In module 3, an SDCC network learns the hypotheses' priors. Assume that we have $N$ hypotheses, $\left\{h_{1}, \ldots, h_{N}\right\}$, with probability mass function given by equation (3). We present the results for this specific mass function, but the results are similar for other discrete distributions. Our training set is the collection of 401 equidistant points from -10 to 10 (with steps of size 0.05 ), and our testing set is the collection of 399 equidistant points from -9.975 to 9.975 , all paired with the correct outputs derived from (3). We choose these sets such that there is no overlap between the testing and training sets in order to measure the generalization abilities of the module. Note that we do not specify the form of the probability mass function in any way and the network learns it by generalization from the training input. Also note that in the case we consider here, $N=399$ as we define our hypotheses to be the collection of points in the testing set.

After learning, the network's weights decay exponentially over time steps as follows:

$$
\begin{equation*}
W_{i}(t+1)=(1-r) \cdot W_{i}(t)=(1-r)^{t} \cdot W_{i}(1) \tag{6}
\end{equation*}
$$

where $W_{i}(t)$ is the weight of connection $i$ at time $t$ and $r$ is the decay rate. Clearly, as the connection weights of the learned network decay, the output will change. Fig. 7 demonstrates the effects of weight decay on the output of module 3. In Fig. 7a, for $r=0.2$, we observe that as time passes, and hence as the weights continue to decay, the distribution of the hypotheses approaches a uniform distribution. We consider a discrete case where we have a finite number of hypotheses, and therefore Fig. 7 represents the probability mass function where the sum of all probabilities must be equal to 1 . Note that in the 15th time step, the distribution is almost uniform; thus, the value of the probability is $1 / N=1 / 399$ (this small value should not be mistaken with zero in Fig. 7(a)).

There is a literature on using weight decay to improve the ability of neural networks to generalize (Krogh \& Hertz, 1992). Krogh and Hertz showed that a weight decay can improve generalization by suppressing any irrelevant components of the weight vector. This effect is evident in Fig. 7a, as the bumps (overfitting) get smoothed out as time passes.

In Fig. 7b, entropies are plotted as a function of time for four values of decay rate. In all four cases, entropy increases with time until it converges to its maximum which corresponds to uniform prior distribution. In our case, the maximum entropy is $\log _{2} N=\log _{2} 399=8.64$.

In conclusion, we show that the proposed neural network model contributes to the resolution of the discrepancy between demonstrated Bayesian successes and failures by modelling base-rate neglect as weight decay in a connectionist network implementing Bayesian inference. This is done by showing that as weights decay, the priors' probability mass function approaches a uniform distribution and its entropy increases. Consequently, the prior terms eventually cancel out from Bayes' rule, resulting in the neglect of base rates.

## Discussion

We propose a modular neural-network structure to implement Bayesian learning and inference. Through simulations, we show that the proposed three modules, responsible for computing Bayes' rule, likelihoods, and priors, succeed in learning their assigned task. Employing a weight-decay mechanism, we provide a novel explanation of base-rate neglect, the most well-documented deviation from Bayes' rule. We show that weight decay increases the entropy of priors in a Bayesian system. In nature, this is very similar to the second law of thermodynamics which states that the entropy of isolated systems never decreases and that they evolve towards equilibrium - the state of maximum entropy. Our model of base-rate neglect predicts that older, less continuously supported (i.e., more isolated) priors would be subject to more decay, and consequently more neglect.

Our model is a first step towards implementing the Bayesian framework with neural networks. As such, it still
has several limitations. For instance, our current model is only capable of handling a finite number of hypotheses. When the number of hypotheses gets uncountably infinite, the current structure will be infeasible due to large numbers of outputs that must be remembered.

Our networks learn to approximate Bayesian functions with the output being a function value. However, this assumption might be unrealistic and does not explain how the brain innately represents probabilities. It is more realistic to approximate such functions from input instances occurring at various frequencies. Although we do not address this here, our further experiments show that SDCC networks can do this, which is effectively probability matching. With that, our modular neural network, similar to human brain, makes sense of data by representing probability distributions and applying Bayes' rule to find the best explanation for any given data.

In this paper, we apply our model to base-rate neglect. However, there are many other subtle and potentially difficult Bayesian phenomena, such as hierarchical Bayesian structures and causal networks, to consider. Also, our work does not address the origin of the Bayesian competencies; all we show is that neural networks can implement Bayesian inference and learning. The origin of theses capacities could be in evolution, learning, development or some combination. Finally, we only use SDCC as the learning method and do not try other neural-network approaches.

There is plenty of scope for future research to address the issues just discussed. For instance, we can illuminate the issue regarding the origin of the Bayesian competencies of our model by agent-based simulations of evolution of Bayesian inference and learning. Preliminary results in the context of social learning strategies have shown that evolution favours Bayesian learning, based on passing posteriors, over imitation and environment sampling (Montrey \& Shultz, 2010).

With no doubt, Bayesian models provide powerful analytical tools to rigorously study deep questions of human cognition that have not been previously subject to formal analysis. These Bayesian ideas, providing computation-level models, are becoming prominent across a wide range of problems in cognitive science. On the other hand, connectionist models offer an implementation-level framework for modelling mental phenomena in a more biologically plausible fashion. We present this work in the spirit of theoretical unification and enhancement of these two approaches. We are not advocating replacement of one approach in favour of the other.

#### Abstract

In daily conversations, what information do people use to assess their conversational partner's explanations? We explore how a metacognitive cue, in particular the partner's confidence or uncertainty, can modulate the credibility of an explanation. Two experiments showed that explanations are accepted more often when delivered by an uncertain conversational partner. Participants in Experiment 1 demonstrated the general effect by interacting with a pseudoautonomous robotic confederate. Experiment 2 used the same methodology to show that the effect was applicable to explanatory reasoning and not other sorts of inferences. Results are consistent with an account in which reasoners use relative confidence as a metacognitive cue to infer their conversational partner's depth of processing.

Keywords: explanations, confidence, uncertainty, collaborative reasoning, human-robot interaction

## Introduction

What makes an explanation believable? Researchers have recently discovered several conceptual and structural properties that distinguish credible explanations (for reviews, see Keil, 2006; Lombrozo, 2006). Good explanations are often relevant and informative (Grice, 1975; Wilson \& Sperber, 2004). Likewise, people appear to prefer explanations that are simple (Chater, 1996; Lagnado, 1994; Lombrozo, 2007; but cf. Johnson-Laird, Girotto, \& Legrenzi, 2004), and in situations of uncertainty, they appear to prefer explanations that have narrow latent scope, i.e., those that account for only observed phenomena (Khemlani, Sussman, \& Oppenheimer, 2011). These preferences show that properties intrinsic to the explanation itself can cause individuals to judge the explanation to be better, more likely, more plausible, and more credible.

However, individuals also rate explanations by appealing to extrinsic information, e.g., information about the context in which the explanation was provided rather than the material content described by the explanation. Extrinsic information is particularly important when reasoners have to evaluate another individual's explanations. In those situations, factors such as the individual's motivation, mood, and confidence can affect the believability of his or her explanation. In this paper, we focus on how confidence can modulate an explanation's credibility. We first describe confidence as a metacognitive signal, and then explain how confidence can affect the believability of an explanation. Two studies show that when an agent appears uncertain, individuals accept the agent's explanations more often. We discuss the phenomenon in light of intuitive and analytic reasoning systems.

## Confidence and explanatory credibility

Subjective confidence is among the most widely investigated metacognitive signals (Dunlosky \& Metcalfe, 2009). In many cognitive tasks it is correlated with accuracy, though people are often systematically overconfident about their performance (Lichtenstein, Fischhoff, \& Phillips, 1982; Lindley, 1982; McClelland \& Bolger, 1994). Much of the research on subjective confidence addresses how individuals integrate cues from their task performance or else their declarative knowledge to assess their confidence in a particular decision of theirs. Confidence is often construed as a signal predictive of translating judgments to actions (Dunning, 2007; Tversky \& Koehler, 1994), and researchers have accordingly proposed many models of how that signal is constructed (Albert \& Sponsler, 1989; Erev, Wallsten, \& Budescu, 1994; Ferrell \& McGoey, 1980; Gigerenzer, Hoffrage, \& Kleinbölting, 1991; Griffin \& Tversky, 1992; Juslin, 1994; Koriat, 2012; May, 1986; Pfeifer, 1994; Wallsten \& Gonzáles-Vallejo).

In daily interactions with others, people frequently provide cues to their own level of confidence for their conversational partners to interpret, and they use their partner's cues to interpret the content of their partner's statements. Despite the prevalent use of confidence signals in modulating informational content, little work has established how individuals integrate cues to a partner's confidence or lack thereof into their own decision-making, and few if any of the aforementioned models of subjective confidence can explain how confidence is assessed in others. Suppose, for example, that you ask a friend what she thinks of a new restaurant that has opened up in her neighborhood. If she says, "It's good!" her intonation may provide a cue to a high level of confidence in her response. Alternatively, if she hesitates and says, "It's...good..." then you may negate the material content of her response and prefer instead to explain her lack of confidence as indicative of her disapproval.

In the present investigation, we examined how individuals incorporate their partners' levels of confidence when they assess their partner's explanations of a confusing scenario. Reasoners could modulate their acceptance in their partner's explanation in one of two ways. An intuitive prediction is that people should accept an explanation more often when the explanation is delivered by a confident partner than an uncertain partner. People who exhibit this behavior should infer, implicitly or explicitly, that the partner's confidence is proportional to the explanation's credibility. Preliminary support for this prediction comes from recent studies on so called "powerless language", which show that statements that include hedging phrases such as "sort of", "kind of",
and "probably" are rated more negatively compared to nonhedged statements (Blankenship \& Holtgraves, 2005; Durik, Britt, Reynolds, \& Storey, 2008; Liu \& Fox Tree, 2012). Hedges may provide a cue to a low level of confidence, and therefore cause people to attenuate their belief in the statement.

Alternatively, if people prefer explanations when they are delivered by an uncertain partner, then it may be because the partner's uncertainty provides pragmatic cues to the strength of the explanation. For example, an uncertain expressional cue such as a furrowed brow may suggest that the partner was engaged in more analytical thinking (Alter, Oppenheimer, Epley, \& Eyre, 2007), and an analytical response may be preferred to an intuitive one.

In what follows, we report two experiments that tested whether confidence or uncertainty affects explanatory credibility. In both studies, participants engaged in a dyadic interaction with a pseudo-autonomous humanoid robot. The robot allowed us to impose stringent controls on the verbal and expressional cues that participants received.

## Experiment 1

Experiment 1 tested whether an explanation was more or less acceptable if it came from a confident or an uncertain confederate. To generate systematic social interactions, the experiment called on participants to engage in a dyadic interaction with a pseudo-autonomous robotic confederate, a humanoid mobile, dexterous, social (MDS) robot (Breazeal et al., 2008). Participants were told that they were interacting with the robot through a web-based chat interface (see Figures 1 and 2). Participants' task was to read a problem to the robot, listen to the robot's response, and then decide whether they agreed, did not understand, or disagreed with the robot. If they did not understand, or else if they disagreed with the robot, they verbally explained their reason for not accepting the robot's response, and their verbal protocols were recorded. All of the robot's responses were pre-recorded, and we manipulated whether the robot delivered its responses using cues of confidence or uncertainty.

## Method

Participants. 38 native-English speaking undergraduates from George Mason University participated in exchange for partial course credit. None of the participants had received any training in logic.

Procedure. Participants engaged in a dyadic interaction with a pseudo-autonomous robotic confederate. Before they began the study, they were shown a video of humans engaged in natural language dialogue with an MDS robot (Hiatt et al., 2011). Participants were told that they would interact with the robotic confederate online, but that the confederate had only limited abilities to comprehend natural language, and that the confederate would be unable to respond to unrelated questions. In actuality, all of the robot's responses were pre-recorded. Participants were
instructed to use a chat interface to read problems to the confederate and listen to the confederate's responses. The interface was written in Objective C for an iPad tablet computer.

The experiment began when the confederate introduced itself as "Lucas", an MDS robot, and waited for the participant to initiate the study by reading the first problem. Figure 1 shows a schematic of the interface. Participants first read a description of a problem to the confederate (Figure 1a); when they finished, they pressed a button and listened to the confederate's response (Figure 1b); when the robot finished speaking, the participants indicated whether they agreed with, did not understand, or disagreed with the robot's response (Figure 1c); finally, if they disagreed or did not understand the robot, they were given an opportunity to explain their disagreement verbally (Figure 1d), and they moved on to the next problem.

c.

d.

Figure 1. A schematic diagram of the chat interface used for the pseudo-interaction in Experiments 1 and 2.

Design and materials. Problems consisted of a conditional generalization (1), a categorical statement (2), and an inferential prompt, e.g.,

1. If James does regular aerobic exercises then he strengthens his heart.
2. But, James did not strengthen his heart.
3. What, if anything, follows?

The problems invite both explanatory (e.g., "James had a congenital heart defect") and deductive (e.g., "James did not do regular exercises") responses. However, people tend to elicit explanations for such problems (Lee \& Johnson-Laird, 2006). In the present study, participants listened to and evaluated the confederate's explanation of ten separate problems, which were drawn from five different domains: biology, economics, mechanics, psychology, and natural phenomena (see the Appendix for the full set of materials). Explanations were adapted from reasoners' most frequently generated spontaneous explanations in studies that used similar materials (Khemlani \& Johnson-Laird, 2012). For each explanation, the robotic confederate delivered its response using a verbal cue and an expressional cue to its level of confidence. Half of the participants received confident verbal and expressional cues, and the remaining received uncertain cues. The explanations in both conditions were delivered with the same intonation. Figure 2 provides examples of the verbal and expressional cues. The
materials were balanced for their length across both conditions.

Post-experimental questionnaire. Participants who perceive their interaction with the robot as staged may respond differently than those who believe the interaction is real. To examine this factor, participants completed a postexperimental questionnaire after they finished the experiment proper. The questionnaire assessed whether the participants had believed (erroneously) that they were interacting with an autonomous robot, or whether they believed (accurately) that the interaction was staged. In our analyses, we present data from the most direct question they answered, which was as follows:
"Did Lucas's responses seem natural?

1. No, his responses usually looked like pre-recorded videos.
2. I'm not sure.
3. Yes, he usually responded like a human would."

After participants answered the questionnaire, they were debriefed that the interaction was staged.

## Results and discussion

Figure 3 shows the percentage of agreement for the explanations as a function of the confederate's confidence. Surprisingly, participants accepted explanations more often when the confederate was uncertain ( $75 \%$ agreement) than when it was confident ( $63 \%$ agreement; one-tailed MannWhitney test, $\mathrm{z}=1.75, \mathrm{p}=.04$, Cliff's $\delta=.33$ ). In both conditions, participants accepted explanations signifi-

Figure 2. The interface used in Experiments 1 and 2 (a). The robotic confederate was either confident (b) or uncertain (c) for the duration of the study. Confident expressional cues included wide open eyes, raised eyebrows, and a straight mouth orientation. Furthermore, the confident confederate preceded its responses with confident verbal cues, e.g., "Oh, I've got it!" or "That's easy." Uncertain expressional cues included narrow eyes, half-cocked eyebrows (a furrowed brow analog), and a slanted mouth orientation. Uncertain verbal cues included expressions such as, "Hmm, that's a tough one" and "Huh, I don't know for sure."
cantly more often than chance (Wilcoxon tests, zs $>2.25$, ps $<.02$ ). Their agreement varied across the different types of materials (Friedman analysis of variance, $\chi^{2}=49.9, \mathrm{p}<$ .0001 ). Across the study, $45 \%$ of the participants responded that they believed the interaction was pre-recorded.

To assess whether the effect of uncertainty on explanatory credibility was robust across the different materials, we fit the data to a generalized mixed-effects model (Baayen, Davidson, \& Bates, 2008) with a binomial error distribution and a logit link function using the lme 4 package (Bates, Maechler, \& Bolker, 2012) in R (R Core Team, 2012). The model took into account a single fixed effect, i.e., the confederate's confidence, as well as three additional random effects: the participant variance, the problem variance, and whether or not the participant believed that the interaction was pre-recorded. The model yielded a significant main effect of confidence $(b=.77, \mathrm{SE}=.37, \mathrm{p}=.04)$. The results suggest that the effect held whether or not the participants believed that the interaction was staged.

Figure 3.
Agreement percentages for explanations as a function of whether those explanations were delivered by a confident or an uncertain confederate. $95 \%$ confidence intervals shown.

Experiment 1 tested whether reasoners would accept explanations more or less often when given by an uncertain confederate compared to a confident confederate. However, the study did not establish whether the effect is unique to explanatory reasoning. It may be the case that the effect is widespread, and that it is applicable to any sort of inference, not just to the evaluation of explanations. To test the boundary conditions of the effect, participants in Experiment 2 evaluated both explanations and deductions.

## Experiment 2

Experiment 2 sought to replicate the effect of uncertainty on explanatory credibility, as well as to test whether it applied to any sort of inference, or whether it was localized, in part, to explanatory reasoning. The study was similar to the previous one, with one exception: the robotic confederate in the present study provided two types of responses, either an explanation or else a deduction. Recall that the problems used in the previous study, e.g.,

If James does regular aerobic exercises then he strengthens his heart.
But, James did not strengthen his heart.
What, if anything, follows?
invite two different sorts of reasoning strategies. One could construct an explanation that goes beyond the information in the premises (Khemlani \& Johnson-Laird, 2011). Or else one could make a modus tollens deduction, which is a logical deduction that takes the following abstract form. If $A$ then B. Not B. Therefore, not $A$. The inference is valid, i.e., the conclusion is true whenever the premises are true, but it is difficult for naïve reasoners. Thus, in the present study, the robotic confederate's responses concerned either an explanation or else a modus tollens deduction. Half of the participants interacted with a confident confederate and the other half interacted with an uncertain one. If the effect of uncertainty on credibility applies to any sort of response, then there should not be an interaction between the type of inference and the confederate's confidence. In contrast, if the effect is unique to explanatory reasoning, then there should be no difference between participants' evaluations of confident and uncertain deductions, but there should be a difference in their evaluations of explanations.

## Method

Participants, design, and procedure. 45 native Englishspeaking participants were recruited though the same participant pool as in Experiment 1. None of them had received training in formal logic. They solved ten reasoning problems by engaging in a web-based chat interaction with a pseudo-autonomous robotic confederate (see Figures 1 and 2), and they were taught to use the interface using the same procedure as in the previous study. Their task was to read each problem aloud to the confederate, listen to the confederate's response, and then judge whether they agreed, did not understand, or disagreed with the response. On half of the problems, the confederate would produce an explanation, and on the other half, it would produce a deduction (see Appendix). Twenty-three participants interacted with a confederate that produced confident responses and the remaining interacted with one that produced uncertain responses. After completing the last problem, participants filled out the same post-experimental questionnaire that was described for Experiment 1.

## Results and discussion

Figure 4 presents the percentage of agreement to deductions and explanations as a function of whether the response was delivered by a confident or an uncertain confederate. Participants agreed with deductions almost at ceiling ( $87 \%$ ) and accepted them reliably more often than they accepted explanations ( $63 \%$; Wilcoxon test, $\mathrm{z}=3.8$, p $<.0001$, Cliff's $\delta=.55$ ). Likewise, they accepted uncertain responses more often than confident responses ( $81 \% \mathrm{vs}$. $71 \%$; Mann-Whitney test, $\mathrm{z}=2.47, \mathrm{p}=.01$, Cliff's $\delta=.43$ ). However, the main effect of confidence was driven entirely

Figure 4. Agreement percentages for deductions and explanations as a function of whether they were delivered by a confident or an uncertain confederate. $95 \%$ confidence intervals shown.
by the difference between confident and uncertain explanations, and the data yielded a significant interaction between the type of inference and the confederate's confidence (Mann-Whitney test, $\mathrm{z}=1.95, \mathrm{p}=.05$, Cliff's $\delta$ $=.48$ ). The results suggest that the effect of uncertainty on credibility applies to explanations and not deductions. As in the previous study, agreement varied as a function of the contents of the problems (Friedman analysis of variance, $\chi^{2}$ $=43.49, \mathrm{p}<.0001$ ), and $58 \%$ of the participants reported that they believed the interaction was pre-recorded.

To assess whether the effect and the relevant interaction were both reliable across the different materials, we fitted the data to another generalized mixed-effects model. The model took into account two fixed effects, i.e., the confederate's confidence and the inference type, and the three pertinent random effects, i.e., the participant variance, the problem variance, and whether or not the participant believed that the interaction was pre-recorded. The model yielded a significant main effect of the type of inference (b $=-2.07, \mathrm{SE}=.36, \mathrm{p}<.0001$ ), however it yielded no main effect of confidence $(\mathrm{b}=.05, \mathrm{SE}=.42, \mathrm{p}=.90)$. Instead, it yielded a significant interaction between the type of inference and the confederate's confidence ( $\mathrm{b}=1.07$, $\mathrm{SE}=$ $.54, \mathrm{p}=.045$ ). As in Experiment 1, the analysis shows that the effect held in spite of any variance from the different materials or the perception that the interaction was staged.

## General Discussion

We used a novel experimental methodology to study how reasoners incorporate metacognitive information to judge one another's explanations. In two experiments, reasoners interacted with a robotic agent that appeared to deliver its responses in a confident or else an uncertain demeanor. One might expect that people should agree with confident explanations more often. Yet Experiment 1 showed that participants accepted explanations more often when they came from an uncertain confederate compared to a confident one. Experiment 2 tested whether the effect held
more generally for deductions, but it found instead that it was limited to explanations.

Why do reasoners accept explanations more often when they come from an uncertain source? The results are counterintuitive, particularly since confidence is correlated with informational accuracy. Indeed, at first blush, the results of our studies conflict with recent findings on hedging behavior and powerless language (Blankenship \& Holtgraves, 2005; Durik, Britt, Reynolds, \& Storey, 2008; Liu \& Fox Tree, 2012). However, we hypothesize that one reason for a speaker to produce uncertain expressions, gestures, and verbal cues is to signal to a listener that the speaker is engaged in deeper analytic processing, and furthermore, that the speaker is considering alternative possibilities. This proposal accounts for why the effect is manifest for explanations but not modus tollens deductions: explanations require reasoners to think about multiple possibilities and to go beyond the information presented in the premises, whereas modus tollens deductions do not. If our hypothesis is true, then we should find a similar effect of uncertainty on credibility for deductions that require reasoners to consider multiple possibilities compared to those that do not.
The present data reveal a robust credibility effect for human-robot interactions, and critics are justified in wondering whether the effect will still hold in dyadic human-human interactions (but cf. Moon \& Nass, 1996, for evidence that people treat interactive computers as though they were human). Similar studies with human confederates are feasible, but the human-robot interaction paradigm we employed has several advantages to traditional studies with human confederates. First, robotic confederates can be programmed to yield very precise expressional and gestural cues that are consistent for all participants in the study, while even the best human confederates are susceptible to irregular behaviors. Second, robotic confederates can be programmed to implement complex experimental designs and counterbalancing schemes. For example, the software in Experiment 2 was written so that exactly half of the robot's responses were explanations. Despite these advantages, however, future studies should examine the credibility effect in, albeit less controlled, human studies. One promising methodological compromise is to run pseudo-dyadic interaction studies over the Internet (Summerville \& Chartier, 2012).

The results we present have psychological implications, as well as implications for robotics researchers. A major goal for the interdisciplinary community of human-robot interaction research is to develop social robots that humans trust (Fong, Thorpe, \& Baur, 2001; Goodrich \& Schultz, 2007; Steinfield et al., 2006). The credibility effect we show implies that humans are likely to take into account metacognitive signals (and their robotic analogs) in assessing information from autonomous systems. Research on the modulatory effects of confidence on higher order reasoning is of multidisciplinary relevance, and can be applied to developing broader theories of confidence
monitoring in humans as well as more natural and trustworthy autonomous robots.

#### Abstract

We describe two studies that show that when individuals who are not programmers create algorithms, they rely on mental simulations. Our studies concerned a railway domain in which carriages are rearranged - a simple environment but equivalent in computational power to a Turing machine. Participants successfully solved rearrangement problems (Experiment 1), and created algorithms to solve them (Experiment 2) and their performance corroborated the use of simulation. The participants tended to use loops and to prefer while-loops even though they are of greater computational power than for-loops. Their ability to create algorithms for abstract problems improved when they first had to create algorithms for more concrete problems. We devised a computer program that creates its own algorithms for rearrangement problems. It generates Lisp functions that operate on lists and creates descriptions of them in everyday language. The complexity of the resulting algorithms predicts participants' difficulty in devising them.

Keywords: algorithms, computer programming, creativity, deduction, problem-solving, reasoning

## Introduction

A long controversy about human thinking is whether it depends on logic (Rips, 1994), probabilities (Oakford \& Chater, 2007; Tenenbaum \& Griffiths, 2001), or mental simulations (Craik, 1943; Johnson-Laird, 1983; Hegarty, 2004). Many inferences such as syllogistic deductions can be explained by mechanisms that depend on any of the three approaches (see Khemlani \& Johnson-Laird, 2012, for a review). Indeed, few inferential tasks unequivocally depend on one approach. Computer programming may be such a task: it is readily explained by appealing to mental simulation (Bornat, Dehnadi, \& Simon, 2008; Caspersen, Bennedsen, \& Larsen, 2007; Kurland \& Pea, 1985). To debug faulty code, programmers have to mentally simulate the algorithm to discover the situations in which the computer failed to produce the expected output. It is less apparent how mental rules of logic or probabilities could be used develop algorithms. Logic can be used to deduce the consequences of a program, but the creation of a program goes beyond logic (cf. Gulwani, 2010; Kitzelmann, Schmidt, Mühlpfordt, \& Wysotzki, 2002). Probabilities hardly enter into the process, because computer programs are deterministic, and the language of the probability calculus is ill equipped to operate over the structures of programs. Mental simulation is therefore an appropriate framework with which to characterize the ability to create algorithms, and researchers can benefit from studying the simulations programmers use to solve tasks (Holt, BoehmDavis, \& Schultz, 1987).

Expert programming depends on more than just mental simulation, however. Programmers often have specialized knowledge of programming languages, of relevant software platforms and tools, and about computer science in general (Boehm-Davis \& Ross, 1992). For that reason, many studies have tested the ability of novice programmers to write computer programs (see, e.g., Anderson, Pirolli, \& Farrell, 1988). Few have investigated how those without any background in programming try to create algorithms. Miller (1974) pioneered such studies. He examined the way college students unfamiliar with computers wrote instructions for others to follow, and found that they tended not to use loops in their instructions, even though they could understand them (Miller, 1981). More recently, Pane and his colleagues carried out a study in which they presented nonprogrammers with static descriptions of an agent moving in a popular video game, PacMan, and the participants had to summarize how agents moved in general. They again preferred not to make use of loops, but when they did, they appeared to rely on while-loops (Pane et al., 2001).

Despite these results, there exists no psychological theory of how non-programmers construct algorithms. To develop such a theory, and to study algorithmic creativity in nonprogrammers, we designed a novel problem-solving task environment in which reasoners have to sort the order of a list in various ways. We introduce the environment below, and then explain how individuals build kinematic mental models to construct algorithms for their solutions. We then describe two experiments that show that reasoners intuitively understand the environment (Experiment 1) and that they can mentally create algorithms for the problems in the environment (Experiment 2).

## Rearrangement problems and the railway environment

We studied how individuals who have never learned computer programming create algorithms in everyday language. For problems that they readily understood, we used the railway environment shown in Figure 1. The environment consists of a railway track and a siding. It is an analog of a finite-state device with two stacks - the left track (a) holds the input and also acts as a stack, the siding (b) acts as another stack, and the right track (c) holds the final output. Participants' task is to move the cars from the left track to the right track into a specific order. Cars can move only from the siding to and from the left track, and from left track to right track. Multiple cars can be moved at once, i.e., any move of a selected car applies to all cars in front of it. For example, in Figure 1, if you moved the E car

Figure 1. The railway domain with an example of an initial configuration in which a set of cars is on the left side (a) of the track, the siding (b) can hold one or more cars while other cars are moved to the right side of the track (c).
to the right track, then the F car would move along in front of it. To restrict the environment to a single stack, cars could move from the siding only to the output on the right track. In summary, only three sorts of move are possible in the railway environment:

R: one or more cars moved from left track to right track.
S : one or more cars moved from left track to siding.
L : one or more cars moved from the siding to left track.
One constraint is that cars can be neither removed nor added to trains in our rearrangement problems - if they could be, then the railway environment would be equivalent to a universal Turing machine power.

Experiment 1 below investigated all 24 possible rearrangements of four cars, and examined whether the participants perseverated, i.e., made one or more unnecessary moves. They can use a simple variant of "means-ends" analysis in which they work backwards from the required goal, invoking operations relevant to reducing the difference between the current state and the goal (e.g., Newell \& Simon, 1972; Newell, 1990). For rearrangement problems, they need only envisage each successive car in the goal. Suppose, for instance, they have to re-arrange the order ABCD into ACBD . The starting state is: $\mathrm{ABCD}[$ ], where the square brackets denote the contents of the siding, which is empty at the start. Their immediate goal is to get D to the far end of the right track: [ ] . . . D. So, they move D from left to right track: ABC [ ]D. The next partial goal is to get B to the right track, and so they need to move C out of the way onto the siding: $\mathrm{AB}[\mathrm{C}] \mathrm{D}$. Now, they can move B to the right: $\mathrm{A}[\mathrm{C}] \mathrm{BD}$. They move C off the stack: $\mathrm{AC}[\mathrm{BD}$. The next move is intriguing. They should move both A and C together from left to right track. But, if reasoners perseverate, they may move only C to the right track. Their solution won't be minimal, because they then have to make a separate move of A to right track.

We investigated how reasoners solve single instances of such problems, but our primary goal was to understand the processes and representations non-programmers use to create algorithms. In the following section, we explain how kinematic mental models can be used to construct algorithms, and illustrate the predictions that the modelbased theory makes.

## A model-based theory of algorithmic creativity

How do naïve individuals create informal algorithms? We hypothesize that individuals simulate solutions to problems, where a simulation consists of a sequence of kinematic mental models representing states of the world, real or imaginary, and the sequence itself represents a logical or temporal order of the states (Johnson-Laird, 1983, Ch. 15). Reasoners use such simulations to carry out three separate steps to create an algorithm: 1) they solve at least two different instances of a rearrangement problem using a kinematic sequence of moves; 2) they scan the kinematic sequences to abduce a pattern; 3) they translate the pattern into a verbal description. We address the three steps in turn.

Step 1: Problem-solving as simulation. The first step is to solve two different instances of a rearrangement problem. Otherwise, re-arrangements are ambiguous. At any point in the simulation, only a single move is made, and so to reverse, say, four carriages, reasoners can begin by envisaging the transformation from the start state:

$$
\mathrm{ABCDEF}[] \rightarrow[\mathrm{]} \ldots \mathrm{~A}
$$

This partial goal calls for a move of five cars onto the siding, $\mathrm{A}[\mathrm{BCDEF}]$, so A can be moved to right track, [BCDEF]A. The next partial goal is to get B to right track, and so it should be moved to left track, $\mathrm{B}[\mathrm{CDEF}] \mathrm{A}$, and over to right track, [CDEF]BA. A repeated loop of these two operations moves each car in turn off the siding and to right track, and solves the problem.

Two variables should affect performance in the solution of rearrangement problems: the number of moves and the number of their operands. Obviously, the greater the number of moves, the more difficult a problem should be - the only sort of theory that would not make this prediction would be one that made no appeal to simulation. A more subtle prediction concerns the number of operands. In a reversal problem, such as the one above, each move after the first has an operand of one car. We can contrast this case with the solution of a palindrome problem, such as:

## ABCCBA[ ] $\rightarrow$ [ ]AABBCC

There are three cars, BCC , on the left that match the goal, but they are blocked, and so to solve the problem, the blocking cars are moved onto the siding: $\mathrm{ABCC}[\mathrm{BA}]$. The three cars on the left are moved to the right: $\mathrm{A}[\mathrm{BA}] \mathrm{BCC}$. One car on the siding matches the goal, and so it is moved to the left: $\mathrm{AB}[\mathrm{A}] \mathrm{BCC}$. Two cars on the left match the goal, and so they are moved to the right: $[\mathrm{A}] \mathrm{ABBCC}$. The car on the stack matches the goal, and so it is moved to the left and then over to the right, and the problem is solved. Its minimal solution required a total of 10 cars to be moved in 6 moves. This solution has a mean number of operands per move greater than that for the reversal problems, and so the theory predicts that the palindrome problems should be more difficult than reversal problems of the same number of
moves. And individuals may make an unnecessary move in their solution of the problem, i.e., they may fail to solve the problem parsimoniously. Number of operands has a family resemblance to "relational complexity", which concerns the number of arguments in a relation, and which affects problem difficulty (Halford, Wilson, \& Phillips, 1998). However, the number of operands concerns, not the number of arguments of an operator, but whether the value of a single argument is one or more entities.

Step 2: Pattern abstraction and abduction. The second step in creating an algorithm is to recover the structure of the solutions - the loop they contain, and any operations before or after it. Consider the moves to reverse trains of four and five cars, respectively:

## (S3 R1 L1 R1 L1 R1 L1 R1) (S4 R1 L1 R1 L1 R1 L1 R1 L1 R1)

where 'S3' means move three cars from left track to the Siding, 'R1' means move one car from left track to Right track, and 'L1' means move one car from the siding to Left track. The loop of operations is (R1 L1). But, how many times should it be iterated? There are two ways to find the answer. The simpler is to observe the conditions in the simulation when the loop ceases, respectively:

```
D[ ]CBA
E[ ]DCBA
```

In both cases, the siding is empty, and so this condition determines that a while-loop should continue until the siding is empty. The alternative answer depends on computing the number of times that a for-loop should be executed, and it calls for the solution of a pair of simultaneous linear equations to obtain the values of $a$ and $b$ in:

$$
\text { number-of-iterations }=\mathrm{a} * \text { train-length }+\mathrm{b} .
$$

Step 3: Conversion to natural language. The third and final step is to map the structure of the solution into a description. A general algorithm for reversing the order of cars applies to trains of any length. Hence, it needs to describe a loop of moves. When reasoners convert the algorithm to a natural language description, their responses should yield the condition in which the loop stops (an indication that they've constructed while-loop) or else reflect the number of times for which the loop should be executed (an indication that they've constructed a for-loop). The solution of simultaneous equations calls for more than just simulation, whereas the halting conditions of a loop can be observed in a simulation, and so the theory predicts that correct responses should tend to use while-loops more often than for-loops.

We have implemented all three steps in a computer program that discovers and outputs algorithms to solve any re-arrangement problem that depends on a single loop. It
outputs a for-loop, a while-loop, and a translation of the while-loop into informal English (see Appendix). Each of these algorithms solves any instance of the relevant class of rearrangements.

Experiment 1 tested whether solutions to rearrangements depend on the number of moves and the number of operands. Experiment 2 tested whether reasoners use simulation to construct algorithms, and therefore formulate while loops, and whether the theory predicts the relative difficulty of different sorts of problem.

## Experiment 1

Experiment 1 tested the effects of number of moves and number of operands on the solution of simple rearrangement problems in the railway environment. The problems were simple and called for the rearrangement of only four cars. Hence, our interest was in whether the participants could solve the problems without making redundant moves. The participants had to solve all the 24 possible rearrangements of trains containing four cars. Their minimal solutions call for various numbers of moves ( $1,4,5,6,7$, or 8 ), and as a consequence the theory predicts an increasing trend in redundant moves for these problems. The total numbers of operands in minimal solutions was $(4,6,8,10$, or 12 ), and as a consequence there should be an increasing trend in redundant moves. Because these two variables are only partially correlated, we were able to examine their effects independently (see Table 1 below).

## Method

Participants. Twenty undergraduate students at Princeton University served as participants, and none had had any prior training in logic or computer science.

Design and procedure. Participants acted as their own controls and carried out all 24 problems, which were presented in a different random order to each of them. When they had completed the experiment, they carried out two of the problems again, but they had to think aloud as they did so. They were tested individually, and carried out the experiment on a PC running LispWorks 4.4. They interacted with the system using the mouse and the keyboard of the computer. They were shown a three-minute instructional video that guided them through the elements of the railway environment, and that presented the instructions. The key instruction stated that they should try to solve each problem with as few moves as possible.

## Results and discussion

Non-programmers were able to solve rearrangement problems with ease: they produced very few incorrect solutions. Table 1 presents the participants' mean numbers of moves to solve the problems depending on the minimum number of moves and the total number of operands. We dropped the two extreme problems from the statistical

|  | Total number of operands <br> \# of moves in <br> a minimal |  |  |  |  | (cars) <br> moved in minimal solutions |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| solution | $\mathbf{4}$ | $\mathbf{6}$ | $\mathbf{8}$ | $\mathbf{1 0}$ | $\mathbf{1 2}$ | Mean \# of <br> actual moves |  |  |
| 1 | 1.0 |  |  |  |  | 1.0 |  |  |
| 4 |  | 4.3 | 4.7 | 4.6 |  | 4.5 |  |  |
| 5 |  | 5.5 | 5.2 |  |  | 5.4 |  |  |

| Mean \# of |  |  |  |  |  |  |  |  |
| actual moves | 1.0 |  |  |  |  |  |  |  |

Table 1. The mean numbers of moves in Experiment 1 in rearrangement problems as a function of the total number of moves in their minimal solutions and the total number of operands (cars) to be moved.
analysis so that they would not bias the results, i.e., the problem that required only one move to solution, and the problem that had a total of 12 operands. Given that the participants solved the problems, it is hardly surprising that the mean number of the participants' moves increased with the minimal number of moves required to solve a problem (Page's trend test, $\mathrm{L}=1809.5, \mathrm{z}=8.47, \mathrm{p}<.0001$ ). But, the results also showed that their mean number of moves also increased with the number of operands (Page's trend test, L $=276, \mathrm{z}=5.69, \mathrm{p}<.0001$ ). In other words, the participants tended to fail to find minimal solutions, and as the mean number of operands increased so the number of their moves increased, independently of the total number of moves in a minimal solution. (For brevity, we spare readers the latency results, but their patterns corroborated both of these effects.) There was a reliable tendency for the participants to make redundant moves. Every participant made at least one redundant move (Binomial, $p=.5^{20}$ ).

In summary, the experiment shows that naive individuals can solve simple rearrangements. It corroborated the prediction that the number of moves affected the difficulty of the problem, and thereby supported simulation-based accounts. Likewise, it corroborated the prediction unique to the model-based theory that the number of operands should affect the difficulty of a problem. The following experiment tested whether non-programmers could formulate general solutions for rearrangement problems.

## Experiment 2

In Experiment 2, the participants had to formulate algorithms to solve three sorts of rearrangement: reversals, such as ABCDEFGH becomes HGFEDCBA; palindromes, such as ABCDDCBA becomes AABBCCDD; and parity sorts, such as ABCDEFGH becomes ACEGBDFH. Participants had to construct the algorithms in their mind's eye with no access to the railway environment. They were familiar with the environment, because they had just solved five practice problems on it, but these problems were simple rearrangements that differed from the problems in the experiment proper. They were then shown the inputs and outputs for each of the problems, and they had to write down algorithms for solving them. They did so for fixed-
length problems in which trains of eight cars had to be rearranged, and indefinite-length problems in which trains of any number of cars had to be rearranged. The fixedlength problems should be easier than indefinite-length problems, because only the former can be solved without loops. Likewise, complexity and number of operands predict a trend in difficulty over the three sorts of general rearrangements: reversals should be easier than palindromes, which in turn should be easier than parity sorts. The latter should be the hardest to solve because they call for an extra operation in their algorithm (see the Appendix).

