important steps of decision making is determining when to stop collecting evidence and proceed with the final decision. This is defined as the stopping rule and it is thought to be an irreplaceable component of almost all cognitive models of decision making.

Take, for example, a patient who is facing a risky medical treatment. The treatment can have a good outcome-that is, the patient will benefit from it-or it can have a bad outcome-that is, the patient will suffer serious side effects. To the patient's surprise, doctors don't have a unanimous opinion on whether the treatment is beneficial or harmful. Thus, the patient decides to ask for several doctors’ opinions. The patient collects either positive opinions (+1) in favor of the risky treatment or negative opinions ( -1 ) against the risky treatment. The total sum of evidence is defined as the critical difference, $d$. But how many opinions should he collect to reduce the risk of making the wrong decision? To help the patient with the decision, his best friend, a statistician, tells him that the number of opinions can be calculated based on the most optimal solution.

## The Optimal Stopping Rule for Evidence Accumulation and Deviations

The determination of the optimal stopping rule in statistical decision making has been examined in great detail by Wald (1947) and from the Bayesian perspective by

Edwards and colleagues (Edwards, 1965). The optimal Bayesian model defines the stopping rule as the minimization of the expected loss, $E(L)$ (De Groot, 1970). The rule prescribed by the optimal model is to continue collecting evidence and to stop only when the expected value of loss is equal to or lower than the expected loss associated with deferring the decision and collecting more evidence.

To calculate the optimal number of doctors the patient should consult, his friend the statistician acquired the conditional distributions of doctors' positive ( + ) opinions given that the treatment can be either beneficial or harmful, $P(+$ opinion | beneficial treatment), $P(+$ opinion | harmful treatment), and also the prior probabilities of beneficial and harmful treatments, $P$ (beneficial treatment) and $P$ (harmful treatment) (e.g., Edwards, 1965; Schechter, 1988). The statistician used all these probabilities to calculate the socalled posterior odds in favor of the hypothesis that the treatment is beneficial given the evidence acquired from $n$ number of doctors, $\Omega\left(\left.\frac{\text { benefical treatment }}{\text { harmful treatment }} \right\rvert\,\right.$ opinion $)$. The posterior odds would indicate the best decision for the finite number of collected doctors' opinions, if the costs and payoffs associated with the risky treatment and the expected diagnostic value of a single opinion are considered. Using mathematical software, the statistician got the number 3 as the optimal stopping rule value for that risky decision. This means that the patient should collect positive and negative doctors' opinion ( +1 s and -1 s ) as long as their cumulative sum $(d)$ is lower than the value of $d=+3$ or higher than the value $d=-3$. The patient should stop evidence collection and make a decision as soon as $d=3$, in which case the patient should accept the risky treatment, or $d=-3$, in which case the patient should reject the risky treatment (e.g., Schechter, 1988).

The relevant literature has revealed that humans do not use the optimal stopping rule. (1) In a deferred decision task in which subjects had the option to defer their decision until they had purchased new information, subjects bought either too little evidence (Phillips \& Edwards, 1966; Pitz, 1968) or too much evidence (Pitz, 1968) compared to the optimal model's predictions. (2) The critical difference value $d$ can change over the course of sampling evidence in a single trial (e.g., Busemeyer \& Rapoport, 1988; Pitz, 1968; Newell, 2005). Subjects tended to make final decisions on smaller critical difference values for larger sets of evidence. To
account for these results, the optimal model should adjust the critical difference value such that it decreases as more evidence is acquired (Pitz, 1968; Viviani, 1979). (3) Subjects frequently terminated evidence collection when the critical difference value was zero ( $d=0$; Pitz, 1968; Pitz, Reinhold, \& Geller, 1969). From the optimal Bayesian viewpoint, this means that decision makers made a final decision even though there was no evidence to support any decision. (4) It has also been shown that human decision makers sometimes stop on a nondiagnostic sequence of evidence (Busemeyer \& Rapoport, 1988). For example, after a series of three positive pieces of evidence the subjects stopped on a negative piece of evidence, $\{+,+,+,-$ $\}$, and made a decision that supported the positive evidence. Note that the last two pieces of evidence were nondiagnostic and stopping on such a pattern of evidence is logically inconsistent with the optimal model.

The optimal approach to decision making has suffered more general criticism. The optimal model can be successfully applied only when a decision maker possesses perfect knowledge of all aspects of a situation. Following Savage (1954) and Binmore (2009), perfect knowledge of an environment is possible if one resides in a so-called small world. Examples of a small world are a controlled laboratory experiment, a lottery, and certain games. In a small world a detailed statistical representation of the environment exists and an optimal model can predict the exact amount of evidence needed to be collected to find the optimal stopping value.

But most decision makers live in a large world. A large world is quite unpredictable and dynamic-it is constantly changing and it is almost impossible to form an exact statistical representation of such an environment. In a large world a decision maker has limited time to make decisions, possesses limited cognitive powers in terms of memory and attention, and usually acts inconsistently (Berg, Biele, \& Gigerenzer, 2008; Gigerenzer, 2008; Schooler \& Hertwig, 2005; Shanteau, 1992; Tversky \& Kahneman, 1974). It is unrealistic to expect that a decision maker living in a large world would be able to employ an optimal model to determine when to stop accumulating evidence. Alternative approaches have been aimed at exploring how to make effective decisions with a limited amount of information and a limited cognitive system.

## Bounded Rationality and Nonoptimal Stopping-Rule Models

According to the bounded rationality approach, making decisions involves simple decision strategies and shortcuts that allow for quick and effortless decisions (e.g., Gigerenzer, 2004). Boundedly rational models require neither exact statistical representation of the environment nor optimization. (For a review of different nonoptimal models for evidence collection see Busemeyer \& Rapoport, 1988; for examples see Fifić, Little, \& Nosofsky, 2010).

Boundedly rational models for determining stopping rules are more suited to real-life decision-making problems and cognitive limitations than is the optimal model. Let us return to our patient example. The patient started to question the optimal value $d=3$ after he learned that the conditional distributions used to estimate the doctors' diagnostic accuracies do not exist for his country. Instead, his friend the statistician used the data from another, much smaller country across the ocean. Not trusting the optimal solution ( $d=3$ ), the patient decided to use another rule. He decided to obtain five doctors' opinions and make his decision based on the majority. This is defined as the fixed-sample-size stopping rule ( $s=5$ in the example). A decision maker determines a fixed amount of evidence to be collected before the collection starts. Our patient may have used a five-opinion stopping rule before-years ago when he bought a car. Alternatively, the patient could rely on another useful cue-a streak of either positive or negative opinions. The patient could stop looking for more opinions after receiving three successive positive or negative doctor opinions ( $r=3$ ) and make a decision accordingly. This is defined as the runs stopping rule (cf. Audley \& Pike, 1965; Estes, 1960). In sports games the runs rule is also known as the hot or cold hand rule (Bar-Eli, Avugos, \& Raab, 2006; Gilovich, Vallone, \& Tversky, 1985; Wilke \& Barrett, 2009). A player who scores a streak of shots in a row is perceived to be "hot" and is a preferred shooter. A player who has a streak of misses is likewise perceived to be "cold."

Although boundedly rational models have been able to explain some observed deviations from the optimal predictions (for details see Busemeyer \& Rapoport, 1988), no single such model has been able to account for them all. Take, for example, the fixed-sample-size stopping rule, which can account for the finding that decision makers sometimes stop on a nondiagnostic sequence of evidence. This rule predicts that the probability of termination should be equal for nondiagnostic sequences of identical length. In contrast, it has been observed that subjects prefer some nondiagnostic sequences over others of the same length (Busemeyer \& Rapoport, 1988). The runs stopping rule can account for the finding that decision makers stop on $d=0$, for example $\{+,+,-,-\}$. To stop on that evidence, the stopping rule value for the negative evidence has to be set on two pieces of negative evidence ( $r=-2$ ). The stopping rule for positive evidence has to be set on a value larger than two pieces of positive evidence (say $r=+3$ ). However, the runs stopping rule has limited explanatory power (Busemeyer \& Rapoport, 1988). For example, it cannot explain stopping when streaks of evidence are missing. In general, more explanatory power is gained by combining several stopping rules (see Pitz et al., 1969) within one framework. We lack a systematic theory to tie together different stopping rules in a single framework for decision making. To remedy this theoretical gap, I propose the stopping rule selection (SRS) theory.

## The SRS Theory

The SRS theory provides the basis for a general approach to decision-making operations. This theory is consistent with the idea of a boundedly rational decision maker who utilizes simple decision rules in real time. In different environments, a decision maker acts adaptively, constantly looking for the best decision strategies, stopping rules, and critical values.

## A formal description of the SRS theory and proposed stopping rules.

The SRS theory aims to provide a unifying framework for the storage and retrieval of multiple stopping rules. It consists of three hypotheses.

Hypothesis 1: Multiple stopping rules. The SRS theory assumes that several different stopping rules can operate concurrently. Decision makers act adaptively to changes in the environment, not only by calibrating different stopping rule values (value criterion) but also by switching between different stopping rules if needed. In real life, multiple stopping rules can be combined in a complex fashion (e.g., Pitz et al., 1969). Take, for example, scoring in tennis: The winner of a tennis game is the player whose score is at least two points higher than the opponent's ( $d \geq 2$ ) and if at least four points have been won so far ( $s \geq 4$ ).

Hypothesis 2: Storage for stopping rules-the decision operative space (DOS). A major component of the SRS theory is a storage place for the stopping rules and their values, which is called the decision operative space (DOS). The DOS can be seen as a variant of an "adaptive toolbox," a collection of domain-specific specialized cognitive mechanisms for decision making built through evolution (Gigerenzer \& Todd, 1999; Payne, Bettman, \& Johnson, 1993; Todd, 1999). Unlike the toolbox concept, the DOS is conceptualized as a structured psychological space. The stopping rules stored in the DOS are sorted on two dimensions: the cognitive effort needed for a certain stopping rule, and the time needed to make a decision using a certain stopping rule (Figure 1A). Depending on the environment, a decision maker can use these two dimensions to estimate which decision tools are the most appropriate to use.

The time scale, on the $x$-axis, is defined as chronological time. The exact expected duration of each stopping rule can be calculated from an analytic expression (e.g., see Feller, 1957, p. 317; also Busemeyer \& Rapoport, 1988; Pitz, 1968; Pitz et al., 1969). Cognitive effort, on the $y$-axis, is defined as the processing complexity of a decision strategy and can be measured by the number of elementary information processes (EIPs, after Payne et al., 1993) engaged in making a decision. As shown in Figure 1A, each point in the DOS represents a stopping rule with a certain stopping value. Stopping values belonging to the same
stopping rule lie on one line: For the runs stopping rule it is $r$, for the critical difference rule, $d$, and for the fixed-samplesize rule, $s$. Overall decision accuracy increases as one chooses as one chooses larger values for the stopping rules. However, the price of improvement is increases in both time and cognitive effort. As depicted in Figure 1, two stopping rules - the critical difference and the fixed-sample-size-are estimated to be of approximately the same complexity. They share the same EIPs, which are counting, differencing, averaging, and memory engagement. They differ on the time needed to complete the operations. The critical difference stopping rule needs more time to finish than the fixed-sample-size rule, for the same critical value. The runs stopping rule uses EIPs that are far simpler than those used by the previous two. To detect runs, a decision maker has only to count evidence, with minimal memory. Although based on simple EIPs, the runs stopping rule requires considerably more waiting time for larger critical values of runs.

Figure 1: (A) The decision operative space (DOS) for three stopping rules. Each point represents a single stopping rule with a stopping value. A straight line connects the same stopping rule with different stopping values. (B) A cast-net retrieval from the DOS. Dotted circles represent three different cast nets.

Hypothesis 3: Retrieval of the stopping rules. A retrieval mechanisms called "cast-net" retrieval is proposed. (cf satisficing approach; Todd, 1997; Todd \& Miller, 1999).

Cast-net retrieval. Selection of stopping rules resembles throwing a cast net and catching fish. A decision maker acts much like a fisherman, casting a net into the operative space. Here, on each throw the catch is a subset of possible stopping rules. To behave adaptively in different environments, decision makers adjust the location in the DOS where the net will be cast, and the size of the net. A decision maker who is not familiar with the environment or encounters much uncertainty in evidence collection may cast a larger net. If familiar with the environment, the decision maker may throw a smaller net. The larger the net is, the more different stopping rules are collected to make a single decision. The SRS theory specifies how several stopping rules could be used simultaneously to make a final decision.

The second property of the cast-net retrieval approach is the double tradeoff. Depending on where stopping rules are retrieved from the DOS, a decision maker may choose to trade off speed and accuracy (cf. Diederich, 2003; Kocher \& Sutter, 2006; Payne et al., 1993) or cognitive effort and accuracy (Payne et al., 1993). Figure 1B shows examples of both tradeoffs. Three cast-net locations are marked by red circles. Moving upward from the lower left circle on the vertical "work harder" path indicates a cognitive effortaccuracy tradeoff, keeping the time value constant. A decision to move vertically in the DOS means choosing to sacrifice frugality of effort to achieve better accuracy. A decision maker works harder to improve overall decision accuracy, as mainly the critical difference stopping rule is sampled. Moving from the lower left circle on the horizontal "take longer" path indicates a speed-accuracy tradeoff, keeping the cognitive effort value constant. A decision to move horizontally means choosing to sacrifice speed to achieve better accuracy. A decision maker takes longer, as mainly the runs stopping rule is sampled. The two tradeoffs can be used to explain adaptive decision making. Under the condition of increased uncertainty, it is expected that a decision maker would increase cognitive effort, and take the "work harder" path. Under time pressure, it is expected that a decision maker would use less time-consuming stopping rules and follow the "take longer" path.

## The SRS Theory: A Walkthrough of the Decision Process

In this section I provide a walkthrough of the decision process behind the SRS theory using the cast-net retrieval approach. The SRS model has two stages. The first stage is characterized by the selection and retrieval of stopping rules and their stopping values. The second is characterized by sequential evidence collection and application of stoppingrule criteria. The process is broken into six steps, three in the first stage and three in the second.