## Method

Design and materials. The participants acted as their own controls and carried out six problems: the three sorts of rearrangement as both fixed-length problems of eight cars and indefinite-length problems of any number of cars. The session began with five practice problems akin to those in Experiment 1, which the participants merely had to solve by interacting with the railway system. These problems were unrelated to the experimental problems: each of them had a train of 6 cars, and a solution depending on 8 moves. The experiment proper followed, and the participants' task was to type out a procedure that would solve each problem, but they were not allowed to interact with the railway environment. They carried out two blocks of trials, one of the definite problems and one of the indefinite problems, presented in a counterbalanced order to two groups of participants. The order of the three sorts of rearrangement was randomized for each participant within the blocks. For the indefinite-length problems, the participants were told that a car containing an ellipsis stood in place for any number of cars that had the same pattern.

Participants and procedure. Twenty students from the same population as before took part in the experiment. They watched an instructional video and were told how to interpret the car containing an ellipsis. They then solved the practice problems using the same procedure as before. In the experiment proper, the participants were told to write a description of a procedure for solving each of the experimental problems as efficiently as possible. They were free to use their own words in any way that they wanted, but they no longer were allowed to manipulate the cars in the railway environment.

## Results and discussion

Two independent raters scored the correctness of the algorithms and whether they contained a while-loop, a for loop, or no loop whatsoever (see Appendix for examples of correct responses). Inter-rater reliability was high for judgments of correctness (Cohen's $\kappa=.82$ ) and the sorts of loops that participants devised $(\kappa=.73)$. A third independent rater resolved the disagreements. Performance with the fixed-length problems was at ceiling ( $90 \%$ correct)
a.
b.

Figure 2. The percentages of correct algorithms (panel a) and the response times in s (panel b) for the indefinite-length problems as a function of the sort of rearrangement, and whether they occurred in the first or second block of trials.
and much better than the indefinite-length problems (52\% correct; Wilcoxon test, $\mathrm{z}=3.5, \mathrm{p}=.0004$; Cliff's $\delta=.64$ ). Figure 2 accordingly shows only the performance for the indefinite-length problems, and the Appendix provides examples of participants' correct algorithms. The three sorts of rearrangement yielded the predicted trend in accuracy and in the time to respond (see Appendix; Page's trend tests, zs $>3.08$, ps $<.002$ ). Likewise, the participants used many more while-loops ( $74 \%$ of correct solutions) than for-loops ( $26 \%$ of correct solutions) for indefinite-length problems. The use of while-loops correlated with accuracy ( $\mathrm{r}=.32$, p $<.0005$ ), whereas the use of for-loops did not ( $\mathrm{r}=.14$, $\mathrm{p}=$ .10). The differences in ability were striking: the best participant created a correct algorithm for every problem, whereas the worst did so for only a third of the fixed-length problems and for none of the indefinite-length problems.

## General Discussion

The ability to create algorithms might seem to be a case of competence in pure mathematics with little relation to everyday life. Problems in rearranging cars in toy trains may similarly seem remote from the exigencies of daily life. However, algorithmic thinking is regularly called for, e.g., in laying place settings on a table, in determining kinship relations, in following a recipe or a set of instructions. Other sorts of algorithmic thinking are needed to determine the consequences of knitting patterns, instructions for kits, maintenance manuals, and, above all, algorithms in computer programs.

Algorithmic thinking is easier when you can manipulate an external environment and solve a problem using only partial means-ends analysis, i.e., you can use the railway environment and solve a rearrangement of the cars in a train, one car at a time (Experiment 1). But suppose that your task is to devise an algorithm for the general problem of sorting cars in this way - so that cars in odd-numbered positions precede cars in even-numbered positions. The algorithm for this task is not obvious. According to the present theory, the way that you carry it out is to make another simulation so that you can figure out what is going on. You should then
notice that there is a loop of two operations (move one car to the right, and then one car onto the siding) that has to be repeated while more than two cars remain on the left track. It follows that while-loops should occur more often than for-loops in putative algorithms, because it is easier to envisage halting conditions for while-loops from simulations than to use them to compute the number of iterations for a for-loop. The difficulty of the task also depends on the Kolmogorov complexity of the program, as indexed in the number of its instructions (in Lisp or in everyday language), and on the number of operands (Experiment 2).

Computer scientists often complain about the lack of any valid test of the likely ability of naive individuals as computer programmers (e.g., Bornat, Dehnadi, \& Simon, 2008). The rearrangement problems in our experiments may provide the basis for such a test. At the very least, we now know that individuals differ reliably in their ability both to solve problems in the railway domain (Experiment 1), and to formulate informal algorithms for their solutions (Experiment 2). The question remains as to whether such tasks are reliable predictors of ability. Mathematicians, logicians, and computer programmers, learn to reason about the repeated loops of operations that are needed in recursive functions. Previous studies have examined how novice programmers cope with such reasoning in trying to specify algorithms in a programming language (see, e.g., Anderson \& Jeffries, 1985). Our studies have shown that naive individuals with no training in computer programming are able to make simulation-based deductions, to solve rearrangement problems, and even to abduce informal algorithms for their general solution.

The evidence we have reported corroborated the theory based on mental models. To the best of our knowledge, no other theory of naïve algorithmic creativity exists. But, a theory could be developed in principle from an axiomatization of the domain in first-order logic (see, e.g., McCarthy \& Hayes, 1969; McCarthy, 1986; Rips, 1994). A typical axiom would capture the effects of a move, e.g.:

For any $\mathrm{x}, \mathrm{y}$, if x is a car $\& \mathrm{y}$ is a train $\& \mathrm{z}$ is a train $\& y$ is on right track $\& z$ is on left track \& $x$ is at the front of $y \& R 1$ is carried out then $x$ is at back of $\mathrm{z} \& \operatorname{not}(\mathrm{x}$ is at front of y ).

No one has proposed such an account, and so it is not yet possible to pit it against the model-based theory. But, we cannot rule it out, and remark only that the approach runs into difficulties. Our participants' think-aloud protocols raise problems for it, because they report moving cars around in a mental simulation of the railway environment. Likewise, their reliance on simulations predicts their use of while-loops in algorithms, because simulations yield the halting conditions for while-loops more readily than the number of iterations for for-loops. These results seem difficult, if not impossible, to explain without recourse to the use of mental simulations.

Keywords: discourse; communication channels; understanding; multimodality

## 1. Introduction: Communication channels

The mainstream view of linguistic form, characteristic of modern linguistics, can be formulated as follows: language consists of hierarchically organized segmental units, such as phonemes, morphemes, words, phrases, and sentences. Mainstream linguistics thus equates linguistic form with verbal form, that is, the segmental vocal material. However, as we all know, apart from sound, there are other channels (or components) of communication, in the first place through vision. The visual channel is what is sometimes named with the cover term body language, including gesture, mimic, gaze, posture, etc. (see e.g. McNeill, 1992; Kendon, 1994; Goldin-Meadow, 1999; Krejdlin, 2002; Butovskaja, 2004; Andersen, 2007; Burgoon et al., 2011).

Furthermore, the vocal material is not exhausted by verbal elements. There is also prosody, that is, non-verbal (= nonsegmental) aspects to sound, including intonation, tempo, pausing, loudness, discourse accents, tonal registers, etc. (see e.g. Cruttenden, 1986; Kodzasov, 2009).
An unbiased view should probably be the following: all of these components must be taken into account in a realistic model of communication. For example, imagine that you are staying in a hotel room with thin walls and can hear people next door talking. You cannot hear words (the verbal component) but you can hear prosody, and you get something about the conversation, for example you may know that the people are quarreling. On the other hand, prosody-free talk, as sometimes heard from TV simultaneous interpreters on the Euronews channel, is unnatural and hinders comprehension. In this study we address the question of the relative contribution of the various communication channels or components to the overall comprehension of spoken discourse.

## 2. Views on the importance of various communication channels

The traditional approach of mainstream linguistics has been to consider the verbal channel so central that prosody and the visual channel have often been downgraded as "paralinguistics". Many contemporary textbooks in linguistics barely mention prosody and do not mention gesture and body language at all (see e.g. Hall, 2005).

The other extreme is represented by the view common in applied psychology that words matter less than prosody and especially than body language. It is very often that the following figures are quoted, going back to Mehrabian (1971): body language conveys $55 \%$ of information, prosody conveys $38 \%$ of information, and the verbal component only $7 \%$ of information ${ }^{1}$, see e.g. http://jobsearch.about.com/od/interviewsnetworking/a/nonv erbalcomm.htm. According to this view, "words may be what men use when all else fails" (Krejdlin, 2002: 6).

Most likely, the truth lies between these two extremes. All of the communication channels must be valuable and none can be negligible. This kind of balanced approach is characteristic of the modern multimodal paradigm (see e.g. Granström et al. eds., 2002; Norris, 2004; Ventola et al. eds., 2004; Bengio \& Bourlard eds., 2005; Royce \& Bowcher, 2007; Jewitt ed., 2011). According to Kress (2002), "A multimodal approach assumes that the message is 'spread across' all the modes of communication. If this is so, then each mode is a partial bearer of the overall meaning of the message." To use a quotation from the computational domain, "within biology, experimental psychology, and cognitive neuroscience, a separate rapidly growing literature has clarified that multisensory perception and integration cannot be predicted by studying the senses in isolation" (Cohen \& Oviatt, 2006). Kibrik (2010) described the research program of multimodal linguistics, taking into account all of the communication channels in an integrated approach.

Taking up the challenge of Mehrabian (1971), in this study we try to numerically estimate the contribution of each communication channel into the overall process of message understanding. (Cf. two early psychological studies Walker, 1977 and Hollandsworth et al., 1979, arriving at rather opposite conclusions, and also Cutica \& Bucciarelli, 2006.)

[^306]
## 3. Experimental design

The experimental design, first developed by Andrej Kibrik in 2006 at the Deparment of Theoretical and Applied Linguistics, Philological Faculty, Moscow State University (see Kibrik \& El'bert, 2008, Kibrik, 2010), consists of several elements. For the purposes of this study, we differentiate between three communication channels, or components, including two vocal channels, the verbal and the prosodic ones, and the visual channel comprising all elements of body language; see Figure 1.

Figure 1: Three communication channels.
If we take a sample of natural discourse, we can isolate three communication channels. For example, if we have a recording of communication, a video without sound is equivalent to the visual channel alone. We also need to isolate the verbal channel and the prosodic channels; specific technical ways of how that can be made possible are explained in sections 4 and 5 below. Assuming that the three channels have been isolated, we can produce eight $\left(2^{3}=8\right)$ variants of the sample discourse and present them to separate groups of experimental participants. These eight variants include three in which only one channel is represented, three in which two channels are represented, one with the three channels (the original material), and the null variant in which nothing has been shown to participants. We will thus need eight groups of participants, each presented with one of the eight kinds of experimental material.
The null variant of the experimental discourse and the corresponding group is necessary in order to evaluate which part of the overall content can be inferred on the basis of background knowledge and common sense.

At the next stage the degree of the participants' understanding of the discourse can be assessed with the help of a questionnaire, and such assessment may be used as an estimate of a communication channel's contribution to the overall discourse understanding.

## 4. Experiment A: movie-based material

The first line of studies in this paradigm was implemented in a series of experiments by Ekaterina Èl'bert, particularly in her diploma thesis (2007), and further reinterpreted and refined in Kibrik and El'bert (2008). In this line of studies the decision was made to use an excerpt of a movie as experimental discourse. Specifically, the Russian TV serial "Tajny sledstvija" ("Mysteries of the investigation") was
used. The experimental excerpt ran for 3 minutes and 20 seconds, and it was preceded by a 8 minutes context excerpt, starting from the beginning of a series. The experimental excerpt fully consisted of a conversation, to ensure that we are testing the understanding of discourse rather than of the film in general.

The two vocal channels were separated from each other through the following procedures. The verbal channel was presented in the written mode, by means of temporally aligned running subtitles. The prosodic channel was obtained from the original sound by superimposing a filter creating the "behind a wall" effect. Figure 2 illustrates a snapshot from the experimental type "visual plus verbal", in other words, video plus running subtitles.

Figure 2: Frame from the experimental material "visual plus verbal".

99 participants took part in the study, divided into eight groups, each group comprising 10 to 17 persons. All eight groups watched the identical context excerpt. As for the experimental excerpt, each of the eight groups had access to different material. The null group did not see anything apart from the context excerpt, three groups only had access to one communication channel of the experimental excerpt (either verbal or prosodic or visual), the other three groups to two communication channels (verbal+prosodic = original sound; verbal+visual = video and subtitles, see Figure 2; prosodic+visual $=$ video and filtered sound), and the eighth group watched the original version of the experimental excerpt.

The context and the experimental excerpts were shown to the whole group of participants on a large screen. Each participant was instructed to attend the context and the experimental excerpt and then answer a set of questions concerned with the experimental excerpt alone. The questionnaire was constructed in accordance with the received principles of test tasks (Panchenko, 2000). There were 23 multiple-choice questions in the questionnaire; a participant was supposed to choose only one answer out of four listed variants. Here is an example of a question, along with the offered answers (translated from the Russian original):

What Tamara Stepanovna offers Masha before the beginning of the conversation:
a. to take off her coat
b. to have a cup of tea
c. to have a seat
d. to have a drink

One of the available answers (in this particular case, c) was correct, two were plausible but wrong ( $\mathrm{a}, \mathrm{b}$ ) and one implausible (d); the latter was aimed at filtering out incompetent participants.

## Results of Experiment A

Percentage of correct answers was used as a way to assess a participant's degree of discourse understanding. The summarized results are shown in a diagram in Figure 3.

Figure 3: Degrees of discourse understanding in Experiment A.

We see from the second, third, and fourth columns in Figure 3 that each individual communication channel is substantially informative: The verbal channel is leading in this respect ( $72.4 \%$ correct answers), but the two other (prosodic: $51.5 \%$, visual: $61.7 \%$ ) also significantly (MannWhitney test, $\mathrm{p}<0.05$ ) prevail over the null condition (leftmost column, $38.3 \%$ ). The hierarchy of the individual channels turns out verbal>visual>prosodic (significant according to Kruskal-Wallis test $(\mathrm{H}(2,69)=24.2$, $\mathrm{p}<0.01)$ ). In spite of the prevalence of the verbal channel, the difference in the contributions of individual channels is not dramatic, and second, the degree of understanding in the "verbal alone" condition is significantly (Mann-Whitney test, $\mathrm{p}<0.05$ ) lower than in the original material condition (three channels in conjunction, the rightmost column in Figure 3, 87.4\%).
Another conclusion from the results of Experiment A concerns the comparison of the three groups that had access to two communication channels; see columns fifth to seventh from the left. There is a very noticeable (but not reaching the level of statistical significance) dip in the condition "visual+prosodic" (51.6\%), compared to two other pairwise combinations (verbal+prosodic: 70.7\%; verbal+visual: $77.8 \%$ ). Apparently, that dip means that language users have difficulties integrating information from the visual and prosodic channels, in the absence of
verbal material. In a natural setting, this condition can be compared to observing communication via a glass that is penetrable for prosody but blocks the verbal material. Most likely, the dip in the "visual+prosodic" condition is due to the unusual character of such situations in real life, as well as to the participants' inability to integrate information from the visual and prosodic channels in the absence of verbal material.

## 5. Experiment B: conversation-based material

At the following stage of the project, we modified and/or improved a number of the methodological decisions made in Experiment A, including the kind of stimulus material, the technical methods of isolating the prosodic channel and the verbal channel, the questionnaire, and the interviewing procedure. The below description of Experiment B is organized as follows. Each of the mentioned methodological decisions made in Experiment A is assessed, and a modification/improvement realized in Experiment $B$ is presented.

Several problems of the movie-based stimulus material, used in Experiment A, were detected, including the following. First, the plot of the movie in certain instances facilitated guessing by the experiment participants. Second, it was not possible to exclude the familiarity of the movie to some of the participants. Third, the quasi-natural behavior of the actors could affect the results. Fourth, all speakers were of the same gender (women) which made it difficult for the participants to distinguish between voices, especially in the "prosodic alone" condition.

The solution realized in Experiment B was to employ a recording of natural dialogue between two speakers. In order to make the dialogue structured and predictable, a guessing game "Little garages" was recorded. One of the speakers, a woman, was laying a number of toothpicks on the table and was asking the guesser, a man: "How many little garages?" The guesser was trying to figure out how to provide a correct answer, which was difficult (because the intended amount of little garages was in fact the number of the the first speaker's fingers kept on the table at the moment). The guessing process lasted for 19 minutes, out of which the stimulus material of 5 minutes and 55 seconds was produced. The stimulus material consisted of a dialogue between the two speakers, culminating in the guesser's ultimate success. A frame from the guessing game recording appears in Figure 4.

The acoustic filter used in Experiment A produced the material in the "prosodic alone" condition that was excessively noisy. The solution used in Experiment B was to radically decrease the signal at all frequencies except for the speaker's average F0 frequency. This led to a more satisfactory "behind the wall" effect.

Figure 4: Frame from the recording of the guessing game.
The main problem associated with the "verbal alone" condition in Experiment A was that the subtitles operated in the visual, rather than the vocal, mode. This had created a substantial deviation from the situation of spoken discourse, also leading to the undesired interaction and/or competition between the written verbal material and the visually perceived video material. In addition, some participants experienced difficulties in following the subtitles appearing and disappearing at the same pace as spoken words in the original material. The solution introduced in Experiment B was to produce an artificial spoken prosody-free signal. Both speakers participating in the recording were requested to individually pronounce each word that occurred in their conversation. All thus elicited words were then glued together in the right order, thus providing prosody-free discourse, devoid of intonation, reduction, differences in tempo, etc.

As far as the questionnaire is concerned, the imperfection of Experiment A is seen through the insufficient gap between the results of the null group and the original material group: $38.3 \%$ vs. $87.4 \%$. These numbers indicate that the participants were able to reconstruct the correct answer quite often and, on the other hand, even the full original material did not provide reliable access to a correct answer. In order to improve the questionnaire, a testing stage was introduced in Experiment B, in which trivial questions were identified (high null group results), as well as unfortunate questions (low original material group results). Trivial and unfortunate questions were filtered out, and the number of questions was reduced from 30 to 17 . The improved results in the two contrastive groups turned out $24.7 \%$ and $91.2 \%$ of correct answers, see below.

The interviewing procedure was improved in Experiment B. In Experiment A the participants were of various and uncontrolled age and life experience. The presence of multiple participants in the room could have led to undesirable and uncontrolled interference. Finally, the need for a large room, loud speakers, and a big screen is an unnecessary technical complication to the procedure. In Experiment B the participants were controlled for age,
geographical origin, and social status: only students of Moscow origin were recruited, which provided a homogeneous sample. They were also balanced in terms of gender. The experiment was implemented in a remote fashion: the stimulus material was posted on youtube.com, and the questionnaire at Googledocs. The guidelines closely directed the participants' sequence of actions, from one experimental part to another and from one group of questions to another, so there are reasons to believe that the procedures were very similar in all participants. All participants worked in comparable, independent, and comfortable conditions, and there was no need for technical excessiveness such as a big screen and loud speakers. 92 participants altogether took part in the experiment, out of which 20 were employed at the testing stage and 72 at the main stage (from 10 to 15 in each experimental group).

## Results of Experiment B

The quantitative results of Experiment B are shown in Figure 5.

Figure 5: Degrees of discourse understanding in Experiment B.

The main findings of Experiment B are similar to those obtained in Experiment A. All three communication channels, taken in isolation (columns two to four from the left) are substantially and comparably informative: they lead to $58.8 \%, 45.6 \%$, and $48.8 \%$ of correct answers, compare that to the $24.7 \%$ in the null group. The hierarchy of informativeness is again verbal>visual>prosodic. The conditions with two channels available (columns five to seven from the left) demonstrate the following results: $73.5 \%, 88.2 \%$, and $52.4 \%$. Compared to Experiment A, we here get a much cleaner picture as concerns the better participants' performance in the two channels conditions as contrasted with the one channel conditions. Finally, we see again a dramatic dip in the "visual+prosodic" condition: the second last column counting from the left.

## 6. Discussion

The main conclusion of Experiment B is the following: in spite of the substantial differences in the methodology from Experiment A, the results are remarkably similar. With minor differences the overall picture in Figures 3 and 5 is
very similar. This makes us believe that our conclusions about the relative contributions of various communication channels to the overall discourse understanding are fairly robust.
Now, the picture in Figure 5 is cleaner and crisper in two respects: the more obvious advantage of the two channel conditions over the one channel conditions and the better contrast between the null group and the original material group.

In order to provide a response to Mehrabian's (1971) famous (or infamous) numbers, the following method can be applied. Suppose the three communication channels are independent (this is a strong assumption, but it is necessary for calculating the relative contributions of the channels). We can sum up all percentages in the one-channel conditions and then normalize them to $100 \%$. Let us perform this operation on the results of both experiments, looking at the numbers in columns two to four from the left in Figures 3 and 5 (percentages are rounded to 1 per cent). The outcome of this procedure is shown in Table 1.

Table 1: Normalized contributions of the three communication channels.

|  |  | Experiment A | Experiment B |
| :--- | :--- | :--- | :--- |
| Summed percentages |  | $72+52+62=186$ | $59+46+49=154$ |
| Normalized <br> contributions | Verbal | $72 \%: 1.86 \approx 39 \%$ | $59 \%: 1.54 \approx 38 \%$ |
|  | Prosodic | $52 \%: 1.86 \approx 28 \%$ | $46 \%: 1.54 \approx 30 \%$ |
|  | Visual | $62 \%: 1.86 \approx 33 \%$ | $49 \%: 1.54 \approx 32 \%$ |

Once again, we see the striking similarity in the results of the two experiments: the numerically evaluated contributions of the three channels never differ from each other by more than $2 \%$. So the contributions of the channels are stable irrespective of the specifics of methodology.
Also, the gender differences between the participants were explored in Experiment B. Two particularly interesting results were obtained for the conditions "verbal alone" and "visual+prosodic"; they are shown in Table 2.

Table 2: Performance of men and women in two conditions in Experiment B (percentages of correct answers indicated)

| Condition | Men | Women | Advantage |
| :--- | :--- | :--- | :--- |
| Verbal alone | 59.1 | 69.9 | Women: +10.7 |
| Visual + prosodic | 66.1 | 51.6 | Men: +14.5 |

As is clear from Table 2, in the condition "verbal alone" the women have demonstrated a striking advantage, providing correct answers much more frequently than the men. In contrast, the men demonstrated a strong advantage in the condition "visual+prosodic" that, as was discussed above, corresponds to an unusual situation and generally creates a difficulty in comparison with other two-channel conditions. These results conform to certain generalizations about gender intelligence, such as the women's better performance in verbal tasks and men's better performance in novel situations (see e.g. Bendas, 2006).

## 7. Conclusions

This study is the first linguistically-informed demonstration of the importance of several communication channels for understanding natural discourse. The following conclusions can be drawn from the reported study.

First, all communication channels are highly significant in encoding content and understanding of discourse. Therefore, the attitude common in mainstream linguistics, according to which linguistic communication is performed mostly by the verbal component, whereas other channels are negligible, is incorrect.

Second, among the communication channels the verbal channel is the leading one. Therefore, the viewpoint popular in applied psychology, according to which the contribution of the verbal component is negligible, is erroneous as well.

Third, the specific normalized contributions of the verbal, prosodic, and visual channels are in the vicinity of $38 \%$, $30 \%$, and $32 \%$, respectively.

Fourth, participants have difficulties integrating the information from the visual and prosodic channels, in the absence of the verbal channel. This suggests that in normal communication the verbal channel plays the role of an anchor to which the information from other channels is attached.

Fifth, men and women perform differently in the conditions of isolated communication channels, women having advantage in the "verbal alone" condition and men having advantage in the novel and unusual "visual+prosodic" condition.

As was pointed out in section 5 , many questions from the original questionnaire were filtered out for certain substantial reasons, which has reduced the number of questions from 30 to 17 . In combination with the large number of conditions (eight), this has led to the fact that the quantitative tendencies observed in Experiment B do not quite reach the level of statistical significance. In April 2013 we collected additional data, bringing the number of subjects in each group to at least fifteen (total=132). We expect that, when the statistical analysis is completed, full significance of the results will be attained, as well as a formal comparison of the results of the two experiments.

A number of methodological issues remain for further research. In particular, we would like to pinpoint two of those. First, we are planning to experiment with monologic discourse addressed to public audience, such as presentations of travel agents in front of a group of people. This would complement the already attained results from our studies of dialogic communication. Second, we will keep working on refining the methods allowing to isolate the verbal channel. Both of the so far employed methods have their shortcomings, the subtitles switching from the auditory to the visual modality and the prosody-free talk being the unnatural kind of input. We will keep searching for additional methods helping to present the "verbal alone" condition in a more ecologically valid way.

A major problem in the studies of human communication and discourse is associated with the fact that different
disciplinary traditions and paradigms address communication from different angles, not consulting each other's results. Linguists usually only pay attention to the verbal component, while non-verbal communication is mostly explored by social psychologists. In this study we propose an approach that is hopefully relevant for each of the fields studying human communication and bridging the gap between them.
We would like to conclude with a quotation from Ron Scollon (2006): "Any use of language is inescapably multimodal".

## Acknowledgements

We are grateful to Olga Fedorova, Anna Laurinavičiute, and Andriy Myachykov who provided useful and important input during the preparation of this paper. The study was conducted with financial support from grant \#11-04-00153 of the Russian Foundation for the Humanities.

#### Abstract

Coherent collective behavior emerges from local interactions between individuals that generate group dynamics. An outstanding question is how to quantify group coherence in order to understand the nature of these dynamics. We investigate this problem in the context of a small group of pedestrians instructed simply to walk to a goal. To measure the degree of coordination in a group, we employed principal components analysis to estimate dimensional compression, and cross-recurrence quantification analysis to estimate the coupling strength between individuals. The results indicate lower-dimensional behavior and more stable coupling in real groups compared to reshuffled virtual groups. These findings demonstrate spontaneous local coordination in pedestrian groups that gives rise to coherent collective behavior, and offer an approach for investigating group dynamics in more complex contexts.

Keywords: group locomotion; group coordination; crossrecurrence quantification; principal components analysis

## Introduction

Group dynamics arise from local interactions between individuals that are governed by a multi-level set of processes. At the most basic level, these interactions depend on a coupling between individuals based on perceptual information, which may further depend on higher-order cognitive and social constraints. To understand the emergence of collective behavior, it is necessary to begin by characterizing both the local informational coupling and the global group behavior. Such an approach requires a complementary set of analysis tools to quantify observable
properties, such as the degree and stability of coordination, at both the individual and group levels.

In the context of locomotion, we focus on the coupling between individual pedestrians that yields the formation of a coherent crowd. A recent dynamical model of locomotor behavior (Fajen \& Warren, 2003, 2007; Warren \& Fajen, 2008) has characterized both individual behavior and pedestrian interactions, including coordination in leaderfollower and side-by-side dyads (Rio \& Warren, 2011; Page \& Warren, 2012), and may be generalized to coordination in groups (Rio, Bonneaud \& Warren, 2012). Here we investigate measures of the degree of coordination in small groups, or group coherence.

Relevant behavioral variables to index the locomotor trajectory of an agent include (1) the agent's direction of travel, or heading ( $\phi$ ) and (2) the agent's speed (s). Each of these variables can be considered a degree of freedom (DoF) of pedestrian locomotion, and thus the DoF of a group of N pedestrians can be operationally defined as a system consisting of $\mathrm{N} \times 2$ DoF (i.e., $\phi$ and $\mathbf{s}$ ).

It has been proposed that behavioral coordination between two agents arises from the coupling of DoF via shared information variables (Riley, Richardson, Shockley \& Ramenzoni, 2011). Shared information between agents allows the DoF to directly regulate one another. This permits the characterization of interpersonal coordination in terms of the reduction of DoF, or dimensional compression, due to the behavioral reorganization of the newly assembled system. In the context of pedestrian interactions, a follower controls their speed by nulling change in the leader's visual
angle, and a pedestrian walking beside a neighbor controls their speed by nulling change in the neighbor's visual direction. Thus, visual information that serves to couple DoFs (i.e. $\phi$ and $\mathbf{s}$ ) gives rise to pedestrian coordination and, ultimately, coherent crowds (Bonneaud \& Warren, 2012; Moussaïd, Helbing \& Theraulaz, 2011; Ondřej, Pettré, Olivier, \& Donikian, 2010; Rio, Bonneaud \& Warren, 2012).

We aim to advance the analysis of collective behavior by developing methods to quantify the degree of coordination among pedestrians in groups. We focus on both the basic coordination mechanism - the local coupling between pairs of neighbors - and the global characteristic of group coherence. The problem then becomes how to quantify coherence as a measure of collective behavior. To that end, we must identify analysis tools that can be used to characterize coordination at multiple scales of measurement.

Principal Components Analysis (PCA) is one way to quantify the overall dimensional compression of an observed system (Riley et al., 2011). An advantage of PCA is that it can take all of the DoF, or variables of interest, in a given system and identify new collective variables (the principal components), based on relations within highdimensional datasets. It also indexes the load magnitude of the original variables of interest on the identified principal components, and this can help uncover how the behavioral variables are coupled together in the organized system. These characteristics make PCA an important tool for revealing global properties of a system.

However, PCA is a linear analysis and cannot measure the local coordination between agents. That question requires an analysis tool that quantifies patterns of coordination between two behavioral variables. Cross-recurrence quantification (CRQ) is better suited for this purpose. CRQ is a nonlinear analysis that indexes repeating patterns in a pair of time series (Shockley, Butwill, Zbilut, \& Webber, 2002; Webber \& Zbilut, 1994), and has already demonstrated its utility in interpersonal coordination (e.g., Ramenzoni, Riley, Shockley \& Baker, 2012; Richardson, Dale \& Shockley, 2008). In particular, when analyzing side-by-side walking, Page and Warren (2012) found CRQ to output a reliable measure of the coupling strength, or degree of coordination, between the walking speed (s) of two pedestrians as their behavior evolved over time. In contrast to PCA, CRQ is limited to a pairwise analysis of time series, and thus provides a measure of coupling strength in a dyad rather than the overall coordination of the group. Taken together, PCA and CRQ allow us to characterize coordination and coherence at a local (i.e., dyad) and more global (i.e., group) level of behavior.

To study group coherence, we began with observations of a simple and highly controlled locomotor task: four pedestrians walking to a common goal. While quantitative measures of crowd dynamics should apply to more complex scenarios (see Moussaïd et al., 2012), we believed this approach would reveal essential coordination dynamics as a first pass to understanding crowd behavior. In the present
experiment, we instructed groups of four participants to walk toward one of three goals; the group's initial density was varied on each trial (see Figure 1). As described above, we analyzed time series of two behavioral variables for each participant: the heading direction ( $\phi$ ) and speed (s). This resulted in a total of eight DoF for the four-agent system. We hypothesized that the groups would exhibit dimensional compression in all conditions, compared to virtual groups we constructed by randomly sampling the same participants from different trials (see Method section). We also expected a greater reduction in DoF as density increased, due to larger changes in visual angle and visual direction at smaller distances, as well as to spatial constraints on walking. With regard to CRQ, we hypothesized that the coupling strength would be greater in all conditions compared to virtual groups, and that the leader-follower pairs would exhibit stronger coupling than the side-by-side pairs, as observed in our previous studies of two pedestrians (Rio \& Warren, 2011; Page \& Warren, 2012).

## Participants

Five groups of four participants ( $\mathrm{N}=20$; M age $23.57 \pm 0.93$ years; 12 females, 8 male) from Brown University and the greater region were compensated $\$ 15$ for their participation. Participants had no history of cognitive deficits, lower extremity injury, or neuromuscular disorders that would inhibit normal locomotor activity. The experiment was approved by the Brown University Institutional Review Board and adhered to guidelines for the ethical treatment of participants.

## Materials and Apparatus

The experiment took place in a $12 \times 14 \mathrm{~m}$ open room. The head position of each participant was tracked with a MicroTrax inertial tracker affixed atop a lightweight bicycle helmet on the head. Each tracker communicated with an IS900 ultrasonic overhead grid tracking system (InterSense, Billerica MA, USA) and provided 6 DoF position ( 4 mm RMS error) and orientation ( $0.1^{\circ}$ RMS error) data at 60 Hz . Three cardboard goal poles (approximately 2 m tall and 0.5 m in diameter) were placed at an initial distance of 8 m and angular offsets of $12.53^{\circ}$ to the left (pole 1 ), $0^{\circ}$ (pole 2), and $12.53^{\circ}$ to the right (pole 3) of the midpoint of the front two participants (see Figure 1). Colored tape was used to mark four possible starting positions in a square configuration, with initial spacing of $0.5,1.0,1.5$, or 2.5 m on a side.

## Design \& Procedure

Each group completed eight trials in each of 12 conditions, four densities ( $0.5,1.0,1.5,2.5 \mathrm{~m}$ spacing) crossed with three goal positions (left, straight, right; see Figure 1). This resulted in a total of 96 trials, presented in a random order, in each experimental session. Goal position was changed only to vary the task between trials, and thus was not included as a factor in the statistical analyses.

At the beginning of each trial the four participants were randomly assigned to the four positions in the square
configuration: (1) front right, (2) front left, (3) back right, or (4) back left (Figure 1). Once they were standing in the correct location, an experimenter gave a "go" signal and the group began to walk straight ahead. As the last participant crossed a line 1 m in front of the initial positions of the front participants, the experimenter gave a verbal command to walk to goal 1,2 , or 3 . The only instruction given to the participants was to continue walking to the specified goal at a comfortable pace without stopping. Participants were not told to stay together as a group or to maintain the initial configuration. Each trial lasted approximately 6 to 8 s .

Figure 1: The four possible starting positions for each of the four possible starting densities. From this view, the participants would walk from left to right. Note the dotted line 1 m from the midpoint between the front two participants that represents when the experimenter "goal" command was given. The heading and speed variables ( $\phi$ and $\mathbf{s}$, respectively) under each agent indicate the eight DoF of the system (i.e., the eight variables analyzed in the present experiment). $\mathrm{FR}=$ Front Right; FL = Front Left; BR = Back Right; BL = Back Left.

## Data Reduction and Analysis

The tracking system recorded the head position ( $x$ - and $z$ coordinates) of each participant at a sampling rate of 60 Hz . The raw (unfiltered) position data were used to compute the participant's speed (s) and heading ( $\phi$ ) from the displacement between successive samples, according to the following equations:

$$
\begin{align*}
& \boldsymbol{s}_{i}=\frac{\left(\left(x_{i}-x_{i-1}\right)^{2}+\left(z_{i}-z_{i-1}\right)^{2}\right)^{.5}}{\Delta t}  \tag{1}\\
& \phi_{i}=\tan ^{-1}\left(\frac{x_{i}-x_{i-1}}{z_{i}-z_{i-1}}\right) \tag{2}
\end{align*}
$$

where $x_{i}$ and $z_{i}$ are the head position on the $i$ th frame, in room coordinates. The $\phi$ and $\mathbf{s}$ time series were used for all subsequent analyses.

Virtual Group Construction For each real group trial, a paired virtual group trial was constructed by randomly selecting a time series from the same participants in the same group and condition, but from different trials. Thus all task constraints were matched, except that the four
participants in the virtual group were not perceptually coupled with each other. The virtual groups were created to ensure that any results that indicated significant coordination between participants were due to the perceptual coupling, not the task constraints (e.g., the common goal, the simultaneous goal command, or similar preferred walking speeds). After random selection of the four time series, they were temporally aligned based on the time the goal command was given by the experimenter. To equate their length (a requirement of both PCA and CRQ analysis), a time series was then potentially cropped at the beginning and/or end. This resulted in four time series of equal length that were aligned by the goal command.

Principal Components Analysis (PCA) PCA identifies linear relationships within multi-dimensional datasets and then maps the original data into a newly defined space. The principal components (i.e., axes of space) represent the dataset's primary dimensions of variation, but do not necessarily map directly onto the original dimensions of the actual measurement. The end result is a representation of potentially new, important variables that best account for the variance within the observed system.

In the context of the present experiment, eight variables of interest representative of the 8 DoFs of the observed system (i.e., $\phi$ and $\mathbf{s}$ for each participant) were submitted to a single PCA. The data were normalized using a $z$-score transform prior to analysis. PCA was performed in Matlab using the princomp function and the results were examined in a similar fashion to Ramenzoni et al. (2012).

First, the number of components that together account for $90 \%$ or more of the variance in the data set was determined. To investigate dimensional compression in the real vs. virtual group, a $4 \times 2$ mixed-model analysis of variance (ANOVA) was conducted on number of components, with initial density as a within-subjects factor and group (real vs. virtual) as a between-subjects factor, averaged across goal position.

Next, the amount of variance accounted for by the first principal component (PC) in the real vs. virtual group was compared using an identical mixed-model ANOVA. The analysis was limited to the first PC because the subsequent components were dependent on the first PC. Greater variance accounted for by the first PC in the real group indicates dimensional compression, and thus greater coherence, in the visually coupled system.

Finally, the mean correlation coefficient ( $r$ ) for the loading of each behavioral variable on the first PC was examined to investigate which of the eight variables were most influential in characterizing the group's behavior. The $r$ values were transformed using a Fisher's z' transform and submitted to a $4 \times 8 \times 2$ mixed-model ANOVA with initial density and agent position as within-subjects factors, and group as a between-subjects factor, again averaged across goal position. The aim of this analysis was to examine whether the speed or heading of an agent in a particular
position more strongly influenced the group's behavior and whether this influence depended on density.

Cross-recurrence Quantification (CRQ) A nonlinear, two-dimensional cross-recurrence quantification (CRQ) analysis was used to quantify the time-correlated activity between the heading time series of each dyad in the group, and, separately, the speed time series of each dyad (see Figure 2 for the analysis steps). A CRQ analysis is conducted by first embedding the pair of normalized time series in a multidimensional, time-delayed phase space (see Marwan, Romano, Thiel \& Kurths, 2007; Ramenzoni et al., 2012; Richardson, Schmidt, \& Kay, 2007; Shockley et al., 2002; Webber \& Zbilut, 1994). Because not all variables that make up the behavior in a dynamical system are necessarily knowable a priori, phase space reconstruction allows for the behavior of these potentially "hidden" variables in the dynamical system to be evaluated via their interaction with, or influence on, the known variable (in this case the $\mathbf{s}$ time series). Thus, the structure of the reconstructed phase space can reveal the underlying dynamics of the dynamical system as a whole. Specifically, the "neighborliness" of points within some tolerance or radius in phase space can indicate recurrent points in the two time series. These represent states in one time series that closely correspond to previous or future states in the other time series, and can illustrate behavioral patterns of coordination in the observed system. The recurrent points are identified and represented in a cross-recurrence plot (see Figure 2, bottom), from which a suite of measures can then be computed to quantify these patterns (see Shockley et al., 2002 and Marwan et al., 2007 for a review of analysis procedures).

In the present experiment, only cross-maxline (CML) was computed and analyzed: specifically the longest diagonal line of consecutive recurrent points on a cross-recurrence plot. This provides a measure of the longest time interval that the speed (or heading) of two participants was coupled during a given trial. CML is known to be sensitive to the temporal stability of coordination between two time series, associated with the coupling strength between agents (Richardson et al., 2007). A previous CRQ analysis of speed with two pedestrians revealed stronger coupling between leader-follower pairs than side-by-side pairs (Page \& Warren, 2012). The parameters used for CRQ were as follows: embedding dimension $=5$; delay $=3$ data points; radius within which points are counted as recurrent $=1.0 \%$ of the actual distance separating points in reconstructed phase space.

## Results

## PCA

Number of Components The number of components required to account for $90 \%$ of the variance was significantly reduced in real groups $(M=3.71 \pm 0.12)$ compared to virtual groups $(M=5.76 \pm 0.07), F(1,8)=$
233.22, $p<.001$ (see Figure 3, top). Thus, the visual coupling between agents reduced the DoF of the group significantly more than the external task constraints, indicative of emergent global coherence. Surprisingly, there was no effect of initial density ( $p>.05$ ), implying that group coherence at low densities was comparable to that at high densities.

Figure 2: A schematic of the steps in the CRQ analysis. For each trial, the speed time series of the FR agent (top left) and BR agent (top right) are unfolded separately into a shared reconstructed phase space via time-delayed copies of each measured time series, denoted as $\mathbf{s}_{\mathrm{FR}, \mathrm{BR}}(\mathrm{A})$. Recurrent points within a given radius (B) and strings of recurrent points (C) are identified with respect to each point in phase space and represented in a cross-recurrence plot (bottom) with each axis representative of the $\mathbf{s}_{\mathrm{FR}}$ and $\mathbf{s}_{\mathrm{BR}}$ time series at each time step. Each pixel indicates a recurrent point, and the diagonal line structures indicate the length of a string of recurrent points, or the co-evolution of the two time series at different time delays. The longest diagonal line, cross-maxline (CML), was computed for each dyad in the group.

PC 1 The first principal component accounted for significantly more variance in real groups ( $M=52.43 \% \pm$ 0.79 ) than in virtual groups ( $M=39.74 \% \pm 0.45$ ), $F(1,8)=$ 190.42, $p<.001$. This result confirms dimensional compression in group behavior, due to the visual coupling. There was, again, no effect of initial density ( $p>.05$ ) on the variance accounted for by PC 1.

Contribution of Variables to PC 1 The composition of the first principal component was further examined to determine the relative contributions of each behavioral variable, by computing the loading ( $r$ ) of each variable on PC1 (see Figure 3, bottom). A significant agent position $\times$ group
interaction was observed for $r, F(7,56)=408.03, p<.001$. Follow-up $t$-tests (Bonferroni corrected $p \leq .01$ ) indicated that the $\mathbf{s}$ variable was more strongly correlated with PC 1 in the real groups than in the virtual groups (all $p<.001$ ), whereas the $\phi$ variable was not (all $p>.01$ ), for all four agent positions. Within the real groups, the $\mathbf{s}$ variable was more strongly correlated with PC1 than the $\phi$ variable ( $p<$ .001 ), whereas $\mathbf{s}$ and $\phi$ did not significantly differ in the virtual groups (all $p>.01$ ), for all agent positions. Thus, the behavior of real groups was more coherent than that of virtual groups, primarily due to the coordination of walking speed; thanks to the presence of a common goal, heading was independently aligned in both groups.

Figure 3: The amount of variance accounted for by each component beginning with PC1 (top), and the loading ( $r$ ) of behavioral variables onto PC 1 (bottom). Black bars = real groups, white bars $=$ virtual groups, significant differences $(p$ $<.001)$ indicated with Duncan Grouping.

## CRQ

The results of PCA indicated the importance of speed (more than heading) as a variable of interest in the current dataset. Accordingly, the CRQ analyses focused on the speed time series for all six dyads on each trial. Representative crossrecurrence plots for a real and virtual dyad appear in Figure 4. A significant main effect of group was observed for cross-maxline length (CML), $F(1,8)=34.83, p<.001$. Specifically, the real group exhibited a mean CML ( $M=$ $49.93 \pm 0.03$ ) more than twice as long as the virtual group ( $M=20.73 \pm 0.02$ ), irrespective of dyad, goal position, or initial density. Surprisingly, this implies that the coupling is equally stable at high and low densities, and for leaderfollower and side-by-side dyads.

Figure 4: Sample cross-recurrence plots for speed time series from a real (top) and a virtual (bottom) leader-follower dyad. Note the diagonal lines visible in the cross-recurrence plot for the real dyad, indicative of a temporally stable speed coupling between agents.

## Discussion

The present experiment attempted to measure the degree of coherence in pedestrian groups, based on analyses of two behavioral variables, heading $(\phi)$ and speed (s), during goaldirected locomotion. We expanded the analysis from interpersonal coordination to the behavior of small groups, as a path to understanding collective crowd dynamics.

The PCA found that visually coupled pedestrian groups exhibited significant dimensional compression across all experimental conditions, compared to virtual groups. The results indicate that the task constraints (e.g. common goal, simultaneous command, preferred walking speed) accounted for a reduction of approximately 2.2 DoF (from 8 to 5.8 ) in the virtual groups. However, the visual coupling produced a further reduction of approximately 2.1 DoF (from 5.8 to 3.7). This is indicative of a functional reorganization of DoF thanks to the informational coupling of behavioral variables, yielding the emergence of coherent collective behavior.

In addition, PC 1 analysis offers preliminary evidence of a new collective variable that accounts for group coherence in the present case. The loading of behavioral variables on PC1 suggests that agent speed is a primary contributor to the new group dynamics. However, the comparatively weak contribution of the behavioral variable of heading direction is likely due to the external constraint of a common goal in this particular task. Taken together, these findings support the reduction of DoF in interpersonal coordination proposed by Riley et al. (2011; Ramenzoni et al., 2012).

The CRQ analysis provided more specific results about the coupling strength between particular dyads in the group.

The speed variable exhibited a significantly more stable coupling in real groups than virtual groups, with no differences between leader-follower, side-by-side, and diagonal dyads. Taken together, the PCA and CRQ results indicate that the reduction in group DoF in the present task is due in large part to the coordination of speed at the dyad level, resulting from the visual coupling between neighbors.

While the overall results supported the hypothesis of group coordination via local coupling, the analyses diverged from our expectations in two important respects. First, we anticipated that the degree of coordination would increase as group density increased, but we did not observe an effect of density. It is possible that the range of densities tested was too small to observe an effect, or that the task constraints combined with a short walking distance limited the degree of variability in individual trajectories. But consistent with this finding, we previously observed that speed coordination in pairs of pedestrians is also independent of distance over 1-3m (Rio \& Warren, 2011). Second, we were surprised that coupling strength did not differ among dyads, given we had previously observed greater speed coordination between leader-follower than side-by-side pairs. Again, it is possible the task constraints may have limited the variability in individual behavior. In subsequent experiments, we are measuring pedestrian groups over longer distances without a common goal or timing signal.

The present work is a starting point for understanding collective behavior in pedestrian groups. We have begun by focusing on the local coupling between agents, on the hypothesis that this generic coordination mechanism will scale up from small groups to large crowds and perhaps to swarms across species. It is likely that other cognitive and social variables also constrain this coupling. For example, cognitive processes such as decision-making and motivation, and social factors such as group membership, dominance relations, and social communication, may influence the selection of goals, neighbors, speeds, and control laws and shape group dynamics. The present experiment suggests an approach to quantifying multi-agent coordination in many of these contexts. Future work will continue to scale up these analyses to larger groups in various pedestrian scenarios, with the aim of understanding the emergence of collective behavior and global patterns in large crowds.

#### Abstract

We describe a model designed to learn word-concept pairings using a combination of semantic space models. We compare various semantic space models to each other as well as to extant word-learning models in the literature and find that not only do semantic space models require fewer underlying assumptions, they perform at least on par with existing associative models. We also demonstrate that semantic space models correctly predict different word-concept pairings from existing models and can be combined with existing models to perform better than either model can individually.

Keywords: Childes; natural language processing; semantic space models; associative learning.

## Introduction

While the task of word-concept matching may seem trivial to an adult, imagine the task from the perspective of a young child. A child hears a series of vocalizations, which are then parsed into word units, and must perceive instances of objects in their environment through visual inspection. From that information the child must determine a set of objects or concepts that are present. These two tasks are challenging enough, but the child must then find a way to correlate the words that he/she has heard with the objects in the immediate environment. Extracting the correct mappings from the myriad possible ones is complicated by things such as the potential absence of matches between object and word (e.g., an object is mentioned that is not present), and the fact that not all words refer to objects (e.g., verbs and function words).

Several techniques have been proposed to help simplify the word-concept acquisition problem, the majority of which require the child to have prebuilt assumptions (e.g., a novel word must map to a novel object), or to perform complex Bayesian logic calculations (Frank et al. 2007). In this paper, we explore a new class of model that is based on the rapidly growing field of semantic space models. In particular, we generalize Kintsch's (2001) predication algorithm to the problem of word-concept learning in semantic spaces.

Kintsch's (2001) algorithm simulates the process of matching based on shared neighbors in a semantic space. The result of our adaptation is a model that learns to map words and objects to semantic clusters, greatly simplifying the problem of word-object mapping. Rather than casting the problem as one of learning associations between independent words and independent objects, a semantic
space approach can take advantage of the fact that similar words carry mutually reinforcing information about each other's object referents. In addition, the similarity between a noun and semantically related verb or adjective contains information about the noun's referent. Bounce may often be used when a ball is present in the environment, even in absence of the noun ball. The semantic similarity between the words bounce and ball may be used as an indirect cue to the mapping between the noun and object.

We next provide background on the problem, data, and existing models of word-concept learning. Then we turn to a summary of a variety of semantic space models used, and a general purpose technique for creating word-concept learners from semantic models adapted from Kintsch's (2001) algorithm. Finally, we test these models on a labeled fragment of the CHILDES corpus and explore the benefits of combining different semantic models into hybrids.

## Child Learning Models

While there are a number of existing word-concept mapping models from the child learning literature, we will focus on two recent models that have both been applied to the objecttagged corpus data that we use (described below).
The data used for training in these simulations are from an annotated version of the Rollins section of the CHILDES corpus (MacWhinney, 2000) used by Frank et al (2007). The entire corpus takes place over approximately ten minutes of talk taken from a caregiver to a child. Each sentence is annotated with the objects that are visible to the child when that sentence was being spoken. Thus the corpus consists of entries in the form $\left\{\mathrm{W}_{0}, \mathrm{~W}_{1}, \ldots, \mathrm{~W}_{\mathrm{n}}, \mathrm{C}_{0}, \mathrm{C}_{1}, \ldots\right.$ $\left.\mathrm{C}_{\mathrm{m}}\right\}$ where $\mathrm{W}_{\mathrm{i}}$ is a word token and $\mathrm{C}_{\mathrm{i}}$ is a concept token (each represented by a string). A unique identifier was used to differentiate concepts from words, as both are represented in the dataset by similar strings of characters. In this paper, we will use the angle brackets as delimiters, such that "dog" represents the word dog, and " $<\operatorname{dog}>$ " represents the concept or object dog.

## Frank et al.'s (2007) Bayesian Framework

Frank et al. (2007) propose a Bayesian model to jointly learn word-concept mappings, as well as which objects a speaker intends to speak about in a situation. Using a model similar to Latent Dirichlet Allocation (LDA) used by Topic models, they assume that words are generated from the lexicon according to what objects are present and are likely
to be talked about (i.e., the intention of the speaker). This model is a computational-level model that does not specify learning mechanisms, but rather specifies how to calculate the likelihood of a particular lexicon, given all of the situations that one has observed. The inferred lexicon is simply a collection of word-object pairings, and tends to be small because the prior favors smaller lexicons. The model handles nonreferential words: if a given word appears with many objects only a few times, these mappings will likely not be added to the lexicon. The inferred lexicon will mostly be comprised of the highest co-occurring word-object pairs; there is no explicit penalization for linking words to multiple objects, nor a word to multiple objects. There is no learning of associations among words, nor among objects. Frank et al. demonstrate impressive performance from this model on subsequent testing of word-object pairings.

The semantic space approach we propose differs theoretically from the Frank et al. (2007) model in at least two ways. Firstly, while the Frank et al. approach attempts to calculate an underlying generator that maps from concepts to words through the lexicon, the semantic space approach is more passive, projecting words and concepts onto points in psychological space. Secondly, the semantic space approach attempts to learn the relations between words, including the relations between concepts. This added structure allows a semantic space model to bootstrap additional partial information from indirect relationships.

## Kachergis, Yu, \& Shiffrin (2012) Associative Model

Kachergis et al. (2012) introduced an incremental model that learns word-object associations. Competing attentional biases for familiarity (i.e., already-strong associations) and for stimuli with uncertain associates (i.e., high entropy) allow this model to exhibit mutual exclusivity and other word-learning principles, as well as associative learning effects such as blocking and highlighting (Kachergis, 2012).

The model stores knowledge in $M$, a word-object association matrix that grows during training. Cell $M_{w, o}$ is the strength of association between word $w$ and object $o$. Before the first trial, $M$ has no information: each cell is set to $1 / \mathrm{m}$. Association strengths decay, and on each new trial a fixed amount of associative weight, $\chi$, is distributed among the associations between words and objects, and added to the strengths. The rule for distributing $\chi$ (i.e., attention) balances a preference for attending to unknown stimuli with a preference for strengthening already-strong associations. When a word and referent are repeated, extra attention (i.e., $\chi$ ) is given to this pair-a prior knowledge bias. Pairs of stimuli with no or weak associates also attract attention, whereas pairings between uncertain objects and known words, or vice versa, do not attract much attention. Stimulus uncertainty is captured using entropy $(H)$, a measure that is 0 when the outcome of a variable is certain (e.g., a word appears with only one object), and maximal $\left(\log _{2} n\right)$ when all of the $n$ possible object (or word) associations are equally likely (e.g., for a novel stimulus, or one that appears with all stimuli equally). In the model, on each trial the entropy of
each word and object is calculated from the normalized row (column) vector of associations for that word (object), $p\left(M_{w,}\right)$, as follows:

$$
H\left(M_{w, \cdot}\right)=-\sum_{i=1}^{n} p\left(M_{w, i}\right) \cdot \log \left(p\left(M_{w, i}\right)\right)
$$

The update rule for adjusting and allocating strengths for the stimuli presented on a trial is:

$$
M_{w, o}=\alpha M_{w, o}+\frac{X \cdot e^{\lambda \cdot(H(w)+H(o))} \cdot M_{w, o}}{\sum_{w \in S} \sum_{o \in S} e^{\lambda \cdot(H(w)+H(o))} \cdot M_{w, o}}
$$

In this equation, $\alpha$ is a parameter governing forgetting, $\chi$ is the attention weight being distributed, and $\lambda$ is a scaling parameter governing differential weighting of uncertainty and prior knowledge (familiarity). As $\lambda$ increases, the weight of uncertainty (i.e., the exponentiated entropy term, which includes both the word and object's association entropies) increases relative to familiarity. The denominator normalizes the numerator so that exactly $\chi$ associative weight is distributed among the potential associations on the trial. For stimuli not on a trial, only forgetting operates. This model aims to capture the process of learning simple wordconcept associations using basic cues a learner may have.

## Semantic Space Models

Semantic space models have seen a great amount of both attention and success in the literature over the past decade. There are a variety of semantic space models currently in the literature, but all are fundamentally based on the assumption that the contexts in which a word occurs may be used to infer its meaning, commonly projected into a highdimensional psychological space. Words that frequently cooccur in contexts together, or that frequently occur in similar contexts, become more proximal in semantic space. We explore a variety of semantic space model representations of the CHILDES data here, all using the same mapping mechanism adapted from Kintsch's (2001) algorithm. We next very briefly describe each representation model used in our comparison.

## BEAGLE

The BEAGLE model (Jones \& Mewhort, 2007) uses holographic vector manipulation to represent word similarities. In BEAGLE, each new word encountered is assigned an environmental vector with elements generated independently from a Gaussian distribution, and a lexical vector of the same length but initialized to zeros. When encountering a sentence, the environmental vector of each word is added to the lexical vector of each word it co-occurs with. Similarity is measured using cosine similarities between words' lexical vectors.

## ESA

Explicit semantic analysis (Gabrilovich \& Markovitch, 2007) was designed for use with the Wikipedia corpus. It uses a centroid-based classifier that correlates given input
text to a weighted list of concepts associated with each target word.

## FDTRI

Fixed Duration Temporal Random Indexing, introduced by Jurgens and Stevens (2009), attempts to bypass the computational difficulty inherent in singular value decomposition through the use of random projections onto lower dimensional space. Similar to BEAGLE, each word has an environmental vector, although FDTRI vectors are generated to be sparse. Rather than producing a word-bymeaning matrix, FDTRI incorporates time in a word-by-meaning-by-time tensor. The additional temporal information could be useful in word-concept pairing, if the sequential information given by the caregiver is relevant to object detection. For example, a caregiver may be more likely to start with the label and then continue with a description of the object.

## HAL

The Hyperspace Analogue to Language (HAL; Lund \& Burgess, 1996) uses a fixed size window that is slid along the corpus. A matrix is built which is an accumulation of pairs of words that co-occur within any given window of text. Order information is partially preserved through the use of "occurring before," and "occurring after" cooccurrence matrices.

## LSA

Latent Semantic Analysis (LSA; Landauer \& Dumais, 1997) operates by applying singular value decomposition to a word-by-context frequency matrix, reducing the matrix from high dimensionality (documents) to lower dimensional space (latent semantic components). The premise is that the reduction removes irrelevant features of the word usage, yielding a semantic abstraction in the resulting space.

## ISA

Baroni, Lenci and Onnis (2007) developed incremental semantic analysis (ISA) to analyze children's speech data. ISA is based on random indexing models with a few variations. First, updating occurrence information includes both the signature (or environmental vector) as well as information on the learned history of the other word. This allows ISA to capture higher order relations. Second, word frequency discounts are updated online as the model learns for information about the distribution of words in the world.

## PMI

Pointwise Mutual Information (PMI; Church \& Hanks, 1989) is a basic information theoretic metric that looks at the probability of two words occurring together relative to the probability of each word occurring individually. This provides a first order word co-occurrence metric, and has demonstrated remarkable effectiveness at explaining human
semantic data without resorting to complex inference mechanisms.

## Word-Concept Models

We developed a generalized technique to transform any semantic space model into a word-concept learning model. Word-concept models are divided into a learning phase and a prediction phase. In the learning phase, the model is applied to sentences composed of words. The generalized modification for a word-concept model is to simply concatenate the word tokens with the concept tokens into a single concept/label sensory episode. In the prediction phase, we attempt to assign an object token to each word token.
All semantic space models have the ability to determine similarity between any word pair, thus prediction can be as simple as finding the object with the maximum similarity to the given target word:

$$
\begin{equation*}
\operatorname{maxarg}_{i}\left(\operatorname{sim}\left(w_{\text {targ }}, o_{i}\right)\right) \tag{1}
\end{equation*}
$$

While this performs reasonably, it is possible to improve on this technique by adding a second step. Building from Kintsch's (2001) predication algorithm, we first activate the neighbor set of N most similar words to our target word:

$$
\begin{equation*}
\mathrm{NSet}_{\text {targ }}=\operatorname{maxarg}_{i}\left(\operatorname{sim}\left(w_{\text {targ }}, w_{i}\right)\right) \tag{2}
\end{equation*}
$$

Then for every object, we calculate its activation, $A c t_{i}$, as the similarity between that object and every one of the top N word matches, weighted by the similarity of that word to the target word:

$$
\begin{equation*}
A c t_{i}=\square_{j \varepsilon N S e t} \operatorname{sim}\left(w_{t a r g}, w_{j}\right)^{p} * \operatorname{sim}\left(o_{j}, w_{j}\right) \tag{3}
\end{equation*}
$$

The mechanism provides a match not only to the target word but also to the target's region of semantic space. This is particularly important because there are always more words than concepts. Using Kintsch's (2001) predication allows non-nouns to influence the outcome of the similarity measurement through their similarity to the nouns. Thus, if the word "red" is strongly associated with the word "apple" in the discussion and "red" is also associated with the concept <apple>, then "red" can be used to discover the underlying link between "apple" and <apple>. This mapping can be done implicitly, without knowledge of the part of speech as long as the target words that are to be matched to objects are known.

## Experiment

Each of the above models was trained on the CHILDES corpus and the results were compared to the gold standard model in Frank et al. (2007), as well as to a baseline model that simply counts which words and objects co-occur. There are many different ways to evaluate model performance, and
there does not seem to be agreement in the field about the correct measure to use. To remain comparable to Frank et al (2007), we examined the best F-score (the harmonic mean of precision and recall) achieved by each model. We also looked at the overall proportion of pairings matching the golden standard if all 37 words are assigned a concept meaning. We do this in order to determine what mappings the system makes if forced, although we note that this random slice of parent-child interaction may not be enough to disambiguate all of the mappings.

We also explore hybrid models, asking which two models contribute the most complementary (non-redundant) information. This exercise may hint at what combinations of mechanisms are most important for learning in the natural language environment.

## Results

One popular way of visualizing the results of word-concept learning is through a confusion matrix as shown in Figure 1. The confusion matrix shows the similarity between wordconcept pairings as gradients from black to white (with lighter being a higher association) filling each grid cells. According to the gold standard, each word is associated with exactly one object (except for "bird" which can refer to $<$ duck $>$ or $<$ bird $>$ ). The cells outlined in red indicate the correct word-object pairings according to the gold standard.

In Figure 1a and 1b, a winner-takes-all filter has been applied for each word. Thus, the object that has the highest association has been assigned the similarity of 1 , and all others have been assigned a similarity of 0 . The values returned by the semantic space models cannot be directly interpreted as probabilities for pairing selections. Hence, only relative similarity measures are used here. In Figure 1c, we display the gradient similarity ratings after having been scaled to a power of five (thus exaggerating the differences between predictions).

Figure 1: Confusion matrix results.

Figure 2: Word space. For each model by word, a black square indicates if model correctly identified that word.

It is important to understand which word-object pairs each individual model gets correct or incorrect. It is also important to see which word/object pairs are overall more or less likely to be found by the model. Figure 2 shows for each model, and each word, the probability of accurately identifying the target word. Black squares indicate word-bymodel pairs in which model correctly identifies the object associated with that word. There is also a calculated average correctness for each word (rightmost column) and for each model (bottom row). Some of the semantic space models are non-deterministic (BEAGLE, FDTRI and ISA). For these models, 100 runs were computed and a correct identification granted when more than half of the runs correctly identified that pairing. No partial credit was given in any form for coming close to correctly matching each word. Parameter values were selected to be those optimized (relative to expected overall matches) for the individual model.
The F-scores are important indicators to help understand how well each model has correctly inferred the word-object pairings. To calculate the F-scores for each model, we first computed a similarity matrix for every word-object pair. For non-deterministic models, the similarities were averaged across 100 similarity runs for the given model. Next, maximum values were determined within each word to select an object. Pairings that were correct were labeled true, and pairings labeled that were incorrect, were labeled false. These similarity measures were then ordered based on strength (both correct and incorrect measures). For each N, precision and recall figures were then calculated for each of the top N word pairings.

This results in the receiver operator curves shown in Figure 3, and Table 1 shows the maximum F score values taken from the ROC curve chart for the top 5 models.

Figure 3: ROC curve for all models.
Table 1. Top F Scores

| Model | Hybrid | BEAGLE | Frank | ESA | COOC |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Best F | .83 | .55 | .54 | .54 | .53 |

Using the Word 2 Word language visualization tool (Kievit-Kylar \& Jones, 2012) we can visualize all of the word/object pairings as a graph. In Figure 4, words are nodes and each similarity measure is an edge. In the visualization below, we see all concepts lined up across the top with each word referring to them shown below. The green connections indicate the strongest similarities observed by the system. Ideally, all lines would link to the word directly above.

Figure 4: Word network visualization of BEAGLE model solution.

Because different models seem to make different mistakes, we also explored how hybrid models might be able to exploit these differences. Each model $M$ is able to assign some similarity measure to and word-object pair $\mathrm{M}_{\text {sim }}\left(\mathrm{W}_{\mathrm{x}}, \mathrm{O}_{\mathrm{y}}\right)$. We considered hybrid models of the following form: $\mathrm{M}_{\mathrm{A}, \mathrm{Bsim}}\left(\mathrm{W}_{\mathrm{x}}, \mathrm{O}_{\mathrm{y}}\right)=\mathrm{M}_{\text {Asim }}\left(\mathrm{W}_{\mathrm{x}}, \mathrm{O}_{\mathrm{y}}\right) * \mathrm{c}+\mathrm{M}_{\mathrm{Bsim}}\left(\mathrm{W}_{\mathrm{x}}, \mathrm{O}_{\mathrm{y}}\right)$. Each pair of models was optimized, relative to the average number of matches with the golden standard, for the constant c .

Figure 5 shows the correct number of matches for each optimum pairing of models. A heat map of colors has been added to indicate highest (red) to lowest (purple) values. The optimum model is a co-occurrence by BEAGLE hybrid with the later having a weight three times greater than the former. This hybrid model results in 30 correct mappings on the gold standard.

Figure 6: Word network visualization of optimum hybrid.

Figure 7: Thresholded confusion matrix for best hybrid.

## Conclusions

The semantic space approach to word-concept learning is a fruitful endeavor with potential to better understand how humans make use of mechanisms and mutually reinforcing information sources across learning. The best pure semantic space models was able to predict the gold standard to a higher degree of accuracy than existing models while still conforming to known semantic and processing constraints. The adaptation of Kintsch's (2001) mechanism for predication allows semantic models to consider not only the semantic similarity between a word and object, but to also consider mutual information from the semantic neighborhoods. This procedure provided a benefit to each of the semantic space models tested.

Hybrid models also provide interesting insight into the word/concept-learning problem. The optimum hybrid model merged the co-occurrence model with BEAGLE. This optimal fusion makes intuitive sense, as the co-occurrence model provides first-order co-occurrence information that can be best supplemented by the higher-order co-occurrence information inherent in the semantic space models. The performance of the hybrid model suggests that infants may be capitalizing on both raw co-occurrence information and an emerging ability for higher-order semantic abstraction. Knowledge of which words are similar to each other from linguistic experience may be used to bootstrap word-object mappings across learning.

# Selection of Linker Type in Emphatic Reduplication: Speaker's Intuition meets Corpus Statistics 

Özkan Kılıç (ozkan.kilic@gmail.com)<br>Cem Bozşahin (bozsahin@metu.edu.tr)<br>Department of Cognitive Science, Graduate School of Informatics<br>Middle East Technical University (METU), Ankara, Turkey

#### Abstract

Turkish Emphatic Reduplication (TER) occurs in adjectives and adverbs to accentuate their meanings. The current experimental study to investigate the selection of the linker type in TER indicated that responses from the participants correlate with some lexical statistics. The result relies on the statistics from a corpus with approximately 2 million Turkish words, which we use in lieu of lexical statistics. The frequency order of linker choice reported by the participants was exactly the opposite of the order of frequency of words in which the linker and the first consonant co-occur consecutively in the corpus. Such a direct link to lexicon was unexpected. We suggest that TER, an apparently phonological operation, depends on lexical access for selecting the appropriate linker whose cooccurrence with the initial consonant of the reduplicated word is infrequent. Our results relate morphology and lexicon in more ways than the blocking phenomena, and suggest that TER may be morpholexical.

Keywords: Morphology; emphatic reduplication; lexicon; lexical frequency.

## Introduction

Turkish is generally considered to be a language with subject-object-verb word order, and it is morphologically agglutinating, with considerably involved morphology. The Turkish word structure depends heavily on suffixes, which are transparently stacked on the leftmost stem like "beads on a string" (see Kornfilt, 1997; Lewis, 2000; Göksel \& Kerslake, 2005 for a detailed review of Turkish). However, not all Turkish morphology is suffixal, and it is not always the case that we can enumerate the allomorphies clearly in non-suffixal morphology and phonology, with some good variation among speakers, which is not the case for suffixal morphology. Perhaps not surprisingly, these cases involve items which might appear to look like prefixes. We suggest a way to relate these differences in the processing of bound items to lexical statistics, as evidence for another case of interaction between morphology and lexicon.

Turkish Emphatic Reduplication, henceforth TER, is one such resource showing greater speaker variation. It is a derivational process which intensifies the meaning of adjectives and some adverbs. Phonologically it involves the duplication of the initial ( $C$ ) $V$ of the base, and addition of a prefix-like item as a linker to the root, which is a consonant from the set $\{p, s, m, r\}$. (Demircan, 1987; Oztaner 1996; Wedel, 1999; Yu, 1999; Kelepir, 2000; Kim, 2007; Dhillon, 2009). All words beginning with a vowel are infixed with $-p$ as the linker. In some cases the $(C) V+$ linker "prefix" is also followed by an additional "infix" from the set $\{-A,-I l,-A m\}$ as in some of the examples below.

| (1) ka-s-katı | ç1-r-1l-çıplak |

## Related Work

Inkelas \& Zoll (2005) use cophonology to explain emphatic reduplication. A cophonology is a morphological function associated with particular morphological constructions to model morphologically conditioned phonology. Cophonologies receive words or morphemes as input, and perform some operations such as constraint ranking, truncation, and velar deletion on the input to be sent to the phonological interface (Inkelas \& Orgun, 1995; Inkelas, 2000). Truncation and addition act on the word beyaz 'white' to produce bem-. Then, the mother node links the subconstituent daughters to the input and shifts stress to the truncated one to form bémbeyaz 'snow white'. Demircan (1987), and later Wedel (1999, 2000), examined TER as a phonological operation and summarized the linker selection constraints as follows:
(2) (i) The linker from the set $\{p, s, m, r\}$ cannot be identical with the initial consonant $\left(C_{1}\right)$ of the base: pembe 'pink' $\rightarrow$ *peppembe, although $p \in\{p, s, m, r\}$. Perpembe is possible but not likely (see below).
(ii) The linker cannot be identical to the second consonant $\left(C_{2}\right)$ of the base: pembe $\rightarrow$ *pempembelpespembe, although $m \in\{p, s, m, r\}$.
(iii) The phonetic features \{coronal, sonorant, labial, continuant $\}$ of the linker cannot be identical with those of the second segment of the base. The linker with the most contrasting features is selected for perceptual salience.
(iv) The linker is selected in a way that it can establish an optimization or balance among the features contributing to the featural contrast with respect to base.

Some examples in Turkish seem to be orthogonal to these constraints. For example, in addition to çı-r-ll-çıplak, which is the commonly assumed reduplicated form of çıplak as in (1), çı-s-çıplak, çı-r-çıplak, çı-m-çıplak and çı-p-çıplak do occur in the Web.

The constraints in (2i-iv) can be violated when phonological productivity is put to the test in relation to morphology and the lexicon. We asked 50 participants to reduplicate pırasa 'leek', and along with the expected pımpırasa and pıspırasa, we also received pırpırasa and pıppırasa, in more or less equal distribution.

In this paper we report our experimental study which investigates the selection of the linker type, and its relation to morphology and the lexicon. The results indicate that responses from participants show disagreements with the literature about familiar words which are known to be non-TER targets. It also suggests that TER may be morpholexical, which is quite contrary to current literature.

The database for our statistics is a corpus of approximately 2 million Turkish words. We consider the database to be a rough approximate of a native speaker's lexical statistics. We asked the participants to emphatically reduplicate some words from this corpus. We asked them to play a "what-if" game to reduplicate the words that they would normally resist to reduplicate, such as masa 'table'. Among 50 participants and 31 target words, only one target, the only one that begins with a vowel, showed unanimous agreement, all others showing varying degrees of agreement. We present our method and the experiments toward understanding these results.

## TER vs. Reduplication

Kim (2007) points out that the most productive "prefixation" in Turkish is observed in reduplication. According to Göksel \& Kerslake (2005), Turkish duplication can be observed in three ways: M-reduplication, doubling, and TER, as explained above. We show below that, unlike TER, the first two kind are phonological-syntactic operations, therefore not operating on morphological properties but phonologicalsyntactic ones. In this regard they are expected to be less susceptible to lexical statistics.

## M-reduplication

If a word or compound to be m-reduplicated starts with a vowel, the original word is prefixed with $m$-, and then duplicated as shown in (3a). If it starts with a consonant other than $m$-, the consonant is replaced with $m$-, and the new form is duplicated as shown in (3b). In case the word or the compound starts with $m$-, it is followed by the word falan 'like, so and so'. M-reduplications can occur in all syntactic positions.
(3) a. $[\text { Çocuklar }]_{N P}\left[[\text { akıcı makıcı }]_{A D V}[\text { konuşmazlar }]_{V}\right]_{V P}$ child-PLU fluent M-DUP speak-NEG-AOR-3PL lit. 'Children do not speak fluently (and the like)'
b. $[\text { Çocuklar mocuklar }]_{N P}\left[[\text { akıcı }]_{A D V}[\text { konuşmazlar }]_{V}\right]_{V P}$ child-PLU M-DUP fluent speak-NEG-AOR-3PL lit. 'Children (and the like) do not speak fluently'

We note that the results of this process are two independent words, both phonologically and syntactically. We can, for example, choose the duplicated form in (3b) as the target of a construction:
(4) a. Çocuklar mocuklar akıcı konuşmazlar. childPLU M-DUP fluently speak-NEG-AOR-3PL 'Children (and the like) do not speak fluently'
b. Mocuklar hiç konuşmazlar. M-DUP never speak-NEG-AOR-3PL lit. 'The likes do not speak at all.'

## Doubling

Doubling occurs in two ways: simple doubling, and doubling in lexical formations. In simple doubling, the word is repeated, as in (5). Depending on the syntactic category of the targeted lexeme, it can produce adverbials, adjectivals and measure terms (Göksel \& Kerslake 2005).

## (5) tek tek zaman zaman <br> one DUP time DUP <br> 'one by one' 'time to time'

Some additional morphemes, such as the plural suffix and the question particle ( QP ), are attached to the sister constituents as in (6a) and (6b), or one of the constituents undergoes phonetic changes, as in (6c), for doubling in lexical formations.
(6) a. güzel-ler güzel-i bir kız beautiful-PLU beautiful-POSS a girl 'a very beautiful girl'
b. güzel mi güzel bir kız
beautiful QP beautiful a girl
'a very beautiful girl'
c. ufak tefek bir kutu
little $\phi_{i}$ (little) a box
'a tiny box'
Among these alternatives, the last one seems closest to a morphological-lexical operation. $\phi_{i}$ in (6c) stands for cophonology (Orgun, 1996; Orgun, 1999; Inkelas \& Zoll, 2005), which is the morphological function associated with particular morphological constructions to model morphologically conditioned phonology. The basic idea is shown in Figure 1 .

Figure 1: Template for cophonologies.

Inkelas \& Zoll (2005) employ cophonologies in their Morphological Doubling Theory (MDT), and stress that the theory is morphologically motivated because it makes use of roots, morphs and affixes, rather than mora, coda or foot. The model works in a binary manner, in which there are two inputs called daughter nodes, and the output in the tree's root is called the mother node. In MDT, the reduplicant and base are both generated by morphology as part of a construction that also embodies semantic and phonological generalizations concerning the output of reduplication (Inkelas, 2005).

However, Göksel \& Kerslake (2005:101) classify lexical formations as idiomatic expressions, and our intuitions are consistent with this observation. Take for example the following from the same page in their book:

```
(7) a. konu komşu
    LEX-FORM neighbor
    'neighbors', lit. 'neighbor-neighbor'
b. süklüm püklüm
crestfallen LEX-FORM
'in a crestfallen manner'
```

Firstly, they are not always right-headed or left-headed, which seems a bit unusual for a purportedly morphological operation. Secondly, as Göksel \& Kerslake (2005) point out, the copy may or may not exist independently. We add to this an additional observation that the doubled word is indeed a phonological word, not a suffix, prefix, and not necessarily a lexeme.

It is not clear to us whether examples such as ( 6 c ) should be made part of an experiment on lexical statistics versus speaker production of bound elements, because it is not clear whether something other than multi-word word formation is involved here, although we are quite certain that independent words should be left out, i.e. examples such as ( $6 \mathrm{a}-\mathrm{b}$ ). We chose to take idiomatic lexical formations ( 6 c ) outside the scope of our experiments too, and concentrate only on TER.

In Morphological Doubling Theory, MDT, the features given above can be ranked by the cophonologies to determine the linker in the emphatically reduplicated form of TER. Yu (1999) argued that the allomorphy in Turkish reduplication could be accounted for by positing morphotactic constraints, which spell out the form of each of the allomorphs that dominate certain phonotactic constraints. The ultimate selection of the appropriate morph depends on the harmonic satisfaction of the lower-ranked phonotactic constraints on the linker.

Demircan (1987) analyzed 121 emphatically reduplicated adjectives, and concluded that the frequency of reduplicated adjectives showed the ranking $-p>-m>-s>-r$, in which $-p$ is the most selected linker, and $-r$ the least. Of all the adjectives, $46 \%$ are reduplicated with $-p, 29 \%$ with $-m, 18 \%$ with $-s$, and $7 \%$ with $-r$. In another study, $\operatorname{Wedel}(1999,2000)$ concluded that TER with the linker $-r$ might be lexicalized.

In contrast with these findings, and with the constraints summarized in (2), we noted some frequently occurring "exceptions" in §1, for example, among others, çı-r-ll-çıplak,
which is the expected reduplicated form of çıplak, but also çı-s-çıplak, çı-m-çıplak, çı-r-çıplak and çı-p-çıplak.

There seems to be no easy generalization across the speakers about how they emphatically reduplicate a novel word. Auspiciously, there are tendencies depending on the linker type, with respect to lexical co-occurrence frequencies, which we explain below.

## Method and Findings

In order to thoroughly understand the linker selection choices available to native speakers of Turkish, a questionnaire consisting of 31 nonadjectival words composed of Turkish nouns and verbs was prepared. The word list was given to 25 male and 25 female participants, all university graduates, average age 34.20, and all native speakers of Turkish. Nonadjectives were deliberately selected to guarantee that the participants would be very unlikely to have applied TER to the words in the list before. The participants were asked the following questions: if the words were to be treated as adjectives, how would they emphatically reduplicate them? They were allowed to give single word answers. We also asked whether they had ever reduplicated the words, how they knew how to reduplicate the words, and the average time in seconds it took them to reduplicate each word. Because our plans did not involve reaction time experiments, we considered the last piece of information as the perceived difficulty and/or effort on behalf of the speaker. About two-thirds of the subjects took the experiment in our presence, and our timing seems to concur what they reported.

We have been told that they had never reduplicated any of the words before. For their own explanation of self performance, the participants responded that they reduplicated the words 'intuitively', and that each word required about $5 \mathrm{sec}-$ onds or less for reduplication. All the participants used $-p$, $-m,-s$, and $-r$ for the linker position, but none used $-A,-I l$ or $-A m$ as an additional infix. This result is shown in more detail in Table 1.

Looking closer at the results, most productions seem to satisfy the constraints previously reported (Demircan, 1987; Wedel, 1999; Wedel, 2000), but, certainly, some formations such as böpböcek, firfirın, mammasal and kemkemir, violate these constraints. Unlike the study by Demircan (1987), the order of the linker type frequencies in this study is $-p>-s>-$ $m>-r$. Moreover, the reduplicated forms with $r$-linkers seem to disconfirm Wedel's $(1999 ; 2000)$ conclusion that $r$-forms might be lexicalized. They seem to be just less frequently used.

Explanations for these findings might lie in lexical statistics, in particular n-grams of graphemes, which we use in lieu of phonemes because of lack of speech data. For this end we used corpora to approximate a lexical statistic. When we examined the METU-Sabancı Turkish Treebank (Atalay et al., 2003), we found that there are 43,571 roots, of which 5,533 are distinct. The linker order found in the current study is exactly opposite of the frequency of words with roots that end

Table 1: TER results for the nonadjectives.

| Word | $p$-linker | $m$-linker | $s$-linker | $r$-linker |
| :---: | :---: | :---: | :---: | :---: |
| bıçak | 11 | 10 | 28 | 1 |

| (\%) | 57\% | 11\% | 28\% | 4\% |

with the grapheme found in the linker; see Table 2, the second column. The third column repeats the same count in a much larger corpus, the BOUN corpus of 490 million words (Sak, Güngör, \& Saraçlar, 2011). The database has 45,035 distinct stems, whose frequency of ending with $p / \mathrm{m} / \mathrm{s} / r$ is reported in the third column. They have the same rank as the other corpus. We take the rank as an adequate relative measure of the lexical choice of endings in Turkish.

Next we consider the co-occurrence of the linker type with other consonants that are likely to be at the initial segment. For a word without TER beginning with the sequence $C_{1} V_{1} C_{2} \ldots$, the consonant co-occurrence on the boundary of the "prefix" and the base will be one taken from the set $\left\{p C_{1}\right.$, $\left.m C_{1}, s C_{1}, r C_{1}\right\}$. Prefixation is a morphological operation, and we wanted to see if early lexical access can be contrasted with early morphological processing by frequency.