Step 1: Select hypotheses. Depending on the decision problem, a decision maker chooses the choice hypotheses (e.g., Thomas, Dougherty, Sprenger, \& Harbison, 2008). For example, in the patient decision situation described above, the two hypotheses $\mathrm{H}_{1}$ and $\mathrm{H}_{2}$ could be about the risky treatment: $\mathrm{H}_{1}$ : The risky treatment is a beneficial procedure, and $\mathrm{H}_{2}$ : The risky treatment is a harmful procedure. This stage is not under the scrutiny of the SRS model.

Step 2: Cast a net. The plethora of stopping rules and their values presents a challenge for the selection process. To select a subset of the stopping rules and their values, a decision maker throws a cast net into the DOS. To determine the position of the cast net and its span, a decision maker estimates how much time and cognitive effort can be invested in making the decision (on time and cognitive effort dimensions). These position estimates can be influenced by knowledge the decision maker possesses about this particular environment or similar ones. If no knowledge is available then a random starting point can be chosen. For illustration, assume that the following set of rules determines the cast $\{r=1, r=2, s=2, s=3, d=3, d=2\}$.

Step 3: Select a stopping rule. Once the DOS has been reduced by casting a net, several stopping rules and their values are randomly sampled from the net. All stopping rules and their values contained within the net can be retrieved with the same probability, defined by the probability density function $f(x)=\frac{1}{\text { number of retrieved rules }}$. For example, a decision maker could select the following set of stopping rules and their values from the cast net: $\{r=2$, $s=2, d=3\}$. Alternatively the probability of retrieving a certain rule from the cast net can be described by the bivariate normal distribution, $\mathbf{x} \sim(N(\boldsymbol{\mu}, \Sigma))$ (where the bold symbols are vectors), allowing rules that are closer to the center of a net to be retrieved with a higher probability than rules that are caught around the edges of the net.

Step 4: Collect evidence. The second stage starts with evidence accumulation. This step is repeated until a decision is made.

Step 5: Check stopping rule. The SRS model tests whether the evidence accumulated so far meets one of the criteria of the stopping rule selected from the net in Step 3. Assume that the model performs a serial test across three selected stopping rules. If none of the criteria have been met the decision maker looks for more evidence and repeats from Step 4. If any of the stopping value criteria are met, the decision maker stops evidence collection and proceeds with making the final decision.

Step 6: Stop and make a decision according to the hypothesis that was supported by the evidence.

## Face Validity of the SRS Theory: Preliminary Work and Results of Fitting

To establish face validity, I fit the SRS model to challenging data sets published in two separate studies on
determining stopping rules (Busemeyer \& Rapoport, 1988; Pitz, 1968). Our preliminary work showed that the SRS computational model can provide an excellent account of reported human data patterns. It is able to account for between $93 \%$ and $100 \%$ of the variability of Pitz's (1968) data and for about $86 \%$ of observed evidence patterns in Busemeyer and Rapoport's (1988) data. The model has 6 parameters describing the "span" of the cast net. Two parameters for each stopping rule define the range of the stopping rule values captured. As a part of the future exploration is the goal to reduce the number of parameters to only three describing the location and the size of the net.

In addition to showing high fitting accuracy, the SRS model was able to account for all four findings that falsified the optimal approach, described above: (1) People bought too much or too little evidence (Pitz, 1968); (2) the value of the critical difference ( $d$ ) could change over the course of sampling evidence in a single trial (e.g., Busemeyer \& Rapoport, 1988; Pitz, 1968); (3) people terminated evidence collection when the critical difference was zero ( $d=0$; Pitz et al., 1969); and (4) people stopped on nondiagnostic patterns. Regarding the accumulation of evidence, the observed data depart from the optimal model predictions (Table 1): For smaller values of $d$, the subjects collected too much evidence; for larger values of $d$, the subjects collected too little evidence. The SRS model captures this observed data trend as shown in the SRS model-fitting data. Regarding the value of the critical difference ( $d$ ), as can be seen in Table 1, less evidence was needed for larger values of $d$ to terminate evidence collection, compared to the optimal model prediction. This trend is accounted for by the SRS model fit. Regarding the termination of evidence collection when the critical difference was zero ( $d=0$ ), again as seen in Table 1, the SRS model shows that $n>0$ for $d=0$. Finally, regarding stopping on nondiagnostic patterns, the SRS model can also predict the nondiagnostic sequence of evidence (see Table 2). The SRS model fitted the observed patterns $\{1,1,1,0\}$ and $\{0,0,0,1\}$ (see Table 2; remember that 1 stands for positive and 0 for negative evidence). Note that the last two pieces of evidence in each pattern provide the nondiagnostic information for the optimal model.

Table 1: The average number of pieces of evidence ( $n$, shown in the table's cells) collected as a function of critical difference ( $d$ ) for three source reliability values ( $p=.8, .7$, and .6). The observed column shows averaged observed human data (from Pitz, 1968). The SRS column shows the best fit values when the stopping rule selection (SRS) model is fitted to the observed data. The optimal column shows the $n$ values predicted by the optimal model. The $r^{2}$ values are the proportions of explained variability the SRS model can account for.

|  | Source reliability $p=.8$ |  |  |
| :---: | :---: | :---: | :---: |
| $d$ | $r^{2}=1$ |  |  |
|  | Observed | SRS | Optimal |
| $\mathbf{0}$ | 2.73 | 2.71 | 0 |
| $\mathbf{1}$ | 2.75 | 2.8 | 1 |
| $\mathbf{2}$ | 3 | 2.92 | 2.93 |
| $\mathbf{3}$ | 3.67 | 3.59 | 4.71 |
| $\mathbf{4}$ | 5.04 | 5 | 6.41 |

|  | Source reliability $p=.7$ |  |  |
| :---: | :---: | :---: | :---: |
| $d$ | $r^{2}=0.98$ |  |  |

Table 2: The results of the SRS model fit to Busemeyer and Rapoport (1988) data, from the constant cost condition of their Experiment 2. Table shows the matching patterns correctly recognized by the SRS model, as well as the nonmatching patterns. Evidence refers to the observed patterns of evidence prior decision making, where " 1 " and " 0 " stand for positive and negative opinions (recommendations). Response accuracy refers to whether the final decision based on collected evidence was correct. Observed refers to the observed proportion of each pattern. SRS fit refers to the best fitted proportions by the SRS model.

| Evidence | Response <br> accuracy | Observed | SRS fit |
| :--- | :--- | :--- | :--- |
| Observed matched patterns |  |  |  |
| $\{1,1\}$ | Correct | 0.06 | 0.1 |

#### Abstract

Human language is characterized by variability in that the way in which language is used varies depending, for example, on facts about the identity of the speaker or author, the social context, and surrounding linguistic material. Variability poses formidable challenges to the systems underlying language comprehension, which are known to exploit statistical contingencies in the input to overcome the inherent noisiness of perception; nevertheless, we seem to comprehend language with apparent ease. How is this possible? Here we argue that we are able to comprehend language efficiently in part by continuously adapting to the statistics of novel linguistic situations. We argue further that adaptation specifically allows comprehenders' expectations to converge towards the actual statistics of the linguistic input. Concretely, we show that readers can adjust their linguistic expectations in light of recent experience such that (a) previously difficult structures become easier to process, and, even more strikingly, (b) previously easy to process structures come to incur a processing cost.

Keywords: Sentence processing; experience-based language processing; parsing; reading; learning; adaptation; priming

## Introduction

Human language is variable in the sense that the way in which language is used varies across situations according to, for example, the social context, the surrounding linguistic material, and various facts about the identity of the speaker or author. Variability in this sense pervades our linguistic experience, and has been observed at virtually every level of linguistic representation.

Despite the extent to which language use varies, communication is typically successful. That is, even when faced with novel speakers or accents, we seem to be able to quickly and accurately infer the messages intended by our interlocutors.

Our apparent facility with language is particularly remarkable considering the extent to which linguistic experience has been demonstrated to play a role in language processing. Experience-based accounts of language processing hold that comprehenders generate expectationsabout the probability of observing particular sounds, words, sentence structures, etc.-during online language processing, and that these expectations are informed by and reflect the statistics of previous linguistic experience. By generating expectations that reflect the actual distribution of
events in the environment, comprehenders should, in principle, be able to reduce the average prediction error experienced during online processing, and thus process language efficiently. But if the distribution of words or sentence structures varies according to individual speakers, dialects, etc., then, at first blush, it is no longer clear that generating online linguistic expectations that reflect aggregate statistics over previous experience would be advantageous to the comprehender. How do we comprehend language as well as we do despite variability in the linguistic signal?

Here we present evidence that comprehenders are able to rapidly adapt to or implicitly learn the statistics of novel linguistic situations, focusing specifically on sentence comprehension ("parsing"). We argue that syntactic adaptation allows comprehenders' expectations about the statistics of the input to converge towards the actual statistics, providing an explanation for why experiencebased processing is advantageous despite the variability present in the statistics of the signal. Our experiments build on and attempt to synthesize insights from three lines of research that have till now proceeded largely in parallel: (1) experience-based language processing (e.g., MacDonald, Pearlmutter, \& Seidenberg, 1994), (2) syntactic priming (e.g., Traxler, 2008), and (3) research exploring the link between online processing and implicit learning (e.g., Misyak \& Christiansen, 2012; Wells, Christiansen, Race, Acheson, \& MacDonald, 2009).

To test our hypothesis, we exploit a well-known temporary syntactic ambiguity that provides a window onto comprehenders' expectations, illustrated in (1).

1. The experienced soldiers...
a. ...warned about the dangers before the midnight raid.
b....spoke about the dangers before the midnight raid.
c. ...warned about the dangers conducted the midnight raid.
d. ... who were warned about the dangers conducted the midnight raid.

Verbs like warned give rise to temporary ambiguities since they may occur both as the main verb (MV) of a
sentence ((1a)) or as the verb in a relative clause (RC; (1c)). Sentences (1a) and (1c) can be disambiguated toward the RC reading at conducted, like in (1c). By contrast, (1b) is unambiguously an MV structure because spoke is unambiguously a past tense matrix verb; (1d) is unambiguously an RC because of the relativizer who, which serves as an early disambiguating cue. Sentences like (1c) consistently elicit what are known as ambiguity or gardenpath effects: reading times (RTs) in the disambiguating region (in bold) spike when the ambiguity is resolved towards the relative clause interpretation (1c), compared to unambiguous RCs (1d). No such ambiguity effect is found for ambiguous compared to unambiguous MVs. Experienced-based accounts predict the garden-path effect because verbs like warned are overwhelmingly more likely to occur with MVs than RCs in subjects' previous experience, as evidenced in corpora of written and spoken language.

Given that this frequency difference has a reliable correlate in human behavior, we can take advantage of the MV-RC ambiguity to explore syntactic adaptation. We provide subjects with experience with written language in which the environment-specific syntactic statistics differ sharply from subjects' previous experience with language. If subjects are adapting to the statistics of the input, as we propose, then the manner in which subjects process these structures should change over the course of the experiment. Specifically, if exposed to locally stationary syntactic distributions-i.e., distributions whose parameters remain fixed within the environment-comprehenders' syntactic expectations should converge towards the statistics of the environment. In Experiment 1, we find evidence for rapid, incremental, and cumulative syntactic adaptation: over the course of an experiment where RCs are many times more likely than in subjects' previous experience, the ambiguity effect for these structures continuously decreases until it disappears. Experiment 2 goes a step further. There, we reason that if subjects indeed adapt their expectations to converge towards the statistics of the input, then as subjects come to assign a higher subjective probability to RCs, they should commensurately come to assign a lower subjective probability to MVs. Since MVs by hypothesis compete with RCs for probability mass (in the type of garden path sentences we investigate) it should be possible to make MVs sufficiently unlikely that this structure would actually come to incur a processing cost. This is what we find.

## Experiment 1

In Experiment 1 we ask whether comprehenders can rapidly adjust their syntactic expectations in response to the statistics of a novel linguistic situation (i.e., in response to the statistics of the experiment). We expose subjects to 40 ambiguous and unambiguous RCs, as in (1c) and (1d). Because RCs are infrequent structures, we predict that subjects will display an initially high processing cost for ambiguous relative to unambiguous RCs (i.e., a large ambiguity effect), but as the experiment progresses, and
evidence accumulates that RCs are highly probable within the context of the experiment, we predict that the ambiguity effect should diminish.

## Subjects

80 subjects were recruited via Amazon's Mechanical Turk platform. Only subjects with US IP addresses were allowed to participate. Additionally, instructions clearly indicated that subjects were required to be native speakers of English, and only subjects with at least a $95 \%$ approval rating from previous jobs were included.

## Materials

Critical items were constructed from sentence pairs like (1c) and (1d). Eight different verbs giving rise to the MV/RC ambiguity (watched, washed, taught, served, called, warned, dropped, pushed) were repeated 5 times to yield 40 critical items (only the verbs were repeated; the remainder of the sentences differed between items). Ambiguity was counter-balanced across two experimental lists. In addition, each list contained the same 80 fillers. Filler sentences featured a variety of syntactic structures and, crucially, did not include verbs that give rise to the MV/RC ambiguity (e.g., All the undergraduates in the class had trouble keeping up; The foreign delegates arrived at the embassy surrounded by security guards). Both lists presented stimuli in the same, pseudo-randomized order with 1-3 fillers between each critical item. Two additional lists were created in which the order of items was reversed, yielding a total of 4 orders.

## Procedure

Stimuli were presented in a self-paced moving window display. At the beginning of each trial, the sentence appeared on the screen with all non-space characters replaced by a dash. Subjects pressed the space bar using their dominant hand to view each consecutive word in the sentence. Durations between space bar presses were recorded. At each press of the space bar, the currently viewed word reverted to dashes as the next word was converted to letters. A yes/no comprehension question followed all experimental and filler sentences, with the correct answer to half of all comprehension questions being "yes".

## Results

RTs less than 100 ms or greater than 2000 ms were excluded before computing length-corrected RTs (i.e., RTs with the effect of word length removed) following a procedure similar to the one described in Ferreira and Clifton (1986).