One hypothesis is that the linker may be selected so that the

Table 2: Number of distinct stems/roots terminating with the same grapheme as a linker type, in two large corpora.

| Root ending | METU-Sabanc1 | BOUN |
| :--- | :---: | :---: |
| $p$ | 100 | 639 |
| $s$ | 128 | 780 |
| $m$ | 281 | 1,620 |
| $r$ | 470 | 3,523 |

first segment of the reduplicated word has less resemblance to an existing root. One way to check this effect is to see if the consonant co-occurrence is minimized for the linker type- $C_{1}$ pairs. In order to test this hypothesis, the statistics from the METU Turkish Corpus (Say et al., 2002) is studied. Table 3 shows the number of distinct words containing the consonant co-occurrences composed of one linker and the initial grapheme of the nonadjectival word from the corpus. For example, 46 words in the corpus have $p b$ as substring. Similarly, 482, 101 and 633 words have $p m, p s$ and $p r$ as substrings, respectively.

Table 3: Linker-consonant co-occurrences in the corpus.

| Consonant | Linkers |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  | $p-$ | $m-$ | $s-$ | $r-$ |
| $b$ | 46 | 482 | 101 | 633 |
|  | $(p b)$ | $(p m)$ | $(p s)$ | $(p r)$ |
| $c$ | 44 | 435 | 136 | 705 |
| $c$ | 112 | 13 | 48 | 602 |
| $d$ | 106 | 1599 | 148 | 9958 |
| $f$ | 25 | 28 | 66 | 191 |
| $g$ | 11 | 92 | 54 | 1519 |
| $h$ | 189 | 114 | 168 | 200 |
| $j$ | 7 | 1 | 7 | 90 |
| $k$ | 275 | 134 | 845 | 2575 |
| $l$ | 1799 | 3171 | 1655 | 8005 |
| $m$ | 340 | 257 | 519 | 5156 |
| $n$ | 90 | 82 | 140 | 559 |
| $p$ | 100 | 447 | 404 | 499 |
| $r$ | 952 | 201 | 139 | 277 |
| $s$ | 529 | 926 | 612 | 3119 |
| $s$ | 10 | 90 | 10 | 624 |
| $t$ | 820 | 109 | 4338 | 3321 |
| $v$ | 25 | 25 | 61 | 61 |
| $y$ | 132 | 122 | 719 | 346 |
| $z$ | 36 | 161 | 16 | 195 |
| $(\%)$ | $6 \%$ | $16 \%$ | $17 \%$ | $61 \%$ |

The order of the linker type selection frequencies reported by the participants is exactly the opposite of the order of the frequency of the words in which the linker and the first consonant $\left(C_{1}\right)$ co-occurred in the corpus. To exemplify: if the participants' choices occurred in the order $p C_{1}>m C_{1}>$ $s C_{1}>r C_{1}$ (where $x C_{1}$ indicates frequency of co-occurrence of $x$ and $C_{1}$, in this sequence), then the linker type and conso-
nant co-occurrences in the corpus independent of reduplication are in the order $p C_{1}<m C_{1}<s C_{1}<r C_{1}$. This seems to be true for all cases that we have tried. For example, the following are produced by the participants in varying frequencies for the word masa 'table': mammasa, masmasa, mapmasa, marmasa. When we look at the co-occurrence of $\mathrm{mm}, \mathrm{sm}$, $p m, r m$ in the corpus, their frequency rank is the opposite of the ranking of the four alternatives by the participants. Such a direct relation to lexical frequency would be surprising if phonological and morphological contrasts were the sole bases of ranking as suggested by the constraints listed in (2). The same considerations apply to cophonology.

The Mann-Whitney non-parametric test was employed to compare the distributions of the two sets given in Table 1 and Table 3. It shows that the two sets are significantly different ( $U=693, p<.05, r=.79$ ). For the participants' responses, the frequency of answers significantly and negatively correlated with linker types, ranging from $-p$ to $-r$ (Pearson's $r(124)=-.64, p<.01)$. On the other hand, the frequency of consonant collocations in the corpus significantly and positively correlate with linker types, ranging from $-p$ to $-r$ (Pearson's $r(124)=.34, p<.01)$.

## Discussion and Conclusion

The study of Turkish Emphatic Reduplication (TER) on unexpected targets, e.g. on nonadjectival words, and the 'intuitive' responses on part of the participants which violate the phonological feature constraints, show that although TER is a morphologically conditioned phonological process, it seems to depend on the knowledge of distributions such as consonant co-occurrence statistics and root ending statistics. The participants tended to dissimilate the linker type they chose from the known consonant co-occurrences and root endings of their language.

Besides the phonological constraints, selecting an appropriate linker so that the first segment of the reduplicated word has less resemblance to an existing root-word is additionally effective in the process of reduplication. This dissimilation tendency can be observed in Table 1. For example, dar-davet, dur-duvar, göm-götür, gör-götür, ger-getir, gem-getir, hürhüzün, var-vazo and zar-zarf were not produced because dar 'tight', dur 'stop', göm 'bury', gör 'see', ger 'stretch', gem 'curb', hür 'free', var 'exist' and zar 'die' are already existing stems in Turkish. Thus, selecting a linker which has a frequent (admittedly orthographic) representation in the corpus would seem to steer the speaker to considering as if there was a root instead of a prefix. This we think might point out more ways to look at morphology-lexicon relation, rather than just the "blocking" kind such as went/*goed and git/*gittir/götür (leave/cause to leave/take away). Also, considering the fact that participants were able to respond within 5 seconds, it seems to us that the speakers are putting the co-occurrence frequencies in their language to online use.

The findings underline that cophonologies, i.e. morphological functions (Inkelas \& Zoll, 2005), might require prior
knowledge of known words' frequencies to select the appropriate linker after the truncation of the base in light of the phonological constraints. To be able to employ these statistics, TER as a process needs access to a speaker's lexicon.

We therefore suggest that Turkish emphatic reduplication, an apparently phonological operation, depends on global lexical knowledge for selecting an appropriate linker whose cooccurrence with the initial consonant of the reduplicated word is infrequent. (Yavas, 1980 was first to point out the lexical source of the linker type.)

We argue further that there are sufficient reasons to take emphatic reduplication as morpholexical, rather than phonological or cophonological. First, the ranking of TER elicitations from non-TER targets conforming to TER's base form paradigm is not consistent. This suggests that something other than phonological ranking is also at work.

The lexical constraints on TER seems to be more than the stem's part of speech and lexical statistics. The process is very productive when we can entertain a $((e, t),(e, t))$ reading for TER, from a $((e, t),(e, t))$ base, be it adjective or adverb, to $((e, t),(e, t))$ result. This is a semantic constraint. Yemek 'food' is not the right type (currently it seems to be $(e, t)$ ), and we have *yepyemek/*yemyemek/*yesyemek/*yeryemek, although the first syllable of the base would be a phonologically legitimate input to TER if the semantic type could be satisfied: yeşil 'green' $\rightarrow$ yemyeşil 'all green'. Place names cannot be of the right semantic type either, and similarly fail to undergo TER if not forced: Mordoğan $\rightarrow$ *mosmordoğan.

The semantics of reduplication works on aspectual properties or intensive aspects, depending on the morphological and lexical property of the $((e, t),(e, t))$ base: çabuk 'quick' $\rightarrow$ çarçabuk 'in haste', which is aspectual and derivational (cf. syntactic/phonological reduplication çabuk çabuk 'hurriedly'), and mor 'purple' $\rightarrow$ mosmor 'deep purple', which is intensive. Note also the case of yeşil $\rightarrow$ yemyessil above, which seems to be intensive in some other way.

Connectives and postpositions are the hardest targets for TER, presumably because of their semantic type in addition to morphology: ama 'but' $\rightarrow$ *apama, göre 'according to' $\rightarrow$ *göpgöre. Other semantically potential targets for TER, e.g. VPs, are in fact $(e, t)$, and as such they behave as expected: иуи 'sleep' $\rightarrow$ *upиyu, düşün 'think' $\rightarrow$ *düpdüşün. Additional linkers $\{-A,-I l,-A m\}$ are never used by our participants, which suggests that such forms in (1) are probably lexicalized.

It is clear that the reduplicated "prefix", the linker types $\{p$, $s, m, r\}$, or the "infix" from $\{-A,-I l,-A m\}$ are not morphological objects. They are not affixes or morphemes. It seems also clear that the process is not purely lexical or phonological. Its "allomorphy" is open-ended; there seems to be no discernible TER morpheme, or a purely morphophonological process.

We point out that (i) the process is codetermined by morphology and the lexicon, (ii) its semantics depend on lexical properties, and (iii) it cannot be repeated: masmavi $\rightarrow$ *masmasmavi and apaçık $\rightarrow$ *apapaçık. Therefore it is most likely
a morpholexical rule, with subsequent phonological effects, rather than causes, as exponence.

#### Abstract

Growing bodies of research have investigated how digital games might be used as pedagogical tools and separately, how playing commercial games influences basic cognitive capacities or skills. The goal of the present research is to draw from these separate lines of research to ask how changes in basic cognitive capacities and formal learning gains may be related. The present study employed a game in which a ship moves through different environments using forces. The game teaches the basic relationships between objects and forces in Newton's Laws of Motion. Students played one of two versions of the game. The predictive version encouraged planning and reflection, by allowing students unlimited time to place forces along a path. In the real-time version, forces immediately affected the player when selected. The results suggest that learning was equivalent across the versions, but changes in attentional capacities may differentially contribute to learning between versions.

## Introduction

Video games have been present in mainstream culture for decades, but have recently become a popular topic for research. One branch of research on video games in Cognitive and Social Psychology, has investigated the impact of recreational game play on basic cognition and behavior. A second branch of research has investigated the impact of games specifically designed to teach concepts within a discipline. Though these divisions do not cover all the relevant work, they do account for a majority of publications on videogames. In the present work, we investigate how games can train concepts and basic cognitive capacities. Beyond this, we begin to address the complex question of how cognitive skill training and discipline-specific learning may each contribute to learning gains on an assessment of students' basic understandings of Newton's Laws of Motion.

Much of the recent research on videogames in Cognitive Psychology has been connected to the somewhat surprising finding that some of commercial action video games may actually train basic cognitive capacities of players (e.g. Dye, Green, \& Bavelier, 2009; Feng, Spence, \& Pratt, 2007). One particularly interesting finding is that games may train networks that control three basic aspects of visual attention (Dye et al., 2009). There have been some concerns about the conclusions drawn in these studies (Boot, Blakely, \&

Simons, 2011). However, the possibility of a positive impact of games that may otherwise have negative social effects (e.g., Carnagey, Anderson, \& Bushman, 2007) has been a compelling topic for research.

Other research on videogames for learning has focused on learning discipline specific content knowledge, skills, processes, attitudes, and engagement (e.g., NRC, 2010). This education-focused work spans several fields and is often referred to as research on "serious games" or "games for learning" although there are multiple other names as well. Again, this work has typically focused on how games produce learning gains in a particular discipline or skill.

The present project differs from most prior Cognitive Psychology and Education-focused work, but is designed to benefit from the approaches of both of those areas of research. The present work uses a conceptually-integrated game (Clark \& Martinez-Garza, 2012) under development called EGAME in which the target concepts are integrated directly into gameplay mechanics, rather than being presented through separate activities. The basic prototype of the game involved in this study (see Figure 1) was designed to promote an accurate intuitive understanding of Newton's Laws. The game provides puzzle-like scenarios in which players use a limited palette of forces to move a ship to a target. Unlike in many popular games, movement in this game is controlled by combining unidirectional forces of varying magnitudes and durations. Furthermore, the game models realistic motion and is sensitive to the constraints of the environment (e.g., the presence or absence of friction).

Two versions of our game prototype were used in this study. The first, predictive, version of the game was designed to encourage planning and reflection. In this version, students dragged forces from a palette onto a level map. The students would then "run" the simulation to observe the results of their choices. This design minimized competition between cognitive resources necessary to select forces and the resources available to observe and evaluate the effects of choices. The placement play phase involved selecting locations for forces, looking at the palette, and dragging icons with the mouse. The observation play phase involved watching the ship respond to forces placed on the map (and optionally stopping the simulation).

The real-time control version of the game combined placement and observation. Students had unlimited time to look at a level and plan before selecting a force, but as each force icon was clicked, the ship moved accordingly. In this
version, students made force selections as the ship moved and had to time actions appropriately. Our expectation was that this design imposed greater cognitive demands on students. For example, the real-time game encouraged more strategies such as memorizing available forces and preparing actions before beginning a level. Moreover, the real-time version required continuous monitoring of the position of the ship and continuous shifting of attention between the force palette and the game map [see Droll \& Hayhoe (2007) for how attention and working memory may be coordinated in related contexts]. Due to the presumably greater load imposed by the real-time game, we hypothesize greater learning gains for the predictive game version than for the real-time game version (hypothesis 1).

Neither version of game was truly an "action game," like those that have been shown to train cognitive capacities in other studies, but our manipulation of game versions allowed us to isolate certain features of typical action games. More specifically, as in typical action games, the real-time game type encouraged monitoring multiple regions of the screen and timing actions with onscreen motion. Thus, the primary differences between the game types are in terms of how players must distribute attention and select relevant information. Therefore, in investigating differences in capacities that might be trained by the two game types, we focused on changes in scores on the attention network test (ANT) across players in each version of the game. Based on brain imaging and behavioral evidence, the ANT is reported to measure attentional capacities in terms of three distinct network components: (1) an executive component, related to inhibiting irrelevant information, (2) an orienting component, related to shifting the focus of attention to particular spatial locations, and (3) an alerting component, related to preparing to process upcoming information (see Dye et al., 2009 and Rueda et al., 2004). In research by Dye et al. (2009), the authors find that frequent action game players had larger scores on the executive and orienting components of the ANT and had faster baseline RTs with equivalent accuracy. Given these findings and the similarities between the real-time game and typical action games, we hypothesize that changes in orienting and executive attention networks (and baseline RT) after gameplay will be larger for the real-time game group (hypothesis 2).

In addition to measuring changes in attention networks, we investigated the relationship between gains in basic cognitive capacities, gains on our formal assessment, and measures of motivation. At the most basic level, we predict that motivation will support learning and that we will observe a positive correlation between motivation and physics learning gains for both game types (hypothesis 3). We also predict that network scores on the ANT pretest and will be more strongly positively correlated with learning gains on the physics test for the real-time game (hypothesis 4). This hypothesis is based on the premise that the real-time game imposes greater attentional demands and thus, students with a greater initial capacities might learn
more more than others fort that game. Though we do not have a specific prediction for how changes in basic cognitive capacities will relate to changes in physics understanding across versions, we also predict that changes in ANT network scores may have different relationships to learning gains across the two game versions (hypothesis 5). Our final hypothesis, following Dye and colleagues (2009) is that students that more frequently played action video games will have higher initial orienting and executive scores on the ANT (hypothesis 6).

Figure 1: Screenshot of EGAME level.

## Method

## Subjects

143 middle school students ( 70 female and 73 male) in the Southeastern United states participated in this study. The school served a racially diverse, primarily middle-class population. Students participated together during their normal $8^{\text {th }}$ grade science class for approximately 3 hours of game play and 1 hour of pre-post assessments spread across one week. The sample consisted of students from 6 classes under the same teacher. Data was only used from students who completed the assent form. All analyses only included students that completed the measures reflected in those analyses.

## Equipment

Students used MacBook Air computers to play the game. The game and cognitive tests were designed using Adobe Flash. The prototype versions of the game used in this study as well as current versions of the game can be viewed at www.surgeuniverse.com.

## Assessments and Questionnaires

Physics Understanding Students completed pre-and posttests consisting of 12 questions based on the Force Concept Inventory (Hestenes et al., 1992). Questions covered the following basic concepts relevant to understanding Newton's Laws: vector combination and diagonal motion (vectors); the relationship between velocity, acceleration, and position (acceleration); the influence of friction on
motion (friction); the influence of mass on motion (mass); and the influence of gravity on motion (gravity).

Attention Networks (ANT) We administered an adapted child-friendly version of the ANT developed by Rueda et al. (2004). The ANT evaluates the efficiency of three distinct attentional networks (executive, orienting, and alerting). In the pre- and post-test, 144 critical trials were presented in a fixed random order. On each trial (after a 1500 ms ITI), a fixation cross was presented ( 400 to 1600 ms ). Following this, one of four cue types was presented ( 150 ms ). Cues were gray circles occupying approximately the same area as the target $\left(1.7^{\circ}\right)$. Cue conditions were: no cue, a central cue (at fixation), a double cue (at possible target locations), or a spatial cue (at the upcoming target location). After a 450 ms delay, the target stimulus was presented either $1.9^{\circ}$ above or below the prior fixation location. The target was a spherical furry character used in game tutorials. The target was presented alone (neutral trials) or flanked by distractors ( 2 to the left and 2 to the right). Students responded to what direction the target was facing. On incongruent trials, distractors faced the opposite direction of the target. On congruent trials, all characters faced the same direction. The critical stimuli were presented for up to 1500 ms . Feedback was provided in the following forms at fixation: correct response: "+10 pts", incorrect response: "oops", and delayed response: "too slow".

Mental Rotation Students completed a mental rotation task adapted from Widenbauer \& Jansen-Osmann (2008). The task required students to decide whether two images were identical or mirrored. Because numerous students misunderstood the instructions and for the sake of brevity, data from this task are not discussed further.

Motivation and Engagement (QCM and GEQ) The game engagement questionnaire (GEQ) is a measure developed by Brockmyer and colleagues (2009). The questionnaire yields a single composite score of engagement in terms of: presence, flow, absorption, and immersion. Each item had three choices: "no", "sort of", and "yes". We adapted this questionnaire to refer to our game. For more details on the GEQ, see Brockmyer et al. (2009).

The QCM is a measure of achievement motivation. The QCM differentiates the following factors: anxiety, challenge, interest, and probability of success. We used a modified version of the short form of the QCM (Freund et al., 2011). Specifically, we replaced "task" with "game" in all questions and removed one concerning item: "I am afraid I will make a fool out of myself".

Gaming Experience Survey Following Dye et al. (2009), we asked students to list the 10 games they had played the most frequently in the past 12 months. Using this, students were classified as action game players or not.

## Design and Procedure

The study used a pretest-intervention-posttest design. Students were seated at lab tables mostly in pairs, though some students were alone. Students were pseudo-randomly assigned to one of two game versions (predictive or realtime) in each class. 79 students played the real-time game and 64 played the predictive game. Assignment was not random because students were allowed to sit in their typical seats and pairs of students seated together were placed in the same condition. This prevented students from seeing the alternate game version and allowed them to consult one another if they chose. All students worked individually. Before playing the game, students completed three separate tasks that were integrated with the game content: the physics pre-test (adapted from the FCI), the ANT, and the mental rotation task. After the pre-tests, students played the their version of the game. The content of the game levels roughly corresponded with one or more of the aforementioned categories of questions on the FCI-based test.

Students played the game for approximately three days of class time and completed different numbers of levels in this period according to their abilities. Several simple tutorials were included and two questions were included within the first 10 levels of the game to help students connect the material in the game to Newton's Laws.

Students completed the questionnaire on current motivation (QCM) after playing the first level of the game and the game engagement questionnaire (GEQ) after playing approximately 38 levels. Students were asked to stop playing after approximately 20 minutes on the third day. After playing, students first completed the FCI, ANT, and the mental rotation post-tests, then completed the gaming experience survey and provided feedback about the game.

## Results

## Initial Equivalence of Student Groups

The distribution of students classified as action gamers on the gaming experience survey did not significantly differ by across the game version groups (predictive vs. real-time). Furthermore, game type groups did not significantly differ prior to treatment in terms of any subscales on the physics understanding test or the ANT (i.e., Alerting, Orienting, or Executive scores).

## Measures of Motivation and Engagement

A univariate ANOVA was conducted with GEQ scores as the dependent variable and game version as a betweensubjects variable. There were no significant differences between student engagement ratings across the predictive ( $M=45.25, S D=8.09$ ) and real-time $(M=44.27, S D=$ 5.96) game versions, $F(1,124)=.62, p=.43, \eta_{p}^{2}=.01$. Additionally, separate univariate ANOVAs were conducted with QCM components as dependent variables and version as a between-subjects variable. The univariate ANOVA for

QCM "probability of success" showed a significant difference between versions, $F(1,139)=46.57, p<.0001$, $\eta_{p}^{2}=.25$. Students in the real-time game had significantly higher estimates $(M=5.00, S D=1.08)$ than students in the predictive game $(M=3.45, S D=1.62)$. Thus, it appears that students in the real-time game version may have had higher achievement motivation to start. To note, the QCM challenge component was dropped from covariate analyses due to a large correlation with the interest component, $r(139)=.61, p<.0001$.

## Student Gains and Version Comparisons

Physics Understanding A repeated-measures MANCOVA was conducted with test administration (pre vs. post) as a within-subjects factor. Game version (predictive vs. realtime) was included as between-subjects factors. Each question type (vectors, acceleration, friction, mass, and gravity) was entered as a separate dependent measure. The multivariate analysis showed that overall learning gains were non-significant from pre- to post-test, $F(5,137)=$ 2.27, $p=.05, \eta_{p}^{2}=.08$. Separate univariate ANOVAs for each question type were examined with the same factors as above. These tests showed that only the vectors question type showed small but significant learning gains, $F(1,141)$ $=6.55, p=.01, \eta_{p}^{2}=.04$, from pre- $(M=.22, S D=.26)$ to post-test ( $M=.29, S D=.29$ ). No interactions with game version were significant for any of these tests, so our hypothesis of an overall advantage for the predictive game was not supported.

Attention Networks (Baseline and Network Scores) A repeated-measures ANOVA was used to evaluate baseline RT (neutral trials) between test administration times. Game version was included as a between-subjects factor. This test did show a significant effect of test administration, $F(1$, $100)=36.27, p<.0001, \eta_{p}^{2}=.27$, with faster post- $(M=$ $542, S D=91)$ than pre-test $(M=582, S D=90)$ RTs. The interaction between test administration and version was not significant, $F(1,100)=.20, p=.66, \eta_{p}^{2}=.002$. A similar ANOVA with baseline accuracy showed no significant effects.

Following this analysis, individual repeated measures ANOVAs were used to compare gains in network scores. We calculated network scores from difference scores among median RTs following Rueda et al. (2004): Executive score = incongruent - congruent trials, orienting score $=$ spatial single cue trials, alerting score $=$ double - no cue trials. Test administration was included as a within-subjects factor and game version was included as a between-subjects factor. The ANOVA for alerting scores showed that scores significantly increased, $F(1,100)=27.48, p<.0001, \eta_{p}^{2}=$ .22 , from pre- $(M=5.96, S D=36.52)$ to post-test $(M=$ 44.46, $S D=58.71$ ) administration. The ANOVA for orienting scores showed that scores significantly increased, $F(1,100)=100.88, p<.0001, \eta_{p}^{2}=.50$, from pre- $(M=-$
33.75, $S D=46.54$ ) to post-test $(M=18.53, S D=43.08)$ administration. Additionally, there was a significant interaction between test administration and game version for orienting scores, $F(1,100)=7.46, p=.007, \eta_{p}^{2}=.07$. This interaction reflected that the differences (post-pre) in orienting scores were larger for the predictive version ( $M_{\text {Diff }}$ $\left.=74, S D_{D i f f}=55\right)$ than the real-time $\left(M_{D i f f}=42, S D_{D i f f}=60\right)$ version.

Finally, the ANOVA for executive scores showed that scores significantly increased, $F(1,100)=139.40, p<$ $.0001, \eta_{p}^{2}=.58$, from pre- $(M=32.95, S D=36.22)$ to posttest ( $M=96.82, S D=55.20$ ) administration. These findings do not support our second hypothesis. In fact, the only difference between the two game versions we observed was in the opposite of the predicted direction (with larger gains in orienting scores for the predictive game).

Attention Networks (Omnibus ANOVA, RTs and Accuracy) To compare the specific effects of cues and flankers, separate repeated-measures ANOVAs for RTs and for accuracy were conducted. However, given these analyses are not of primary importance to our research questions, the details of these analyses are not reported here. We note three important results from these analyses, however. First, no interactions involving game version were significant. Second, main effects for accuracy ANOVAs were similar to those for RT ANOVAs. Finally, we observed spatial cues reducing congruency effects, which has been observed other ANT studies. Furthermore, this effect was greater for the pre-test.

## Covariate Analyses of Student Gains

Attention Networks (Gaming Experience) A univariate ANOVA was conducted to evaluate baseline RT differences on the ANT pre-test between recreational action game players and others. Recreational action game playing was included as a random factor. Action game playing did not influence baseline RT in this comparison, $F(1,81)=.01, p$ $=.92, \eta_{p}^{2}<.001$. Following this, separate univariate ANOVAs were conducted for each ANT network score. None of the network scores were significantly different for action game players: alerting scores: $F(1,81)=.03, p=.87$, $\eta_{p}^{2}<.001$; orienting scores: $F(1,81)=3.17, p=.08, \eta_{p}^{2}=$ .04 ; and executive scores, $F(1,81)=.01, p=.93, \eta_{p}^{2}<$ .0001. Orienting was the only component to approach significance [action game players $(M=-27, S D=37)$, non action game players ( $M=-45, S D=49$ )]. Overall our results did not corroborate those of Dye and colleagues. However, we did observe a marginally larger pre-test orienting score for action game players.

Physics Understanding with Covariates First, to determine how baseline measures of attention influenced learning gains, separate repeated-measures MANCOVAs were conducted for each game version. Test administration (pre vs. post) was included as a within-subjects factor. ANT
pre-test network scores (alerting, orienting, and executive) were included as covariates. Each question type (vectors, acceleration, friction, mass, and gravity) was included as a separate measure. Neither multivariate nor univariate tests showed any significant effects of the covariates for either game version. Thus, our fourth hypothesis, that ANT pretest scores will be more closely correlated with learning gains for the real-time game was not supported.

Following the above analyses with ANT pre-test scores, a similar analysis was conducted including difference scores between the ANT pre- and post-tests, aggregate GEQ scores, and QCM component scores (probability of success, anxiety, and interest). First, separate repeated-measures MANCOVAs were conducted for each game version. For the real-time game, there was a significant interaction between test administration and ANT orienting score in the multivariate test, $F(5,45)=3.31, p=.01, \eta_{p}^{2}=.27$. None of the other effects for the real-time game were significant in the multivariate test.

Because we were interested in the specific effects for each question type, univariate tests were explored as well. For the real-time game, the interaction between test administration and ANT orienting gains was significant for the vectors question type, $F(1,49)=6.09, p=.02, \eta_{p}^{2}=.11$, and for the friction question type, $F(1,49)=6.38, p=.02$, $\eta_{p}^{2}=.12$. The interaction between test administration and ANT executive gains was significant for the vectors question type, $F(1,49)=5.17, p=.03, \eta_{p}^{2}=.10$, and for the friction question type, $F(1,49)=4.87, p=.03, \eta_{p}^{2}=.09$. Partial correlations with difference scores controlling for other covariates showed that gains on vectors and friction questions increased with smaller ANT orienting, $r(47)=-$ $.33, p=.02$, and executive gains, $r(47)=-.31, p=.03$.

For the predictive game, no effects were significant in the multivariate test. In unvariate tests for the predictive game, interactions with test administration were significant for the mass question type with the QCM anxiety, $F(1,29)=4.98$, $p=.03, \eta_{p}^{2}=.15$, and GEQ score, $F(1,29)=4.85, p=.04$, $\eta_{p}^{2}=.14$. Gains on the mass question increased with increasing QCM anxiety, $r(27)=.38, p=.03$ and GEQ engagement, $r(27)=.38, p=.04$. Similarly, gains on the gravity question increased with increasing QCM interest scores, $F(1,29)=5.83, p=.02, \eta_{p}^{2}=.17$. These findings partly support our fourth hypothesis that increased motivation would support greater physics learning gains, however this was limited to the predictive game.

Finally, the predictive game showed a significant interaction between test administration and ANT executive gains for the friction question type, $F(1,29)=4.39, p=$ $.045, \eta_{p}^{2}=.13$. Gains on the friction question increased with smaller executive gains, $r(27)=-.36, p<.05$. Together, the differences in correlations between learning gains and ANT gains for the real-time and predictive games support our fifth hypothesis.

## Discussion and Conclusions

Overall, few of our initial hypotheses were supported: Players did not demonstrate better learning with the predictive than with the real-time game (hypothesis 1), changes in attention network scores were not greater for the real-time game (hypothesis 2), scores on the ANT pre-test did not predict learning gains for either version (hypothesis 4), and action videogame players did not have higher initial network scores (hypothesis 6). However, we did observe that motivation was correlated with learning gains, at least for the predictive game (hypothesis 3 ), and we did find that changes in ANT network scores had different relationships to learning gains across the two game versions (hypothesis 5). The remainder of this section is devoted to discussing specific findings of interest.

Perhaps the most interesting finding from the above analyses is that there was a robust negative correlation between participants' orienting/executive ANT gains and physics understanding gains in the real-time game. ANT scores increased from pre- to post-test for both game version groups, suggesting that students may have had more attentional resources available to distribute attention after playing either game version (see Dye et al., 2009). However, the greater the ANT gains, the smaller were the learning gains observed in the real-time game. One interpretation of these findings is that learning gains for the real-time game were greater for those students that gained less in terms of available attentional resources though realtime game play. There may be competition for resources between learning to spread attention quickly and widely in the real-time game and resources for extracting disciplinespecific content from the game.

Another notable finding is that there were no overall differences in learning between the real-time and the predictive game. Despite the additional load presumably imposed by the real-time game, learning was equivalent. Several possible explanations will be explored in future work. Students might simply replay levels more often in the real-time game, so that load limitations are overcome. Additionally, the real-time game may have certain advantages over the predictive game. One possible advantage is that students are not required to anticipate or visualize the results of cumulative force applications to form a coherent plan - students implement plans piecemeal, as needed. Each decision can be made relative to the current direction of motion and about how each force will alter the current trajectory. Furthermore, in the real-time version, students get immediate feedback about whether each action undertaken results in an expected outcome.

For the predictive game, multivariate tests showed a somewhat greater influence of motivation and engagement, such that greater motivation/engagement was correlated with larger learning gains. One possibility is that performance on the predictive game was influenced by motivation due to the time gap between planning, execution/observation, and revision. If students failed to use what they observed to inform a subsequent placement phase,
then they may have adopted something more like a trial-and-error approach at each placement phase. However, the real-time game delivered just-in-time feedback on choices, which may have facilitated identifying incorrect actions even with lower motivation.

Another interesting finding was the interaction between game version and test administration for ANT orienting scores. Considering orienting/executive scores were both larger for game players in the Dye study, we might expect to see larger orienting scores for the real-time game because the rapid responses required game are more similar to those required in action games. However, we observed the opposite (greater orienting score changes for the predictive game). In the predictive game, (1) there were additional visual landmarks (forces placed by the student) to monitor as the ship approached and (2) attention could be devoted exclusively to orienting to relevant landmarks in the observation phase (as forces were not being selected). Such differences may account for gains in ANT orienting scores. Interestingly, these gains in orienting scores did not correlate with learning gains for the predictive game. This could strengthen the claim that orienting gains were obtained from improving monitoring of relevant landmarks during motion, which one would not expect to influence physics learning.

A final point involves the comparison of individuals classified as action game players to other students. Dye and colleagues (2009) showed that action game players had higher scores on orienting and executive ANT components and faster baseline RTs (but with equal accuracy). In contrast to these prior findings, we found only a marginal relationship between prior gaming experience and ANT orienting scores. These differences may be due to differences in the form of the ANT administered. Another difference that may have contributed was our testing the ANT in a classroom whereas Dye et al. tested in the home. Despite these differences, it is worth noting that our participants showed increased scores from pre- to post-test in the direction expected from Dye et al.'s results for recreational playing. Thus, it does seem that playing our game may induce changes in attentional networks.

One limitation of this study is that there was no baseline condition with which to compare the game version treatments. Therefore, gains on the physics assessment and in the components of the ANT could result from a testing effect. Preliminary results do indicate that EGAME produces larger physics learning gains than a control game with adult participants. Future research will need to address this issue.

A second limitation of this study involves the prototype nature of the versions of the EGAME game at the heart of this study. EGAME is being continually improved based on these and other findings, but the game is still a work in progress. Our assumption (underscored here) has been that without scaffolding, formal learning gains will be minimal. Two future plans involve (1) introducing feedback based on the game play and (2) incorporating dialog interactions to
support explicit articulation through self-explanation and directed questioning. The results of the current study are an important step toward integrating basic research on cognition and learning with applied research informing the design of digital games for learning.

#### Abstract

Bilingual speakers are confronted with a unique challenge when learning language as they must learn to express the same concept in two separate languages. Here, we examine whether learning number words in one language (i.e., L1) facilitates the acquisition of analogous number words in a second language (i.e., L2) or whether extensive experience and familiarity with numbers within the second language is required to learn words in L2. To do so, we tested 68 bilinguals speakers between the ages of 2 and 4 years and show that conceptual knowledge of numbers in L1 reliably predicted children's conceptual knowledge of numbers in L2, suggesting that knowledge transferred from one language to the other. The effect, however, was limited to two developmental transitions: one-knower to two-knower and subset knower to CP-knower. Familiarity with L2 numbers as well as age were also significant predictors of children's conceptual understanding of numbers.

Keywords: bilingualism; conceptual transfer; word learning; number words.

## Introduction

When children learn language, they are confronted with the problem of discovering how words encode conceptual content and thus encode their experience of the world. Although children eventually overcome this challenge and learn to associate specific words with specific concepts, this process is slow and often involves making difficult inductive inferences regarding the meanings of words (Quine, 1960). In these cases where slow, inductive inferences are required it is often unclear whether children's difficulty lies with forming the concept to be referenced (see Carey, 2009) merely mapping the correct linguistic symbol to the correct concept. This distinction between conceptual and linguistic development is difficult to disentangle because linguistic experience is almost always correlated with other factors that influence conceptual development including biological maturation and non-linguistic experience. Although there are some striking examples where language can be isolated from these other developmental factors, for example international adoptees as well as late learners of sign language, these cases may have limited generalizability due to severe linguistic delay or a sharp disruption of first language learning.

In contrast, bilingual children sometimes have limited knowledge of their second language (i.e., L2) while still having an intact first language experience (i.e., L1). This separation of conceptual development and L2 linguistic development can provide a unique test case for exploring how linguistic competence and conceptual development are
related, while avoiding the challenges introduced by latelearners of sign language and international adoptees.

More specifically, bilingual speakers allows us to test whether conceptual learning accomplished first in one linguistic medium might facilitate the acquisition of corresponding content in a second language by eliminating several steps in the second language acquisition, thus resulting in a faster second language acquisition rate relative to the first language acquisition. In cases where children must acquire concepts before mapping language to those concepts, L2 acquisition of those words should be faster than L1 acquisition because these concepts can transfer from L1 to L2. In contrast, when children merely require increased exposure to the language in order to map a word to a pre-existing concept, no L2 facilitation would be expected because this process is necessarily languagespecific.

In the present study we explored this idea by investigating the acquisition of number words (e.g., one, two, three) - a central test case in the study of conceptual change (see Carey, 2009). To do so, we tested children learning two languages and asked whether learning number word meanings in one language (i.e., L1) facilitates the acquisition of analogous number words in a second language (i.e., L2).

Early in acquisition, children as young as two years learn to recite a partial count list in a serial order (e.g., one, two, three, four, five, etc.), pointing at objects as they do so (see Gelman \& Gallistel, 1978; Frye, Braisby, Lowe, Maroudas, \& Nicholls, 1989; Fuson, 1988). Despite this seemingly procedural understanding of the relationship between counting and cardinality, children at this stage in development typically have little to no understanding of how counting represents number (i.e., how the last number of the count list represents the exact cardinality of the set) nor have they acquired the meanings of any of the number words (i.e., that numbers refer to specific quantities of a set). Soon, however, children begin to acquire an exact meaning for the number one, reliably giving one object when asked for one and more than one when asked for a contrasting number. After six to nine months as a 'oneknower,' children learn the meaning of two, becoming a 'two-knower' and, following this sequential pattern, learn the meanings of three and four (Wynn, 1990, 1992). During these early stages of number word learning, these children who are classified as one-, two-, three-, and four-knowers have meanings for only a subset of their number words (i.e., one, two, three, and four) and are thus collectively referred to as 'subset knowers.' Eventually, twelve to eighteen
months after children first acquire the concept of one, they discover the cardinal principle that governs counting and recognize that the counting procedure can be used to label the cardinality of sets, at which point they are considered Cardinal Principle knowers or 'CP-knowers' (for evidence and discussion regarding these stages, see Le Corre \& Carey, 2007; Lee \& Sarnecka, 2011; Piantadosi, Goodman, \& Tenenbaum, 2012; Sarnecka \& Carey, 2008; Wynn, 1990, 1992; for discussion of what these children actually know, see Davidson, Eng, \& Barner, 2012).

By the time children acquire the concept of cardinality, they have experienced at least three important qualitative shifts in their conceptual understanding of numbers that differentiates non-knowers from one-knowers, one-knowers from two-knowers, and subset knowers from CP-knowers (for review, see Carey, 2009). First, in order to learn the meaning of one, children must have already acquired their first linguistic representations of an exact cardinality. During this stage, children begin to recognize that number words represent specific numerosities, for example that one represents precisely one item rather than an undefined quantity or an amount defined by contrasting a number, such as not one. Second, when children acquire the meaning of two in languages that mark the singular-plural distinction, they experience a fundamental shift in their understanding of quantity that differentiates one-knowers from twoknowers. Unlike the concept of one, which corresponds with the singular marker ' $a$,' the specific concept of two is not marked by morphology in English, French, and Spanish (the languages targeted in this study) as the plural morphology can refer to sets of any size two or greater. This suggest that once children acquire the concept of two, they may undergo a conceptual leap as they must acquire this new concept of duality. Third, when children become CP-knowers, they learn of the unique relationship between counting and cardinality, specifically that the counting procedure assigns number words to sets. That is, children understand that the last number recited in the count list refers to the specific cardinality of the set.

The idea that each stage involves significant conceptual change predicts that, once such changes have occurred in one language (i.e., the PNL), subsequent learning of words that encode identical concepts in a second language (i.e., the SNL) should be substantially easier, at least to the degree that acquisition in the PNL is delayed by the process of constructing the relevant content. For those children who understand the unique relationship between counting and cardinality, learning may also be facilitated by recognizing that the two count lists server similar functions in the respective languages, thus allowing the formation of an analogical mapping between the two (for a discussion of analogical mapping, see Gentner, 1983; 2003; Gentner \& Markman 1997).

Although the construction of conceptual content predicts that children's understanding of numbers may transfer from one language to another, it is equally possible that acquiring concepts in one language is independent of acquiring
identical concepts in a second language. For example, children may learn the meaning of one as a function of the frequency of associations between the word 'one' and sets of one, a process that is irrespective of children's acquisition of 'uno' in Spanish or 'un' in French. That is, knowledge may be acquired as a result of exposure to the number word and, therefore, may be represented and stored in the language in which the concept was originally acquired and fail to automatically transfer to a second language.

Previous studies of mathematical competence in bilinguals find little evidence of transfer across languages. For example, bilingual speakers exhibit a strong preference for one language over another when performing arithmetic, sometimes preferring the language of original instruction despite being a dominant speaker of another language (Dehaene, 1997; Dehaene, Spelke, Pinel, Stanescu, \& Tsivkin, 1999; Spelke \& Tsivkin, 2001). When asked to perform simple mathematical computations in their second language, bilinguals not only perform calculations more slowly but also do so with lower accuracy (Kolers, 1968; Marsh \& Maki, 1976; McClain \& Huang, 1982). However, these studies tell us little about how earlier processes of bilingual learning and representational transfer take place. This is because these studies focus on mathematical operations, which may depend on a different, broader, set of representational resources, including memorized procedures and facts that may be uniquely dependent on linguistic encoding (for discussion, see Dehaene, 1997). Thus, although relevant to understanding the bilingual representation of number, these studies do not directly address whether early transfer of numerical concepts is possible in bilingual learners, and thus whether the foundations of arithmetic learning can be shared across languages. Here, within the context of number word acquisition, we explored this issue by testing children who were second language learners and assessing their ability to successfully denote the cardinalities of number words in each language.

In the present study, we tested two populations of bilingual 2- to 4-year-olds: French-English speakers and Spanish-English speakers. Children participated in two tasks in each language. First, they completed a Give-a-Number task, which assessed their comprehension of number words, and second they completed a counting task, which assessed their familiarity with the count list in each language thus acting as a proxy for their relative exposure to numbers. Both of these measures allowed us to ask whether, when controlling for counting ability and, thus, familiarity with numbers, knowledge of number words in the L2 was predicted by knowledge of number words in the L1. More specifically, we asked whether there was evidence of conceptual transfer in subset knowers, CP-knowers, or both. Thus, we tested whether transfer is mediated by earlier acquisition of exact cardinal meanings, like one, two, three, and four, and whether it can be mediated by learning how the counting procedure works when children become CPknowers.

## Method

## Participants

Sixty-eight bilingual learners of either English and French or English and Spanish from the San Diego metropolitan area participated. In the French-English (FE) sample, 23 children (13 male) between the ages of 2;11 and 5;0 ( $M=$ $3 ; 9, S D=0 ; 6$ ) participated. These children were primarily recruited from a French language preschool where instruction is conducted exclusively in French. In the Spanish-English (SE) sample, 45 children (22 male) between the ages of $2 ; 2$ and $5 ; 0(M=4 ; 2, S D=0 ; 9)$ participated after being recruited from either a Spanish immersion preschool or a departmental database. Participants were from predominately Non-Hispanic Caucasian or from Hispanic middle-class families and were contacted either through letters distributed by teachers at local preschools or by phone using a departmental recruitment database. An additional 15 children participated but were excluded for completing the tasks in a language other than the one being tested, for example, speaking in Spanish when the tasks were conducted in English ( $\mathrm{N}=2$ ), for being trilingual speakers $(\mathrm{N}=2)$ and for failure to complete the counting task in at least one language ( $\mathrm{N}=$ 11).

As reported by the caregivers, 5 of the FE children were primarily French speakers, 14 of the SE children were primarily Spanish speakers, and 43 of the FE $(\mathrm{N}=14)$ and SE ( $\mathrm{N}=29$ ) children were primarily English speakers. Two additional children were listed as having both Spanish and English as their primary language. For the remaining four children, no primarily language was reported.

## Procedures

Testing sessions lasted approximately 20 minutes and consisted of two tasks: a Give-a-Number task followed directly by a counting task. Both tasks were administered once in English and once in either French or Spanish, such that each child completed both tasks in one language before completing identical tasks in his or her second language. The order in which the languages were tested was randomized across children. As an additional measure of a child's fluency in both languages, we initially asked caregivers to complete the Language Development Survey in English and either French or Spanish (Rescorla, 1989). However, because many parents were unable to complete the survey in both languages (e.g., parents were monolingual), we discontinued its use and do not report the data here.

Give-a-Number Task This task was adapted from Wynn (1992) using the non-titration method developed by Sarnecka and Carey (2008) and was used to assess children's comprehension of number words in each language. The experimenter began by presenting the child with a red paper plate and ten plastic fish and inviting the child to play a game with her toys. For each trial, the
experimenter asked the child to place a quantity of the fish inside the red circle, omitting singular and plural markings by asking, for example, "Can you put $N$ in the red circle? Put $N$ in the red circle and tell me when you're all done." Once the child responded, the experimenter then asked, "Is that $N$ ? Can you count and make sure?" and encouraged the child to count in the language tested. If the child recognized an error, the experimenter allowed the child to change his or her response. Following the completion of each trial, the objects were returned to their original positions and the next trial was administered until all were completed.

Participants completed up to twenty-one trials, consisting of three trials for each of the seven numbers tested (i.e., 1, 2, $3,4,5,8$, and 10 ). The order was quasi-randomized such that each number was tested once before any number was repeated, thus resulting in three sets of seven numbers. Children were defined as an $N$-knower (e.g., three-knower) if they correctly provided $N$ (e.g., 3 fish) on at least two out of the three trials that $N$ was requested and, of those times that the child provided $N$, did so in response to a request for $N$ on at least two-thirds of all trials. If children responded correctly on two out of the three trials for each number tested, then they were classified as CP-knowers.

Counting Task After administering the Give-a-Number task, the experimenter asked the child, "Can you count as high as you can?" If the child failed to respond or indicated that he or she did not know how to count, the experimenter provided the first number of the count list (e.g., one) with rising intonation in an attempt to clarify the instructions and encourage the child to continue counting. In the event that the child failed to respond after the prompt, the experimenter reassured the child and ended the task.

After the task, the experimenter recorded the highest number recited, noting any errors such as omission (e.g., "...13, 14, 16") and cyclical repetition (e.g., "...8, $9,10,1$, 2 "). The child's highest number was defined as the largest number counted to before error. For example, fourteen was the highest number recorded for a child who omitted fifteen, whereas ten was the highest number recorded for a child who cyclically repeated the first ten numbers. In cases where children failed to accurately count at the onset of the task yet recited a string of numbers (e.g., " $6,7,8 \ldots$.."), the highest number was recorded as zero. In contrast, children who refused to count were excluded from the analysis.

For each child, the language with the highest number recorded (e.g., fourteen) was coded as his or her Primary Number Language (i.e., PNL), while the language with the lowest number recorded (e.g., diez) was coded as the child's Secondary Number Language (i.e., SNL). For example, a child who counted to fourteen in English and diez in Spanish was coded as having English as her PNL and Spanish as her SNL. In cases where the highest number recited was matched in both languages (e.g., ten and diez), PNL was defined as the child's primary language as reported by the parent $(\mathrm{N}=1)$ or, when the parent indicated no preference for either language, was instead coded as

English ( $\mathrm{N}=1$ ). The highest number children counted to without error ranged from 1 to 100 in PNL and from 0 to 39 in SNL. Except in the one case noted earlier, parental report was not used to determine a child's primary language for numbers. This is because children frequently encounter number words in formal classroom settings where instruction is often conducted in a language that is not spoken by the parent.

## Results

Figures 1 and 2 reveal the mean performance on the counting task in each language at each knower level separated by FE speakers and SE speakers. As expected, children's familiarity with the count list as reflected in the highest number recited increased as their comprehension of number words progressed. Preliminary analyses revealed no significant difference in performance between FE and SE children. As a result, all analyses are collapsed across languages.

Figure 1: The mean performance on the counting task by knower level for French-English speakers.

Figure 2: The mean performance on the counting task by knower level for Spanish-English speakers.

To examine the relationship between children's comprehension of numbers, children's familiarity and exposure to number words, and children's general maturation, we conducted Spearman's correlations between knower level, highest count, and age. Not surprising, SNL knower level was significantly correlated with PNL knower level, $\rho=0.81, p<0.01$, SNL counting, $\rho=0.72, p<0.01$, and age, $\rho=0.67=, p<0.01$, indicating that children's understanding of numbers deepened as a function of their familiarity with the count list and their general cognitive development.

To isolate the individual effects of familiarity with the count list on the one hand and comprehension of numbers on the other hand, we conducted a logistic regression to predict children's knower level in SNL using SNL counting, PNL knower level, and age as predictors. The full model, when compared against a constant only model, significantly predicted SNL knower level, indicating that the predictors as a set reliably differentiated children's knower level in SNL, $r^{2}(U)=0.45, \chi^{2}(6)=85.8, p<0.01$, with a misclassification rate of 0.27 . A likelihood ratio test further revealed a main effect of PNL knower level, $\chi^{2}(4)=24.07, p$ $<0.01$, suggesting that children's comprehension of numbers in PNL significantly predicted children's comprehension of numbers in SNL, perhaps through conceptual transfer (see Figure 3). However, the effect was restricted to two developmental transitions, as reflected in the parameter estimates: a transition from a 1 -knower to a 2 knower, $\beta=2.91, \beta(\mathrm{SE})=1.13 ; \chi^{2}(1)=5.20, p=0.02$, and a transition from a subset knower to a CP-knower, $\beta=2.41$, $\beta(\mathrm{SE})=0.91 ; \chi^{2}(1)=3.51, p=0.06$. There were also effects of SNL counting, $\chi^{2}(1)=12.05, p<0.001$ and age, $\chi^{2}(1)=$ $3.90, p=0.05$.

## Discussion

We asked how transfer of number concepts from a first language and familiarity with numbers in a second language may facilitate the acquisition of number words in the second language. We found that familiarity with number words
facilitated the acquisition of number concepts and that when children acquired the meaning of number words in their primary language that knowledge transferred to their secondary language during two stages of conceptual development. Transfer was seen when children became twoknowers and when they became CP-knowers.

One possible mechanism explaining the effect of transfer at the level of CP-knowers is a process of analogical reasoning that results in the mapping of analogous concepts across languages. As CP-knowers, children not only learn the meanings of numbers greater than four but also recognize the unique relationship between counting and cardinality. More specifically, CP-knowers learn that counting can be used to label the cardinality of sets and eventually that each successive number is one greater than the preceding one (i.e., $\mathrm{N}+1$ ). Importantly, however, by recognizing that number words belong to a class that forms a structured list, children may infer that the lists in each of their languages operate according to the same principles. As a result, children who are CP-knowers may transfer their knowledge of counting from one list to the other through this process of analogical reasoning.

Another possible mechanism is that number word learning, in general, is a process of conceptual change in which new concepts, such as one, two, and three, are constructed. According to Carey (2009), prior to learning small number words, children cannot represent exact cardinalities via language (see also Le Corre \& Carey, 2007; Sarnecka \& Gelman, 2004; Wynn, 1990, 1992). Although infants can keep track of small numbers of individual objects (Feigenson \& Carey, 2005), and can represent the approximate cardinality of large sets (e.g., Xu \& Spelke, 2003), they may not be able to represent the precise numerosity of sets as a property distinct from the individuals themselves. On this view, number word learning is hard, in part, because it involves creating new conceptual resources. Consequently, once these resources have been built, learning the same meanings in a second language should be substantially easier - i.e., there should be "conceptual transfer." In this case, language transfer might also be observed in bilingual speakers during each of the subset stages of number word acquisition.

In contrast, we failed to find evidence of any transfer from the primary to the secondary number language when children become 1-knowers and 3-knowers. This supports an alternative view that children learn the meanings of these number words (three and one) as a function of their exposure to the number words in their secondary number language, indicating that they must employ a languagespecific mapping between words and meanings. That is, children may consistently hear the word "uno" in association with sets of one and, as a result, form direct mappings between the specific word, "uno," and the quantity, one. Without knowledge of the count list structure that CP-knowers are privy to, bilingual subset knowers are unable to draw comparisons between these numbers. Consequently in these two cases, children gained little
advantage in their SNL number knowledge by graduating to the next level of n-knower in PNL.

While transfer failed to occur at most subset knower levels, there was evidence that the transition from being a one-knower to a two-knower did transfer across languages despite these children's lack of knowledge of the count list structure. This particular transition may mark a significant, conceptual milestone in number word learning that can be transferred across languages. Whereas English, French, and Spanish use singular-plural morphology to mark the exact quantity of one (e.g., "a"), none of these languages use morphology to mark the exact cardinality of two (e.g. a dual marker like that used in Slovenian, Corbett, 2000). For this reason, there may be a conceptual barrier that children have to pass before they are able to map number words two or greater onto their corresponding quantities. Once this barrier is passed in one language, children are able to learn the words two and three in both languages, given that they have sufficient familiarity with number words in both languages. After passing this barrier, the transition from two-knower to three-knower is not transferred across languages, unlike the previous transition from one-knower to two-knower.

The singular-plural morphology in English, French and Spanish also explains why no transfer was seen when children become 1-knowers. The singular-plural morphology may facilitate a concept of the exact cardinality of one before children begin the number acquisition process (Barner, Libenson, Cheung, \& Takasaki, 2009).

In conclusion, we found that learning number words in one language facilitates the acquisition of the analogous number words in a second language at particular points in the number word acquisition process that are characterized by conceptual milestones. Although we suggest that relatively simple concepts, like counting, transfer across languages, it remains uncertain to what extent this occurs. Future studies should explore the generalizations and limitations of conceptual transfer by testing more advanced numerical abilities like estimation.

#### Abstract

The contextuality of changing attitudes makes them extremely difficult to model. This paper scales up Quantum Decision Theory (QDT) to a social setting, using it to model the manner in which social contexts can interact with the process of low elaboration attitude change. The elements of this extended theory are presented, along with a proof of concept computational implementation in a low dimensional subspace. This model suggests that a society's understanding of social issues will settle down into a static or frozen configuration unless that society consists of a range of individuals with varying personality types and norms. Keywords: contextual models; quantum decision theory; attitude change; agent based modelling

## Modelling Attitude Change in a Social Context

The ability to model and predict human responses to changing social conditions is fast becoming highly desirable in a world facing a number of global challenges. This social behaviour is frequently driven by their internally held attitudes of the individuals in a society (Ajzen, 2005; Fazio \& Petty, 2008). For example, privately held attitudes play a critical role in people's personal choices about their health, education, social groups, and housing, as well as the importance they attribute to national issues such as the environment, immigration and state security. However, attitudes are highly contextual, and this makes them extremely difficult to model formally. People's attitudes are not static immutable objects, but change in response to persuasion (Seiter \& Gass, 2010), and the attempt to maintain cognitive consistency (Cooper, 2007). We often express different attitudes and opinions in accordance with the social scenario we find ourselves in (Bond \& Smith, 1996), and it is frequently the case that an explicitly expressed attitude is quite different from an internally held one (Greenwald \& Banaji, 1995).

The Elaboration Likelihood Model (ELM) (Petty \& Cacioppo, 1986); and the Heuristic-Systematic Model (HSM) (Chaiken, 1987) are the two traditional models of attitude change, but both depend upon a number of poorly defined variables, which led Mosler, Schwarz, Ammann, and Gutscher (2001) to create a computational model of attitude change in order force a more accurate specification of the largely heuristic ELM. In essence, both models posit that some processes of attitude change require relatively high amounts of mental effort, resulting from situations where individuals are motivated to pay attention to a message, or have the cognitive capacities to consider it carefully. In these high
effort or high elaboration processes, people's attitudes will be determined by an effortful examination of all relevant information, and so changing them will expend high amounts of cognitive energy. In contrast, other low effort or low elaboration processes of persuasion require relatively little mental consideration by the persuadee, resulting in attitudes determined by factors like emotions, 'gut feeling', liking, and reference to authority.

There are few analytical models capable of describing the dynamics of low elaboration attitude change. While high elaboration processes are more logical and considered, hence frequently following processes similar to first order logic, low elaboration processes are more difficult to control, and are frequently more open to subtle social influences. While it must be acknowledged that involuntary factors such as disgust can play a very important role in low elaboration attitude change (Griskevicius et al., 2013; Rozin, Haidt, \& McCauley, 2008), these responses are themselves often mandated by previous social conditioning. It is very difficult to separate low elaboration attitude change from the social context (both current and historical) in which it occurs.

Furthermore, the underlying personalities of individuals in a society can reveal stark differences in how they will respond to their social context. For example, the Asch conformity experiments (Bond \& Smith, 1996), while not directly applying to attitude change, revealed stark differences in the conformity of subjects when responding to a group of confederates who had been instructed to lie about a perceptual task. While a control group of subjects who performed the same task alone revealed an error rate of less than $1 \%, 75 \%$ of the experimental group of subjects gave an incorrect answer to at least one perceptual task. These incorrect responses often matched those of the lying confederate group. Interestingly, by performing post task interviews, Asch established that there was a wide range of individual responses to these tasks. Some individuals reacted confidently to their individual perceptions, whereas others became more withdrawn and hesitant. Some yielded easily to the group decisions, even to the point of actively believing that the group answer was the correct one. This suggests that the underlying personality of the subjects was a key factor affecting their likelihood of conforming with the group, or truly reporting their differing perceptual observations.

In this paper, we shall introduce a dynamical model of
low elaboration attitude change, showing how it is possible to mathematically represent the manner in which the social context of an agent can affect their expressed attitudes. The model uses a cognitive state to represent an attitude, but is non-deterministic, with the probability of an agent acting taken to depend not just on this state, but also on: (1) the social context in which an agent finds themselves; and, (2) their underlying personality. A simple computational implementation will be discussed, and the way in which agent personalities affect individual attitude changes, and in turn affect the dynamics of the society as a whole will be explored.

## Modelling Decisions in a Social Context

Our model takes Quantum Decision Theory (QDT) (Busemeyer, Pothos, Franco, \& Trueblood, 2011; Busemeyer \& Bruza, 2012) as its starting point, due to its implicit capacity to represent the effect of context upon a decision. QDT has been shown capable of providing a unified explanation for many of the so called 'violations' of rational decision theory that are exhibited by individual humans, and so offers a promising new approach to the modelling of human decision making in context. A recent work by the authors (Kitto \& Boschetti, 2013) has introduced a social extension of the basic QDT model. It proposes a mechanism by which a society of agents self-organises into a set of ideologies representing their combined, and often contradictory, attitudes towards a social issue. This section will briefly introduce that model, but full details can be found in the longer paper.

## The Basic QDT

We shall begin with a consideration of an agent $A$, called Alice, who is deciding whether or not to 'act' in response to a given social issue. Recognising that $A$ 's decision is likely to depend upon their social context, we shall represent her cognitive state as a vector $|A\rangle$ in a vector space, ${ }^{1}$ the structure of which will depend upon the nature of the issue under consideration. If $A$ has decided to act on this issue, then we shall denote this state of action as the vector $|1\rangle$, to represent a situation where it is true that she has chosen to act (in contrast to a state of inaction which we denote as $|0\rangle$ ).

These decisions only make sense with respect to a particular social context, and the probability of $A$ acting could change with a new social setting. However, the quantum formalism can easily incorporate this contextuality due to its vectorial representation of the state $|A\rangle$. Thus, QDT represents the cognitive state of Alice, defined with respect to the

[^307]

Figure 1: An agent attempts to decide whether or not to act. (a) Their probability of action is proportional to the length squared of the projection of their state onto the axes labelled $\left|0_{p}\right\rangle$ (no action) and $\left|1_{p}\right\rangle$ (action); (b) The changing context of a decision. The probability of the agent acting changes between the two depicted contexts, which can immediately be seen by the different lengths of the projections from the state $|A\rangle$ onto the two different 'act' axes $\left|1_{p}\right\rangle$ and $\left|1_{q}\right\rangle$.
context $p$ as

$$
\begin{equation*}
|A\rangle=a_{0}\left|0_{p}\right\rangle+a_{1}\left|1_{p}\right\rangle, \text { where }\left|a_{0}\right|^{2}+\left|a_{1}\right|^{2}=1 \tag{1}
\end{equation*}
$$

a situation that is illustrated in Figure 1(a). Pythagoras theorem is used to extract the probabilities of $A$ acting (or not) in this context, with the probability of action given by $\left|a_{1}\right|^{2}$ and that of inaction similarly given by $\left|a_{0}\right|^{2}$. Thus, the projection of the state $|A\rangle$ onto the current context decides the probabilities of action for this model (Isham, 1995).

With reference to Figure 1(a), we see that in the context $p$ Alice is genuinely undecided. The cognitive state $|A\rangle$ represents an agent who has yet to decide how to act within some context, in contrast to the more standard modelling scenario where the agent has decided how to act, but we as modellers do not know what that decision is. Thus, the probabilities that arise in this model are fundamentally different from those of the more standard Kolmogorovian approaches (both Bayesian and frequentist), and this difference can have a profound effect with a change in context.

This can be seen with a consideration of figure 1(b), which is an elaboration of figure 1(a), and represents the changing probabilities of action that arise in the case of two different contexts, $p$ and $q$. With reference to figure $1(\mathrm{~b})$ we can quickly see that while our agent is highly likely to act in context $q$, this is not the case in context $p$, where $A$ is much less likely to act (since by examination of the figure we can see that while $\left|a_{0}\right|>\left|a_{1}\right|$ in context $p,\left|b_{1}\right|>\left|b_{0}\right|$ in context $q$ ).

## Social Framings of an Issue

This simple model can be naturally extended across a set of multiple agents which we shall call a society $\{|A\rangle,|B\rangle,|C\rangle \ldots\}$, all of whom are considering an issue, where each individual agent $X$ is described with a cognitive state $|X\rangle$ which is expected to change in time.

We assume that agents can make decisions to act within one of two contexts, which we denote as local, and global.

This is taken to represent the manner in which, while we frequently make internal or private decisions (as represented by a local frame), we must sometimes cast our choices within a societal domain (as represented by a global frame) when for example, we are required to vote in a general election. The local frames of the individuals in a society might be similar to a global understanding, or they might differ substantially, depending upon the agent and how they think about the world. Local frames might arise from a wide range of both external and internal factors, such as the socioeconomic status of an agent, their educational background, race etc. and so are likely to be highly complex, and multidependent variables. As a first approximation we shall model them as another basis in the two dimensional vector space already introduced for the states and global frame. This allows us to anticipate that global frames will result from an aggregation function applied to the local frames of every agent who somehow identifies with that ideology. At this point in time, we define identification by performing a distance measure; the global frame that most closely aligns with the local frame of the agent is the one to which the agent is deemed to belong. However, we note that this identification is not intrinsic to the theoretical model per se, rather it is expected to evolve as the model is applied to different social scenarios, and extended into a higher dimensional state space than the early 2D implementation discussed below. We currently use clustering for the definition of global frames via aggregation, but we anticipate that there are many potential methods for defining global frames, and that different ones will prove necessary for different issues (List, 2012)

Kitto and Boschetti (2013) claimed that this framework provides an opportunity to model low elaboration processes of attitude change nontrivially, due to its explicit recognition of the context in which an agent makes a decision. The QDT approach allows for the probability of an agent acting to vary over the full range $(0,1)$ in response to the range of angles that can be taken by the cognitive state of the agent within the Hilbert space that represents the issue currently under consideration. Thus, in order to evaluate Alice's probability of acting, we must take both her current cognitive state $|A\rangle$, and her current social context $p$ (as represented by a global or local frame) into account.

We postulate that an agent who has made a decision is likely to feel a certain amount of cognitive dissonance (Cooper, 2007) as their internal cognitive state will not be aligned with their decision (unless their cognitive state was already aligned with the relevant frame from which they are currently considering an issue). This means that they will feel a certain amount of psychological discomfort, which will drive them to alter their view of the world to fit with their decision within the context that it was made. They can do this in the current model by adjusting either their cognitive state, or their local framing of the issue, to more accurately reflect their decision. However, the literature suggests that some people are more comfortable with cognitive dissonance than others; their personalities will therefore play a
key role in how this adjustment occurs. For example, some agents will feel far less comfortable with uncertainty than others, and so be more affected by dissonance (Sorrentino \& Roney, 2000; Sorrentino \& Hewitt, 1984). In order to model these intuitions, we note that an agent whose cognitive state lies close to the axes representing their current frame will be more certain about their likely future actions than one whose cognitive state lies between those axes (i.e. has the cognitive state forms a $45^{\circ}$ angle between choosing to act and choosing not to act in the frame $p$ ). This leads us to introduce a measure of the uncertainty that an agent experiences about their likely future decisions, using binary entropy $H_{b}(P) \equiv-P \log _{2} P-(1-P) \log _{2}(1-P)$, which is a function taking its minimum values at $P=0$ and $P=1$, and its maximum at $P=1 / 2$. Here, the probability $P$ is defined with reference to the probability of the agent acting (or not) within the given context. Referring to Figure 1(a), we can rewrite the binary entropy of our agent within the context $p$ using a set of geometric variables

$$
\begin{equation*}
H_{b}(P(\theta))=-\left|a_{1}\right|^{2} \cdot \log _{2}\left(\left|a_{1}\right|^{2}\right)-\left|a_{0}\right|^{2} \cdot \log _{2}\left(\left|a_{0}\right|^{2}\right) \tag{2}
\end{equation*}
$$

where $\theta$ is the angle between the $\left|1_{p}\right\rangle$ basis state and the state of the agent $|A\rangle$. This entropy measure is then used in a model of the two different drives for cognitive consistency that we hypothesise are experienced by an agent making a decision in a social context:

1. A desire for internal cognitive consistency. This drives agents to align their cognitive state with the local frame within which they are currently considering an issue.
2. A desire to 'fit in' with the society and its current norms. This desire is expressed by a pull of agent's local frame towards the current global frame (or ideology) to which they belong, which serves to reframe their understanding of the issue.

Defining $\Theta$ as the angle between the agent's current state $|A\rangle$ and the decision to act in the global frame to which they currently belong we introduce a function which measures the uncertainty of the agent $A$ with respect to both frames:

$$
\begin{equation*}
H(|A\rangle, \theta, \Theta)=w_{i}(A) H_{b}(P(\theta))+w_{s}(A) H_{b}(P(\Theta)) \tag{3}
\end{equation*}
$$

where the weights $w_{i}(A)$ and $w_{s}(A)$ refer to agent $A$ 's need for internal consistency and social conformity respectively. These weights can be set to range over a population of agents, indicating a rough parameterisation of a society's social make-up. This measure can naturally be extended to consider the uncertainty of the whole society of $N$ agents:

$$
\begin{align*}
H_{b_{\text {Tot }}} & =\sum_{i=1}^{N} H\left(|i\rangle, \theta_{i}, \Theta_{i}\right)  \tag{4}\\
& =\sum_{i=1}^{N}\left[w_{i}(i) H_{b}(P(|i\rangle, \theta))+w_{s}(i) H_{b}(P(|i\rangle, \Theta))\right] \tag{5}
\end{align*}
$$

which should decrease as the agents achieve cognitive consistency and so settle into a set of stable ideologies, or global attitudes about the world.

## Time Evolution

The weights $w_{i}(A)$ and $w_{s}(A)$ can be considered as personality variables, and they will affect each agent's future actions, in addition to their current cognitive comfort (as is represented by (3)). At present, we update agent states and local frames slightly differently according to the frame in which the decision was initially made.

Local Decisions If the decision was in the local frame, then only the cognitive state of the agent is updated (within the local frame). Thus, an agent who has chosen to act within a certain framing of a problem will shift their state towards the decision ('yes' or 'no') that they made in that context. The size of this shift is defined as dependent upon two factors: (1) the personality profile of the agent (given in this case as $w_{i}$, as it represents the desire of an agent to align their cognitive state with their local frame); (2) the angle $\theta$. Writing $\theta_{0}$ for the angle between the agent's state and the $\left|0_{p}\right\rangle$ axis, and $\theta_{1}$ for the angle between their state and the $\left|1_{p}\right\rangle$ axis, the new angle between the agent's state and the frame will become:
if $A$ decides $\left\{\begin{array}{l}\text { to act: } \theta_{1}\left(|A\rangle_{t+1}, w(A)\right)=\theta_{1}\left(\left|A_{t}\right\rangle\right) \times w(A) \\ \text { not to act: } \theta_{0}\left(|A\rangle_{t+1}, w(A)\right)=\theta_{0}\left(\left|A_{t}\right\rangle\right) \times w(A)\end{array}\right.$
where $w(A)$ depends upon the comfort of $A$ with holding an attitude that is dissonant from their decision. Thus, for this update process $w(A)=w_{i}(A)$. Agents who decide to act will thus experience a rotation of their cognitive state by a certain distance dependent upon their personality towards the $\left|1_{p}\right\rangle$ axis (recall that $\theta$ is the distance between the $\left|1_{p}\right\rangle$ axis and the current state of the agent $|A\rangle$ ), and agents who decide not to act will experience a rotation of their cognitive state in the opposite direction.

Global Decisions If the decision was made in the global frame, then both the cognitive state of the agent and their local frame are updated (with reference to their global frame). Thus, in addition to the update of the cognitive state that is represented in equation (6), the local frame of the agent will shift towards the global axis that represents the decision made by the agent. The amount by which the local frame shifts is given by an equivalent version of equation (6), thus the new angle between the local frame and the global frame is given by (6), but with $w(A)=w_{s}(A)$.

## Implementation

A proof of concept model has been implemented in MATLAB, which allows for an investigation of the timewise behaviour of this new agent based modelling paradigm. Space does not permit a full explanation of this implementation, however, we direct the interested reader towards the actual MATLAB script ${ }^{2}$ which implements the basic pseudocode shown in Figure 2.

While the model that we have presented is admittedly very simple, it does exhibit a number of key features which one