Length-corrected RTs during the disambiguating region (in bold in (1) above) were regressed, using mixed effects regression, onto the full factorial design (i.e., all main effects and interactions) of ambiguity (ambiguous vs. unambiguous) and item order (coded 1-40 and centered). Item order captures the number of RCs observed at a given point in the experiment. Additionally, we included a main
effect of log-transformed stimulus order, which provides an index of how many trials (including both critical items and fillers) have been read at a given point in the experiment. Stimulus order captures the effect of "task adaptation", i.e., general speed-up effects, which can be rather strong in selfpaced reading experiments (all results reported below hold with or without this predictor, and regardless of whether it is log-transformed). For this and all other analyses reported in this paper, we included the maximal random effects structure justified by the data (Jaeger, 2009).

We replicated the significant main effect of ambiguity found in previous studies: RTs in the disambiguating region were greater for ambiguous relative to unambiguous sentences $(\beta=19, \mathrm{p}<.001)$. Also replicating previous work, we found a significant main effect of log stimulus order ( $\beta=-39, \mathrm{p}<.05$ ) and a marginally significant main effect of item order $(\beta=-2, p=.09)$. That is, subjects read stimuli increasingly faster as the experiment progressed, presumably reflecting task adaptation effect (getting used to the self-paced reading paradigm, Fine, Qian, Jaeger, \& Jacobs, 2010) Crucially, there was a significant two-way interaction between ambiguity and item order: the processing cost incurred by ambiguous RCs-the ambiguity effect-significantly diminished as experience with RCs accumulated ( $\beta=-1, \mathrm{p}<.05$ ). In Figure 1, we visualize this interaction by plotting mean length-corrected RTs for ambiguous and unambiguous sentences across four bins of item order, and by plotting the ambiguity effect at all 40 points in the course of the experiment. Both the ambiguity effect and its interaction with item order were observed only in the disambiguating region. The effect of stimulus order was significant or marginally significant in all sentence regions.

Figure 1: Mean length-corrected RTs during the disambiguating region for ambiguous and unambiguous RCs across four bins of item order in Experiment 1, with embedded visualization of the change in ambiguity effect
across the course of the experiment. Error bars give 95\% confidence intervals on the mean.

## Discussion

Experiment 1 demonstrates that comprehenders are capable of rapidly, incrementally, and cumulatively adapting to the statistics of a novel linguistic environment, even after controlling for the effect of practice or task adaptation.

In the Introduction we articulated a conceptualization of syntactic adaptation according to which subjects continuously adjust their expectations such that their expectations about the linguistic environment converge towards the statistics of the linguistic environment. The results of Experiment 1 are compatible with such an interpretation, but do not rule out other plausible ones. For example, it is possible that the results of Experiment 1 are driven by boosts in the base-level activation of the RC structure, but that this happens without specific reference to the statistics of the input (Pickering \& Garrod, 2004), or that adaptation occurs by virtue of episodic memory for the repeatedly encountered structure, which similarly would not need to make reference to the statistics of the environment (Kaschak \& Glenberg, 2004). In Experiment 2, we present a more direct test of the prediction that comprehenders adjust their expectations to converge towards the statistics of the input.

## Experiment 2

Experiment 2 exploits the same temporary ambiguity between MVs and RCs used in Experiment 1. However, unlike in Experiment 1, we expose subjects to both RCs and MVs. As we mentioned above, the ambiguity effect observed for sentences like (1) is driven by large differences in the probabilities of the two structures: upon observing the string The experienced soldiers warned..., subjects have a stronger a priori expectation for an MV interpretation relative to the RC interpretation. In other words, MVs and RCs compete for probability mass: MVs receive a high subjective probability at the expense of RCs. Therefore, if the results of Experiment 1 are driven by convergence towards the statistics of the input, then as subjects come to find RCs more probable, they should also, in turn, find MVs less probable. This effect should be observable in a decreased ambiguity effect for RCs and an increased ambiguity effect for MVs as the experiment progresses.

Experiment 2 employs a between-subject block design to test this prediction. In this experiment, subjects were assigned to one of two groups, which we will call the FillerFirst and the RC-First groups. Subjects were exposed to three blocks of sentences. The composition of the materials in each block, for each group, is shown in Table 1.

Table 1: Summary of the between-subject, block design of Experiment 2.

| Group | Block 1 | Block 2 | Block 3 |
| :---: | :---: | :---: | :---: |
| $\begin{aligned} & \text { RC-First } \\ & (\mathrm{n}=40) \end{aligned}$ | $\begin{aligned} & 16 \quad \mathrm{RCs} \\ & \text { ambiguous) } \end{aligned}$ | $\begin{aligned} & 10 \quad \mathrm{RCs} \quad(5 \\ & \text { ambiguous) } \\ & 20 \text { fillers } \end{aligned}$ | $\begin{aligned} & 10 \quad \text { MVs } \quad(5 \\ & \text { ambiguous })+ \\ & 15 \text { fillers } \end{aligned}$ |
| FillerFirst ( $\mathrm{n}=40$ ) | 16 fillers | $\begin{aligned} & 10 \quad \text { RCs } \quad(5 \\ & \text { ambiguous })+ \\ & 20 \text { fillers } \end{aligned}$ | $\begin{aligned} & 10 \quad \text { MVs } \quad(5 \\ & \text { ambiguous })+ \\ & 15 \text { fillers } \end{aligned}$ |

We conducted Experiment 2 with three specific predictions in mind. We predict (1) that the ambiguity effect for RCs will be diminished from block 1 to block 2 for the RC-first group. This would conceptually replicate Experiment 1. We further predict (2) that the ambiguity effect for RCs during block 2 for the Filler-First group will be greater than that of the RC-first group. If the effects observed in Experiment 1 are due to task adaptation or fatigue, then the ambiguity effect for RCs in Block 2 should be the same for both the Filler-First and the RC-First group. In other words, reading a given number of sentences should have the same effect on reading times regardless of the content of those sentences. Finally, and most crucially, we predict (3) that the ambiguity effect for MVs should increase as experience with RCs increases. If adaptation is a matter of subjects' expectations converging on the statistics of the input, then as the ambiguity effect for RCs decreases, the ambiguity effect for MVs should increase. Thus, we predict a greater ambiguity effect for MVs in block 3 for the RC-First group (where subjects have encountered more RCs by the time they reach block 3) relative to the Filler-First group.

## Subjects

80 subjects were recruited from the University of Rochester community. Informed consent was obtained from all subjects according to the University's scientific research ethics policies. Subjects received $\$ 10$ for their participation.

## Materials

Subjects read a total of 71 sentences over 3 blocks (as outlined in Table 1). RC and MV sentences were created that followed the same template as the critical items from Experiment 1. Two experimental lists were constructed for each group that counter-balanced the conditions (ambiguous vs. unambiguous) for the sentence type (MV or RC) used within each block, totaling four lists. It is important to note that the block structure of the experiment was entirely implicit. From the perspective of the subjects, they simply read 71 sentences without breaks.

## Procedure

The same procedure as in Experiment 1.

## Results

RTs less than 100 ms or greater than 2000 ms were excluded before computing length-corrected RTs, as in Experiment 1. We tested three predictions that follow from the hypothesis that readers adapt to the local statistics of the linguistic environment, enumerated above.

Prediction 1 (does the ambiguity effect in the RC-First group diminish from block 1 to block 2?): We regressed length-corrected RTs during the disambiguating region (underlined in (1)) of sentences read during blocks 1 and 2 in the RC-First group onto ambiguity (ambiguous vs. unambiguous), block (block 1 vs. block 2), and the two-way interaction between these predictors. There was a significant effect of ambiguity ( $\beta=65, \mathrm{p}<.05$ ): ambiguous RCs were read more slowly than unambiguous RCs. There was also a significant main effect of block ( $\beta=-72, \mathrm{p}<.05$ ): subjects read faster during the second block relative to the first block. Finally, the interaction between these two variables, capturing the change in the ambiguity effect from block 1 to block 2, was in the predicted direction and trended towards but did not reach significance $(\beta=18, \mathrm{p}=.2)$. It is likely that the binned comparison of reading times across blocks 1 and 2, combined with fewer observations than in Experiment 1, provides less power than the treatment of RCs as a continuous variable in Experiment 1. To address this, we took data from blocks 1 and 2 for the RC-First group and submitted it to the same analysis reported for Experiment 1. We examined length-corrected RTs during the disambiguating region using the same analysis as in Experiment 1. All critical effects from Experiment 1 were replicated including, importantly, a two-way interaction between ambiguity and item order ( $\beta=2, \mathrm{p}<.05$, after Bonferroni correction for multiple comparisons), replicating Experiment 1.

Prediction 2 (is the ambiguity effect in block 2 greater for the RC-First group than for the Filler-First group?): we regressed length-corrected RTs during the disambiguating region onto group (RC-First vs. Filler-First), ambiguity (ambiguous vs. unambiguous), and the interaction between these two variables. Again, there was a main effect of ambiguity $\mathrm{RCs}(\beta=19, \mathrm{p}<.05)$. There was also a main effect of group: subjects in the RC-First group had overall faster reading times $(\beta=-7, \mathrm{p}<.05)$. Crucially, the two-way interaction between ambiguity and group was marginally significant ( $\beta=-5, \mathrm{p}=.08$ ): the ambiguity effect was smaller in the RC-First group than in the Filler-First group. That is, reading a block of filler sentences does not reduce the processing cost of RCs to the same extent that reading a block of RCs does. This result is shown by the pairs of bars corresponding to block 2 for both groups in Figure 2.

Prediction 3 (is the ambiguity effect for MVs in block 3 greater for subjects who have seen more RCs, i.e. for the RC-First group?): We regressed length-corrected RTs during the disambiguating region of sentences read during block 3 onto ambiguity (ambiguous MV vs. unambiguous MV), group (RC-First vs. Filler-First), and the interaction between these variables. There was a main effect of ambiguity, such that ambiguous MVs were read more
slowly than unambiguous MVs ( $\beta=8, \mathrm{p}<.05$ ). The main effect of group did not reach significance $(\beta=4, \mathrm{p}=.3)$. Crucially, the two-way interaction between ambiguity and group was significant ( $\beta=5, \mathrm{p}<.05$ ): the ambiguity effect for MVs during block 3 was greater for the RC-First group than for the Filler-First group. In other words, subjects who read more RCs subsequently experienced both (1) a reduction in the ambiguity effect for RCs and (2) an increase in the ambiguity effect for MVs. This pattern is visualized in Figure 2 in the right-most pair of bars for each group.

Figure 2: Mean length-corrected RTs during the disambiguating region for ambiguous and unambiguous conditions across all three blocks of Experiment 2. Error bars give $95 \%$ confidence intervals on the mean.

## Discussion

Experiment 2 was designed to further address the hypothesis that comprehenders adjust their syntactic expectations to converge towards the statistics of the input. Specifically, we predicted that, since RCs and MVs compete with each other for probability mass, when subjects come to assign a higher probability to one structure, they should come to assign a lower probability to the other. In Experiment 2, this led to the concrete prediction that a diminished ambiguity effect for RCs should lead to a larger ambiguity effect for MVs, and that this should be greater for the RC-first relative to the Filler-first group. This is what we observed (cf. Figure 2).

## General Discussion

We tested the hypothesis that language comprehenders are able to adapt their syntactic expectations to novel linguistic environments according to the statistics of those environments. In two reading experiments, we provided subjects with experience with distributions of syntactic structures that diverged sharply from their previous experience with English. We predicted that subjects would adapt their expectations (as reflected in changes in RTs)
according to their cumulative recent experience. As predicted, in Experiment 1 subjects came to process a priori infrequent structures that had initially produced longer RTs more quickly when those structures were frequent in the experiment. Experiment 2 replicated this and went a step further: there, subjects not only came to process an a priori infrequent structure more quickly, but also came to process an a priori frequent structure more slowly when it was infrequent in the experiment. Our experiments suggest that readers are capable of adapting to the relative frequencies (/probabilities) of syntactic structures in the current linguistic environment. The results of our experiments have implications for questions concerning the mechanisms underlying language comprehension and for debates about the mechanism underlying syntactic priming. We discuss these in turn.

Previous work on syntactic adaptation has demonstrated that exposure to syntactic structures can have immediate (Traxler, 2008) and cumulative (Kaschak \& Glenberg, 2004) effects on language comprehension, that these effects can be indexed to individual talkers (Kamide, 2012), and that the effects may endure for several days (Wells et al., 2009). Moreover, work on statistical learning has demonstrated a remarkable capacity in children and adults to rapidly extract statistical regularities in novel artificial languages (cf. Gómez \& Gerken, 2000), and has suggested that statistical learning may correlate with language processing in general (Misyak \& Christiansen, 2012). As mentioned in the introduction, however, previous work on experience-based processing, syntactic priming, and statistical learning has all proceeded largely in parallel, and has left open the question of how the immediate effect of experience on language comprehension accumulates over time to give rise to cumulative priming, experience-based processing effects, and environment-specific adaptation. We have attempted to build on all of this work by demonstrating that syntactic adaptation can be profitably construed as the rapid, incremental, and cumulative convergence towards the statistics of a novel linguistic environment. Syntactic adaptation of the kind observed here may therefore offer a route by which the immediate effects of experience ("priming") accumulate to give rise to long-term experience-based processing.

Our results also speak to ongoing debates surrounding the type of mechanism that underlies syntactic priming. Two main views have emerged from previous work. Transient activation accounts hold that priming results from a shortlived boost in the activation of a syntactic representation (Pickering \& Garrod, 2004). By contrast, implicit learning accounts hold that priming is a consequence of an implicit learning mechanism (Chang, Dell, \& Bock, 2006). We believe that implicit learning accounts cover the current results most naturally for at least two reasons. First, subjects in both experiments were sensitive to the cumulative statistics of the environment: the degree to which subjects' expectations for a structure had changed at a given point in the experiment depends on how many times
subjects saw (a) that structure and (b) other structures competing with it for probability mass. To the extent that transient activation accounts do not predict cumulative priming and insofar as learning accounts do (cf. Kaschak, Loney, \& Borreggine, 2006), our results appear to support an implicit learning account. Second, our results provide indirect evidence for error-sensitivity: we observed changes in RTs over the course of both experiments for both RCs and MVs, but changes of a greater magnitude for RCs relative to MVs (see Figure 2): observing a low-probability linguistic event (and therefore one with a relatively large error signal) leads to greater changes in RTs. Errorsensitivity has been argued to be a hallmark of implicit learning (Chang et al., 2006; Fine \& Jaeger, 2013; Jaeger \& Snider, 2013).

Taken together with recent work on adaptation in phonetics and pragmatics (Kurumada, Brown, \& Tanenhaus, 2012; Norris, McQueen, \& Cutler, 2003), our results suggest that adaptation is likely to be a general property of language processing, and a manifestation of a general ability to cope with a dynamic environment.

Finally, our findings demonstrate the fundamental role that experience plays in language processing. Our work suggests that not only is language processing influenced by aggregated prior experience (e.g., MacDonald et al., 1994), but that experience incrementally and rapidly shapes our expectations about the language we speak, thereby allowing us to comprehend language more efficiently.

## Acknowledgments

We gratefully acknowledge Andrew Watts and Narissa Gogos for their assistance in collecting the data reported in this paper. The work presented here was partially funded by an NSF GRF to ABF and NSF IIS-1150028 as well as an Alfred P. Sloan Fellowship to TFJ.

#### Abstract

The current study investigated whether children and adults can distinguish between actions they are afforded and those afforded to an actor. Participants judged the maximum height they could reach while jumping and they judged the maximum height that the actor could reach while jumping. They did so with and without a weighted backpack, and they did so with and without walking several laps. Results show that before the addition of the weighted backpack, participants rated the actor's abilities as much closer to their own. While wearing the weighted backpack and then walking with it, participants' estimates decreased for themselves, but remained mostly unchanged for the adult.

Keywords: social perception; affordances; agency; embodiment; ecological psychology; development

## Introduction

For individuals to successfully navigate their environment, they must be able to perceive when different actions are possible. How does an individual know whether they can reach a jar from a shelf, step over a barrier, or navigate through traffic without incident? The ability to perceive potential actions is not limited to the individual's actions. Daily activities are filled with social interactions, such as conversational turn-taking (Shockley, Santana, \& Fowler, 2003), helping someone lift an object (Richardson, Marsh, \& Baron, 2007), or detecting whether two people can fit through a doorway (Davis, Riley, Shockley, Cummins-Sebree, 2010). Because people can readily interact and coordinate with other individuals, this suggests that individuals can perceive the actions afforded others and groups of people working together.

In the case of social interaction however, the perceiver doesn't necessarily have a priori information about another person's action capabilities. Two approaches to this problem-the ecological and embodiment perspectivecontend that minimally, perception serves the purpose of guiding action. The ecological approach focuses on the physical and spatial relationship of an observer to the
environment. The embodied approach claims that individuals neurally simulate (Grush, 2004) how they or another might accomplish an action. Both theories' ability to explain social perception in a jumping estimation task was tested in the current study.

## Affordances as the Object of Perception

Several researchers studying how individuals perceive possibilities for action in their environment have narrowed in on Gibson's (1979) concept of affordances. An affordance is meant to capture the relationship of an individual's morphology and action capabilities to the spatial layout of the environment and objects. For an individual to detect an affordance is to perceive an opportunity for action.

Affordance detection is seen in behaviors such as stair climbing (Warren, 1984) or chair sitting (Mark, 1987). Warren (1984) found that individuals selection of the tallest climbable stair is best described by a nearly, invariant ratio of leg-length to stair-riser height. Rather than focusing solely on riser height information, estimates are predicted by a ratio that exists only as a function of perceiver and stair.

Individual's daily routine rarely consist of just solo actions. For example, soccer players must decide whether their teammates are in the correct position to receive a pass. The natural tendency towards such social coordination suggests individuals readily detect what actions other people are afforded; people can accurately report what objects others can reach (Rochat, 1995), lift and move together (Richardson, Marsh, \& Baron, 2007), what chairs another person can sit on (Stoffregen, Gorday, Sheng, \& Flynn, 1999), and how high another person can jump and reach (Ramenzoni, Riley, Shockley, \& Davis, 2008a). This detection ability suggests information is readily available regarding the perceived person and their environment. Stoffregen et al. (1999) found that observers use affordance based information to detect the possible sitting height for other individuals. They asked individuals to watch a video of an actor standing next to a chair and estimate the maximal and preferred sitting height for the actor. As long as the spatial relationship between the
actor and apparatus was preserved, participants could accurately estimate the heights. Estimates were also accurate when participants only saw a kinematic display. The estimates were found to be most accurate when they were scaled by the leg length of the actor in the video, not the participant.

In this case, the estimates are based on scaling the physical morphology of the person to the spatial layout. Studies have also shown that people can perceive the capabilities for others to produce actions that are scaled by biomechanical properties such as jumping to reach an object (Ramenzoni et al., 2008a). In this case, it is less clear what information an observer might use to form a perception about another person's ability.

## Simulations and the Embodied Perceiver

An alternative perspective on social perception and action rests on neurologically driven mechanisms as a basis for behavior. This approach has been brought under the banner of the Common Coding (Prinz, 1997) or Embodied Simulation (Grush, 2004) approach. This approach suggests that social behaviors are explainable by a proposed overlap in how individuals represent perceived and performed actions. In other words, if a person watches an action being performed or plans to produce an action, they simulate the motor program and sensory consequences underlying that action. Simulation behavior is akin to covert imitation behavior (Wilson \& Knoblich, 2005).

The mirror neuron system is thought to underlie such perception and action overlap (Rizzolatti \& Craighero, 2004). The finding that mirror neurons, found in the F5 area of a Macaque monkey's premotor cortex, activate similarly to the viewing and production of an action (e.g., reaching for a glass), provide a mechanism for simulations. The perception of action possibilities in the embodied stance, thus, relies on neural based representations of the observer in the environment.

Behavioral support is found in stimulus-response incompatibility studies and action perception studies. For example, Brass, Bekkering, Wohlschlager, \& Prinz (2000) showed that finger movement reaction times are slower after watching a video of a hand performing the opposite of the instructed movement. They propose this is due to neural interference. Upon seeing the stimulus cue to respond, participants automatically simulate the action they saw; this creates a delayed response due to the overlap between the intended and observed action.

Researchers have suggested that such overlap between perception and action may provide a basis for understanding many social behaviors (Gallese, Keysers, \& Rizzolatti, 2004; Sebanz \& Knoblich, 2009). Knoblich and Jordan (2002) postulate that the mirror neuron system and embodied simulations support the ability to predict potential actions and their outcomes for perceivers and other people. Simulations are derived through a perceiver detecting or representing the actions they are afforded. These simulations are also used to judge the action capabilities of other individuals.

Results supporting a simulation theory of social perception have drawn on behavioral and physiological data. CalvoMerino, Glaser, Grezes, Passingham, and Haggard (2005) found greater activity in cortical regions containing mirror neurons when participants watched videos containing dance movements they were trained to perform. Individuals watching point-light displays are also more sensitive to movements produced by themselves than the movements of other people (Loula, Prasad, Harber, \& Shiffrar, 2005). These findings suggest that an observer's perception of another person's ability is derived from the observer's own capacity for action.

The proposal by Knoblich and Jordan (2002), regarding social action perception, suggests that the perceiver's estimation of other person's capacity to produce actions should be scaled to the perceiver's ability. Interestingly, Ramenzoni et al (2008a) found that putting weights on a participant reduced jump and reach estimates for themselves and an actor even though the actor was not wearing weights. This finding suggests that people may use simulations to estimate others, but use themselves as a frame of reference. It is not clear however, whether such estimates are really based on one's own ability to act per se, or are scaled by another relationship. Ramenzoni, Riley, Shockley, \& Davis (2008b) manipulated observer eye-height in another study as well. They found significant changes in the participants' estimates for themselves and the actor. These findings suggest that eye-height scaled information and embodied simulations both contribute to determining the ability to judge actions for others. Simulation behavior may provide a template for judgments while detection of eye-height or other optically specified information is used to tune those judgments.

## Study Overview

The current study examined whether a person's inherent and manipulated jumping ability affect their judgments of their own and another person's ability equivalently. Specifically, we tested whether individuals' judgments are based solely on their own ability to jump and reach an object or whether estimates are underpinned by simulations tuned by detecting optically specified information. In this case, the detectable information is the eye-height difference between the participant and another person. Thus, we predicted that an observer's estimation accuracy for another person should be related to the difference in eye-height of the perceiver and actor and the similarity of their inherent jumping abilities. If individuals only use simulations to make judgments, reducing observer's abilities should significantly reduce estimates for themselves and the actor. If estimates for the actor remain mostly unchanged, we predict that participants are using simulations tuned by differences in the eye-height between participant and actor.

To test the current predictions, we asked children and adults to estimate the maximum jumping abilities for themselves and an actor. Past studies (Ramenzoni et al., 2008a) have only used adult participants. This population
doesn't discriminate between groups who possess naturally different abilities and potentially different simulation capabilities. Both groups were used under the assumption that children naturally have lower jumping abilities then adults. Thus, they should have inherently different action capabilities to simulate. Participants had never seen the actor walk, jump, or reach for anything, removing any cues regarding the actor's biomechanical abilities, which has been shown to improve individual's judgments of other's (Ramenzoni, Riley, Davis, Shockley, \& Armstrong, 2008c). We manipulated participant's perception of their own jumping abilities and potentially the actors jumping abilities (Ramenzoni et al., 2008a) by increasing their weight. This was accomplished by having participants wear a backpack containing weights. Weighted estimates were provided before and after walking with the backpack.

## Methods

## Participants

Participants were 15 children between 4.5 and 5 years old ( $M$ $=4.9, S D=0.32$ ) and 15 adults between 18 and 24 years old ( $M=21, S D=2.5$ ). Children ranged in weight from 30 to 55 lbs $(M=48.6, S D=7.3)$, in height from 94 to $130 \mathrm{~cm}(M$ $=112, S D=9.3$ ), and in eye-height from 85 to $123 \mathrm{~cm}(M$ $=104, S D=9.6$ ). Adults ranged in weight from 141 to 210 lbs ( $M=159, S D=30.2$ ), in height from 162 to $195 \mathrm{~cm}(M=171$, $S D=7.7)$, and in eye-height from 152 to $185 \mathrm{~cm}(M=162$, $S D=8.6$ ). The actor had a weight of 140 lbs, height of 166 cm , and eye-height of 152 cm . All participants were either undergraduate students at the University of Cincinnati or children of undergraduates.

## Materials

To estimate jumpability, a figurine was suspended by a pulley and rope from the ceiling (see Figure 1). It could be lowered down a wall. Participants stood on a flat surface ( 100 cm x 100 cm ), 7 feet from the suspended object. The actor was positioned one foot to the left of the apparatus, facing the participant. The room was covered in black felt, including the background of where the figurine was suspended. Two adjustable backpacks, one adult-sized and one child-sized, were used to add weight to the participants. The weights used in the bag weighed 15 g each. The amount of weight used per person was approximately $5 \%$ of their body weight ( $\pm 15 \mathrm{~g}$ ). Participants were given help to put on the bags during the experiment.

## Procedure and Design

Participants were asked to play a guessing game. They were instructed to accurately estimate their own and another person's maximum ability to jump for the figurine. Prior to a trial, the figurine was lifted to the ceiling and then lowered down slowly. This was accomplished by an experimenter standing behind the wall and using the pulley system. The instruction was to tell the experimenter to stop lowering the figurine when it was at the reachable height. Participants
were allowed to have the experimenter adjust the apparatus, if the figurine was lowered too much. Estimates were coded using a tape measure drawn onto the wall. The figurine was then lifted to the top of the wall and a new trial started. Participants closed their eyes between each trial, preventing the usage of any spatial cues provided by resetting the apparatus. When estimates were made for the participant's own abilities, the actor was not in the room. When estimates were made for the actor, the actor stood next to the apparatus. A trial started by giving a verbal "go" signal, upon which the participant opened her/his eyes and the figurine was lowered.

Figure 1: Experimental setup. The girl represents the participant making a judgment about herself as well as the actor (the boy in front of the wall). The person behind the wall represents the experimenter lowering the figurine.

The experiment consisted of six types of trials, dependent on whether the participant was making estimates for themselves or the actor, and whether the participant had no weights (no-weights trial), had weights (weights-beforewalking trial), or had walked with weights (weights-afterwalking trial). In the no-weights condition, individuals made estimates from the designated spot. Participants were then given a backpack to wear (pre-weighed to approximately 5\% body weight), but were not allowed to move from the spot. After making their judgments, they were asked to walk 10 circular laps around the room. They then made the two remaining estimates. Two estimates were made for each trial type. The average of the two was used for the dependent variables. After all of the judgments, participants were asked to perform two jumps with the backpack on and two jumps without the backpack. The average across the two jumps of each kind was used to measure actual jumping abilities.

Because we wanted to examine the effects of going from a non-manipulated (no-weights) to a manipulated, but unadjusted (weights before walking), and adjusted (weights after walking) scenario, we did not counterbalance the order of trial type. We did however, counterbalance the order of the Person factor (self vs. other). Combining all of the factors, we utilized a mixed-design of Age Group (Child vs. Adult) x Person (Self vs. Actor) x Trial Type (no-weights, weights-before-walking, and weights-after-walking).

## Results

The following analyses present variables, described below, to analyze the actual jumping abilities, the mean estimated jumping height for the participant and actor (per trial type), and the estimation error (calculated as actual jump-height estimated ${ }_{j u m p}$-height). To examine whether optical information is related to jumpability estimates, the relationship of eyeheight difference to estimation error is also considered.