[^308]```
Number of global frames \(=G\)
Number of agents = N
For \(i=1\)..N
    Assign coherence \& consistency variables
    If RandomPersonality \(=0\) then
        conformity \(=0.5\) and consistency \(=0.5\)
    If RandomPersonality \(=1\) then
        consistency \& conformity range over [0-1]
    Assign cognitive states \& local frames randomly
For each timestep
    Find the position of the global frames (use k-means)
    For each agent
        Calculate which global frame the agent belongs to
        Probabilistically choose to act or not in one frame
        If acting in local frame then update cognitive state
        If acting in global frame then update cognitive
        state and local frame
        Calculate entropy of the agent
        Calculate total entropy of system
```

Figure 2: Pseudocode for the computational implementation.
could reasonably expect should be found in an agent based model of attitude change. For example, Kitto and Boschetti (2013) describes the manner in which a population selforganises into a set of ideologies, which evolve and update in time. As predicted, the entropy (4) has a tendency to decrease in time. It is also possible to guide the behaviour of the population, through shifting a global frame, and to then watch the system reorganise into a new semi-stable configuration. In this paper we shall instead focus upon one key feature that has not yet been described, namely, the importance of personality in driving the attitude changes of a society of individuals.

## The Importance of a Personality Spread

Two different seeding strategies have been utilised to initialise the consistency and conformity parameters ( $w_{i}(A)$ and $w_{s}(A)$ ) for each agent within the computational model. A random distribution is possible, where each agent is seeded with parameters that randomly range from 0 to 1 , or alternatively all agents can be seeded with a fixed personality distribution. This allows for an investigation of the effect that varying personality spreads can have upon a population.

Random Personality When agents are seeded with a random personality mix the time evolution of the system is predictably at its most erratic. While the entropy of the system has a tendency to decrease throughout a run, the agents tend not to find a stable configuration, and the system remains in a state of flux and change; states, local, and global frames can all move throughout a run.

Figure 3 shows a set of shots from a typical run for this scenario, along with the entropy plot as it gradually decreases through time, subject to some stochastic variance as agents realign their local frames. Two global frames were specified, and their location at each timestep found using a k -means style algorithm. Agent's cognitive states are represented using black lines, global frames by the large dots above the cog-
nitive states, and local $|1\rangle$ frames as small black spots.

Figure 3: A typical run of a system initialised with agents of random personality spread. Note that the entropy of the system has a tendency to decrease in time, but that it never fully minimises or stablises.

Figure 4 shows a collection of entropy plots for two, three, and four global frames, all initialised with a random mix of personality parameters. Note that in all cases the entropy decreases, but that the system shows more erratic behaviour when more global points of view are available for the agents to align with. The limited nature of the current computational implementation (which has only been performed for two dimensions) means that arbitrarily adding more frames to what is a very small space does not result in realistic behaviour, however, work is currently in progress to extend this model to a higher dimensional state space, and this would allow for the interaction of far more social contexts to be investigated.

Fixed Personality In contrast, when the personality mix of the agents is fixed at $w_{i}(A)=0.5, w_{s}(A)=0.5$ the system

Figure 4: A collection of entropy plots for differing numbers of global frames, initialised with a random mix of personality.
exhibits a far more stable time evolution pattern, and becomes fixed in a static configuration around timestep 25. Figure 5 shows a typical run for this scenario. Note that the entropy minimises very early during a run, as the agents settle into a stable scenario that does not need to re-adjust. All agents can find a state and local frame that minimises (3), and the system rapidly settles down. This dynamics is also evident for for higher numbers of global frames.

Figure 5: A typical run of a system seeded with a population of fixed personality type. (In this case $w_{i}(A)=0.5$ and $w_{s}(A)=0.5$.) The system quickly stabilises into a configuration where all agents are of one, or the other, state of mind. This behaviour is observed for all fixed personality profiles.

## Evolution Requires Consistency and Cohesion

This brief discussion highlights the need for a society to contain a range of personality types. A society of individuals who all have the same personality mix quickly becomes static in this model, it settles down into a scenario where the attitudes of the agents, and their framing of those attitudes, do not change in time. This situation becomes even more dramatic when the society is seeded with individuals who have nonzero values only for conformity or for consistency. In both of these scenarios the model does not evolve at all, it remains in the same state as the one that it was initialised in.
This behaviour plausibly reflects the behaviour of societies in general. Difference of opinion and a varying response to the social context are both key and essential features of a society, and yet such behaviour does not tend to be well captured by current modelling technology. Thus, the contextualised apparatus of QDT offers an interesting new perspective on the modelling of social behaviour that we feel holds promise for future extension and expansion to a more realistic set of scenarios.

## Conclusions

We begin our conclusion with something of a caveat. The model presented here does not utilise the standard complex Hilbert space of quantum theory, nor even the standard Schrödinger based time evolution equation of that model. Indeed, while the dynamics of equation (6) are unitary (Isham, 1995), they are not a part of the standard formalism of quantum theory. We propose that QDT is the first of a class of contextual models of human cognition, but do not expect that a straightforward application of the quantum formalism will suffice to model every contextually dependent cognitive system.
The geometric nature of the model presented here provides a dramatic departure from more standard state based modelling methodologies. In particular, the interaction between the cognitive state of the agent $(|A\rangle)$ and of the basis in which they choose to make their decision (as represented by the basis $\{|0\rangle,|1\rangle\}$ ) means that in a different social context, the agent is highly likely to make a different decision as to how to act. Thus, in adopting a framework inspired by QDT, a very new approach to the treatment of context has been obtained. Furthermore, as the model presented here is developed, we anticipate that it will become necessary to progress to a complex space in order to represent the full range of personality variables and their associated cognitive states. In particular, the interference effects that are apparent in QDT, are not implemented in the current simple form of this model. In summary, it is the contextuality of human decision making in a social context that is captured by this model, but more cognitive effects are likely to be possible within this framework.
However, this initial step is important. Uncertainty dominates in scenarios where contextuality arises, but it is a cognitive effect apparent in the minds of the agents themselves, not in that of the modeller (Payne, Bettman, \& Schkade, 1999), and this is not well captured by our current probabilistic approaches. We have shown one viable approach towards capturing contextual social effects, based upon QDT. A proof of concept computational model was discussed, and a set of varying personalities was shown to be essential for the dynamical evolution of the model. Thus, a way forwards presents, and future work will seek to develop this exciting new approach.

## Acknowledgments

KK was supported by an Australian Research Council Post Doctoral Fellowship (DP1094974) during her completion of this work. The authors would like to acknowledge many helpful discussions with Peter Bruza and Iain Walker.

## Comprehension cueing strategies in elderly: a window into cognitive decline?

#### Abstract

Language abilities gradually decline as we age, but the mechanisms of this decline are not well understood. The present study investigated comprehension of subject vs. object who and which direct questions (DQs), embedded questions (EQs) and relative clauses (RCs) in 39 cognitively healthy native speakers of Spanish. The elderly participants (n $=21$ ) were further classified according to their scores on a general cognitive test, Montreal Cognitive Assessment (MoCA), into a group with low MoCA scores, LM ( $\mathrm{n}=10$ ), and a group with normal MoCA scores, NM ( $\mathrm{n}=11$ ). A mixed-model, repeated-measures analysis of variance (ANOVA) showed that the elderly participants achieved significantly worse accuracy and speed than the young participants (Y) in all tasks. Accuracy was significantly lower and reaction times significantly longer in the LM group compared to the NM group in DQs and RCs. Accuracy in comprehension of EQs was also worse in LM compared to NM, with no significant difference in RTs between the two groups. The results are explained within the competition model and reliance on a language-specific cueing strategy. Reliance on cueing strategies in sentence comprehension may be an effective indicator of cognitive decline associated with aging.

Keywords: comprehension; wh-dependencies; aging.

## Introduction

Cognitive aging is typically associated with a decline in speed of processing and deterioration of memory and attention (Salthouse, 2009). Language abilities also gradually decline as we age, which is reflected in decreased vocabulary, smaller mean number of clauses per utterance, simplified syntactic structure of produced sentences, reliance on optimization strategies when choosing referring expressions as well as difficulty in comprehension of complex sentences (Kemper, Thompson \& Marquis, 2001; Grossman, Cooke, De Vita, Chen, Moore et al., 2002; Hendriks, Englert, Wubs \& Hoeks, 2008). Older adults’ language comprehension decline appears to be due not to sensory, but cognitive demands of spoken language, with complex syntax slowing down the comprehension even when sentence understanding is accurate (Tun, Benichov \& Wingfield, 2010). Research on English has shown that comprehension of structures that require a syntactic operation of movement and involve a longer gap between a moved element and its trace $(t)$, such as object relative clauses (e.g., The cat ${ }_{i}$ that the dog chased $t_{i}$ is black), is impaired in elderly adults, while comprehension of subject relative clauses, in which this gap is smaller (e.g., The cat ${ }_{i}$ that $t_{i}$ chased the dog is black), is spared (e.g., Zurif, Swinney, Prather, Wingfield \& Brownell, 1995; StineMorrow, Ryan \& Leonard, 2000). One explanation of this finding is that the object relative clauses require allocation of more working memory (WM) resources than subject
relative clauses, and WM limitation is one of key features of cognitive aging (Zurif et al., 1995; Caplan \& Waters, 1999; Stine-Morrow et al., 2000; Grossman, Cooke, De Vita, Alsop, Detre et al., 2002).

Furthermore, neuroimaging research has shown that when processing complex sentences, healthy seniors compared to young participants show reduced activation in the core language areas (e.g., inferior frontal regions), while showing additional activation of some areas that are not considered the "core" sentence processing network as well as difference in the coherence of connectivity of the involved brain areas (Peelle, Troiani, Wingfield, \& Grossman, 2010; Tyler, Shafto, Randall, Wright, Marslen-Wilson et al., 2010). Activation of the brain regions that are not typically involved in language processing has been interpreted as an indicator of compensatory processes (Grossman et al., 2002; Wingfield \& Grossman, 2006; Tyler et al., 2010).

Better understanding of the earliest changes in typical cognitive aging is also an important step towards better understanding of the Alzheimer's disease (AD) continuum. Structural and metabolic changes in AD brain occur long before cognitive symptoms become apparent (Dubois et al., 2007, 2010; Sperling et al., 2011). Crucially, even small metabolic and structural alterations in the brain may affect the dynamics enabling cognitive function (Buckner, Snyder, Shannon, LaRossa, Sachs, et al., 2005). Thus, it is important to understand the brain's ability to engage alternate networks and rely on cognitive strategies compensating for a deteriorating cognitive function.

One goal of the present study was to determine whether elderly native speakers of Spanish rely on compensatory strategies in sentence comprehension. We chose to study comprehension of wh-structures (i.e., structures formed by wh-words, such as what, who, which, etc.): direct and embedded questions introduced by interrogative pronouns qué ("what, which") and quién ("who") and relative clauses introduced by que. Like in English, the distance between a moved element and its gap is longer in object than in subject $w h$-structures, as shown in (1-2):
(1) ¿Quién ${ }_{i} t_{i}$ comió una naranja?
(2) ¿A quién mordió $_{j}$ el perrito $t_{j} t_{i}$ ?

However, in Spanish preposition a marks object whquestions and therefore it could serve as a processing cue. Since it appears before the moved $w h$-word, it signals an object structure, allowing the parser to assign a temporary thematic role before encountering the gap. Thus, reliance on this cue would facilitate comprehension of object structures, resulting in their good comprehension, even though they are syntactically more difficult than subject structures and require more WM resources.

## 2. Present Study

### 2.1 Participants

We tested 39 neurologically healthy native speakers of Spanish, of which 21 were older and 18 were young persons. There was a statistically significant difference in age between the groups $(t(27)=28.457, p<0.05)$ and years of education ( $t$ (30) = 6.76, $p<0.05$ ), but not in gender distribution $\left(\chi^{2}(1)=1.857, p=0.17\right)$.

The group of elderly was divided into two subgroups, based on their MoCA scores: since the scores lower than 26 indicate mild cognitive impairment (MCI) (Chertkow, Massoud, Nasreddine, Belleville, Joanette, et al., 2008), we used a cut-off score of 26 to dichotomize the elderly participants into a Normal MoCA scores group (NM) ( $\geq 26$ ) and a Low MoCA group (LM) (<26). Comparing the age means of the latter two groups revealed that the LM group ( $73.8 \pm 6.25$ ) was significantly older than the NM group ( $66.45 \pm 5.14$ ): $t(19)=2.95, p=0.008$ ). The two groups did not differ significantly in years of education $(t)=6.14, p$ $=0.54)$ or in gender distribution $\left(\chi^{2}(1)=0.064, p=0.8\right)$.

All participants were healthy, with no history of stroke, neurological disorders, alcohol/drug abuse, or other conditions that could affect cognition. They all reported normal hearing, and normal/ corrected to normal vision. All participants were recruited through the Ingema Foundation. Participants' characteristics are summarized in Table 1.

### 2.2 Evaluative measures

In addition to a test of global cognition (MoCA), we administered the Month Ordering Test to assess verbal WM (VWM). This test assesses storage and manipulation of material with semantic content, i.e., names of the months in calendar, which makes it highly relevant for studies of sentence comprehension (Almor et al., 2001; Goral, ClarkCotton, Spiro, Obler, Verkuilen et al., 2011). The months are given in a non-canonical order and participants' task is to repeat them canonically. There are 20 strings of months in total, distributed across 5 levels, with 4 strings at each level, containing a different number of months to order. Each correctly ordered string is scored as one point. Thus, the total possible score is 20 . Participants' scores on evaluative measures are summarized together with their demographic characteristics in Table 1.

Table 1: Participants characteristics.

|  | Elderly |  | Young |
| :--- | :--- | :--- | :--- |
|  | $\mathbf{L M}(\mathbf{n}=\mathbf{1 0})$ | NM $(\mathbf{n}=\mathbf{1 1})$ | $\mathbf{Y}(\mathbf{n}=\mathbf{1 8})$ |
| Age | $73.8 \pm 6.2$ | $66.45 \pm 5.1$ | $24.6 \pm 2.6$ |
| Age range | $65-85$ | $60-78$ | $20-30$ |
| Gender $(\mathrm{m} / \mathrm{f})$ | $4 / 6$ | $5 / 6$ | $4 / 14$ |
| Education $(\mathrm{y})$ | $10.56 \pm 5$ | $11.25 \pm 3$ | $17.44 \pm 1.9$ |
| MoCA | $21.9 \pm 3.0$ | $27.42 \pm 2$ | $28.83 \pm 1.2$ |
| VWM | $10.78 \pm 2.4$ | $14.67 \pm 1.8$ | $15.17 \pm 2.1$ |

There were three experiments in the study. Experiment 1 tested comprehension of who and which NP direct questions (DQs) extracted from a subject vs. object position in a sentence. It contained 40 sentences: 20 who DQ (ten subject and ten object questions) and 20 which NP DQs (ten subject and ten objects questions). Each question was preceded by a declarative sentence describing a situation from everyday life, such as: Pablo is eating apples and Juan is eating oranges. Thus, for a subject position, a who question would be: Who is eating oranges? And a which-NP question would be: Which boy is eating oranges? The sentences were presented auditorily, and possible answers-Pablo, Juanappeared in a written form, on the left and right side of the computer screen, respectively. The participants indicated their responses by pressing the left or right arrow on the keyboard, depending on whether the correct answer was on the left or on the right side of the screen.

Experiment 2 tested comprehension of embedded questions (EQs). There were 80 EQs: 40 who and 40 which $N P$ questions, with 20 subject and 20 object questions within each group. Half of the questions ( $n=40$ ) contained one prepositional phrase (PP) and the other half contained two PPs. EQs were tested in a verification paradigm: participants were required to listen to a sentence, followed by a verification statement, and decide whether the statement was correct or incorrect relative to the sentence. The participants indicated their answers by pressing the left vs. right arrow on the keyboard, depending on whether "Correct" and "Incorrect" appeared on the left or right side of the computer screen.

In Experiment 3, we tested comprehension of relative clauses (RCs). There were 10 subject and 10 object RCs introduced by que. The tested structure was preceded by a simple sentence providing a context. As in Experiments 1 and 2, participants were required to indicate their answers by pressing the left or right keyboard arrow.

Sentence stimuli for each experiment were first randomized in Excel and then recorded in Audacity (http://audacity.sourceforge.net/). Prerecorded sentences were imported in the DMDX (www. http://www.u.arizona.edu/~kforster/dmdx) and presented auditorily over a PC computer and a set of speakerphones.

### 2.4 Procedures

Participants were instructed to respond to a question as fast and as accurately as possible. The next sentence was initiated by the subject's response. The left and right arrow responses for correct answers were counter-balanced across conditions in each experiment. There was a time window of $5,000 \mathrm{msec}$ for answers. If the participant did not respond within that time, the answer options disappeared from the screen, and a fixation cross appeared, indicating that a new auditory stimuli was about to appear. A failure to respond within $5,000 \mathrm{msec}$ was scored as an error. There was a $30-$ second break after every 20 sentences. Feedback showing whether the answers were correct or incorrect was given on

### 2.3 Experimental measures

the computer screen only during the practice trials. There was no feedback during the actual testing.

Each session began with the experimenter describing the study, and the participant reading and signing the informed consent. After that, demographic details were collected and precise instructions on how to execute the experimental tasks were given. This was followed by the participant's taking 8 practice trials. After a satisfactory performance on the practice trials, the participants were tested on the experimental measures. Finally, MoCA and the Month Ordering Test to assess verbal WM (the VWM test henceforth) were administered.

All the materials were administered in the same order to each participant, except for the experimental stimuli, which were administered as two different randomizations, which were introduced to allow controlling for the effects of stimulus ordering. Testing was carried out in a quiet room at Ingema laboratory facilities in San Sebastián. It was conducted individually with each participant and completed in a single session, which lasted approximately 1 hour and 10 minutes. The study was conducted in accordance with the Declaration of Helsinki and was approved by the local Ethics' Committee.

## 3. Results

### 3.1 Evaluative Measures

There were statistically significant differences between the elderly group overall and the young participants on MoCA $(t(25)=4.431, p<0.0005)$ and VWM test $(t(36.5)=2.714$, $p=0.01$ ), indicating better performance of the younger compared to the older participants. Within the group of elderly participants, the NM group outperformed the LM group on both tests - MoCA: $t(19)=5.42, p=0.001$, and VWM: $t(19)=3.792, p=0.001$. There was a significant positive correlation between years of education and MoCA ( $\mathrm{r}=0.597, \mathrm{~N}=39, p<0.01$ ), and between MoCA and VWM scores ( $\mathrm{r}=0.611, \mathrm{~N}=39, p<0.01$ ). There was a significant negative correlation between age and MoCA scores ( $\mathrm{r}=-0.607, \mathrm{~N}=39, p<0.01$ ), and between age and VWM scores ( $\mathrm{r}=-0.495, \mathrm{~N}=39, p<0.001$ ). All tests were two-tailed.

### 3.2 Experimental Measures

Accuracy and RTs of understanding wh-dependencies were analyzed in a mixed-model, repeated-measures analysis of variance (ANOVA), with a between-subject factor comparing groups (LM, NM, Y) and within-subject factors comparing the extraction site in a sentence (subject/object) and the type of wh-word (who/which).
Experiment 1: Direct Questions. The accuracy analyses showed that the main effect of group was significant, i.e., there were statistically significant differences in the participants' overall sentence comprehension between the groups $(F(2,36)=30.421, p=0.001)$. The results of a posthoc Tukey test showed significant differences in
comprehension between the Y group and the LM group ( $p<$ 0.005 ), and between the NM group and the LM group ( $p<$ 0.005 ). In both comparisons, the LM group had lower accuracy. The difference between the Y and the NM groups was not significant ( $p=0.81$ ). The main effect of extraction site (subject/object) was significant $(F(1,36)=4.564, p<$ 0.04 ), reflecting better comprehension of object structures, whereas the main effect of $w h$-word was not significant $(F(1,36)=0.187, p=0.668)$.

The analysis of RTs also showed that the main effects of the group $(F(2,36)=37.844, p<0.001)$ and extraction site were significant $(F(1,36)=4.479, p=0.041)$, and so was the effect of the two-way interaction between the extraction site and group $(F(2,36)=3.593, p=0.038)$. Tukey test showed significant differences between the Y group and the NM group ( $p<0.005$ ), between the Y and LM groups ( $p<$ 0.005 ), and between the NM and the LM groups ( $p<$ 0.001 ), with the LM group reacting slower in both cases.

Experiment 2: Embedded Questions. Comprehension of EQs did not show a significant effect of extraction site (subject/object) $(F(1,36)=3.517, p=0.69)$. However, the main effect of wh-word (who/which) was significant $(F(1,36)=5.623, p=0.023)$, and so was the interaction between the extraction site and type of wh-word $(F(1,36)=$ 5.001, $p=0.032$ ). The type of $w h$-word also interacted with PP $(F(1,36)=5.454, p=0.025)$. There were significant differences in the participants' overall sentence comprehension $(F(2,36)=61.990, p<0.001)$. The results of Tukey test showed significant differences for every pair of groups (LM vs. Y: $p<0.005$; LM vs. NM: $p<0.005$; NM vs. Y: $p<0.001$ ), where the Y group was the most accurate, while the LM group was the least accurate. Since the lowest scores were achieved on tasks in Experiment 2, percent correct responses across all conditions are given in Table 2 as another view into the data.

Table 2: Percent correct responses on Experiment 2.

|  | Who | Who | Who | Who | Whi | Whi | Whi | Whi |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | S1PP | O1PP | S2PP | O2PP | S1PP | 01PP | S2PP | O2PP |
| LM | 60 | 51 | 57 | 58 | 56 | 65 | 55 | 45 |
| NM | 69 | 62 | 87 | 70 | 88 | 83 | 85 | 78 |
| Y | 94 | 93 | 97 | 92 | 98 | 94 | 98 | 94 |

Since questions in all experiments required a choice between two possibilities, $50 \%$ correct represented chance performance on all tasks, and scores between 26-75\% were considered to be within the range of chance. A score of 75\% or better was considered better than chance performance, while a score of $25 \%$ or below was taken to indicate a systematic reversal in the interpretation of a particular construction (there were no such scores in our data).

The analysis of the RT data has shown that the main effects of $w h$-word and extraction site were not significant, but the interaction between these two factors was significant $(F(1,36)=11.263, p=0.002)$. There was a significant effect of PP $(F(1,36)=22.369, p<0.001)$, and it interacted with
the group $(F(2,36)=4.139, p=0.024)$. A three-way interaction between PP, group, and $w h$-word was also significant $(F(2,36)=3.315, p=0.048)$. RTs differed significantly among the groups $(F(2,36)=14.049, p<$ 0.001 ), and the post-hoc Tukey test showed that the Y group was faster than the LM group ( $p=0.001$ ) and the NM group ( $p=0.031$ ). The difference in RTs between the latter two groups was also significant ( $p=0.05$ ).

Thus, the results of Experiment 2 indicate that embedded questions containing additional phrases such as PPs are in general difficult to process for cognitively healthy older adults, in particular to those with mildly affected general cognition and VWM.
Experiment 3: Relative Clauses. There were no significant within-subject effects in participants' comprehension of RCs. Neither the main effect of extraction site was significant $(F(1,36)=1.651, p=0.2)$ nor its interaction with the group $(F(1,36)=0.744, p=0.42)$. There were significant differences in the participants' overall comprehension of RC among the groups $(F(2,36)=9.662$, $p<0.001$ ). The results of Tukey test showed that there were significant differences in the comprehension between the Y and the LM groups ( $p=0.001$ ), and between the NM group and the LM group ( $p=0.024$ ). In both cases the LM group had lower accuracy. RTs differed significantly among the groups $(F(2,36)=26.784, p<0.001)$, and the Tukey test showed significant differences between every pair of groups: the Y group was the fastest, while the LM group was the slowest one.

### 3.3 Summary of results

Overall, lower accuracy and longer reaction times in comprehension of DQs and RCs were found in LM compared to NM participants. Comprehension of EQs was also worse in the LM group compared to the NM group (accuracy), but this was not associated with significant differences in RTs between the two groups. The Y group showed significantly better comprehension accuracy and speed in all tasks. Adding one or two PPs to the whstructures in EQs pushed the comprehension of the LM group to the chance level on all EQs, as well as comprehension of the NM group of 3 out of 4 types of who EQs. Note that adding the PPs only extended the length of sentences, without adding new layers of structure. Thus, extra processing load, even if imposed only linearly and not hierarchically, leads to a difficulty in comprehension of whstructures in healthy elderly adults. This finding supports the notion that excessive processing demands may turn the cueing strategy ineffective.

## 4. Discussion

The fact that the LM group turned out to be significantly older than the NM group may reflect dynamics of language deterioration associated with aging. While the results of evaluative measures showed that age affected both MoCA and VWM scores (the higher the age, the worse the results),
education also affected the scores, with the more years of education being associated with the better scores. However, lack of a statistically significant difference in years of education between the LM and NM groups indicates that the differences in results of cognitive tests between these two groups cannot be explained in terms of a general difference in years of education. Our results generally agree with previous findings on more accuracy errors and longer RTs in syntactic processing in elderly native speakers of English (Obler et al., 1991).

### 4.1 Subject vs. object

An interesting finding of the present study is better comprehension of object than subject who DQs. Given that the distance between the moved wh-word and its trace is longer in object questions (2) than in subject questions (1), we would expect object structures to be more demanding for processing. According to distance-based accounts, the shorter distance between the trace and its gap poses less burden on WM in subject- than in object-wh-questions, which explains the data from English discussed in the Introduction. However, our finding that object DQs were better comprehended than subject DQs is not in line with such accounts.
The idea that processing in structurally different languages reflects the structural differences among languages and that in different languages different types of information may serve as cues in sentence processing is the backbone of the competition model (Bates \& MacWhinney, 1987; MacWhinney, 1987). According to this model, the language processor chooses which information to attend to in determining sentence meaning based on specific characteristics of cues. For instance, the preposition $a$ in Spanish is not a highly available cue, because it appears only with animate direct objects. It is not a highly reliable cue, because it can convey several different meanings. However, it is not costly to process, and despite its weak cue validity, it can guide sentence comprehension: the preposition $a$ has "an extremely high contrast validity... Among normal speakers, in fact, it is the most overriding cue in determining semantic role" (Benedet et al., 1998, p. 332).

Thus, the finding that object DQs were comprehended better than subject DQs reflects a strategy based on syntactic cueing: object DQs in our experiments are introduced by a PP (a qué), beginning with the preposition $a$, which signals the grammatical role of object and the thematic role of Patient. Therefore, it is possible for the processor to rely on $a$ in correctly predicting the grammatical function and temporarily assign a thematic role to the initial constituent in a sentence such as (2) before encountering the gap. Once it encounters the gap, the temporarily assigned thematic role is confirmed or disconfirmed. Our data show that this information was utilized by the LM group in the comprehension of direct object who questions. This strategy reduces the processing demands on WM and facilitates comprehension when WM resources are reduced. However,
if the processing demands are too high, as in examples of EQs extended with additional PPs, the cueing strategy is not effective.
Another indicator that comprehension of EQs in two groups of elderly was at chance due to processing limitations is related to the finding that their comprehension of RCs was accurate. This finding shows that in older Spanish speakers this cuing strategy can be effective in syntactically more difficult conditions (e.g., object RCs and DQs), but it may not be effective when processing load is too high, regardless of syntactic complexity (extended EQs). Since the strategy of reliance on the preposition $a$ is language-specific, it is not available to speakers of English, and therefore the patterns of comprehension of object structures differ in the elderly speakers of these two languages.

### 4.2 Who vs. which

Wh-word-order in Spanish requires that a wh-word occupies a sentence- or clause-initial position, prohibiting preverbal subjects (Jaeggli, 1982; Goodall, 2004). Wh-words in multiple wh-questions, however, can switch between subject and object positions, as shown in (4-7):
(4) ¿Quién compro qué?
"Who bought what?"
(5) ¿Qué compro quién?
"What did who buy?"
(6) Juan sabe qué dijo quién.
"Juan knows what who said."
(7) Juan sabe quién dijo qué.
"Juan knows who said what." (Jaeggli, 1982, p.156).
Since quién and qué can switch their positions in a sentence, it appears that they do not obey the Superiority requirements (Chomsky, 1973; Pesetsky, 1987). This further means that there are no syntactic differences between quién and qué, and thus no syntactic reason to expect differences in their processing.
There are, however, differences between quién and qué at the discourse level: quién "who" is non-referential and non-discourse-linked, while qué "which" is referential and discourse-linked (D-linked). Some researchers argue that this difference affects processing (Hickok \& Avrutin, 1995): D-linked expressions are easier to comprehend, because they refer to a set of objects that is already known to the hearer. By contrast, who/what refers to an unlimited set of objects with which the hearer is not familiar, which makes them more difficult to process. Other researchers, however, pointed out that it is precisely their D-linked nature that makes which expressions more difficult, because they require processing and integration of information at two levels - syntax and discourse (Avrutin, 2000). Our data support the former view, showing the effect of $w h$-word in EQs, i.e., better comprehension of which questions. However, additional processing load of 1 or 2 PPs cancelled out the cuing strategy based on structural sentential features,
which facilitated comprehension of direct object who questions.
In conclusion, the main finding of the present study is a decline in comprehension of $w h$-structures and reliance on cueing as a compensatory mechanism in sentence comprehension in older native-Spanish-speaking adults. This strategy is effective in syntactically demanding conditions, when WM demands are not too high. However, excessive WM load prevents the use of the strategy. Thus, our results agree with previous findings in suggesting that it is not syntax per se, but limitation of WM resources which are necessary for processing that is affected in aging.
Further research needs to address questions pertaining to language-memory interface in older people with lower scores on tests of global cognition, such as MoCA, whose language, although appears to be normal, shows signs of decline when tested more carefully. Studying the compensatory mechanisms and strategies employed in language processing in such individuals may help us to understand better the transition from healthy aging to mild cognitive impairment and the AD continuum.

# Returning the Ticket - Mental Time Travel Reconsidered 

Markus Kneer<br>Institut Jean Nicod<br>kneer@ens.fr

#### Abstract

Mental Time Travel (MTT) is, roughly, an individual's capacity to project herself into the past or future by remembering or imagining first-personal experiences respectively. MTT is further presumed to have a distinct, concrete though dispersed neural correlate, and hence describes a neuro-cognitive phenomenon.

Opening with a brief sketch of the development and current state of the art, the essay pursues three central aims: Firstly, it constitutes a plea for more conceptual rigour on the cognitive side of the fence, so as to ensure that meaningful lessons can be drawn from neurological enquiry about it. Secondly, a partial conceptual qualification of the necessary requirements of MTT as traditionally conceived is proposed, as they seem vague, uninformative and arbitrary. Finally, a revision of MTT is attempted, which aspires to include a variety of mental states so far not associated with MTT. MTT, as it is currently defined and investigated, I will argue, stands too heavily in the genealogical debt of research into episodic memory, and suffers from an astonishing neglect of considerations pertaining to imagination.

## 1. What is Mental Time Travel?

The fact that certain types of imagination activate the same brain zones as episodic memory provoked the hypothesis that there is a single neuro-cognitive system which enables human beings to engage in mental time travel (MTT). Mental time travel is, roughly, an individual's capacity to project herself into the past or future by remembering or imagining first-personal experiences respectively. As a neuro-cognitive phenomenon, MTT is presumed to have a distinct, though dispersed, neural correlate.

Evidence from various disciplines is consistent with the MTT hypothesis. Studies in ontogenetics have confirmed that episodic memory and prospection (mental time travel into the future) emerge in parallel in children aged around three to four. Furthermore, episode specific details decrease with age both for generated past and future events. ${ }^{1}$

Lesion studies show that ventromedial frontal damage leads to loss of episodic memory and prospection, while leaving large parts of the cognitive apparatus in tact. ${ }^{2}$ Moreover, patients with hippocampal amnesia are unable to generate everyday imaginary experiences. ${ }^{3}$

[^309]Neuroimaging draws a similar picture. According to a variety of studies, episodic states about future and past have a common underlying cerebral base: When talking freely about past or future events, PET and fMRI scans revealed shared activity in regions including the ventromedial prefrontal cortex, and parts of the medial temporal lobe. ${ }^{4}$

I'll open with a brief sketch of the leading account of mental time travel. ${ }^{5}$ I will then proceed to argue that this account is misconceived for two fundamental reasons: (1) Its genealogical debt to episodic memory and autonoetic consciousness as well as the shallow conception of imagination in play give rise to an ad hoc and unnecessarily constrained account of episodic states. (2) The necessary capacities for MTT as traditionally conceived are unfounded, their formulation is conceptually vague and uninformative. This will severely obstruct empirical research into the ontogenetic and neurological foundations of the phenomenon.

## 2. Foundations of the Traditional Account

MTT has developed out of the psychological study of memory, and in particular Tulving's (1972) landmark distinction between semantic and episodic memory. The former takes propositional form since it is factual. I

[^310]can e.g. recall that Paris is the capital of France. Episodic memory, by contrast, refers to an individual's engaging in an episode of past personal experience, e.g. when I remember what my first arrival in Paris was like. It is characteristically accompanied by a particular feeling of "warmth and intimacy" (W. James, 1890), in other words it is phenomenologically rich. Later on, autonoetic - "self-knowing" - consciousness became the distinguishing mark of episodic memory. Tulving, who coined the term "autonoetic consciousness", defines it as "the kind of consciousness that mediates an individual's awareness of his or her existence and identity in subjective time extending from the personal past through the present to the personal future" (1985: 1). In response to neuropsychological findings, the restriction of episodic states soon dropped away; episodic states were henceforth considered to encompass mental time travel both into the past and future.

My first criticism concerns the scope of the leading account: MTT is restricted to episodic states exclusively concerned with an individual's personal past, present and future. Employing a detailed typology of imaginative states I will draw up a rival account which construes the phenomenon in question more broadly. I will argue from the following two hypotheses:

## Common Kind Hypothesis:

There exists a basic mental state, called "episodic state", in which we undergo phenomenologically rich experiences from a first person perspective. Such states are "quasi-perceptual" in so far as they resemble perceptions, and draw heavily on past perceptual and proprioceptive intake, but are not direct representations of reality. Episodic states comprise of episodic memory - quasiperceptions of the past, and participatory imagination - quasi-perceptions of hypothetical and potentially future episodes.

## Common Capacity Hypothesis:

Episodic states supervene on a single type of brain state; they can be characterized by a differentiated neuronal correlate and are the product of a particular neurosystem of the brain.

## 3. Problems of Scope and a Rival Account

MTT, as it is traditionally conceived, is construed unnecessarily narrow, since it insists on (i) a clearly defined temporal component, which (ii) involves an explicit awareness of a narrative self and concerns (iii) episodes which are explicitly personal/autobiographical - in the sense that the subject involved must be the thinker's empirical self, and the scenarios must be true past or probable future experiences. Both constraints can be directly derived from Tulving's characterization of MTT taking place in "subjective time extending from the personal past through the present to the personal future" and countless other passages. They are equally present in Suddendorf \& Corballis $(1997,2007)$.

The main reason for the narrow construction of MTT seems to lie in the genealogy of the term, coming from episodic memory and hence focusing heavily both on a temporal component and some sort of autobiographical element. Autonoetic awareness as the central property of episodic states has further helped to foster such a questionable conception. The problem extends into the experimental paradigms: Not only is rather few research done on future MTT (i.e. the imagination component as narrowly conceived), but furthermore hardly any experiments included imagination not structured autobiographically or temporally in the relevant way.

Mental voyage, as I propose it, explicitly includes three types of episodic imagination which are not encompassed in MTT: (i) Episodes about what would have happened to myself if I had acted differently in the past. (ii) Imaginations involving my empirical self in scenarios which do not have a temporal specification whatsoever. (iii) Imaginations not involving my empirical self, but another self, or a general self - i.e. episodes concerning what it is like for Jack to win an Oscar, or for someone to win the lottery respectively. ${ }^{6}$

[^311]
## 4. Central Capacities for MTT

## Methodological Considerations

Mental time travel is generally conceived as a neuro-cognitive or brain/mind system ${ }^{7}$, that is, as a mental capacity which has a real, singular, though dispersed neural correlate. Crucially, the description of its functions and properties take place in two conceptual spaces: an abstract vocabulary pertaining to mind as elaborated in psychology and philosophy and the vocabulary referring to concrete phenomena of the brain as employed by neuroscience. The mental vocabulary is dominant due to our still very limited understanding of the brain. Hypotheses concerning the functioning of the brain as well as experiential paradigms are largely formulated in mental terms, which gives rise to a variety of complications: (i) The conceptions of the mind and its capacities are manifold, so a choice has to be taken which (ii) is likely to leave its mark on the formulation of the respective hypothesis, experiments, and hence the empirical "findings". (iii) A neuro-cognitive hybrid vocabulary facilitates conceptual confusion if (for instance) a brain phenomenon is "associated" with a mental phenomenon which gives rise to different interpretations in distinct conceptual frameworks of the mind.

Given the complications arising from two distinct types of interacting vocabularies, empirical underdetermination, and the sensitivity of the subtraction method in hemodynamic techniques (PET and fMRI), two things should be clear: Adequate enquiry into such neuro-cognitive phenomena can only succeed if its constituents are (i) conceived of in minimal, rather than complex units and (ii) defined as rigorously as possible on the cognitive side so as not to obstruct and confuse enquiry on the neurological side. The literature on MTT does not adhere to these criteria. The central capacities of MTT are both theoretically ad hoc and so ill defined that while scholars take themselves to be in conceptual agreement they frequently operate with - and do empirical research based on - radically different concepts. We will now turn both to the misspecification of

[^312]the central capacities of MTT and the latent conceptual anarchy.

## Autonoetic Consciousness

The central criterion of episodic memory and states of mental time travel more generally, is autonoetic awareness (Wheeler, Stuss \& Tulving, 1997; Tulving 2002; Suddendorf \& Corballis 1997, 2007). Though a relatively recent, and entirely technical concept, astonishingly there are four conceptions of autonoetic consciousness which stand in rivalry.

Autonoetic consciousness understood as the distinguishing mark of mental states which have a particular "feel" to them is roughly equivalent with Block's (1995) "phenomenal consciousness". Autonoetic awareness in this sense is usually cashed out by reference to the feeling of "warmth and intimacy" (W. James, 1890), or the "subjectivity" of such states in comparison to, for example, "objective" semantic memory. A second account puts the stress on (narrative) selfawareness, reasonably enough, since autonetic consciousness has frequently been characterized as "self-knowing" consciousness (Tulving, 1985), and it is due to autonoesis that an individual is supposedly able to project his self into the past and future. A third account focuses on the kind of (phenomenal) feature which allows us to distinguish, for instance, an episodic memory from an imagination or a daydream. Episodic states seem to come pack and parcel with a certain phenomenological feature pertaining to time, which allows us not to confound past, present and future episodic states; in the case of memory we witness, for instance, a "feeling of pastness". Finally, there are various hybrid accounts which include some or all of the mentioned features. Unsurprisingly, with autonoesis - "the hallmark of episodic memory" (Tulving) being such a promiscuous concept, the episodic/semantic memory distinction is also drawn in all sorts of ways.

The three mentioned aspects, phenomenality, narrative self-awareness, and subjective temporal indexing are neither inconsistent nor necessarily unrelated, but nonetheless distinct. Problematically, however, different authors seem to work with different
definitions. ${ }^{8}$ There is, furthermore, no apparent reason for lumping them together especially inexplicitly, and in varying constellations. In fact, it seems favourable to keep them separate so as to curb the spreading conceptual confusion, and in particular so as to control - as far as possible - separately for each in experiments.

## Consciousness

How best to reorganize what is left of autonoetic consciousness? Block (1995) distinguishes four concepts of consciousness: Self-consciousness constitutes the possession and competent mastery of the concept of the self; monitoring consciousness is the metacognitive process of one's realizing to be in a certain state (e.g. to know that one believes X). Access-consciousness is the property of a representation which "is broadcast for free use in reasoning and for direct "rational" control of action (including reporting)". Finally, and for our purposes probably most importantly, there is phenomenal consciousness, which is notoriously hard to define. Under phenomenal consciousness we understand the experiential properties of a conscious state, or what it "is like" to be in that state. ${ }^{9}$ Block highlights that phenomenal and access consciousness are conceptually distinct, though admits that they might contingently always appear in parallel in human subjects.

My proposal is to abolish the concept of autonoetic awareness since it is vague and unnecessarily lumps together all sorts of phenomena which are best kept separate. Phenomenal consciousness (or phenomenality) is most salient in perceptual experiences, however it also characterizes episodes of remembering and sensory imagination, though the phenomenal properties are not as pronounced. It is probably phenomenality, intimately related to the first-person perspective, which determines the distinctions between episodic

[^313]and semantic memory and between sensory and propositional imagination in the first place.

## Subjective Time

As mentioned before, time (like colour or smell, for instance) also seems phenomenologically salient, in particular, duration ("an instant seeming an eternity") and the subjective temporal location ("it being early"; "something being a long time ago"). It is a feature of episodic states that they frequently present themselves as a particular episodic state (e.g. memories through an attached feeling of "pastness"). However, as pointed out above, various types of participatory imagination do not have an explicit temporal component, and are hence not located in what Tulving calls "subjective time" (Tulving, 2002, 2005; a feature reproduced in virtually all articles on MTT). Furthermore, though there frequently seems a phenomenally salient indicator present in episodic states, it can easily be wrong (as for example in implanted or false memory, possibly in states of déjà-vu experiences if one wants to count them amongst episodic states). ${ }^{10}$

In short, the temporal component should be abolished, as there is reason to include episodic states without them into the common kind; the fact that temporal features do not form part of memory traces (Friedman, 1993) leaves us with the perfectly viable option of their being "attributed" by an extra capacity, if at all.

## Involvement of the Self

Self-awareness to a rather high extent is considered a fundamental prerequisite of MTT by all leading accounts. ${ }^{11}$ For Tulving

[^314]and colleagues, the relevant degree of selfawareness required for MTT corresponds to Stuss \& Benson's (1986) third functional level of the frontal lobes ${ }^{12}$. The latter provides "the ability to introspect on one's own thoughts and to realize the relation of self to one's social environment" (1997:334), and is further deemed "intimately related" to autonoetic consciousness.

Mitchell's (1994) threefold account of the self is employed by Suddendorf \& Corballis with questionable success to illuminate the role of the self in MTT. In Mitchell's framework, the second type of self - a "self as built on kinaesthetic-visual matching" allows us to engage in pretense, planning, imaginative experience and fantasy. Suddendorf \& Corballis deem this insufficient for MTT, which apparently calls for a self "built on symbols, language and artefacts" so as to allow the individual to understand social norms, and to dissociate self and other. It rests obscure, however, how pretense, imagination and fantasy (i.e. second-level activities) are possible without the capacity to dissociate from one's present states (only available on the third level) and hence whether Mitchell's account is not rather ad hoc. ${ }^{13}$

Ignoring the specificities of the two proposed accounts of the self, let us note that they both share two essential features: Firstly, they require the mastery and competent application of an explicit concept of the self, and secondly, they pertain to what is frequently called a "narrative" account of the self.

The narrative self contrasts with the "minimal" self, i.e. immediate awareness of oneself as the subject of experience. A minimal self is conceived to be little more than "a bare locus of consciousness, void of personality" (G. Strawson, 1999: 493), aspects of continuity over time are neither included in the definition nor deemed necessary. By contrast, an

[^315]adequate account of the latter - i.e. of how to explain an awareness of oneself from past to present and future, both in terms of one's individual experience and testimony of others' - is the centrepiece of "narrative" conceptions of the self (cf. Gallagher, 2000 for a recent review). Both minimal and narrative self demand the competent mastery of a selfconcept. However, even simpler conceptions are thinkable, amounting to no more than a point of consciousness to which action and experience is relativized.

## The Self Reconsidered

Though self-awareness in the general sense is undoubtedly an important aspect of MTT, it is difficult to say something insightful about it. Coherent ad hoc stories about the involvement of a narrative self in MTT can be told to abundance within the framework of our mental vocabulary; however, it rests entirely in the dark of what should constitute (and how to test for) the involvement of narrative self-consciousness on the level of the brain. ${ }^{14}$

Rather than working with the proposed, extremely complex notions of self-awareness as necessary capacities for MTT, it seems preferable to focus on minimal, separable ingredients. Episodic thought is not fundamentally characterised by its relation to the subject's self, but rather by being a particular mode of thought - it is essentially first-personal, but not essentially autobiographical as often presumed. Furthermore, episodic thought is susceptible to a certain measure of control: I can bring out more vividly, or shift attention to, different aspects of a past event; in imagination the freedom of control is even more pronounced.

On top of narrativity, we might be inclined to question mastery of a self-concept as a necessary requirement of MTT. Perry (1998) for instance, contrasts agent-relative knowledge with self-attached knowledge. The former takes place "from the perspective of a particular agent who does not need to have an idea of self, or a notion of himself' (BBB) but who is nonetheless capable of placing

[^316]himself within his environment. One way to make this process explicit are utterance involving demonstratives, e.g. when he thinks/says "There is an apple". In selfattached knowledge, by contrast, the agent disposes of a self-notion and expresses his knowledge by means of the (pure) indexical "l", e.g. "I see an apple". Both involve the firstperson perspective, essential for episodic states, but only the latter type of subject can make this explicit to herself.

Interestingly, the first kind of knowledge, and the very basic type of self involved would satisfy a variety of episodic states: If I engage in a phenomenally rich first-person episode with the content "There was an apple", or follow the instruction "Imagine an apple", I do not necessarily need the first-person indexical; an appropriately imagined content of the kind "There is a juicy red apple" fulfils the demand no less than "I see a juicy red apple in front of the eye of my mind". However, whenever the person who remembers or imagines is to take himself as the object of his episodic state, he or she is required to have an explicit notion of himself, otherwise he couldn't attribute any experiences or properties to himself. What this confirms, once again, is that the capacity to engage in episodic states is - at least in principle - independent of the capacity to engage in autobiographical episodic states (though due to the contingent set-up of the brain this might not actually be so).