## Actual Jumping Abilities

First, we analyzed the actual jump height for the child and adult participants in a normal and weighted scenario. This measure was used to determine whether the weight manipulation actually affected jumping ability. Mean jumping height was analyzed with a 2 (Age Group: child, adult) x 2 (Condition: non-weighted, weighted) mixed-design ANOVA. As expected, there was a main effect of the between-group variable of Age Group, $F(1,28)=80.30, p<$ $.05, \eta_{p}^{2}=.74$. Overall, there were differences in the jumping abilities of the children ( $M=160.96, S D=23.66 \mathrm{~cm}$ ) and adult ( $M=227.80, S D=17.98 \mathrm{~cm}$ ) group. The main withingroup effect of Conditions was also significant, $F(1,28)=$ 33.10, $p<.05, \eta_{p}^{2}=.54$. In general, both groups exhibited similar changes in jumping without weights ( $M=195.70, S D$ $=40.88 \mathrm{~cm})$ and with weights ( $M=191.96, S D=39.42 \mathrm{~cm}$ ). The two-way interaction was not significant, suggesting both groups were similar in changes between non-weighted and weighted jumping ability ( $M=7.2, S D=2.34 \mathrm{~cm}$ ). The effect of Condition and lack of interaction reveals that the weights reduced participant's abilities similarly, regardless of Age Group.

## Estimated Jumping Abilities

To determine whether participants jumpability estimates for themselves and the actor were equivalently affected by the weight manipulation, we analyzed the participants' mean jumpability estimates using a 2 (Age Group: child, adult) x 2 (Estimated Person: participant, actor) x 3 (Condition: noweights, weights before walking, and weights after walking) mixed-design ANOVA.

The analysis revealed a significant three-way interaction of Age Group x Estimated Person x Condition, $F(1.69,47.57)=$ 4.94, $p<.05, \eta_{p}^{2}=.74$. Follow-up analyses were performed by splitting the Age Group (child and adult) factor into two separate 2 (Estimated Person: participant, actor) x 3 (Condition: no-weights, weights before walking, and weights after walking) repeated-measures ANOVAS. The results for the adult group yielded a significant interaction between Estimated Person and Condition, $F(1.62,22.71)=27.64, p<$ .05, $\eta_{p}^{2}=.66$. Simple effects compare estimates for the participant versus the actor at each level of Condition revealed no significant effects. The analysis for child participants yielded a two-way interaction between Estimated Person and Condition, $F(1.69,23.76)=32.78, p<.05, \eta_{p}^{2}=$ .70. Simple effects analyses comparing the participant and
actor, across each level of Condition, yielded a significant effect for the weights before walking, $F(1,28)=5.63, p<.05$, $\eta_{p}^{2}=.17$, and after walking condition, $F(1,28)=9.70, p<.05$, $\eta_{p}^{2}=.26$. The mean estimates provided by both age groups for the participant and actor are displayed in Figure 2.

Table 1. Mean jumping estimates and estimation error in cm. All values are rounded to whole integers. Standard deviations are in parentheses.

| Group | Condition | Person | Estimate | Error |
| :--- | :--- | :--- | :--- | :--- |
| Adult | No-weights | Self | $222(7)$ | $8 \quad(13)$ |
|  |  | Actor | $219(9)$ | $16(10)$ |
|  | Before walking | Self | $218(8)$ | $7(14)$ |
|  |  | Actor | $218(9)$ | $17(10)$ |
|  |  | Self | $210(11)$ | $-7(2)$ |
|  |  | Actor | $216(8)$ | $19(10)$ |
| Child | No-weights | Self | $179(13)$ | $-14(17)$ |
|  |  | Actor | $185(11)$ | $45(11)$ |
|  | Before walking | Self | $170(12)$ | $-11(16)$ |
|  |  | Actor | $187(10)$ | $47(10)$ |
|  |  | Self | $157(12)$ | $-12(7)$ |
|  |  | Actor | $188(11)$ | $47(12)$ |

## Estimation Accuracy

The accuracy of estimates were analyzed by examining the mean estimation error (actual $_{\text {jump-height }}-$ estimated $\left._{j u m p-h e i g h t)}\right)$ using a 2 (Age Group: child, adult) x 2 (Estimated Person: participant, actor) x 3 (Condition: no-weights, weights before walking, and weights after walking) mixed-design ANOVA. Analyses revealed a significant three-way interaction of Age Group x Estimated Person x Condition, $F(1.42,39.77)=$ 11.86, $p<.05, \eta_{p}^{2}=.29$.

Follow-up analyses were performed by splitting the age groups into two separate 2 (Estimated Person: participant, actor) x 3 (Condition: no-weights, weights before walking, and weights after walking) repeated-measures ANOVAs. The two-way interaction was significant in the adult group, $F(1.28,18.03)=23.25, p<.05, \eta_{p}^{2}=.62$. Simple effects were used to compare estimation error for the participant versus the actor at each level of Condition. Results yielded a significant difference in the weights before walking condition, $F(1,28)=4.60, p<.05, \eta_{p}^{2}=.31$, and in the weights after walking condition, $F(1.28,18.03)=108.79, p<.05, \eta_{p}^{2}=$ .62. Analyses for the child age group were analyzed similarly. In this case, only the main effect of Estimated Person was significant, $F(1,14)=150.77, p<.05, \eta_{p}^{2}=.92$.

## Accuracy and Eye-Height Scaling

Lastly, we examined whether a relationship between the perceiver's and actor's eye-height explains the accuracy of estimates made for the actor. The focus on actor estimates was chosen because participants provided a consistent level
of accuracy for themselves, but varied in their accuracy for the actor.

Figure 2: Mean jumping estimates by condition, for the participant and the actor. Estimates for the adult (panel A) and child participants (panel B) are shown separately.

Analyses were accomplished using a linear regression to predict the mean estimation error for the actor from the difference in eye-height between participant and actor (eyeheight $_{\text {participant }}$ - eye-height ${ }_{\text {actor }}$ ). Separate regressions were used for each condition (no-weights, weights before walking, and weights after walking). For simplicity, analyses were not split between age group.

The results showed that eye-height difference accounted for a substantial amount of the variance in the no-weights ( $\mathrm{R}^{2}$ $=.70, F(1,28)=63.83, p<.05)$, weights before walking, ( $\mathrm{R}^{2}$ $=.73, F(1,28)=76.75, p<.05)$, and in the weights after walking condition ( $\left.\mathrm{R}^{2}=.65, F(1,28)=52.72, p<.05\right)$. The results for the three separate analyses are displayed in Table 2, and the data is in Figure 3.

Table 2: Results of regression analyses of estimation error for the actor predicted by the eye-height difference between actor and participant.

| Variable | $\beta$ | $\mathrm{SE}(\beta)$ | t | Sig. $(p)$ |
| :--- | :---: | :---: | :---: | :---: |
| No-weights | .834 | .104 | 7.98 | $P<.01$ |
| Before walking | .856 | .098 | 8.76 | $P<.01$ |
| After walking | .808 | .111 | 7.26 | $P<.01$ |

## Discussion

The present study examined what information observer's use when estimating another person's ability to jump for an object.

Figure 3: Scatterplot showing the relationship of the participant's estimation accuracy for the actor with the difference in eye-height.

Like previous findings (Ramenzoni et al., 2008a and 2008b), we anticipated individuals could detect the actor's ability with some accuracy. Some studies (Ramenzoni et al., 2008a) have shown that changing the participant's ability to jump by adding weights alters a perceiver's estimate of their own and an actor's ability, despite not changing the actor's abilities. This has been taken as support that an observer's perceptual judgment is driven by a simulation mechanism. Other studies have shown that estimates of another person's abilities are better described by some physical relationship of the actor (e.g., leg-length) to the environment (Rochat, 1995; Stoffregen et al., 1999) or the physical relationship between two people (Richardson et al., 2007).

Based on the current line of theorizing, we predicted that participant estimates for themselves should decrease when weights were initially added and more so after walking with them on. Additionally, if participants were utilizing eyeheight information, then the estimates for the actor should not decrease significantly. Examining the mean jumpability estimates (Figure 2. and Table 1.), it is clear that participant's estimates for themselves decreased significantly in both age groups, but didn't decrease similarly for the actor. Only with child participants, however, were there significant differences between estimates for themselves and the actor across conditions. The lack of an effect in the adult group is similar findings of Ramenzoni et al. (2008a). The non-effect in the adult group, though, might be due to the eye-height similarity between the adult participants and actor. The children, on average, had a greater eye-height difference to the actor than the adult group.

If perceivers used eye-height information to tune affordance judgments of jumping for the actor, then estimate accuracy should scale with eye-height (Ramenzoni et al., 2008b). Specifically, perceivers with the closest similarity in eye-height to the actor should exhibit the greatest accuracy, assuming they have similar jumping abilities. The regression
analyses of eye-height difference across conditions support this proposal. The $R^{2}$ values demonstrate that a high, and similar, amount of variance is captured by the model across all conditions and age groups. Furthermore, the standardized coefficients are significant and similar across all conditions (Table 2.). Examination of Figure 3 reveals increased accuracy for participants closest in eye-height to the actor. The mean estimation errors (Table 1.) also show that adults were more accurate than children. Interestingly, the scaling relationship shows that as the participant's eye-height decreased away from the actor, there was an increasing tendency to overestimate the actor; as participant eye-height increased away, there was a tendency to underestimate. Together, these findings suggest a potential two part process to perceiving action capabilities for others. Observers can estimate boundaries for another person's abilities by simulating a potential action. Detection of optical information - such as eye-height difference can fine tune these estimates.

# The Effect of Non-Linguistic Patterns on Linguistic Biases 

Sara Finley (sara.finley@waldorf.edu)<br>Department of Psychology, Waldorf College<br>Forest City, IA, 50436, USA

#### Abstract

The present study explores the effects of non-linguistic experiences on biases for linguistic judgments, specifically consonant deletion patterns. When two adjacent consonants come into contact as a result of morphological concatenation, many languages will delete the first consonant (e.g., /bepdok/ becomes /bedok/). Speakers of these languages (as well as English speakers) prefer deletion of the first consonant to the second consonant because the first consonant is perceptually weaker, making it more prone to misrepresentations and modifications. Following exposure to a non-linguistic analogue of consonant deletion in which the second consonant was deleted instead of the first, participants no longer preferred deletion of the first consonant in the metalinguistic judgment task. These results suggest that exposure to non-linguistic materials can interact with linguistic judgments.

Keywords: statistical learning, phonotactics, learning biases, analogy.

## Introduction

One of the major questions in the cognitive science of language is how linguistic and non-linguistic experiences interact to build a productive system of language. For example, children learning language benefit from increased cognitive and social skills in their language capacities, but increased language capacities also help to scaffold cognitive and social growth (Dessalegen \& Landau, 2008). Because language interacts with social, cultural and cognitive aspects of human functioning, it is important to understand how language influences non-linguistic cognition, in addition to how non-linguistic cognition influences language.

The discussions concerning linguistic and non-linguistic interaction have often turned to the question of linguistic relativity, the idea that the specific language one speaks has an effect on how the speaker perceives and interacts with the world (Whorf, 1956). In addition, there is a question of how linguistic knowledge can aid in higher level cognition (Gentner \& Goldin-Meadow, 2003).

The question of how language and thought interact can be addressed not only as whether language affects thought, but also whether non-linguistic information can have an effect on language. While language is a direct way to express one's thoughts, there may be other, more subtle ways in which non-linguistic experience can affect language. These subtle effects could be used to understand the ways in which linguistic knowledge is specific to language (domain
specific) and general to other cognitive processes (domain general). In domain specific views, language is believed to be a key component that to human cognition. The mechanisms that underlie language are separate from other species, and (in the most extreme theories) show no interaction with non-linguistic cognitive functions (Berent, 2012; Pinker \& Jackendoff, 2009). In this view, nonlinguistic cognition should have no influence on linguistic judgments. In a domain general view of language, foundations for the human language capacity arise through social and cultural transmission. The key to linguistic knowledge is an interaction between the need to communicate and the existence of high-level cognitive capacities such as abstract pattern learning and memory (Chater \& Christiansen, 2010). Under this view, nonlinguistic patterns should have a strong influence on linguistic constructs.

One of the strong pieces of evidence for a domain specific approach to language is the idea that there are biases for specific linguistic structures that have no non-linguistic analogues (Berent, Steriade, Lennertz, \& Vaknin, 2007; Culbertson, Smolensky, \& Legendre, 2012; Finley, 2012; Finley \& Badecker, 2008). For example, Finley (2012) found that adult native English speaker show a bias for phonological patterns based on vowel height. Since vowel height is a linguistic construct, it is hard to imagine how such a bias could be influenced by non-linguistic factors.

Other evidence suggests that linguistic patterns may be stored as domain-general rules. Studies of statistical learning for speech segmentation showed similar results to linguistic and non-linguistic materials (Aslin, Saffran, \& Newport, 1997; Saffran, Pollak, Seibel, \& Shkolnik, 2007). In addition, Finley and Christiansen (2011) showed that adult learners can generalize a novel reduplication pattern to from non-linguistic materials to linguistic judgments.

In addition, robust use of analogy in both linguistic and non-linguistic learning tasks (Gentner, 2010) opens the possibility that learners will be able to form connections between non-linguistic patterns and linguistic patterns.

The evidence for both domain general and domain specific learning mechanisms suggests that grammatical principles have many influences. The goal of the present study is to provide experimental evidence that manipulation of nonlinguistic patterns can affect linguistic biases. Specifically, we focus on consonant deletion, a phonological pattern whereby a consonant will delete in the presence of two adjacent consonants.

## Biases in Consonant Deletions

Consonant deletion is a phonological pattern in which one of two adjacent consonants delete (e.g., /depkot/ becomes
/dekot/). In these consonant deletion patterns, there appears to be a cross-linguistic preference to delete the first consonant (Steriade, 2001; Wilson, 2001). In Diola Fogny, when two consonants combine as a result of morphological concatenation, the first consonant deletes (e.g., /let+ku+jaw/ $\rightarrow$ [lekujaw] 'they won't go') (Sapir, 1975; Wilson, 2000, 2001). Wilson (2001) argues that the second consonant is in a perceptually stronger position (onset), while the first consonant is in a perceptually weaker position (coda). If a rule requires deletion of a consonant, speakers will choose to delete the weaker one. A perceptually weak consonant is more likely to be misheard or not heard at all, meaning that over time (diachronically), that consonant may be categorically deleted from the lexical item (Steriade, 2001, 2009).

Finley (2011b) provided evidence that the preference for C 1 deletion over C2 deletion is synchronic and present in speakers of English (a language that does not have regular consonant cluster deletion). In this experiment, monolingual English speaking participants were given a two-alternative forced choice test in which participants chose between two triads. In one triad, the first consonant was deleted (e.g., /bep, dok, bedok/). In another triad, the second consonant was deleted (e.g., /bep, dok, bepok/). Participants were more likely to choose the triads where the first consonant deleted (based on the criteria to choose which triad was more likely to belong to a 'real' language). This result suggests that participants prefer to delete the perceptually weak pattern, despite no exposure to this pattern in the native language.

## Sources of Linguistic Biases

While it is agreed that linguistic biases are prevalent, the sources of such biases are not agreed upon. One possibility is that linguistic biases are derived from pre-existing linguistic knowledge or experience. This knowledge could be innate (Berent, et al., 2007), or inferred indirectly through the course of exposure to other patterns in the language. It is also possible that a bias for a particular linguistic pattern may have roots in domain general cognition (Chater \& Christiansen, 2010). For example, cross-linguistic preferences to avoid changes to the first syllable of a word may result from domain general mechanisms (Beckman, 1998). The first and last items in a list are the most likely to be remembered (referred to as primacy and recency), suggesting that the first and last parts of a word will also be easiest to remember. If beginnings of the words are easier to remember, speakers may avoid altering that part of the word.

One issue with discerning whether non-linguistic cues can influence linguistic biases is that the linguistic and nonlinguistic cues often interact, and the direction of interaction is often unclear. For example, initial syllables may be more likely to be remembered because they are less likely to be altered (and thus have fewer alternative forms to consider). In addition, other linguistic cues such as stress, prominence and volume may play also play in phonological processes,
and these different factors may vary across different languages.

The goal of the present study is to determine whether a non-linguistic analogue of a linguistic pattern can alter a linguistic bias. If the non-linguistic cue can remove (or even reverse) the linguistic bias, it suggests that non-linguistic cues do affect how speakers perceive and interpret language. It is important to note that if a non-linguistic cue can affect a linguistic bias, it in no way implies that all linguistic biases have a non-linguistic basis. However, if a linguistic bias can be influenced by a non-linguistic cue, it opens the possibility that domain general influences affect at least some of the linguistic tendencies found cross-linguistically.

The present experiment makes use of the known linguistic bias in adult English speakers for deletion of C1 in a C1-C2 consonant cluster (Finley, 2011). The present experiment asks whether exposure to a non-linguistic analogue of C2 consonant deletion (as opposed to the preferred C 1 deletion) can reduce or reverse the bias for C 1 deletion in learners.

## Methods

The present study used an artificial language that contained a non-linguistic analogue of a deletion pattern. In Finley (2011a, 2011b), consonant deletion was induced via triads in which two CVC (consonant-vowel-consonant) items were combined to form a CVCVC word (e.g., /bek dof bedof/). We created a non-linguistic analogue using sequences of shapes with various patterns. An analogue for perceptual dis-preference for two consonants in a row was created using visual aesthetics. In the present experiment we treated every consonant as a long rectangle with various patterns, and every vowel as a circle filled with various patterns. The fill patterns were used to create differences between the various circles and rectangles, while maintaining a strong sense of continuity between the shape and size of the circles.

## Participants

All participants were adult native English speakers. Eighteen participants were recruited from Elmhurst College and the surrounding community. Each participant was given a $\$ 10$ gift card for participating. Twelve participants were recruited from the University of Rochester community and paid $\$ 10$ cash for their participation. Twelve control participants were recruited from the University of Rochester community were paid $\$ 5$ cash for their participation. Some participants may have previously participated in an artificial grammar learning experiment, but no participant had been exposed to the stimuli or patterns used in the present experiment. The data for two additional participants could not be used due to malfunctions in the experimental program.

## Design

The experiment was designed to test the ability of adult learners to extend a novel non-linguistic analogue of consonant deletion to a linguistic version of the same task. English speakers have been shown to prefer deletion of the
first consonant of a CC consonant cluster, complying with the general cross-linguistic tendencies (Finley, 2011b; Wilson, 2001). Importantly, the preference shown in English speakers appears without any prior exposure to the pattern. In these previous studies, participants were exposed to triads of shapes presented in the center of the screen for 1000 ms . Participants were told that they would see one of two shapes followed by the combination of the first two shapes (participants were given a practice trial in which all squares and circles were identical, and given a chance to ask questions if necessary).

The patterns of the circles and squares were made in exact analogy to a precious consonant deletion experiment in which two CVC words were combined to form a CVCV word (e.g., /bek/ + /dok/ $\rightarrow$ /bedok/) (Finley, 2011a, 2011b). The visual analogue treated every segment as a separate shape. For example, /a/ was a circle with black 'confetti' squares, and $/ \mathrm{k} /$ was a rectangle filled in with a diagonal brick pattern. Creating stimuli in this manner helped to keep the stimuli as analogous to an experiment that used linguistic materials. It also allowed non-linguistic materials to be balanced similarly to linguistic materials. Examples of the training stimuli can be found in Table 1.

Table 1: Examples of Training Stimuli.

Training consisted of 24 triads repeated five times each in a random order. Immediately following exposure, participants were given a two-alternative forced choice test in two parts. The first part tested knowledge of the non-linguistic pattern, with examples found in Table 2. The second part tested biases towards C1 deletion in a linguistic consonant deletion pattern, with examples in Table 3.

Old Items The first type of test item specifically tested the learner's ability to recognize which of the rectangles was deleted in the exposure items. A participant could respond correctly to these items by remembering the specific items in the exposure set.

New Items The second type of test item used novel shape items. A participant could respond correctly to these items if they extend the pattern seen during exposure to novel items.

Sound Items The third type of test item was designed to assess whether participants who were exposed to the visual deletion pattern would show the same bias towards first-
consonant deletion shown in previous studies. The stimuli were nearly identical to those used in previous studies of consonant deletion (Finley, 2011a, 2011b). Participants were told to select which of the following sets of three sounds was most likely to be from a real language. The sound items were presented in the same manner as the Old and New test items, choosing between deletion of the first consonant (C1) or the second consonant ( C 2 ) of a consonant cluster. Each item in the two-alternative forced-choice task was a tirad: $\mathrm{CVC}_{1}, \mathrm{C}_{2} \mathrm{VC}, \mathrm{CVCVC}$. Participants were told that they would be hearing two sets of three non-words where the third word was a combination of the first two (given /tooth+brush $=$ toothbrush/ as an example), and their job was to select which set of three non-words they preferred.

Table 2: Example Old and New Test Items

|  | Set 1 | Set 2 | Combined Form |
| :---: | :---: | :---: | :---: |
| $\quad 1 \quad$ Old Second Deleted (Correct) |  |  |  |
| First <br> Deleted <br> (Incorrect) |  |  |  |
| New |  |  |  |
| Second <br> Deleted <br> (Correct) |  |  |  |
| First <br> Deleted <br> (Incorrect) |  |  |  |

All stimuli were designed so that the final consonant of the first CVC word was different from the first consonant of the second CVC word. For example, [pik ket] was not a possible pair of words in the experiment because it would be impossible to tell which consonant was deleted. Consonants were drawn from the set $[\mathrm{p}, \mathrm{t}, \mathrm{k}, \mathrm{b}, \mathrm{d}, \mathrm{g}, \mathrm{s}, \mathrm{f}, \mathrm{z}, \mathrm{v}, \mathrm{m}, \mathrm{n}]$, and vowels were drawn from the set $[\mathrm{a}, \mathrm{i}, \mathrm{e}, \mathrm{o}, \mathrm{u}]$ Examples of Sound Items can be found in Table 3.

The Sound stimuli were recorded by an adult female native speaker of English in a sound attenuated booth at $12,000 \mathrm{~Hz}$. Stress was placed on the first syllable using standard English pronunciation, with the exception that no vowels were reduced, meaning though all syllables contained partial stress (as English reduces unstressed syllables). All stimuli items were normalized for intensity (set at 70dB) using Praat (Boersma \& Weenink, 2005).

There were 12 Old Items, 12 New Items and 30 Sound Items (however, a glitch in a group of participants caused
several participants to hear a random set of 20 of the 30 sound items). The Old and New test items were presented together in a random order, before the Sound Items. The items in each test condition were balanced such that half of the items showed deletion of the first consonant/rectangle first, while the other half of the items showed deletion of the second consonant/rectangle first.

Table 3: Sound Item Examples.

|  | CVC 1 | CVC 2 | Combined <br> Form |
| :--- | :--- | :--- | :---: |
| Second Deleted <br> (Non-Linguistic Bias) | div | nup | divup |
| First Deleted <br> (Linguistic Bias) | div | nup | dinup |
| Second Deleted <br> (Non-Linguistic Bias) | kaf | gez | kafez |
| First Deleted <br> (Linguistic Bias) | kaf | gez | kagez |

All phases of the experiment were run in Psyscope X (Cohen, MacWhinney, Flatt, \& Provost, 1993). Participants were given both written and verbal instructions. The entire experiment took approximately 20 minutes.

## Results

Proportion of $\operatorname{Set} 2 / \mathrm{C} 2$ deletion responses for all three different test items are given in Figure 1, with numerical values for means and standard deviations in Table 4.

| Table 4: Means (and Standard Deviations). |  |  |  |
| :---: | :---: | :---: | :--- |
| Condition | Old | New | Sounds |
| Control | 0.53 | 0.47 | 0.37 |
|  | $(0.10)$ | $(0.11)$ | $(0.11)$ |
| Experimental | 0.78 | 0.78 | 0.63 |
| (Old Items | $(0.11)$ | $(0.18)$ | $(0.26)$ |
| Above Chance) |  |  |  |
|  |  |  |  |
| Experimental | 0.46 | 0.47 | 0.44 |
| (Old Items | $(0.059)$ | $(0.14)$ | $(0.21)$ |
| Below Chance) |  |  |  |

We compared the results for the experimental condition to the Control condition by a $2 \times 3$ mixed design ANOVA. We found a significant effect of Training $(F(1,37)=10.89, p=$ 0.002 ), a significant effect of Test $(F(2,74)=7.13, p=$ 0.001 ), and no interaction, $F<1$.

In order to test whether the bias existed in the Controls, and whether the bias was reversed in the Experimental condition, we compared the responses to $50 \%$ chance via one-sample t-tests. The results were significant for the Control condition $t(11)=4.33, p=0.0012$ (in that the Control condition was significantly below chance), but the results were not significant for the Experimental Condition,
$t(26)=1.15, p=0.26$. Because the experiment was concerned with whether exposure to the non-linguistic deletion pattern would change the bias towards C 1 deletion in the consonant test, we compared the responses to the Sound Test Items between the Control and the Experimental Condition. There was a significant difference, $t(37)=2.45, p=0.019$.

Figure 1: Overall Results: Means and Standard Errors.

One possibility for the failure to find a significant difference between the Sound test items and chance (in the one-sample t-test) was that some participants failed to learn the nonlinguistic pattern or remember the items heard in training. One cannot expect the non-linguistic pattern to have any effect on the linguistic pattern without learning the pattern (or at least recognizing the items heard in training). For this reason, we divided participants in the Experimental Condition into two groups: those that scored above $50 \%$ in the Old Items, and those that scored $50 \%$ (chance) or below in the Old Items. Of the 27 participants in the Control Condition, 17 scored above chance in the Old Items, and 10 scored at or below chance. These are presented in Figure 2.

Figure 2: Results with Participants in Experimental Condition: Separated by Response Rate: Means and Standard Errors

The participants who scored at or below chance for Old Items showed results very similar the Control Condition. When compared to the Control Condition via ANOVA, we found no effect of Training ( $F<1$ ), a marginal effect of Test $(F(1,40)=3.00, p=0.061)$ and no interaction $(F(1,40)=$ $1.64, p=0.21)$. When the Sounds Test items were
compared to $50 \%$ chance via one-sample t-tests, there was a marginally significant effect, $t(16)=2.04, p=0.0585$. Of the 17 participants who scored above chance for Old Items, three participants scored below $40 \%$ C2 deletion in the Sound Items. For this minority of participants, exposure to the non-linguistic pattern did not affect the bias. However, the majority of the 17 participants showed C 2 deletion at a rate greater than that of the mean of the Control condition.

## Discussion

The results of the present study demonstrate that linguistic biases can be reduced or altered due to exposure to nonlinguistic material. These results have important implications for cognitive science. First, it suggests that biases found for linguistic patterns are malleable. Different experiences can prime the listener to expect different types of linguistic stimuli, and therefore diminish a pre-existing bias. This means that an innate bias for a particular linguistic structure could be overridden if provided with exposure to the right kinds of data. This may help to create a theory of linguistic biases that can account for the fact that there are exceptions to almost every posited linguistic universal (Evans \& Levinson, 2009).

Second, the results support a theory in which linguistic and non-linguistic data interact. In understanding the domain specificity of language, one must understand what aspects of language interact with non-linguistic cognition, as well as the mechanisms that control this interaction. The results of the present study provide an insight into this question. In the present study, the non-linguistic deletion pattern had a direct analogue to the consonant deletion pattern. This direct analogy allowed participants in the Experimental Condition to interpret the linguistic material differently than participants in the Control condition.

A proposed analysis of the influence of linguistic experiences, non-linguistic experience, and linguistic biases on linguistic biases is presented in Figure 3.

Figure 3: The interactive of linguistic experiences, nonlinguistic experiences and linguistic biases on linguistic judgments.

Linguistic judgments are affected by our linguistic experiences; native English speakers are able to make judgments about English due to their exposure to English. Linguistic judgments are also affected by biases that are independent of language exposure, such as the bias for C 1 deletion over C 2 deletion found in the control condition.

The Experimental condition demonstrated that nonlinguistic experiences can affect linguistic judgments. The non-linguistic experience pushed the participants away from a bias towards C1 deletion. The mechanism proposed in Figure 3 also allows for interaction between linguistic and non-linguistic experiences, as well as an integration between linguistic biases and linguistic experiences. Non-linguistic experiences affect the type of language you are exposed to, and linguistic biases affect the likelihood that you will learn and be exposed to certain types of linguistic materials (Finley, 2012).