A variety of insights follow from this: Firstly, we have another argument why autonoesis i.e. "self-knowing consciousness" - might not be a fundamental requirement of MTT in so far as there exists a kind of basic episodic state which does not depend on the mental time traveller having even a very basic notion of himself. Secondly, and relatedly, the firstperson perspective might be entirely severed form any type of complex narrative self in so far as there is a variety of possibilities to "fill" it: Apart from one's own self, it could be another's or a general self. Thirdly, it might be hypothesized that MTT is intimately related to the mastery of demonstratives (and as concerns autobiographical episodic states, also indexicals) and temporal concepts, or their respective non-conceptual counterparts. So an important open question is to what
extend the non-conceptual and pre-linguistic resources (e.g. of small children) suffice for MTT. ${ }^{15}$

In short, there is no need to presume MTT in the need of an awareness of a complex narrative self, whose involvement will most likely prove impossible (or very difficult) to test for. Furthermore, it is not clear why complex introspective abilities, metarepresentation and awareness of one's social environment etc. should be necessary for basic episodic thought. As has been argued, the only true requirements for basic MTT are the involvement of the first-person perspective and a given measure of control of the episodic content. Non-autobiographical episodic states (There was an elephant or This will be wet and cold etc.) might not even demand an explicit notion of the self. Finally, at least in so far as mental voyage is concerned, it will be extremely misleading to stress the requirement of (narrative) selfawareness, both in so far as certain types of participatory imagination are neither relativized to "subjective time" (i.e. are not locatable within a subject's personal narrative) or to the subject's own self at all. They might simply be about what it would be like to win the Nobel Prize or how it would feel to have one's neighbour's problems. Rather than operating with various ad-hoc accounts of the narrative self, it seems advisable to take the first-personal mode and control (or sense of agency) as the basic requirements for MTT, and to devise abilities allowing us to judge to what extent an explicit notion of the self, and conceptual abilities are required as well.

# The time-course of processing discourse connectives 

Judith Köhne (judith.koehne@uni-bamberg.de)<br>Otto-Friedrich-Universität Bamberg<br>Markusplatz 3, 96045 Bamberg

Vera Demberg (vera@coli.uni-saarland.de)<br>Cluster of Excellence, Saarland University,<br>Campus C7.4, 66123 Saarbrücken, Germany

#### Abstract

While there is some evidence that causal discourse relations are processed incrementally, the time-course of comprehending concessive discourse markers (e.g., nevertheless) has hardly been investigated. Given that concessives are often defined as negative causals, there may be similarities between the processing of concessives and negations (e.g., a delay). This paper investigates the time-course of processing causal versus concessive discourse markers in German within both a visual-world experiment and a reading experiment. We find that while concessive discourse markers can be processed rapidly if the context is constraining enough, there is a delay compared to causal contexts.

Keywords: Discourse connectives; prediction; concessives; incrementality; eye-tracking; visual world

## Processing Discourse Relations

A large number of experiments reveals that language comprehension is generally incremental and even predictive (Marslen-Wilson, 1973; Tanenhaus \& Trueswell, 1995). However, there is also evidence that incoming information across the sentence level does not always immediately update local predictions and affect global interpretation (Sanford \& Garrod, 1998). It is therefore an interesting question which information from the discourse the comprehender considers, and how strongly and fast it affects comprehension and active predictions. One way to investigate this issue is to focus on the time-course of discourse connectors. Experimental evidence suggests that discourse connectors such as because, therefore, and however facilitate coherence building and hence comprehension: Millis \& Just (1994) found that when sentences were connected by discourse markers (because and although), people were able to more successfully answer comprehension questions and to more quickly read the second sentence.

We however know much less about the time-course of processing discourse connectors. While some have argued that people only integrate them at the end of a sentence (Millis \& Just, 1994), other experiments indicate that this integration happens much earlier (Traxler et al., 1997).

The experiments described in this paper examine the timecourse of integrating causal connectors (e.g., therefore) versus concessive connectors (e.g., however). These are particularly interesting to compare, because concessives have sometimes be referred to as "negative causals" (König \& Siemund, 2000). That means that the processing of concessives (compared to causals) may resemble the processing negation. In
particular, our experiments aim to answer the following questions:

- Are causal and concessive connectives processed incrementally (possibly eliciting predictions), or with a delay?
- Do concessives elicit an active search for alternatives (as has been shown for negation, Kaup et al., 2006)?
- Regarding global interpretation, are concessive discourse relations integrated as smoothly as causal discourse relations or do they cause processing difficulties (resembling negation; Carpenter \& Just, 1975; Kaup et al., 2006)?

## Background

## The Time-Course of Processing Connectors

Few studies have investigated the time-course of processing causals and concessives. In short discourses of two clauses, Millis \& Just (1994) observed longer wrap-up times at the end of the second clause when a (causal or concessive) discourse connector was present, as compared to the same sentences without a discourse connector. Millis and Just hypothesized that a representation of the second clause was constructed without taking into account the first clause, and only later integrated with the first clause.

Millis and Just's "Connective Integration Model" of late integration of discourse connectors and earlier parts of the discourse was however refuted, at least for causal connectors. Traxler, Bybee, \& Pickering (1997), for instance, found evidence for an early integration of because and the preceding discourse: When comparing processing of causal and diagnostic sentences, the greater difficulty in diagnostics occurred well before the end of the second clause. This indicates that processing of the second clause was affected early on by its relation to the preceding context. Further evidence for incremental processing of causal discourse relations comes from an ERP study without explicit connectives: Kuperberg et al. (2011) found that causally-related sentences were easier to process than sentences which were not standing in a causal relationship, revealing that causal coherence can influence the earliest stages of semantically processing incoming words.

These findings bring up a number of questions with respect to the exact time-course of processing connectives. Specifically, it is an open question in how far, and how quickly, people generate predictions taking into account discourse connectives, and how concessive connectives might differ from causals in this respect.

An interesting theory regarding predictions elicited by causal and concessive connectors comes from Murray (1995): In a series of studies, he found a greater beneficiary effect of the presence of contrastive and concessive (i.e., adversative) discourse connectors as opposed to causal and additive connectors. Murray concludes that adversative connectives create stronger expectations for the upcoming sentence than causal or additive connectors (Murray, 1995, p. 120). Murray does however not control for the ambiguity of discourse connectors, which means that his hypotheses may be taken with a grain of salt. Moreover, his findings could alternatively be accounted for by a causality-by-default account (Kuperberg et al., 2011; Sanders, 2005): The cause for the low facilitation for causal connectors may be that similar expectations are generated in the absence of any connector.

## Concessives as Negative Causals

To date, there is very little research on the time-course of processing concessives. An early study by Townsend (1983) reveals that concessives are processed more slowly than causals and that recall is worse for concessives than for causals. These findings may suggest an interesting relationship between causals and concessives. In fact, concessives are sometimes referred to as "negative causals" (König \& Siemund, 2000). Experimental studies support that causals and concessives establish the same type of relation, but are different in polarity (Louwerse, 2001; Sanders et al., 1992).

A delay of processing concessives on the one hand and defining concessives as negative causals on the other hand seems to be in line with a frequently supported theory of negation processing: Many experiments point to an account where there is a general delay in processing negation (e.g., Carpenter \& Just, 1975).

Kaup et al. (2006), for instance, found in a self-paced reading study combined with a picture naming task that when processing contradictory predicates (e.g., The door is not open / closed), ,
people are first mentally simulating the positive state (open door) and only later the positive state is negated. That means people only later searched for alternatives and mentally closed the door (see also Lüdtke et al., 2008). Ferguson et al. (2008) examined the time-course of processing negation in discourse using eye-tracking in reading and ERP. Interestingly, they also found that counterfactual negated discourse information was not used incrementally but had a delayed effect on comprehension.

Other studies, on the contrary, reveal that a delay can be attenuated or completely removed when the negation is expected or pragmatically licensed (Nieuwland \& Kuperberg, 2008; Dale \& Duran, 2011). Staab (2007), for instance, found in a series of ERP studies that negation in discourse context was processed fast. More than that, if readers were forced to process slowly and deeply, negation was even used as a cue to rapidly anticipate how the sentence continues. These very different results suggest that the time-course of processing negation may be influenced by a number of factors such
as the kind of negated information and the discourse context. It is an interesting question how processing negative causals may enrich this picture.

## Experiment 1: Visual World Study

## Methods

Participants We tested 36 participants, 4 of which had to be excluded due to eye-tracking problems. Data of 32 participants ( 8 male, average age 26) was analyzed.
Design, Materials \& Procedure We constructed 20 items, each consisting of three spoken sentences in German, and a static scene (see Example (1) and Figure 1).

Marc denkt über einen kleinen [Snack nach. Er hat gerade Lust, etwas $]_{\text {topic }}[$ Süßes / Salziges zu essen] category . [Daher / Dennoch holt er sich] ${ }_{\text {connector }}$ [aus der Küche] ${ }_{\text {extended }}$ [die appetitliche / den appetitlichen] ${ }_{\text {pretarget }}$ [Waffel / Kuchen / Brezel / Käse] ${ }_{\text {target }}$.
Marc fancies a [snack. He feels like having something $_{\text {topic }}[\text { sweet }]_{\text {category. }} \quad[$ Therefore / Nevertheless, he gets] $]_{\text {connector }}$ [from the kitchen] $]_{\text {extended }}$ $\left[\text { the }{ }_{[f e m] /[\text { masc }]} \text { delicious }{ }_{[\text {fem }] /[\text { masc }]}\right]_{\text {pretarget }}$ [waffle / cake / pretzel / cheese $]_{\text {target }}$.

Figure 1: Stimulus for visual world experiment.
The first sentence introduces a situation or topic, such as food in Marc denkt über einen Snack nach. ("Marc fancies a Snack"). The second sentence always identifies a category (e.g., sweet things), matching two of the depicted objects (waffle and cake). Two other objects in the scene belong to another category (the counter category, salty things: cheese and pretzel). The third sentence begins either with a causal (Daher/Dennoch) or a concessive (Deswegen/Trotzdem) connector (2-level within-participant factor), followed by subject and verb (holt er sich, "he gets"; connector region). This region precedes another phrase (aus der Küche, "from the kitchen"; extended connector region), the gender-marked pretarget noun region (e.g., die appetitliche), and the target noun (causal: Waffel, concessive: Brezel). Target nouns are always congruent with the preceding discourse. Visuals worlds include the four objects belonging to the category and the counter category and two distractor objects (here, cup and wire whisk), embedded in a simple scene (here, kitchen ).

Category given in Sentence 2, gender of target noun, and condition (i.e., causal/concessive) were fully counterbalanced, resulting in 8 lists. Every participant was assigned to one of the lists and saw each of the 20 items in one version only. 40 filler discourse-scene pairs were included, following the same general pattern but using a range of discourse relations and markers (e.g., später, "later"), making the target noun unpredictable. All items and half of the fillers were followed by a comprehension question about the target noun but referring to it by its category rather than its name (Holt Marc sich etwas Süßes?, "Does Marc get something sweet?"), which participants answered by button press (YES/NO). Half of the questions' correct answer was "yes", the other half "no". Order of presentation was pseudo-randomized with at least one filler in between two items. Participants were tested individually and their eye-movements were tracked. Their task was to look and listen carefully enough to reply to the comprehension questions. The experiment lasted about 30 minutes.
Predictions When the category (e.g., sweet) is mentioned, fast and incremental processing predicts participants to look more often at the two objects matching this category (waffle and cake) in both conditions.

For the third sentence, predictions for causal and concessive sentences differ: In the causal condition, people are predicted to keep looking at the category objects until the casemarked pretarget region. During the pretarget region then, fast and incremental processing predicts more looks towards the gender-congruent object, and finally, when the target is mentioned, more looks to the target. In the concessive condition, however, hypothesizing that the concessive connector is processed eagerly and incrementally predicts participants to change from looking to the category objects to looking to the two counter-category (salty) objects (pretzel and cheese), as soon as the scope of the concessive connector is clear.

In particular, the scope could be inferred and a search for alternatives could be initiated after the subject and verb following the connector (connector region). The hypothesis that the concessive connector is processed fast and incrementally, also predicts participants to start looking more frequently at the final target object during the gender-marked pretarget region. A late integration account, or a simple lexical priming account would not predict this pattern but that participants keep looking at the category objects (sweet things) until they hear the target word.

## Data Analyses \& Results

For eye-movement analyses, we compared inspections to the four areas of interest (AOIs): target (e.g., waffle), category competitor (sharing category with target, e.g., cake), gender competitor (sharing gender with target, e.g. pretzel), and unrelated competitor (sharing neither category nor gender with target, e.g., cheese). Four time regions were of interest: category region, connector region, extended connector region, and pretarget region. Eye-movements were analyzed using logistic regressions, entering the data into linear mixed effect
models with logit-link function (from the lme4 package in R; Bates, 2005). AOI and Condition (causal/concessive) were used as a Fixed Factors and Participant and Item as random factors. Main effects were tested based on model comparison using a $\chi$ test (Baayen et al., 2008). Random slopes for Participant and Item were evaluated based on model comparison as well and included when they improved the model fit. For contrasts between levels (AOIs), we report Wald-z values and p-values as well as coefficients ( $\beta$ ) and standard errors (SE).

Analyses reveal that in the category region, participants inspected the two objects matching this category (causal: target + category competitor; concessive: gender competitor + unrelated competitor) significantly more frequently than the counter-category objects, independent of condition (effect AOI: $\chi(1)=49.26, p<.001$; no effect condition: $\chi(1)=1.99$, $p=.16$; no interaction: $\chi(1)=1.88, p=.17)$. In the connector region, there was an effect of AOI $(\chi(1)=7.78, p<.01)$, no effect of condition $(\chi(1)=0.26, p=.61)$, but, importantly, an interaction $(\chi(1)=4.17, p<.05)$ : In the causal condition, the category objects were still looked at significantly more often than the counter-category objects $(\chi(1)=$ $11.38, p<.001$ ); in the concessive condition, however, participants inspected the two counter-category objects just as much as the category objects $(\chi(1)=0.30, p=.58)$. As illustrated in Figure 2, this is due to them first looking more at the category objects, but gradually starting to look more at the counter category objects, as the scope of the concessive becomes clear. In the extended connector region then, we find significantly more looks to the objects of the countercategory objects in the concessive condition $(\chi(1)=15.19$, $p<.001$ ) as well as still significantly more looks to the category objects in the causal condition $(\chi(1)=18.64, p<.001)$. That means that looking at the target category (i.e., category in causal and counter-category in concessives) was independent of condition in this region (effect of AOI: $\chi(1)=33.65$, $p<.001$, no effect of condition: $\chi(1)=0.76, p=.38$, and no interaction: $\chi(1)=0.11, p=.74)$. This reveals that the concessive marker was immediately interpreted, and that people engaged in an active search for alternatives. In the pretarget region (when shifted 200 ms$)^{1}$, the target was looked at more frequently than all other objects in both conditions (effect AOI: $\chi(3)=20.42, p<.001$, no effect condition: $\chi(1)$ $=0.01, p=.92$, no interaction: $\chi(3)=0.87, p=.87$; effect AOI causal: $\chi(1)=63.16, p<.001$; effect AOI concessive: $\chi(3)=12.62, p<.01)$. In the causal condition, the differences to gender competitor ( $\beta=-1.11, S E=0.19, z=-5.92$, $p<.001$ ) and unrelated competitor ( $\beta=-1.26, S E=0.19$, $z=-6.53, p<.001$ ) are significant and the difference between target and category competitor is marginally significant ( $\beta=-0.32, S E=0.17, z=-1.87, p=.06$ ).

In the concessive condition, the difference between target and category competitor, on the contrary, fails to reach signif-

[^318]icance $(\beta=-0.20, S E=0.17, z=-1.18, p=.24)$, whereas the target was looked at significantly more often than gender competitor $(\beta=-10.89, S E=0.18, z=-4.88, p<.001)$ and unrelated competitor $(\beta=-1.07, S E=0.19, z=-5.65$, $p<$.001).

Accuracies and Reaction Times for comprehension questions were analyzed the same way as eye-movements, except that we used linear regressions rather than logistic regressions for response times. While response times did not differ across conditions ( $\chi(1)=0.44, p=.51$ ), accuracy was significantly lower in the concessive condition (78\%) than in the causal condition ( $84 \% ; \chi(5)=11.17, p<.05$ ). More detailed analyses reveal that this difference was driven by the lower answer accuracy for those questions in the concessive condition in for which the correct answer was "yes".

Figure 2: Results for causal (top) and concessive (bottom) conditions.

## Discussion

These results clearly reveal that both causal and concessive discourse markers were integrated rapidly into on-line comprehension and that processing the concessive led to a search for alternatives.

In the causal condition, processing was rapid and stable enough to combine with grammar information to predictively identify the target referent. In the concessive condition, there is a similar tendency but it did not reach significance. This
may mean that processing concessives is more difficult and does not allow people to rapidly take gender marking into account. The result that looks to the target category exceed looks to the other objects later in the concessive condition than the causal condition may reflect slower processing in the concessive condition. However, since, in the causal condition, the objects belonging to the target category were already looked at most before the connector region, the finding cannot be clearly interpreted.

The finding that accuracy of question answering was worse in the concessive than the causal condition (when the correct answer was "yes') might suggest that processing in the concessive condition was shallower, causing a late cognitive burden for global interpretation. An alternative possibility is that suppressing the category directly mentioned in the second sentence (e.g., sweet) in combination with having to categorize the target (e.g., pretzel - salty) might be difficult (as in sweet... however.. pretzel - ... something salty?)

Experiment 2 evaluates whether our finding that discourse markers can be integrated rapidly, shaping predictions about upcoming words, can be replicated in a reading experiment.

## Experiment 2: Reading Study

## Methods

Participants We tested 30 participants, 6 of which had to be excluded due to eye-tracking problems. Data of 24 participants ( 5 male, average age 24) was analyzed.

Design, Materials \& Procedure Items for Experiment 2 consist of 24 three-sentences discourses, following a similar logic as the ones of Experiment 1. However, rather than reducing the set of possible predictions by providing a picture, a more strongly constraining first sentence introducing two scenarios is employed. The second sentence makes one of these two options more salient. The third sentence begins with either a causal or a concessive marker, followed by a region which determines the focus of the concessive, a pretarget region which contains case-marking, and the target noun region (see Example 2). The target noun is not used in the preceding context. Half of the sentences are congruent (e.g., head and ears cold - therefore - hat), and half incongruent (e.g., neck cold - however - scarf), resulting in a 2(causal/concessive) $\times 2$ (congruent/incongruent) withinparticipant design. All sentences are grammatically correct.

Lotte braucht für den Winter noch Kleidungsstücke um Kopf und Hals zu wärmen. An Kopf und Ohren friert sie besonders. Daher / Dennoch guckt sie als allererstes nach [einer schön warmen / einem schön warmen] pretarget [Mütze/Schal, die/der nicht zu bunt aussieht $]_{\text {target }}$.
Lotte needs clothes to keep her head and neck warm for the winter. Her head and ears feel particularly cold. Therefore / However, she first of all looks for [a nicely warm] gender-marked pretarget [hat / scarf that does not look too colorful $]_{\text {target }}$.

The 24 items were intermixed with 48 filler discourses, which followed the same pattern as the items but using a range of non-causal/concessive discourse markers (e.g., later, in particular). All items and half of the fillers were followed by yes/no-comprehension questions, asking about the target noun without referring to it by name (Schaut Lotte als erstes nach einem Kleidungsstück für den Kopf?, "Does Lotte first of all look for clothing for the head?"), answerable by button press. Half of the questions' correct answer was "yes", the other half's "no". We created 8 lists, according to the numbers of versions per item: 2(salience second sentence) $\times 2$ (causal/concessive) $\times 2$ (match/mismatch). Participants saw only one version of each item.

Discourses were presented on the center of the screen, divided into two parts: The first screen showed the first and second sentence and the second screen contained the target sentence. The question, if present, followed the discourse on a third screen. Reading was self-paced, controlled by button press. The order of presentation was pseudo-randomized with at least one filler in between two items. Participants were tested individually and their eyes were tracked. They were asked to read carefully to be able to correctly answer comprehension questions. The experiment lasted approximately 30 minutes.

Predictions Given our results from the first experiment, we hypothesized that people would be able to eagerly integrate discourse context and the the discourse connector to predict the target noun. This predicts a mismatch effect (as expressed in longer reading times: first pass durations, regressions, and total reading time) in the pretarget region when the grammatical gender of determiner and adjective does not match the grammatical gender of the predicted target noun. This mismatch effect is moreover predicted to continue in the target region.

## Data Analyses, Results \& Discussion

First pass durations, regression durations, and total reading times in the pretarget (determiner and adjective) and target (noun and final phrase) region were analyzed using linear regressions (see Experiment 1). Trials with track loss in more than one of all regions (Sentence 1, Sentence 2, discourse maker region, pretarget region, target region, question) and with reading times smaller than 50 ms were excluded from analyses.

For the causal condition, we found a consistent tendency for people to read more slowly in mismatching than matching sentences in both the pretarget and the target regions in all measures; none of these trends, however, reached significance. In the concessive condition, similar but weaker tendencies were found, but only for first pass reading times. While this could mean that discourse information cannot be integrated fast enough to give rise to prediction neither in causals nor in concessives, we considered the possibility that some of our items were not clear or constraining enough to enable readers to anticipate the target noun.

To still get an idea about the indicated difference between causal and non-causal contexts (i.e., using the causal condition as a baseline), we excluded those items for which no mismatch effect was observable in total reading times in the causal condition in the target region (i.e., when reading times were not higher for mismatches than matches, not even any time after the target noun was encountered). Based on the remaining 19 items, we found significantly longer reading times for mismatches in the pretarget region of causal sentences for all measurements (first pass $\chi(1)=5.38, p<.05$; total time: $\chi(1)=7.27, p<.01$; regression: $\chi(1)=4.99, p<$ .05).

However, even for these 19 predictable discourses, when the discourse relation was concessive, there was only a marginal effect of mismatch for first pass durations in the pretarget region $(\chi(1)=3.43, p=.06)$ but no further effects for the pretarget region (total time: $\chi(1)=.02, p=.89$; regression: $\chi(1)=0.07, p=.80$ ) and not even in the target region (first pass $\chi(1)=1.12, p=.29$; total time: $\chi(1)=0.02, p=$ .88; regression: $\chi(1)=0.15, p=.70)$.

For comprehension-question accuracy, there was no effect of condition (causal: $80 \%$, concessive: $82 \% ; \chi(1)=$ $1.40, p=.24)$, a marginal effect of mismatch $(\chi(1)=$ 3.57, $p=.06$ ) and a significant interaction $(\chi(1)=4.01, p<$ .05): Accuracy was significantly higher for match than mismatch only for causals $(\chi(1)=5.81, p<.05)$ but not for concessives $(\chi(1)=1.17, p=.68)$. For Reaction Times, there was no effect of match $(\chi(1)=0, p=1)$ nor condition $(\chi(1)=0, p=1)$, and no interaction $(\chi(1)=0.38, p=.54)$.

Experiment 2 therefore indicates that, given that the discourse is really clear and constraining, in causally related sentences, readers are generally able to make predictions based on quickly integrating discourse context. In other words, if the target noun was predictable, then it was predicted rapidly (i.e., in the pretarget region). Global interpretation, as well, was influenced by the congruency of the discourse, as indicated by results from question answering accuracy. For concessives, on the contrary, there is no consistent evidence, that either of this was the case.

## General Discussion

While results from Experiments 1 and 2 are not fully in line with one another, it is likely that prediction is easier with a constraining visual scene which is co-present during the entire discourse than with a linguistic context which is only read once and needs to be remembered and re-accessed. Moreover, while there was a prediction effect for concessives in the extended connector region in Experiment 1, prediction was also slower (or more slowly stable) in the concessive than the causal condition (no significant effect in the concessive case in the pretarget region). Possibly, processing concessives was simply more slowly than processing causals in both experiments.

Another possible explanation however is that the scope of the concessive is more ambiguous than the scope of causals
in experimental items of Experiment 2:
causal Timmy wants to do $A$ and B. A is more important.
Therefore .-
concessive Timmy wants to do $A$ and $B$. $A$ is more important. However .

In the causal case, the causal connector can only refer to the previous sentence "A is important", hence only $A$ is a sensible continuation. In the concessive case, the concessive marker might take scope either over the second sentence, in which case the prediction would be, as anticipated, However B. But, it is also possible for the concessive to take scope over both initial sentences, leading to a prediction However $C$, that is, Tommy goes on to do something entirely different. In that case, the space of possible predictions is wide open and cannot be expected to cause a gender mismatch effect.

For the visual world experiment, this difference in scope between causals and concessives is not an issue as the visual scene is very explicit. An interesting aspect about the hypothesis that concessive markers give rise to less specific predictions than causal markers is that it stands in apparent contrast to the hypothesis by Murray (1995) discussed earlier : Murray suggests that concessives are highly constraining while causal connectives are moderately constraining and leave more open hypotheses. We believe that Murray's and our hypotheses are not necessarily contradictory, however: While concessive markers may be less ambiguous with respect to the discourse relation they are marking (see also Asr \& Demberg, 2012a,b), they may at the same time be more ambiguous with respect to the scope of their argument.

Results from Experiments 1 and 2 are generally in line with studies revealing immediate interpretation of discourse markers (e.g., Traxler et al., 1997). However, our data also supports that negating a discourse relation (i.e., via adversative markers) may cause a delay in processing, at least when a directly mentioned state of affairs needs to be rejected and its opposite needs to be both mentally accessed and found (on a scene or in memory). That means that concessive discourse markers are a type of negation that can cause processing difficulties. Moreover, Experiment 1 supports that negation can give rise to a search for alternatives (Kaup et al., 2006).

## Conclusions

We investigated the time-course of processing marked causal and concessive discourse relations within two experiments. Results from a visual world experiment (Exp. 1) provide clear evidence that, at least in this highly constraining scenario, both causals and concessives can be processed incrementally and give rise to predictions. Concessives, specifically, elicit an active search for alternatives. A reading experiment (Exp. 2) confirms this finding for causals but not for concessives. Results of both experiments indicate that concessives may be more difficult to process than causals, causing a delay. In Experiment 2 , difficulties with concessives may also be due to ambiguity in scope.

# The role of morphology in spelling: Long-term effects of training 

Kendall L.D. Kolne (kendall.kolne@mail.mcgill.ca)<br>Katherine Hill (katherine.hill@mail.mcgill.ca)<br>Laura M. Gonnerman (laura.gonnerman@mcgill.ca)<br>School of Communication Science and Disorders, McGill University, 1266 Pine Ave W<br>Montreal, QC, H3G 1A8 CAN

#### Abstract

We compared the effectiveness of two spelling interventions: one focused on morphological structure and one emphasizing word meanings,, on spelling acquisition in French speaking children in $3^{\text {td }}$ and $5^{\text {th }}$ grades. The morphology intervention led to significantly greater improvement in spelling than the vocabulary intervention, especially for children in grade 5 . To compare the long-term effects of the two interventions, we tested the children's spelling ability six-months after the conclusion of the intervention program. Results show that both grades maintain an increase in spelling accuracy compared to their pre-intervention performance. Additionally, the children in grade 5 who received morphological instruction retained more spelling knowledge than those who received the vocabulary instruction. These results suggest that teaching children about the structure of complex words supports their spelling ability in the long-term, providing evidence for the importance of morphological knowledge in literacy development.

Keywords: morphology; spelling; literacy development; vocabulary; intervention; French

## Introduction

Learning to spell is a critical aspect of literacy development, yet research has typically focused on the development of reading skills. Understanding the process of learning to spell has become particularly important in Quebec, where a widespread decline in children's spelling ability has become apparent (Jalbert, 2007). Contributing to this decline is the difficult nature of French spelling. French has a one-tomany mapping of sounds-to-orthography, so the same sound may be written in a number of different ways. Additionally, silent letters are common in written French, so children must learn to spell parts of words for which there is no overt pronunciation to guide them. These features of written French make learning to spell in this language a complex task.

Recent evidence suggests that literacy instruction focused on morphological knowledge, or on the ability to recognize and process sub-lexical units in language (e.g., recognizing that the word reheatable is made up of three sub-parts, the prefix re-, the stem heat, and the suffix -able) may assist children's spelling development. In fact, children who have greater metalinguistic awareness of morphological structure are better able to spell words correctly (e.g., Deacon, Kirby, \& Casselman-Bell, 2009; Sénéchal, 2000) and teaching children explicitly about the morphological relationships
between words improves their reading and writing skills (see Bowers, Kirby, \& Deacon, 2010, for a review).

While morphological awareness training may be a beneficial teaching method for fostering literacy development, there are a number of important issues to be resolved to ensure that children receive the most effective instruction. Firstly, most of this evidence is derived from studies of English-speaking children, and little is known about the contribution of morphological skills to writing ability in French (cf. Sénéchal, 2000; Sénéchal, Basque, \& Leclaire, 2006; Pacton \& Deacon, 2008). French has a richer morphological system than English, so it is likely that morphology may have an even more influential role in learning to spell in French. Intervention studies with French-speaking children are needed to test this hypothesis.

Additionally, children as young as two to three years demonstrate knowledge of morphology (Berko, 1958; Clark, 1993, Gonnerman, 2007), but it is not clear when this knowledge begins to influence spelling ability. Some researchers have argued that morphological knowledge has an early influence as children begin to develop literacy skills (e.g., Deacon \& Kirby, 2004), while others report that the influence of morphological knowledge on spelling ability does not have a large impact until later in development (e.g., Carlisle, 1995; Kirby et al., 2012; Singson, Mahony, \& Mann, 2000). To provide the most effective instruction to children, it is crucial to understand the most appropriate stage of development to introduce morphological training.

Typically, instruction of morphological structure also involves discussion of word meaning, because morphologically related words share similar form and meaning. Previous studies have yet to investigate the distinction between morphological and vocabulary instruction (e.g., St-Pierre \& Dubé. 2012), thus the relative contribution of morphology versus semantics to improving spelling ability is unknown. To disambiguate the potential benefit of morphological knowledge from the benefits of word meaning instruction, it is necessary to isolate the teaching of morphological structure and compare its effects on spelling outcomes to that of vocabulary training.

Finally, it is important to find out whether the benefits of a morphological intervention program can be maintained across time, and whether the knowledge will transfer to new words not taught in the intervention. Carlisle (2010) conducted a review of instructional programs using morphological awareness training to improve literacy outcomes, and reported that the majority of these studies fail
to report the long-term maintenance of the effects, or the transfer of learning to new words. It is critical to evaluate both the maintenance and transfer of learning to ensure that a morphological intervention provides children with longlasting abilities beyond the context of the intervention.

We have conducted an intervention study to investigate the role of morphological training for improving spelling in Quebec French. In a previous study, we analyzed and reported the results immediately after the conclusion of the intervention. The focus of the present study is to examine the long-term effects of the intervention, as measured at a follow-up session six months after the conclusion of the intervention. We compared the long-term effects of morphological instruction for $3^{\text {rd }}$ graders and $5^{\text {th }}$ graders, explicitly contrasting its relative contribution to spelling ability with that of vocabulary instruction. Thus, our research question is two-fold:

1. Is there a difference in relative long-term intervention effectiveness by grade? That is, will a morphology intervention improve long-term spelling performance of children in grade 3 versus 5 ?
2. Is there a difference in long-term intervention effectiveness by instruction method? That is, will a morphology intervention lead to great long-term spelling improvement than a vocabulary intervention?

In the sections that follow, we describe the intervention that was conducted, as well as the spelling outcomes following the intervention for children in grades 3 and 5 To address our research questions, we present data from a sixmonth follow-up test evaluating the long-term effectiveness of the morphology and vocabulary training for improving spelling performance.

Overall, we expect that the children will experience some degree of forgetting, such that their spelling accuracy at the six-month follow-up will be lower than at post-intervention; however we expect that the children will retain some of the spelling knowledge from the intervention, so their spelling scores at the six-month follow-up will be higher than at the pre-intervention. Moreover, we predict that the greater benefit observed for the morphology intervention will be maintained in the long-term.

## The Present Study

We developed an intervention to target the spelling of a set of morphologically complex words, with emphasis on either morphology or vocabulary instruction. The present study aims to assess the long-term outcomes of our spelling intervention. Six months after the intervention ended, we went back to the school and administered the same spelling test to the children who had participated in the intervention. The children's performance on this test at the six-month follow-up will be compared to their performance on the test
as measured before the intervention as well as immediately after the intervention.

## Methods

## Participants

Eighty-four children were recruited from one elementary school in the greater Montreal area and took part in the intervention. Children from two Grade 3 and two Grade 5 classes within the school participated. The primary language of instruction in this school is French. 36 children from Grade 3 participated ( 23 girls and 13 boys), as well as 48 children from Grade 5 ( 27 girls and 21 boys).

Children were randomly assigned to one of the two treatment groups, based on their general spelling abilities prior to their participation in the intervention study. General spelling ability was assessed using a modified version of the Test Ortho3 from the Batterie d'Évaluation du Langage Écrit et de ses troubles (BELEC) (Mousty, Leybaert, Alegria, Content, \& Morais, 1994). Children in each intervention group were also matched on language background (monolingual Francophone, or multilingual), and gender, with approximately equal ratios of boys to girls in each treatment group.

## The intervention

Children in grade 3 and grade 5 took part in the intervention. The children were divided into two groups, one which received instruction explicitly focused on the morphological structure of the words to be learned (Morphology group), the other receiving instruction focused on the meanings of the words (Vocabulary group). For example, the Morphology group was taught that there are two parts to the word finlandais, namely the stem finland and the suffix -ais, while the Vocabulary group was taught that the word finlandais describes something or someone that comes from the country, Finland. The children were taught to spell an identical set of 30 words, with only the emphasis of instruction differing across intervention groups. The intervention was given during 10 weekly sessions, each lasting one hour.

Ten suffixes were taught in the intervention. The suffixes were relatively frequent and productive in Quebec French, such that they are preferentially used to form new words. Three words were chosen containing each of the 10 suffixes, creating the list of 30 words that were taught in the intervention. These words were relatively infrequent, so it would be unlikely that the children in grade 3 or 5 would already know these words.

The 30 words were distributed across the 10 intervention sessions, with three words taught per session. In each session, the children in the Morphology group were taught the three words with the same suffix. For the Vocabulary group, words with the same suffix were distributed across the 10 sessions, such that the words with the same suffix were never taught in the same session. For example, in the first session, the Morphology group was taught finlandais,
japonais, and camerounais, whereas the Vocabulary group was taught ogresse, huileux, and galanterie. Thus, each group was taught the same words, just in different sessions.

## Materials for assessing intervention effectiveness

We developed a test to determine the effectiveness of the intervention on children's spelling ability. This test was administered before (pre-intervention), immediately after (post-intervention), and six months after the intervention concluded (six-month follow-up). We designed this spelling test to measure specific outcomes from our intervention. The test assessed the spelling of complex and simple words, and required children to generalize stems and suffixes taught in the intervention to new words not taught in the intervention. The items on the test were either the exact complex word taught in the intervention (i.e., a taught stem and a taught suffix), a taught or an untaught stem without a suffix, or a combination of a taught/untaught stem and suffix in a complex word (i.e., a taught stem with a new suffix, or a new stem with a taught suffix).

## Procedure

All students took the spelling test in the classroom at the same time. The instructor read each sentence once, repeating the missing words as many times as necessary for all students to fill in the missing word. The instructor was a female native speaker of Quebec French.

## Results and Discussion

We assessed the effects of our intervention immediately following the conclusion of the intervention program, analyzing the changes in spelling performance from pre- to post-intervention. Before we report the results of the sixmonth follow up, the pre- to post- test analyses will be summarized. As the focus of the present study is the longterm spelling outcomes, only statistics including the sixmonth follow-up scores will be reported in this paper.

There were 15 children who participated in the original intervention who were absent from the six-month follow-up session. These children were excluded from the following analyses. Additionally, 3 children were absent from either the pre- or post-intervention assessment, and these children were also excluded from the following analyses.

The children's performance on the spelling test was scored based on whether the whole words were spelled correctly, and also whether the stems and suffixes of complex words were spelled correctly. Accordingly, each complex word received three scores, one for the whole word, one for the stem, and one for the suffix. Mean percent correct scores on the whole words, stems, and suffixes were calculated for the following analyses.

## Question \#1: Is there a difference in relative longterm intervention effectiveness by grade?

Pre- to post- intervention summary We compared the changes in spelling accuracy over all the items on the
spelling test, from pre- to post-intervention, for grade 3 and 5 students. The results of this analysis revealed that children in both grades improved their spelling from pre- to postintervention, with children in grade 5 scoring higher overall than those in grade 3. However, the children in grade 3 showed a greater differential between pre- and postintervention than those in grade 5, indicating that the children in grade 3 were aided more by the intervention, irrespective of the type of instruction.

To test whether these differences remained six months after the intervention, we calculated mean percent correct at each test time. These mean scores for grades 3 and 5 are displayed in Figure 1. We entered the whole word accuracy scores on all of the spelling test items into a $2 \times 3$ ANOVA with the factors Grade (grade 3 or grade 5) and Test Time (pre-intervention, post-intervention, or six month post) to assess the long-term effects of the intervention for each grade. The main effect of Grade was significant, $F(1,64)=$ $16.98 p<.001$, indicating that the children in grade 5 scored significantly higher than the children in grade 3 . The main effect of Test Time was also significant, $F(2,128)=174.92$, $p<.001$, as was the interaction of Grade and Test Time, $F(2,128)=6.73, p=.002$, indicating significant differences between the spelling performance of grade 3 and 5 children across the three testing sessions.

Figure 1: Overall mean percent correct on the spelling test, for grade 3 and grade 5 at pre-intervention, post-intervention and the six-month follow-up.

Post-intervention to six-month follow-up To specifically examine the potential differences in the long-term effects of the intervention for grade 3 and 5 children, a planned comparison of the whole word accuracy scores for all items, with the factors Grade (grade 3 or grade 5) and Test Time (post-intervention or six month post) was conducted. The results show that the grade 5 children had significantly higher spelling scores than the grade 3 students from postto six month post-intervention, $F(1,64)=11.55, p<.001$. Collapsing across both grades, scores were significantly higher at post-intervention than at the six month follow-up, $F(1,64)=12.01, p<.001$, indicating that the children had forgotten some of the spelling knowledge they gained from the intervention six months later. Interestingly, the
interaction of Grade and Test Time was not significant, $F(1$, $64)=.35, p=.55$, indicating no difference between grade 3 and grade 5 in the amount of spelling knowledge that was forgotten. In fact, there was only a small, albeit significant, decrease in spelling ability six months after the intervention, approximately $5 \%$ in each grade.

Pre-intervention to six-month follow up To ensure that six months later the children retained much of the spelling knowledge they originally gained from the intervention, we conducted a planned comparison of the whole word spelling accuracy scores of all items, with the factors Grade (grade 3 or grade 5) and Test Time (pre-intervention or six month post-intervention). Once again there was a significant main effect of Grade, $F(1,64)=17.57, p<.001$, such that the children in Grade 5 scored higher than those in Grade 3. The main effect of Test Time was significant, $F(1,64)=193.01$, as was the interaction between Grade and Test Time, $F(1,64)=10.85, p=.002$. These results indicate that children in both grades maintained their spelling improvement, scoring higher at the six-month follow-up than at pre-intervention. Moreover, the children in grade 3 improved more from pre-intervention to the six-month follow-up than the children in grade 5. Thus, the children display long-term learning, having retained a large amount of the spelling knowledge that they gained from the intervention six months later.

## Question \#2: Is there a difference in long-term intervention effectiveness by instruction method?

Pre- to post- intervention summary Given the differences between grades in intervention effectiveness, we analyzed pre- to post- intervention differences between the Morphology and Vocabulary group for each grade
separately. In general, children in both instructional groups increased from pre- to post- intervention, indicating that both types of instruction effectively improved children's spelling ability for both $3^{\text {rd }}$ and $5^{\text {th }}$ graders. Looking more closely at the accuracy for stems and suffixes of the test items, differential effects according to intervention group emerged, with the Morphology group showing a larger increase in spelling accuracy than the Vocabulary group.

The results immediately following the intervention suggest that the instruction focusing on the morphological structure of words provides an advantage to children over an intervention that focuses on word meanings. Specifically, children who have had morphological-based training were able to generalize the knowledge they gained in the intervention to be able to correctly spell morphologically related words that had not been taught directly. While the Morphology group showed differential improvements over the Vocabulary group in both grades, the morphological intervention provided the strongest benefit for children in grade 5.

To determine whether the advantage of a morphological intervention over a vocabulary intervention for learning to spell was maintained after a period of no instruction, we compared the changes in spelling accuracy of the two intervention groups from immediately after the intervention to the six-month follow-up assessment. Additionally, we compared the long-term effects of the morphology and vocabulary instruction for $3^{\text {rd }}$ and $5^{\text {th }}$ grade separately, to determine the developmental stage for which the spelling intervention is most effective. Each grade was thus examined separately in the following analyses.. The mean percent correct on the complex words, stems and suffixes for both intervention groups are displayed in Table 1 for Grade 5, and in Table 2 for Grade 3.

Table 1. Grade 5 mean percent correct on complex words, stems and suffixes at post-intervention and six-month follow-up.

| Complex <br> Words | 81.25 | 16.08 | 63.39 | 21.63 | -17.86 | 78.33 | 21.89 | 65.00 | 16.50 | -13.33 |
| Stems | 72.98 | 15.27 | 67.70 | 13.82 | -5.28 | 73.91 | 18.00 | 68.12 | 19.28 | -5.79 |
| Suffixes | 88.39 | 7.70 | 81.70 | 13.97 | -6.69 | 79.58 | 19.11 | 76.67 | 16.61 | -2.91 |

Performance on complex words We first looked at the long-term changes in whole word spelling accuracy of the complex words that were taught in the intervention. The whole word scores for the complex taught words were entered into a separate ANOVA for each grade, with the factors Intervention Group (morphology or vocabulary) and Test Time (post-intervention or six-month postintervention). Looking first at the results for grade 5, the main effect of Test Time was significant, with children scoring higher at the post-test session, than the pretest session, $F(1,35)=21.98, p<.001$. The main effect of Group was not significant, $F(1,35)=.05, p=.81$, nor was the interaction of Test Time and Group,, $F(1,35)=2.52, p=$ .12. Thus, both groups display some forgetting of how to spell the complex words that were taught in the intervention, but this change is not differential based on the intervention group.

For the $3^{\text {rd }}$ graders, the main effect of Test Time was once again significant, $F(1,27)=20.68, p<.001$, while the main effect of Group was not significant $F(1,27)=, p=.92$. Unlike the pattern observed in the $5^{\text {th }}$ grade, the interaction of Group and Test Time was not significant, $F(1,27)=.44$, $p=.51$. For children in grade 3 , after six months both groups showed a similar decrease in spelling accuracy for the complex words taught in the intervention.

Performance on stems To assess the long-term effects of instruction on the spelling of taught stems, mean percent correct scores for taught stems were entered into an ANOVA with the factors Test Time (post-intervention or six-month-post intervention) and Group (morphology or vocabulary), for each grade separately. The results for the $5^{\text {th }}$ grade children showed a significant main effect of Test Time, $F(1,35)=12.70, p=.001$, but not a significant main effect of Group, $F(1.35)=1.44, p=.24$, nor an interaction between Test Time and Group $F(1,35)=.35, p=.56$.

Similarly, in the $3^{\text {rd }}$ grade, the main effect of Test Time was significant, $F(1,27)=9.68, p=.004$, while the main effect of Group and the interaction of Test Time and Group were not, $F(1,27)=.01, p=.91, F(1,27)=.02, p=.89$, respectively. For both Grade 3 and Grade 5, performance on the taught stems decreased somewhat for both the morphology and vocabulary groups, but this small decrease was the same across both groups. Thus, the initial learning based on the intervention resulted in approximately 21-31 percent increases in spelling of the stems, and after 6 months, both groups still showed significant improvements in spelling, only dropping 1 to 6 percent in their scores.

Performance on suffixes We compared the long-term effects of the two intervention types on the spelling of suffixes taught in the intervention. For each grade, the mean percent correct scores for taught suffixes were entered into separate ANOVAs, with the factors Test Time (postintervention or six-month post-intervention) and Group (morphology or vocabulary). For grade 5, the main effect of Test Time was significant, $F(1,35)=18.22, p<.001$, while