The diagram in Figure 3 also allows for individual differences in when non-linguistic experiences will affect linguistic judgments. When non-linguistic experiences and linguistic biases are in conflict (as in the present experiment), biases may trump non-linguistic experiences for some individuals. A small majority of participants in the Experimental condition showed a bias for C1 deletion, despite learning the non-linguistic pattern. This suggests that analogy from non-linguistic to linguistic patterns do not occur for everyone.

Third, the present experiment demonstrates that language and thought interact, and that the direction of interaction can go from non-linguistic patterns to linguistic patterns. The question of language and thought need not extend only to whether language affects thought, but whether nonlinguistic patterns can affect how language is perceived language. The present experiment demonstrates that our non-linguistic experiences can affect how we perceive language.

One question that remains for future research is to understand when non-linguistic patterns may affect linguistic judgments in real-world situations. The present experiment made an arbitrary analogy between consonant deletion and shape deletion. Such direct analogies are rarely found in the real world. Given that patterns in language tend to be abstract and arbitrary, it is difficult to find a nonlinguistic pattern that can be directly linked to language. One possibility may lie within the cognitive and linguistic development of infants and young children. As children learn patterns in their behavior and the behavior of others, they may use those patterns to help learn linguistic patterns. Conversely, children may use their ability to learn patterns to help learn both non-linguistic cognitive skills, as well as linguistic skills. For example, Dessalegen and Landau (2008) demonstrated that children can use labels to solve otherwise difficult non-linguistic tasks. In addition, the robust use of analogy in learning (Gentner, 2010), suggests that learners are capable of analogy from linguistic to nonlinguistic material and vice versa. Future research will work to formalize when and how this analogy occurs.

The results of the present experiment provide further evidence for interaction between linguistic and nonlinguistic patterns. Human learners have a remarkable ability to use analogy to extend a pattern from a nonlinguistic domain to a linguistic domain. Despite the fact that English speakers (as well as speakers of several other
languages) show a bias towards C 1 deletion, this bias was reduced after exposure to a pattern in which the nonlinguistic analogue of C 2 was deleted (as opposed to an analogue of C1).

# Using Causal Induction in Humans to Learn and Infer Causality from Video 

Amy Fire (amy.fire@ucla.edu)<br>Song-Chun Zhu (sczhu@stat.ucla.edu)<br>Center for Vision, Cognition, Learning, and Art<br>University of California, Los Angeles<br>Los Angeles, CA 90095 USA

#### Abstract

For both human and machine learners, it is a challenge to make high-level sense of observations by identifying causes, effects, and their connections. Once these connections are learned, the knowledge can be used to infer causes and effects where visual data might be partially hidden or ambiguous. In this paper, we present a Bayesian grammar model for human-perceived causal relationships that is learnable from video. Two experiments investigate high-level causal induction from low-level visual cues. In the first experiment, we show that a computer can apply known heuristics used for causal induction by humans to learn perceptual causal relationships. In the second experiment, we show that our learned model can represent humans' performance in reasoning about hidden effects in video, even when the computer initially misdetects those effects.

Keywords: Perceptual causality; causal induction; statistical models.

## Introduction

A man approaches a closed door. He reaches out to grasp the handle and then stands there. Is it locked? Does he not have the key? He knocks and waits, but the door remains closed. Is there no one on the other side to open it?

Watching these events unfold, humans can readily answer these questions based on their causal knowledge. One way humans can learn causal relationships is through daily observation by internally measuring co-occurrence of events (Griffiths \& Tenenbaum, 2005). Research suggests that humans use a few heuristics to determine whether a cooccurrence is causal, including:

- whether the temporal lag between cause and effect is short, and the cause precedes the effect (Carey, 2009) and
- whether agent actions are responsible for causes (Saxe, Tenenbaum, \& Carey, 2005).

However, learning from daily observation is limited: many actions and effects are hidden. Our prior knowledge about causal relationships between actions and effects allows us to fill in information about the events in the scene.

Some current models represent knowledge with Bayesian networks, e.g., (Griffiths \& Tenenbaum, 2005). These models, however, are disjoint from the low-level visual data that people observe. Instead, models are built using high-level annotations. In reality, agents build knowledge by observing low-level visual data, and models need to be able to deal with uncertainty in observation.

Although Bayesian networks are commonly used to represent causality (Pearl, 2009), grammar models have the expressive power to represent a greater breadth of possibilities than a single instance of a Bayesian network (Griffiths
\& Tenenbaum, 2007). Grammar models allow for multiple configurations and high-level structures, making them more suitable for applications grounded on visual cues; Bayesian networks lack the representative power needed for this.

Grammar models are represented graphically in the AndOr Graph (AOG). In the AOG, Or-nodes represent the multiple alternatives, and And-nodes represent hierarchical decompositions. The AOG naturally lends itself to represent causation where multiple alternative causes can lead to an effect, and each cause is composed of conditions necessary for the effect.

In this paper, we introduce a grammar model for representing causal relationships between actions and object-status changes, the Causal And-Or Graph (C-AOG). We describe methods for learning the model by using co-occurrence to identify potential causal relationships between events and applying the heuristics listed above to those potential relationships. In two experiments, we investigate how the model matches human perceptions of causality. Experiment 1 uses input typical of computer vision detection systems to investigate learning the C-AOG and human perceptions of causality. Experiment 2 demonstrates that the C-AOG models human judgments on imputing hidden variables from video.

## A Grammar Model for Causality

In this section, we introduce the Causal And-Or Graph for causal reasoning, which ties agent actions to fluents.

## Fluents and Actions

Specifically defining those object statuses that vary over time, the term fluents comes from the commonsense-reasoning literature (Mueller, 2006). Relevant here are two kinds of fluents that intentional agents can change: object fluents (e.g., a light can be on or off) and fluents of the mind (e.g., an agent can be thirsty or not thirsty).

The values of these fluents change as a result of agent actions and also trigger rational agents to take action. A lack of change-inducing action (also known as the inertial action) causes the fluent to maintain its value; for example, a door that is closed will remain closed until some action changes it. In this work, fluents are modeled discriminatively.

Actions $\left(A_{i}\right)$ are modeled using the Temporal And-Or Graph (T-AOG), a grammar model for actions (Pei, Jia, \& Zhu, 2011). In the T-AOG, And-nodes group the necessary ways for an action to be performed that allow detection of the action (e.g., object/agent spatial relations, agent poses, scene contexts, and temporal relationships), and Or-nodes provide

Figure 1: A C-AOG for door status as learned in Experiment 1. The value of the top-level fluent is a consequence its children. The fluent transit action nodes indicate the kind of change that occurs in the fluent: step functions for change, flat lines for non-change (or inertial action). Action $a_{0}$ is the inertial action (a lack of state-changing action). Arcs connect children of And-nodes. It should be noted that each photo represents a further set of child And-nodes from the Temporal And-Or Graph (not shown). Thickened lines indicate selections on the Or-nodes that provide a single parse graph.
the alternative methods of performing the action. While hidden Markov models and dynamic Bayesian networks have also been used for action detection from video, the grammar is necessary as it allows representation of high-level structures and multiple configurations.

Our experiments are conducted using a pre-selected set of actions and fluents common to office, hallway, and elevator scenes. Such scenes (and events therein) might be of interest for surveillance, for example.

## The Causal And-Or Graph

The Causal And-Or Graph (C-AOG) is a graphical representation for the grammar of causality. The top levels of one C-AOG learned in Experiment 1 are shown in Figure 1.

In the C-AOG, Or-nodes represent the alternative means of causation (e.g., a monitor, through the computer, can be turned on by someone using a mouse or a keyboard). Arrows point from these causing actions to their fluent effects.

Each And-node is formed from the set of multiple conditions for the action, including its sub-actions. The action nodes in a C-AOG may be inertial actions (resulting in no change); unexplained instances of the fluent are also pooled under the inertial action.

A selection on the Or-nodes is called a parse graph, denoted $p g$ (such as the paths shown by thicker lines in Figure 1). It provides a causal interpretation of each fluent's particular value at a given time, answering "why" the fluent has that particular value.

## Probability on the C-AOG

The probability model over the parse graphs in the C-AOG incorporates the detection probabilities of actions and fluents in a Bayesian manner. In particular, given the video $I$,

$$
\begin{equation*}
\underbrace{P\left(p g_{\mathrm{C}} \mid I\right)}_{\text {posterior }}=\underbrace{P\left(A_{1}, \ldots A_{n} \mid I\right) P\left(\Delta F_{1}, \ldots, \Delta F_{m} \mid I\right)}_{\text {likelihood }} \prod_{v \in V_{\mathrm{C}}^{\mathrm{Or}}} \underbrace{P(w(v))}_{\text {prior }} \tag{1}
\end{equation*}
$$

The likelihood term is the detection probability for the included actions/fluents, and considers actions and fluents independently. $V_{\mathrm{C}}^{\mathrm{Or}}$ is the set of included Or-nodes in the causal explanation, and $w(v)$ returns the selected Or-branch. The prior term gives the switch probability on the Or-nodes for the alternative causes and is learned by maximum likelihood estimation.

## Learning the C-AOG

To learn the C-AOG, potential causal relationships are found by restricting the set of all possible fluent/action interactions with the set of heuristics listed at the beginning. Actions and fluents from all levels of their respective hierarchies are considered.

A joint model is iteratively built up from the initial probability distribution over actions and fluent changes, incorporating a new causal relationship each iteration. In an iteration, the contingency table of each action-fluent pair $\left(A_{i}, \Delta F_{j}\right)$, e.g., Table 1 , is examined. The best causal relationship is determined by maximizing the information gain (IG), which is the Kullback-Leibler divergence (KL) (Kullback \& Leibler, 1951) between the full contingency table of Table 1 and the expected contingency table predicted by the model in the current iteration (similar to work on texture modeling (Zhu, Wu, \& Mumford, 1997)). In particular, in a single iteration, causal relation $c r^{*}$ is added to the model where

$$
\begin{equation*}
c r^{*}=\underset{c r}{\operatorname{argmax}} \mathrm{IG}=\underset{c r}{\operatorname{argmax}} \operatorname{KL}(\mathbf{f}| | \mathbf{h}), \tag{2}
\end{equation*}
$$

$\mathbf{f}=\left(f_{0}, f_{1}, f_{2}, f_{3}\right)$, and $\mathbf{h}$ is the analogous quantity from the current iteration's model. The causal relationships with highest information gains are deemed most significant and are collected into the C-AOG.

Table 1: Contingency table of relative frequencies.

|  | $\Delta F_{j}$ Present | $\Delta F_{j}$ Absent |
| :--- | :--- | :--- |
| $A_{i}$ Present | $f_{0}$ | $f_{1}$ |
| $A_{i}$ Absent | $f_{2}$ | $f_{3}$ |

Our learning method integrates with existing action and fluent detection systems, creating a unified framework for the spatial, temporal, and causal domains. Further, our method is more computationally feasible for large networks of causal connections than Bayesian learning frameworks are (with their prior distributions over graph structures). Traditional causal induction as done by constraint satisfaction (Pearl,

Figure 2: Information gains for causal relations in the order pursued, separated by fluent. Green circles label causes.
2009) or Bayesian formulations (Heckerman, 1995) is intractable to ground on vision sensors. Models such as causal support (Griffiths \& Tenenbaum, 2005) learn a new, larger model each iteration, and the number of possible models grows exponentially. In contrast, the number of computations to learn our model is constant each iteration.

## Experiment 1: Learning Causality

In this experiment, we test the model's ability to learn humanperceived causal relationships. For testing the algorithm, the ground truth is established by linking known causing actions to their fluent effects.

## Video Data Used

To test learning the C-AOG, videos were collected with a Microsoft Kinect, recording the color and depth images simultaneously. The scenes collected include multiple doorways, an elevator, and an office. Figure 1 shows some screenshots of the videos. The entire video collection lasts about 120 minutes, and contains 21 pre-specified action categories. There are 8 to 20 (sometimes simultaneous) instances of each action category.

In this experiment, we first use perfect action and fluent detections to demonstrate learning. We compare these results to those obtained with noisy detections (with varying levels of accuracy), such as would be output from the action and fluent detection system.

## Results and Discussion

Multiple Fluents Figure 2 shows plots of information gains for causal relations in the order pursued, separated by fluent. Causes are added to the model before non-causes with clear cutoffs for the door and light fluents. The cutoff between cause and non-cause is obscure for the computer monitor fluent because the model only acquired partial causal information (the preconditions of power and computer status are hidden).
Noisy Data Randomly flipping action detections leads to the curves shown in Figure 3. As more noise enters the system, the information gained by considering causal relations decreases. While learning works amid noisy scenes (many actions happening simultaneously), clean detections are important.

Figure 3: Information gains for causal relationships in the order pursued for the light fluent.

Hierarchical Action Selection and $\chi^{2}$ Where compound actions (e.g., in the doorway scene, unlocking with a key or entering a code, followed by pushing/pulling the door) are required for the effect, the causing actions may be located within varying levels of the action hierarchy.

For actions hierarchically related to each other in the Temporal AOG, our model incorporates their dependences, minimizing the chance that related actions are selected as causes. Figure 4 shows that Hellinger's $\chi^{2}$ measure (a $\chi^{2}$ that is less sensitive to low expected values in a contingency table (Ferguson, 1996)) fails to identify the correct causes, unable to account for dependence.

Figure 4: Pursuit order for hierarchical causes.

Long Delay, Causal Power, and $\Delta P$ Under the power PC theory (Cheng, 1997), perceptual causality is calculated as:

$$
\begin{equation*}
\text { causal power }=\frac{\Delta P}{P(\text { effect } \mid \text { not cause })} \tag{3}
\end{equation*}
$$

Frame Number (not to scale)
Figure 5: Sample of human judgment key frames.
where $\Delta P$ (Allan, 1980) is given by:

$$
\begin{equation*}
\Delta P=P(\text { effect } \mid \text { cause })-P(\text { effect } \mid \text { not cause }) \tag{4}
\end{equation*}
$$

For an elevator, the only detectable causing action for the door opening is pushing the elevator call button. In this example, our model outperforms causal power as shown in Figure $6 . \Delta P$ performs similarly to causal power.

Figure 6: Pursuit order for the elevator scene.

The failure of causal power and $\Delta P$ originates when an observed event (e.g., walking away) coincidentally always occurs with the true cause (e.g., pushing the elevator call button) and the true cause is not perfectly detected. Both measures favor $100 \%$ correlation, despite how rarely it occurred in the video. The learning method presented here incorporates the frequency that the relationship is observed by examining the full contingency table.

## Further Discussion

Results match exactly with human perceptions of the causal connections between actions and fluent changes, showing that the C-AOG is learnable from co-occurrence and the heuristics listed in the beginning (short temporal lag and agent actions cause fluent changes).

Our results are limited to the action and fluent categories that are pre-specified, despite the fact that many potentially confounding actions were included. Those quantities must be specified in advance so that appropriate detectors can be trained. It is possible, however, that different people would produce different bottom-level actions and fluents.

## Experiment 2: Inference Experiment

In this experiment, our model is validated against humans in the long-term reasoning task of inferring hidden fluent values.

## The Stimuli

Approximately 20 minutes of video data was captured using a Kinect in two scenes: a hallway and an office. Table 2 contains a summary of the fluents contained in the video, as well as the values each fluent can take. While many of these fluents are ordinarily viewable, they are ambiguous in the video (e.g., light status (ambient light may be from a window or a light) or water stream (resolution is not high enough to see it) in Figure 5).

Through a website, volunteer participants $(N=15)$ were shown the test video which paused at preset frames, e.g., those shown in Figure 5. Query points surround either a change in a fluent or a causing action. At each key frame, the participant was asked to assign a total of 100 points to all possible values of each fluent, according to his/her own recognition and reasoning for the events. Assignment of the points corresponded to the subjective probabilities of the fluent values. Each participant was allowed to revise previous judgments with information derived from subsequent frames.

## Reference Estimates

We compare the human responses to predicted fluent values by a baseline random noise model and by the C-AOG.

Baseline Estimate (Random Noise). For a baseline estimate, the hidden fluents were randomly assigned uniformly, without using any detection or causal information (e.g., $50 \%$ for LIGHT ON and $50 \%$ for OFF). The baseline estimate provides a discriminative reference against which we can see how well our model approximates human judgments.
Computer Estimate (The C-AOG). Detectable actions and fluent changes are first extracted from the videos and used

Table 2: List of fluents considered.

```
    Computer: ASLEEP/AWAKE
    Monitor Display: ON/OFF
    Monitor Power: ON/OFF
    Cup: MORE/LESS/SAME
    Water Stream: ON/OFF
    Light: ON/OFF
    Phone: ACTIVE/STANDBY
    Trash Can: MORE/LESS/SAME
    Agent: THIRSTY/SATIATED
    Agent: HAS_TRASH/NOT
```

Figure 7: Sample screenshots for noisy data.
as inputs to the C-AOG model.
The action grammar is pre-specified. Actions are manually segmented, and then poses captured by the Kinect camera are clustered. Temporal parsing transforms the clustered poses into hierarchically-labeled instances from the T-AOG. The maximum probability action detections are used as input.

Fluent changes are detected from the video with the GentleBoost algorithm (Friedman, Hastie, \& Tibshirani, 2000) on features extracted as shown in Figure 7. Non-maximum suppression provides the final detections of fluent changes.

These action and fluent detections (and their probabilities) are then processed with potential causal explanations under the C-AOG (by maximizing the posterior probability of Equation 1). The best-performing consistent causal description over the course of the video is then returned through the Viterbi algorithm (Forney Jr, 1973). Hidden fluents are imputed from this result.

## Results and Discussion

To visualize the results, human, computer, and baseline estimates are reduced to two dimensions using multi-dimensional scaling (MDS) according to the total variation distance between estimates, and plotted in Figure 8.

In the hallway dataset, both fluent and action detections contribute to the causal inference of hidden fluents. The computer performance is very similar to human performance as shown in Figure 8(a). The baseline is far from the cluster of computer and human estimates.

The office dataset only contains detections of actions; all fluents are hidden. The computer's performance is still an improvement over the baseline towards human-level performance, as shown in Figure 8(b).

Misinformation: Correcting Spatio-Temporal Detections In the hallway dataset, multiple changes in the light fluent were detected, yet no causing action was detected, presenting a common situation in vision-detections are usually imperfect. The C-AOG corrects these errors by balancing the maintenance of detections with the consistency of causal explanations. Figure 9 shows typical candidates of the results sorted in order of probability.

The C-AOG result was consistent with human judgments. Humans selected a single value for the light fluent for the duration of the video, but some selected ON while others chose OFF. This reinforces the need to have a probabilistic model

Figure 8: MDS plots of fluent value estimates. Blue dots: human estimates. Red squares: estimates using the C-AOG. Green triangles: baseline estimates. See Further Discussion for notes on the human variability.
capable of maintaining multiple interpretations; the C-AOG result included both solutions.

## Further Discussion

Even though the set of possible fluent values was provided to participants (significantly narrowing their available judgments), the MDS plots show wide variation in human responses. This is due to many factors. First, some participants initialized fluent values differently (e.g., light ON versus OFF in Figure 5), resulting in a large total variation distance. Also, some participants were more cautious than others, recording judgments close to 50/50 where others took an all-or-nothing approach to assigning judgments.

Figure 9: Given action and fluent detections that move the light fluent between ON and OFF without a causing action, the C-AOG prefers this to be explained by incorrect detections of the light fluent. The second most probable class of explanations is that two of the changes had causing actions that were missed by the detection.

As evidenced by the C-AOG's weaker performance, the office dataset was particularly challenging. Action detections were poor and no fluent detections were available to identify conflicts, leaving the system heavily dependent on those incorrect action detections. Despite this disadvantage, the CAOG still provided enough reasoning capability to outperform the baseline. This example underscores the importance of good vision-detection systems.

## Conclusions and Next Steps

In this paper, we have presented a probabilistic graphical grammar model to match human perception of causal relationships between actions and fluent changes, the Causal And-Or Graph (C-AOG).

Experiment 1 showed that the C-AOG of everyday activities can be learned, matching human perceptions of causal relationships. These causal relationships are even learnable amid noise, such as would be present in detection systems. Further, experiment 1 showed that our method models human judgments better than causal power and $\Delta P$.

Experiment 2 showed that the C-AOG can be used as a model of human perception grounded on video to impute values for hidden fluents. This experiment captures the inherent variability of human estimations when confronted with video, and highlights the need for a model that can probabilistically incorporate causality and vision.

One current limitation of the C-AOG is that, if a situation is unexplained, all possible parse graphs are assigned a low probability. In future work, we plan to investigate how adaptive learning can be used to incorporate new instances of fluents into the C-AOG.

#### Abstract

Stock-flow (SF) systems involving the accumulation of a stock over time are pervasive in many areas of human life. However, people make consistent mistakes when regulating such systems, a phenomenon termed SF failure. We introduce holistic (global) versus analytic (local) processing as a cognitive mechanism underlying the hardly understood SF failure. Using a classic SF problem (department store task), we found that (a) solutions to SF problems were up to four times higher when a global task format highlighting global structure compared to a local task format highlighting local elements was used; (b) a more global processing style is connected to higher solution rates to the SF problem; and (c) procedurally priming participants with more global processing results in higher solution rates to the SF problem. In sum, our results point towards global-local processing as a basic explanation for SF failure.

Keywords: Stock-flow failure; global-local processing; dynamic systems.

Many decisions we make in our daily lives are aimed at keeping a system under control, or in equilibrium. For example, we aim at keeping our weight at a healthy stage, don't each too much, don't eat too little; we aim at keeping our bank accounts under control: buy the things that we need but don't spend too much. These types of systems are called dynamic stock management problems, where a stock (i.e., accumulation) is influenced by decisions to increase the stock (i.e., inflow) or to decrease the stock (i.e., outflow) (Sterman, 2000). Keeping a stock in balance implies that the outflow equals the inflow, that is, the stock does not change when the rate of increase equals the rate of decrease in the stock.
Dynamic stock management is extremely difficult to master even after extended amounts of practice (Diehl \& Sterman, 1995; Paich \& Sterman, 1993). The dominant explanation of these difficulties has been dynamic complexity (Sterman, 2000): the idea that systems that involve multiple decisions and delays between actions and observable outcomes create complex interdependencies that go beyond our cognitive capacity.
In light of these difficulties, more recent studies have pared back dynamic stock management tasks to their fundamental elements - one stock, one inflow and one outflow - and asked for simple 'one-shot' decisions about the system (Booth Sweeney \& Sterman, 2000; Cronin \& Gonzalez, 2007; Gonzalez \& Wong, 2012; Sterman, 2002).

Interestingly, even in these extremely simplified problems, a majority of people performs poorly (Cronin et al., 2009).
This general difficulty in understanding the dynamics of accumulation was termed "Stock-Flow Failure" (SF failure). There is very little research, however, aimed at understanding how people make decisions in these types of systems (Cronin, Gonzalez, \& Sterman, 2009). For example, it was repeatedly found that people have the erroneous tendency to perceive a stock's behavior as directly related to that of its flows (Booth Sweeney \& Sterman, 2000; Cronin et al., 2009; Cronin \& Gonzalez, 2007), a tendency termed correlation heuristic (Cronin et al., 2009). Although the correlation heuristic seems to be robust in SF failures, it remains a re-description of the typically observed behavior rather than an explanation of why the behavior occurs. A goal of the current research is to elucidate some cognitive mechanisms underlying SF failure. Specifically, we introduce Global-Local processing ${ }^{1}$ as a fundamental explanation.
We propose that, to make accurate accumulation decisions, one needs to process information globally and not locally. That is, one needs to see the forest and not the trees. For example, to make a prediction about the amount of money in our bank account at a point of time, we need to see broadly the predicted deposits and withdrawals over the preceding time periods.
Processing styles are content-free ways of perceiving the environment (Tulving \& Schacter, 1990). In global processing, one attends to objects holistically and focuses on the entire Gestalt by "zooming out"; in local processing, one attends to objects elementally and focuses on its details by "zooming in" (Navon, 1977; Schooler, 2002). Just as a global view on a Navon letter (global letter made up of smaller letters, Navon, 1977) means perceiving the whole form and not its component parts, a global view on dynamic systems should mean perceiving the systems' behavioral patterns and not its constituent parts. This should hold not only for complex systems containing a range of interacting variables, but even for "simple" SF systems, because in either case the behavior of the stock depends on the relation between in- and outflow, aggregated over time periods. That is, to regulate dynamic complexity in general, an abstraction process is needed from lower-level

[^263]representations (e.g. about a specific inflow at a specific point in time) to higher-order representations (e.g., about the overall relation between in-and outflow). We expect such a super-ordinate framework to enable the problem-solver not to view each component in isolation, but to view all components as structurally related parts of the system, thus allowing for inferences on the behavior of system as a whole.
To see how a human's tendency to process information globally or locally influences SF-reasoning, we measure individual differences in global-local processing and test participants with two task formats of a commonly used SF problem, the "Department Store" (DS) task (Sterman, 2000; Cronin et al., 2009). We argue that the SF task format that was used previously induced local instead of global processing of the problem and that a representation that induces global processing would lead participants to higher accuracy in their judgments of a stock.
In summary, we investigate the effects of three different aspects of global-local processing on SF reasoning: (a) global vs. local task format of SF problems, (b) individual differences in global vs. local processing and (c) global vs. local perceptual priming.

## Procedural Priming of global-local processing

The tendency to perceive the environment locally versus globally does not only exists as a prior bias in participants, but it can also be triggered, e.g. by instructing participants to focus on the global versus the local letters in the classic Navon-letter task (Navon, 1977; Macrae \& Lewis, 2002). Moreover, global-local processing styles can carry over to subsequent tasks (procedural priming). Such procedural priming must be distinguished from semantic priming in that "the how rather than the what is primed" (Förster \& Dannenberg, 2010, p. 176). As predicted by Schooler's theory of processing shifts (Schooler, Fiore \& Brandimonte, 1997), procedural priming effects can be transferappropriate or transfer-inappropriate. For example, after global procedural priming, participants generated more creative answers such as original uses for a brick than after local procedural priming (Friedman, Fishbach, Förster \& Werth, 2003), thus showing a transfer-appropriate shift.
Procedural priming affects both perceptual and conceptual processing by means of a common attentional mechanism that is used both on the perceptual (e.g. to perceive the global and not the local figure) and the conceptual level (e.g., to select the distant and not the proximal node within the semantic network; Friedman, Fishbach, Förster, Werth, 2003; Förster, 2009). A, say, broadened perceptual scope thus carries over to a broadened conceptual scope, resulting, for example, in more remote associates and higher creativity or the use of broader mental categories (Förster, 2012).

## The department store task

In the DS task, participant are presented with a graph showing the rate of people entering and leaving a department store each minute and over a $30-\mathrm{min}$. interval
(Fig.1). The stock is the accumulation of people in the store over the $30-\mathrm{min}$ interval, the inflow is people entering and outflow people leaving the store. Participants are then asked four questions as shown in the figure. The first two questions test whether participants can read the graph correctly, essentially measuring if they are able to identify the inflow and the outflow. The last two questions test whether participants can infer the stock's behavior based on the behavior of the flows over time.
The main measure of SF failure is the typically low solution rates to questions 3 and 4 (see detailed analyses of different kinds of errors in several publications such as Cronin et al., 2009 and Gonzalez \& Wong, 2012).
The SF failure was also demonstrated using bar charts, tables or texts listing the specific in- and outflows per minute (Cronin \& Gonzalez, 2007; Cronin et al., 2009), for different contents (Brunstein, Gonzalez, \& Kanter, 2010), and also when motivation and learning were induced (Cronin et al., 2009). Thus, so far, SF failure has not only proven to be a highly stable construct, but also the involved cognitive mechanisms remain unclear.
We expect global, as opposed to local, processing to be a beneficial cognitive strategy, however, for two reasons.