the main effect of Group was not, $F(1,35)=.30, p=.56$. Interestingly, the interaction of Group and Test Time was significant $F(1,35)=4.08, p=.05$, revealing that six months after the intervention, the morphology group showed greater retention for the spelling of taught suffixes. This finding suggests that for children in grade 5 , instruction focused on morphological structure is more beneficial in the long-term for learning to spell morphologically complex words than instruction focused on word meaning.

The analysis for grade 3 children showed that the main effect of Test Time was marginally significant, $F(1,27)=$ $4.00, p=.06$, and that the main effect of Group was not, $F(1,27)=1.86, p=.18$. In contrast to Grade 5, the interaction of Test Time and Grade was not significant for Grade $3, F(1,27)=.64, p=.43$. There is a slight decrease in the spelling of taught stems at the six-month follow-up for both intervention groups, and this decrease is not different by intervention received. Given the differing pattern of results for performance in the spelling of taught suffixes, with the $5^{\text {th }}$ graders in the morphology group showing greater retention, the morphology-based instruction seems to provide an advantage over a vocabulary-based instruction for learning to spell at later stages of literacy development.

## General Discussion

The present study evaluated the long-term effectiveness of a morphology-based intervention for elementary school-aged French-speaking children. The intervention contrasted the effects of a training program focused on the morphological structure of words, with one that concentrated only on word meaning. While other intervention studies have confounded morphology and vocabulary instruction (see Bowers, Kirby, \& Deacon, 2010, for a review), our study design allowed us to disambiguate the relative benefits of morphology and vocabulary instruction for spelling outcomes. Additionally, by conducting the intervention with children in $3^{\text {rd }}$ and $5^{\text {th }}$ grade, we could assess the effects of morphological instruction at different stages of literacy development.

While both interventions led to significant spelling improvements from pre- to post-intervention, the Morphology group displayed significantly greater improvement in their ability to generalize their spelling knowledge beyond the words that were taught in the intervention. The differential benefit in favour of the morphology group was particularly pronounced for the children in grade 5 . Overall, the results suggest that teaching children about morphological structure successfully improves spelling accuracy more than instruction based on word meaning does.

In addition, in the results reported here, we demonstrate the long term learning effects of the morphology intervention by re-examining the children after a six-month delay. We found that for both the morphology and vocabulary groups, the improvement in spelling accuracy remains six months later, as the children spell significantly better at the six-month follow-up than at pre-test. These effects hold for children in both grades 3 and 5 . The
children do display some forgetting at the six-month mark, with scores significantly decreasing from post-intervention to six-month follow-up, however, the decreases were very small (approximately one to six percent) and there were no differences in the amount of forgetting between grades. This finding suggests that, regardless of instruction type, children benefit from our spelling intervention.

Importantly, when examining the differential effects of instruction type, we found a significant, long-term advantage for grade 5 children in the Morphology group over children in the Vocabulary group. At the six-month follow-up, those who received morphology instruction showed greater retention of spelling knowledge than those who received the vocabulary instruction. Our intervention study and the subsequent follow-up suggest that morphological training provides sustained improvement to children's spelling accuracy in French, greater than instruction on word meaning, particularly for older elementary school-aged children.

## Conclusion

Findings from our follow-up study provide support for an advantageous role of morphology instruction for spelling outcomes in Quebec French. Explicitly teaching children about the components of complex words helps them to spell stems and suffixes better, and to generalize their knowledge beyond the words taught in the intervention. For older children, these effects are maintained well after instruction is finished, indicating that morphology instruction would be a useful tool for dealing with the spelling difficulties observed in Quebec. While we did not see the same differential long-term benefit of morphology training in the younger children, our findings indicate that both types of intervention were very beneficial in the long-term. As such, an intervention combing instruction of morphological structure and vocabulary knowledge may be especially helpful for these children.

## Acknowledgments

This research was supported by a grant awarded to the third author from the Fonds de recherche du Québec Société et culture (FRQSC). We would also like to thank Eve Bergeron and Rebecca Amzallag for their help with testing. Finally, a huge debt of gratitude goes to the school director, teachers, and students for their enthusiastic participation in the intervention study.

#### Abstract

In two experiments we study how redundant size modifiers influence the perceived size of objects. We show that when objects are referred to with overspecified descriptions (for example, using a description like "the large red chair" in a situation where all chairs are equally large but different in color), participants subsequently estimate the object to be larger than when objects are referred to using minimally distinguishing descriptions (e.g., "the red chair"). In Experiment 1, we show this effect with adult language users and different kinds of size modifiers. In Experiment 2, the same effect is shown for children of two different age groups (7- and 10-year olds), and for different kinds of visual size contrasts. Interestingly, we observe an inversely proportional relation between the age of our child participants and the difference in size estimates for minimal and overspecified descriptions, suggesting that language users gradually become better at avoiding false pragmatic inferences from redundant adjectives as they grow older.

## Introduction

Arguably, referring to a giant as "big" is somewhat excessive, certainly when there is only one giant in sight. But would calling a giant "big" and "friendly" (as Roald Dahl, 1982, does in his well-known children's novel The $B F G$; short for Big Friendly Giant), nevertheless have an impact on the perceived size (or friendliness) of said giant? And would this effect be the same for younger children as for older ones or even for adults? These are essentially the questions we address in this paper.

## Background

Speakers frequently produce definite descriptions such as "the big friendly giant", "the red chair" and "the large ball",
since they allow them to link their utterances to the physical world surrounding them. One central problem that a speaker has to solve when planning such a referring expression is to decide which properties to include in the reference. A chair can be red, but also large, plush, modern, with or without cushions and armrests, cheap or expensive, etc. So which properties to select? A successful reference includes sufficiently many properties to allow the addressee to determine which chair the speaker has in mind, but not too many, as Dale and Reiter (1995) propose in their computational interpretation of Grice's (1975) maxims for reference production.

One prima facie plausible option would be to opt for the smallest set of properties that distinguish the target object from the other objects in the context (Dale 1989). However, it has been repeatedly found that this is not necessarily what speakers do (e.g., Olson, 1970; Pechmann, 1989; Belke \& Meyer, 2002; Engelhardt et al., 2006; Koolen et al., 2011). In many cases, speakers produce overspecified descriptions, which contain one or more redundant modifiers. For example, they produce a description such as "the large red chair", in a situation where "the red chair" would have been sufficient to single out the target. A number of speakerinternal factors have been shown to influence the likelihood of speakers producing an overspecified description, ranging from the pressures of incremental speech production (speakers may start producing a referring expression before scanning of a visual scene is complete; Pechmann, 1989) to scene complexity (more overspecification in complex visual scenes; Koolen et al., 2012) and conversational setting (more overspecification when misunderstandings are costly; Arts et al., 2011), suggesting that overspecification does not have a single distinct cause.

However, in this paper we focus on the impact of overspecification on language understanding, and here the picture is less clear. Some researchers have suggested that
overspecification can help addressees with identifying an intended target (e.g., Arts et al., 2011; Paraboni et al., 2007), while others argued that they slow down identification (e.g., Engelhardt et al., 2006; 2011). Importantly, all these studies focus only on object identification. In this paper, we argue that overspecification in referring expressions may also have other important side effects for addressees.

A prominent view in language understanding is based on the assumption that "utterances convey only relevant information" (Frank \& Goodman, 2012). This assumption can be traced back at least to the work of Grice (1975), who postulates among other things that speakers should not make their contribution more informative than is required (this is half of his well-known Maxim of Quantity). A speaker that violates ("flouts") this maxim, by providing more information than needed, thereby triggers a conversational implicature, suggesting to the listener that the additional material is meaningful after all. Imagine, for instance, that a speaker tells you to "sit by the newly-painted table" (Dale \& Reiter, 1995), while there is only one table in the room. In that case, you may think the modifier "newly-painted" is redundant (since it is more informative than required for the purpose of identification), and this might cause you to infer the conversational implicature, intended by the speaker, that it is best not to rest your arms on this table in order to keep your clothes unstained.

However, one can also think of situations where an addressee may reason that the redundant information is somehow relevant, even when the speaker did not intend it in this way (Grice would call this a false conversational implicature). After all, as we argued above, speakers may overspecify for a variety of reasons. Our first hypothesis therefore is that if an object is described redundantly as "large" or "small" this will influence how the size of this object is perceived. Redundantly referring to a target object as large (small) may cause people to perceive or remember the target as larger (smaller) than when such a redundant size modifier is not included in a description. Even though we focus on redundant size adjectives here, we conjectured that other redundant adjectives (e.g., referring to color) could have similar effects (a possibility we discuss below).

Moreover, it has been argued that children are more likely to derive false conversational implicatures than adults (Siegal \& Surian, 2004). On the one hand, we know from earlier research that children have a general tendency to regularly produce underspecified or ambiguous referring expressions until they are about seven years old (Deutsch \& Pechmann, 1982; Matthews, Lieven, \& Tomasello, 2007), and before that age only marginally benefit from redundant information in target identification (Sonnenschein, 1982; Ackerman, Szymansi \& Silver, 1990; Davies \& Katsos, 2010). Indeed, one could argue that it requires relatively sophisticated pragmatic reasoning to understand the implications of redundant information in descriptions. Therefore our second hypothesis is that children are more susceptible to redundant size modifiers than adults when making size estimates. Given that earlier work suggests that
the relevant pragmatic reasoning is under development until children are about 7 years old, we test this both with child participants of on average 7 years (Group 3 in the Dutch elementary school system) and 10 years old (Group 6) in the experiment.

## The current studies

We test these two hypotheses in two experiments (one with adults, one with children of two age groups), which rely on the same basic idea: participants hear descriptions referring to objects in a visual scene. Descriptions can either be minimally specified or overspecified (containing a redundant size modifier). After participants have processed a description, the objects in the visual scene disappear from view, and participants are asked to indicate how large they think the target object (which no longer is visible) was.

## Experiment 1: Adults

## Method

Participants Participants were 68 undergraduate students from Tilburg University (49 female) who participated for partial course credits. Their mean age was 21.5 years ( $\mathrm{SD}=$ 2.4). All were native speakers of Dutch, the language of the experiment.

Figure 1: Example scene consisting of two same size chairs, with different colors (may not be visible in a black and white print). In the minimal condition, the target would be referred to as "the red chair", while in the overspecified condition it would be "the large red chair".

Materials Stimuli were created using pictures of furniture items from the Object Databank, created by Michael Tarr and colleagues, and often used in research on reference (e.g., van Deemter, Gatt, van der Sluis \& Power, 2012). Three furniture items were selected for the current experiment (chair, couch, desk), and manipulated for color (either red or blue) and size (either large or small). Each stimulus consisted of two objects, one target (the object being referred to) and one distractor. There were 12 different targets ( 3 object types x 2 colors x 2 sizes), and the left-right position of the target with respect to the distractor was counterbalanced. In the critical stimuli, the distractor was always of the same type and size as the target and only differed in color (see Figure 1 for an example). Each target was referred to once with a minimal description (e.g., "the red chair") and once with an overspecified description containing a redundant size adjective (e.g., "the large red chair" or "the small red chair", depending on the size of the target). This created a total of $12 \times 2=24$ critical trials. The
experiment also contained 24 filler trials, in which the visual objects consisted of different types, sizes and colors.

Procedure During the experiment, individual participants were seated in front of a computer screen, on which pairs of objects were presented as in Figure 1, together with a prerecorded spoken description (e.g., "the [large] red chair"), produced by a female speaker with neutral intonation (i.e., with nuclear stress on the noun and no pitch accent on the adjective) and presented to participants over headphones. After a fixed interval, both objects disappeared from the screen and a horizontal slider appeared, together with the question "How large was the $\qquad$ ?", where the gap in this question was filled by the type of the target (e.g., "chair") The slider had the shape of an elongated, isosceles triangle with the tip ("small") on the left- and the base ("large") on the right-hand side (see Figure 2). Upon appearance, the slider handle was positioned in the middle; the handle had to be moved before the participant could proceed to the next stimulus. For analysis, the position after being set by the participant was mapped to a score between 0 and 100 (with higher number indicating larger size estimates).

In addition to the size question, participants were also asked to indicate the color of each object referred to on a one-dimensional saturation scale, ranging from lighter to darker, again with the handle initially positioned in the middle, on the assumption that a redundant mention of color (like "red") would cause participants to perceive an object as "redder" than when color was not mentioned in a description. However, no reliable effects of redundant color adjectives were found, and we will not describe the results of this measure further. In the general discussion we do return to this issue.

Experiment 1 had a within-participants design: all participants produced a size estimate for all targets. Stimuli were presented in a random order. Before the actual experiment started, a three trial training session (with a fan as target object type) was presented, to make participants familiar with the experimental set-up. After the training session there was no further interaction between participants and experimenter.

Figure 2: Slider used in Experiment 1 for size estimates.
Statistical analysis To test for significance, we conducted a $2 \times 2$ repeated measures Analysis of Variance (ANOVA), with Size (levels: large, small) and Description (levels: minimal, overspecified) as independent variables and average size estimate as the dependent variable.

## Results and discussion

Figure 3 summarizes the results. First of all, a main effect of Size was found, $F(1,67)=461.94, p<.001, \eta^{2}=.87$. Large targets were estimated to be larger $(M=60.45,95 \% \mathrm{CI}=$ (57.83, 63.07)) than small ones $(M=23.17,95 \% \mathrm{CI}=(20$, 26.34)). This serves as a manipulation check and indicates that the slider worked exactly as intended. In addition, a main effect of Description was found, $F(1,67)=5.30, p<$ $.05, \eta^{2}=.07$. Targets that were referred to using an overspecified description were estimated to be larger than targets that were referred to using minimal descriptions. Importantly, this main effect was qualified by an interaction between Size and Description, $F(1,67)=15.16, p<.001, \eta^{2}$ $=.18$. This interaction can be explained by inspection of Figure 3: large targets that are referred to redundantly are estimated to be larger $(M=62.81,95 \% \mathrm{CI}=(59.85,65.76)$ than ones that are referred to minimally ( $M=58.1,95 \%$ CI $=(55.34,60.85))$, while small targets that are referred to redundantly are estimated to be smaller ( $M=22.10,95 \% \mathrm{CI}$ $=(18.88,25.33))$ than ones that are referred to minimally $(M=24.24,95 \% \mathrm{CI}=(20.86,27.62))$.

Figure 3: Mean size estimates in millimeters (range 1-100) for large and small objects for minimally specified descriptions (e.g., "the red chair") or overspecified ones ("the large/small red chair").

Experiment 1 clearly showed that adults are sensitive to redundant size modifiers in distinguishing descriptions. In Experiment 2, we conduct a comparable experiment with child language users in two different age categories, to see whether younger and older children are similarly sensitive to redundant modifiers. In addition, in this experiment we also vary the visual size of the target, to see whether size differences between target and distractor influence any effects of redundant size modifiers.

## Experiment 2: Children

## Method

Participants Sixty normally developing children were included in the study, in two age groups: 30 younger children ( 13 girls, 17 boys), with an average age of 7.1 years (range: 6.6-8.3), all in Group 3 of the Dutch elementary
school system; and 30 older ones ( 15 girls, 15 boys), with an average age of 10.2 years (range: 8.7-11.5), all in Group 6 . The children participating in this experiment were native speakers of Dutch, the language of the experiment. All children came from the Mgr. Zwijsenschool in Kerkdriel (Gelderland, The Netherlands). Parental consent for participation in the experiment was obtained for all children prior to the experiment.

Materials Pictures of eight different photorealistic children's toys (football, teddy bear, train, slide, rubber duck, doll, boat, spin top) were used as targets in this experiment (see Figure 4 for two representative examples). Each target was presented together with one distractor toy. Four different conditions were created for each of the eight targets by varying the size of the distractor (which could either be depicted as large as or smaller than the target) and by varying the reference to the target (which could either include a redundant size modifier or not), resulting in $8 \times 4$ $=32$ critical trials. Note that in this experiment each target could uniquely be identified by its type ("the football"), so including a size adjective always resulted in an overspecified description. In addition, eight control trials were included, one for each target type, in which the target was combined with a smaller object of the same type (e.g., a small football), so that the size adjective in a description such as "the large football" was informative and not redundant. This allowed us to check whether any differences in size-estimates for non-redundant adjectives between age groups could be observed. In all 40 stimuli the left-right position of the target with respect to the distractor was counterbalanced.

Figure 4: Examples of visual stimuli used in Experiment 2, with two different children's toys. Again the target could either be referred to in a minimal way ("the ball") or an overspecified one ("the large ball").

Procedure Children performed the experiment individually, and were seated in front of a computer monitor in a quiet room in the school building. The procedure for younger and older children was exactly the same and went as follows: after a brief training session, in which the magnitude estimation scale was practiced, stimulus presentation started with a pair of toys presented on a white background for 4 seconds. After this a white screen appeared for 8 seconds, during which children were asked to answer a pre-recorded question "How large was $\qquad$ ?" The gap in this question was filled by a description of the target, which could either be minimal ("the football") or overspecified ("the large football"). For the audio recordings, a male adult speaker
was used, who realized each question with a neutral intonation. Since the experiment was conducted in Dutch, this implies that the nuclear stress always occurred on the noun and the adjective was produced without a pitch accent.

Children were asked to indicate their size estimate on a magnitude estimation scale of 100 millimeters (consisting of a horizontal line without units of length added), with on the left-hand side a picture of the target reduced by a factor of 1.5 , and on the right hand side the same picture enlarged by a factor of 1.5 , in such a way that the real value was exactly in between (remember that the target figure was not visible to the child during the size estimation phase of the experiment, so children could not directly map the perceived size onto the scale). Children could indicate the estimates on paper, using a booklet that was positioned in front of them. After completing one trial, the next pair of toys appeared on the screen. The entire experiment lasted approximately 10 minutes. After the experiment, size estimates were manually measured in millimeters, with higher numbers indicating larger sizes. Measurements were done blind for condition.

Design and analyses The experiment had a $2 \times 2 \times 2$ mixed design, with Description (minimal, overspecified) and Size (target and distractor equally large, target larger than distractor) as within-participant factors, Age group (younger, older) as a between-participant factor and average size estimate as the dependent variable. Tests for significance were conducted using a repeated measures ANOVA.

Figure 5: Mean size estimates in millimeters (range 1-100) of younger (avg. 7.1 years) and older (avg. 10.2 years) children for targets that were minimally specified (e.g., "the ball") or overspecified ("the large ball").

## Results and discussion

The results showed that Size had a significant impact on children's size estimates. If the distractor was smaller than the target, children perceived the target as larger ( $M=47.3$, $95 \% \mathrm{CI}=(42.39,52.22)$ ) than when both target and distractor had the same size $(M=44.2,95 \% \mathrm{CI}=(39,6$, 49.6)), $F(1,58)=5.22, \mathrm{p}<.05, \eta^{2}=.08$. In other words, size
estimates are relative, even though the target always had the same size. Crucially, we also found a significant effect of Description on size estimates. If a target was referred to with a redundant size modifier, children perceived it as larger $(M=50.5,95 \% \mathrm{CI}=(44.99,56.01))$ than when the reference did not include such a modifier ( $M=41.43$, $95 \%$ $\mathrm{CI}=(36.98,45.88)), F(1,58)=47.03, \mathrm{p}<.001, \eta^{2}=.45$. This effect was independent of whether the target was visually larger than the distractor (no significant interaction between Description and Size was found).

Interestingly, we did find a significant interaction between Description and Age, revealing that older children are less sensitive to redundant size modifiers than younger ones, $F(1,58)=5.02, \mathrm{p}<.05, \eta^{2}=.08$. This interaction is illustrated in Figure 5, showing that when the target is minimally referred to ("the football") the size estimates of younger children $(M=41.7,95 \% \mathrm{CI}=(35.4,48.0))$ were almost the same as those of older ones ( $M=41.2,95 \% \mathrm{CI}=$ ( $34.86,47.45$ )), while overspecified descriptions ("the large football") caused younger children to make larger estimates $(M=53.74,95 \% \mathrm{CI}=(45.94,61.54))$ than older ones $(M=$ $47.26,95 \% \mathrm{CI}=(39.48,55.06))$. When we conducted a separate analysis over the eight additional items which were referred to using non-redundant modifiers, no significant age differences in size estimates were found either, suggesting that it is indeed only redundant size modifiers for which younger children are more sensitive.

No further significant main effects or interactions were found.

Figure 6: Average difference in size estimate in millimeters for redundant and minimal description ("the large $X$ " minus "the $X$ ") as a function of age (comparing younger children, older children and adults).

## General discussion

In two experiments we have shown that when target objects are referred to using descriptions containing redundant size modifiers (e.g., "the large red chair" in a situation where two chairs are equally large but different in color), participants subsequently estimate the object to be larger
than when objects are referred to using minimally distinguishing descriptions (e.g., "the red chair"). In Experiment 1, we showed this effect with adult language users and with two different size modifiers ("large" and "small"). In Experiment 2, the same effect is shown for children of two different age groups (7- and 10-year olds), but this time with descriptions for object of different types (e.g., a ball and a teddy bear). Interestingly, this effect was found to be independent of whether the target was actually larger than the distractor or not; in both cases, a redundant size modifier had a comparable effect.

Even though the two experiments were slightly different in the way they were conducted (e.g., furniture targets and digital size estimates in Experiment 1 versus children's toys and size estimates on paper in Experiment 2), the essential idea was the same: participants had to process object description which were either overspecified or minimal, and after the objects had disappeared from view, they were asked to estimate the perceived size of the target object that had just been referred to on a scale from 1 to 100 . Therefore, it is interesting to plot the difference in size estimates for overspecified and minimal description as a function of age, as is done in Figure 6. Inspection of this figure reveals a clear trend. We already saw in Experiment 2 that 7-year olds were more sensitive to redundant information than 10 -year olds, but the pattern for the 10 years olds seems comparable to that of the adults in Experiment 1. A univariate ANOVA confirms this: overall, there is a significant effect of age on the difference in size estimates, $F(2,125)=5.91, p<.01, \eta^{2}=.09$, but pairwise comparisons using the Bonferroni method showed that only the younger children differ significantly from the other two age groups. This appears to be consistent with the earlier work (cited in the introduction) showing that children younger than 8 still regularly produce referring expressions that may be underspecified and do not benefit from overspecified descriptions in target identification.

In this study we concentrated on redundant size modifiers, and the question naturally arises whether different kinds of adjectives could have similar effects. Our experiences with color adjectives in Experiment 1 suggest that this may not be the case. In particular, hearing a redundant description of a target as "the large red chair" (when both chairs are red) did not cause participants' to perceive the target as 'redder' than when hearing a minimal description ("the large chair"). Potentially, this could be due to the one-dimensional saturation slider that was used (after all, colors differ along multiple dimensions, also including lightness and hue, and it is not entirely clear which corresponds to, say, 'redness'). Alternatively, it could be due to the fact that color is an absolute property, while size is a relative one (e.g., Rips \& Turnbull, 1980). An adjective like "large" implies a comparison (an object is only large compared to another object), which may explain why participants are more likely to modify a size than a color estimate. We leave this as an issue for future research.

Our current results suggest that including redundant modifiers in a referring expression can be used strategically. If a speaker subtly wants to emphasize a property of a target, she can just mention it in a distinguishing description, irrespective of whether it rules out any distractors. In fact, mentioning any redundant property may help in attracting attention to a particular target. Koolen, Krahmer and Swerts (2012), in a study with children from two age groups similar to the ones under study here, found that when children were offered a choice between two identical looking sweets, they opted significantly more often for the one which was referred to in a redundant way ("this red sweet") than for the one that was minimally described ("this sweet"), and even thought the former would taste better than the latter. Interestingly, this effect was found to be stronger for younger than for older children, confirming that as they grow older, and their pragmatic skills increase, children are less likely to be influenced by overspecification.

## Conclusion

Wrapping up, we can state that calling a giant both "big" and "friendly" will make him seem larger than merely calling him "friendly", although the size of this effect is presumably inversely proportional to the age of the addressee.

## Acknowledgments

Many thanks to Ellen Evers for her help with setting up Experiment 1, and Maud Broekmeulen for her help with conducting Experiment 2. We received financial support from The Netherlands Organization for Scientific Research, (NWO, Vici grant 277-70-007), which is gratefully acknowledged.

# The case of cognitive ecology for cognitive processes in everyday life situations 

Mattias Kristiansson<br>Department of Computer and Information Science, Linköping University<br>SE-58183 Linköping, Sweden

#### Abstract

Cognitive ecology is a term that has been used in environments that are more tightly coupled and purposespecific than environments of everyday life. In this paper I consider cases from a cognitive ethnography of older adults. These cases show the analytical use of understanding the diachronic and synchronic cognitive ecology in which cognitive processes of everyday life occur. Specifically I discuss how the social and physical ecology and changes in these can shape goals, the use of cognitive artifacts and the use of other cognitive resources in agent environments that are not as purpose created and not as tightly coupled as environments of previous studies in this field.

Keywords: Cognitive ecology; distributed cognition; everyday life; older adults

## Introduction

This paper elaborates on the notion of a cognitive ecology applied to the domain of older adults coping with cognitive problems and situations in everyday life. Examples from a cognitive ethnography of older adults will be analyzed. The reason for doing this is to shed some light on what a cognitive ecology can be in a social and physical environment that is not as tightly coupled or information dense as the cases where the concept of cognitive ecology have been used previously. By focusing on older adults I hope to understand how circumstances in everyday life can constrain, shape and alter the use of certain cognitive strategies that assist and therefore become important for the understanding of the cognitive process. This analysis will have a specific focus on ecology, as contrasted to the idea that the agent actively shapes the cognitive process. I believe this is important because it allows us to understand the role of the active agent more firmly in an environment that often is not as tightly structured, with a specific goal or purpose as a navigational bridge (Hutchins, 1995) or an early modern theatre (Tribble, 2011). First I turn to the concept of cognitive ecology and then I briefly turn to the tension between the idea that individuals contribute to the cognitive process and the idea that cognitive process are shaped by the circumstances. Finally several aspects of cognitive ecologies through the light of examples from the conducted cognitive ethnography are discussed.

## Cognitive ecology

The understanding of cognition in relationship to environmental factors has now been a prominent undertaking in cognitive science for a while. The term "cognitive ecology" is now occasionally used to describe
the study of cognition in context, emphasizing the general notion that cognition is something taking place and developing in an ecology that constrains, alters and forms cognitive processes (Hutchins, 2010a; Tribble \& Sutton, 2011; Tribble, 2011). Tribble (2011, p.151) held that the idea of distributed cognition and the approach of cognitive ecology are basically the same. I will not here assess this statement, but in this paper I view it as a continuum between what can be seen as a distributed cognitive process and what formed, constrained, or altered this process. In this paper I want to focus on the latter aspect. "Cognitive ecology" has mostly been used in the field of animal cognition where the focus is on how the ecology shapes intracranial cognitive process (Dukas \& Ratcliffe, 2009). In this paper I use the term cognitive ecology to explain something that also shapes processes that incorporates both intracranial and extracranial resources.

Hutchins (2010a) notes that cognitive ecology both can be viewed from a synchronic perspective (that is functional relationships in the present), and a diachronic perspective (that is cognition as development of cognitive ecologies). Much of the research into this field has focused on what goes on in the present without saying much about the developmental aspect of the cognitive process or mediated action (Sutton, Harris, Keil, \& Barnier, 2010; Wertsch, 1998). This difference is important because what can constrain the use of resources is not always found in the present, "on the spot" (Hutchins, 2010b). We live and are shaped by cultural practices that to some extent determine the ways we "do things". Clark (2008) also emphasizes the understanding of interaction between different systems and specifically the continuous reciprocal causation between these systems. A key foundation for these related principles is the understanding of how the processes of constraining, altering and forming cognitive processes occur. For instance, why does someone use a particular artifact in a certain way? The answer can be found outside the individual and the specifics of the artifact.

Cognitive ecology suggests a unit of analysis that focuses on "units defined in terms of dynamic patterns of correlation across elements" (Hutchins, 2010a, p.705). What the correct unit of analysis should be to explain cognitive phenomenon is therefore not given before we have some understanding of the synchronic and diachronic ecology of where the phenomenon takes place.

Tribble (2011) used an ecological approach when she studied and historically analyzed theatre practices in the English renaissance theatre. The objective for her analysis was to explain the impressive performance of individuals
performing up to six different plays in a week with irregular and limited practicing time. One explanation of such a fact could easily be that these people had amazing memory abilities. But she proposed a larger dynamical model of this memory performance where it is important to understand the ecological differences that exist between theatre practices today and theatre practice back then. Back then "much preparation was individual, facilitated by the individual parts containing only the character's lines and his cues." (p.14). Much of this success was also facilitated by the ecological niche of the physical and social environment, where for instance parts were written to suit less experienced actors.

In her analysis she introduces the term "cognitive thrift", which is a principle that suggests that in a highly cognitively demanding environment, such as the theatre in this era, "every incentive would have been to minimize any additional cognitive burdens" (Tribble, 2011, p.32). In her conclusion she notes that cognitive ecologies "place more or less weight in internal mechanisms, on central control, or on particular forms of cognitive artifacts and social systems" (p.153). It can be argued that doing comparative studies of cognitive ecologies allow cognitive scientists to understand the relative contribution of different parts of a system to uphold reasonable performance.

In the case of healthy older adults coping with everyday life, it is not as easy to say that this is a highly cognitively demanding environment. Older adults cope well with everyday life in comparison with their performance in labsettings, and one suggested explanation of this is that older adults seldom need to perform at their cognitive maximum in their normal life (Salthouse, 2012). How something as a cognitive ecology works in a setting where performance in a specific way is not often as demanding is to my knowledge rather unexplored. A term such as "cognitive thrift" might not apply in this context. This is because when we talk about cognitive ecology and distributed cognition we often do so in the domain of so called cognitively rich environments where a slight change in the ecology can profoundly shape the process and the performance.

The question that follows is what a cognitively rich environment is? In the case of early modern theatre or on a navigational bridge it can be interpreted as a measure of how much information that flow across various media, which directly relates to the problem at hand. How densely does the information flow across the various (tightly coupled) media to solve problems in everyday life is for me still an open question. Neither can we easily say that the environments and processes that take place within these environments of everyday life are task specific since these environments often have multiple purposes. How a cognitive ecology can form, constrain and alter cognitive processes and to some extent predict (according to some measure) successful performance in the lives of older adults would not necessarily be based on the same principles as in the highly demanding environments.

## The ecology as opposed to the active individual

As noted above, one point made by Tribble (2011) is that even though memory demands were high in the early modern theatre practices, much of this taxing work was not solely placed on individual cognitive abilities. Much of this pressure was left to various aspects of the overall physical and social system of the theatre in work. The tension between the idea of an active individual and a shaping society or environment has been around for some time in various scientific fields (Wertsch, 1998). In cognitive science many have argued that too much emphasis has been put on the individual, placing to many cognitive abilities simply inside the skull as default (c.f. Hutchins, 1995). Wertsch (1998) argues that this is a question without an obvious answer since answers to this question are often not based on empirical grounds. In this paper I use one side of this dichotomy, the circumstances that shape, as an analytical tool to understand important aspects of the process.

Wertsch (1998), by adopting the "pentad" proposed by Burke (1969), uses a further elaborate analytical tool in his focus on mediated action as the unit of analysis. The pentad consists of act, scene, agent, agency, purpose, or in Wertsch:s words "What? Where? Who? How? and Why?" (p.13). The point is not that these are true reflections of reality; it is rather that they are tools for the interpretation of reality. Focusing on mediated action can be understood as emphasizing certain parts of the pentad and de-emphasizing other parts. The scene is for instance not included much in an analysis of mediated actions (Wertsch, 1998). But on the other hand Wertsch argues that focusing on mediated action allows us to be in the middle of an individual and collective/distributed perspective. The agent and her mediational tools (see cognitive tools) are irreducible to each other in terms of the action. In my examples below I will use the idea of a scene as something that realizes and in a true sense constrains and alters the cognitive process in certain directions and therefore also sometimes alters the mediated action. The scene is here part of the cognitive ecology that Tribble uses in her analysis.

Wertsch (1998) also focuses on the fact that mediational tools have often been developed for other purposes than the reasons they are used for in the present. Therefore he emphasizes investigation of both consumption of mediational means and production of mediational means. Regarding the production of mediational tools he notes that tools are often borrowed from other sociocultural contexts and that the processes of what he calls a spin-off of actions with certain mediational tools are not always developed from a clear purpose of an inventor.

Even if we in this description find the notion of an agent that borrows and produce mediational tools, the idea of the pentad suggests that we can analyze what is not physically part of the agent and the tool and say something about how the agent and her mediational tools became orchestrated in an action or in a distributed cognitive process.

The role of the individual can theoretically be pictured as a continuum from a top-down driven agent to a bottomdriven agent to factors that stand outside the role of the agent but still support the cognitive process. Clark (2006) talks about ecological control as something we do when we do not micromanage every point in the process but still search for opportunities. When we do not micromanage the process, much of what constrain the process is outside the individual's scope of control. Certain processes have been developed to suit certain ecologies. To illustrate this I now turn to cases from a conducted cognitive ethnography of elderly people.

## Ethnography of everyday life

Previous research in cognitive aging suggests that older adults actually do have an active role in their compensatory practices for declining memory abilities (c. f. Frias, Dixon, \& Bäckman, 2003). Through self-reports older adults often report that they adopt external memory aids and cooperation with social others (c. f. Cavanaugh, Grady, \& Perlmutter, 1983; Frias et al., 2003). With such premises, even though they are based on self-reports, it is worth asking to what extent such a wide unit of analysis as cognitive ecology is applicable and at all important in these kinds of less problem-centered environments.

The material referred to below was collected as part of a cognitive ethnography during the summer of 2010. The scenery of this is in the home healthcare system where I worked as a healthcare assistant. Within this context I conducted interviews outside the role as an assistant, and observation in the role as an assistant. Most of the participants had normal cognitive functioning for their age and some had diagnosed memory declines. The specifics for each case are provided with the examples (but for more information see Dahlbäck, Kristiansson, and Stjernberg, 2013).

The following sections are categorized according to conclusions I can draw from the specific examples presented, together with the overall material collected in relationship to earlier theorizing in cognitive ecology (Hutchins, 2010a; Tribble, 2011) and earlier presented ideas of Wertsch (1998).

First I consider the general case that environmental factors together can enact certain cognitive processes. Second I relate cognitive ecologies of everyday life in relationship to the use of cognitive artifacts. Third I discuss the social nature of everyday life and how these social circumstances form cognitive processes. Fourth I note that the ecology can form the goal of cognitive processes and last I discuss how we can understand diachronic processes by understanding how ecologies shape cognitive processes.

## Environmental factors enact the nature of cognitive processes

A is 91 years old with a normal cognitive decline for his age. He has problems with hearing and particularly seeing.
(All examples in this paper are verbatim translations from Swedish from my original field notes.)
"He tells me that he goes to the grocery store almost every day: "there is always something you need and there is also a seating arrangement where there is always someone you know from previous work places". [...] When I ask him if he writes shopping lists he says that he doesn't and that he remembers everything in his head. He pictures how he usually goes through the important places in his home before he goes to the store, checking whether something is missing." (Excerpt from A)

His troubles with seeing were apparent at other times during this interview. The case notes how processes of remembering can be (a) constrained, in this case by his seeing impairment, (b) altered, by the fact that he lives rather close by the grocery store and (c) motivated by the fact that going to the store (almost) every day also has a social incentive. If his cognitive ecology would have been different in terms of social network, physical surrounding and limitations, his processes of remembering could have been distributed differently.

A is also aided by his routine of going through the usual places in his home where things often are missing. By doing this he provides himself with a mental anchor for remembering what was missing at the particular places at home. Partly because he more likely can recall what he found missing, but also because certain places constrain what he can possibly need. In a sense he has invented the method of loci himself. This together with the fact that he goes to the store almost every day makes his process of purchasing groceries a resilient one (c. f. Hollnagel, Woods, \& Leveson, 2006). His strategy works rather well in this specific ecology.

Doing ethnography in the context of the home healthcare services creates a special kind of cognitive ecology. This is because the ethnographer is in many cases part of the cognitive process. Since distributed cognition emphasizes the social aspect of cognition being participatory shapes the phenomenon that we try to investigate. Consider the next entry.
"A large part to achieve the smoothest possible performance is to know by heart what routines apply to what person. Of course there is a general routine of logging into the system, saying hi etc. [...] But to do it as smoothly as possible you need to know what the home environment looks like and the viewpoint of this service from the perspective of the person. Where should the socks hang? Where is the medicine locker? How do you prepare a sandwich in the correct way? (Excerpt from B)

This case is also a about the order of doing things. The smoothest possible performance is about coordinating work and to together remember what to do where, in what order, when. "She didn't recognize me because it was the first time I was there. She started pointing at the medicine locker and asked if I had the keys. [...] When I told her that I had the keys she rose and walked to the other room, apparently to
let me take off the socks before taking the medicine". (Excerpt from B)

Notice how the information of me having the keys initiates a more complex routine where the medicine is not the first goal of the routine. Even if this entry is also about how the work environment taxes the cognitive processes of the worker it also highlights an interesting cognitive ecology where it is important that all actors have a somewhat similar picture of how the activity should develop. If this shared picture is not the case this is indeed a cognitively demanding situation for both parts. But here the ecology of the home healthcare services provides with some structure regarding the predetermined goals of the assistance that the assistant know and can use to adapt to the circumstances of the visit. The receiver also adapts and initiates question, but overall the situation in the case above is cognitively taxing since the ecology is not as when the more experienced workers arrive.

In the case of B (as perhaps opposed to A ) the practice between a home healthcare assistant and the healthcare receiver is a rather predefined practice with certain goals, which have been established over several iterations of the service across several assistants. The receiver has adopted a general routine that works in the ecology of this service, a kind of a "cognitive thrift". The routinized coordinated practice is in this sense more equal to how the cognitive ecology is shaping the cognitive processes on a navigational bridge or in a theatre.

## How the cognitive ecology can shape the roles of artifacts

The case of $C$ below shows something similar to the case of the home healthcare setting above, but this case also shows how the role of a cognitive artifact, in this case a shopping list, are given an unspecified or a degraded role when used in a new cognitive ecology. This entry is from the first time she receives shopping assistance due to a physical problem.
"C uses a shopping list for the shopping session. She makes it clear that it is important for her that she remembers paracetamol as she has none at home and is in some pain. She constantly consults the shopping list to remind herself where to go. In the end, we cannot find paracetamol. I am not used to this supermarket, so I am of no help. She stops and asks a worker, who tells her that it is to be found after the check-out. She wants me to remind her if she forgets. After the check-out she has indeed forgotten, so I remind her." (Excerpt from C)

From the perspective of Wertsch (1998) the mediated remembering through this shopping list has been transformed to a mediated remembering both through the shopping list and a social other. Using the perspective of a cognitive ecology makes it possible to predict that we need to view this activity from different units of analysis. Information is propagated mostly between the subject and her shopping list and also between the subject and her assistant; but also to a lesser degree between the assistant
and C:s shopping list. The idea that artifacts exist with a functional relationship to their ecology has also been noted by Garbis (2002) that studied a tightly coupled cooperative process management setting. Remember that the task described above as defined through the home healthcare service was not about remembering things, it was about the physical challenge grocery shopping entails. But nevertheless the activity provides a certain kind of cognitive ecology that provides certain kinds of resources, that in this case inevitably creates a kind of process.

It is possible to view this process from two perspectives. One is that the individual must be active in this process, choosing resources and utilizing the resources sufficiently to perform reasonable good. The other, as noted, is to emphasize the circumstances that give rise to the role and utilization of resources.
" $D$ has memory problems and cannot always remember whether the home healthcare personnel have been on their visit to her, so she keeps the used time and day-specific plastic medicine envelope on her kitchen table after it has been used as a way of helping her to assure herself that they have been there that day. For this visit, she comes running after me as I am about to throw away the plastic envelope in the bin." (Excerpt from D)

The case is that this envelope has information so that it works as memory trace of previous activities. In this case it is worth noting, despite her memory problems, the active role of D to achieve good performance (Dahlbäck et al., 2013). She takes a cognitive artifact developed for one purpose and uses it in a different context for a different purpose (compare Wertsch, 1998).

But again this is also in a relationship to the cognitive ecology and how it realizes the use of an artifact in an efficient way. The experienced and the inexperienced home healthcare worker create different cognitive ecologies taxing mental resources of parts of the system differently. Under normal circumstances this cognitive system is a rather stable one. On the other hand part of the normal cognitive ecology is that there are different agents in operation creating a normal variation in the system. Another thing about the ecology in this case that is worth noting is that she comes running when she hears me throwing away the plastic envelope. She lives in a relatively small apartment and can therefore not be too far away from the action taking place. In this case she hears a sound from the bin that usually is not there. The artifacts in the cases of C and D have certain existences due to ecological factors.

## The social happenstance

I have already talked about the understanding of the cognitive process in the home healthcare services as a special kind of ethnography since the ethnographer is literally part of the cognitive process. In cases when people have a pronounced cognitive decline, that idea is not very strange since they are in the home healthcare system for that reason. But most of the time (at least in this specific unit) people are not in the home healthcare system because of
cognitive problems, but for a variety of physical problems. The point is that much of what in specific situations has formed the cognitive process is not always part of the cognitive process, but can be considered part of the cognitive ecology.

Consider the case of E, who each morning calls a few of her sisters to simply update the status of their lives. The fact that this happens each day tells us that they are rather good at keeping track of each other. The routine gives an arena for distributed processes of remembering. The fact that they are calling each other each morning and having a social environment that allows for such communication is part of their cognitive ecology. This is a kind of cognitive arena since it likely shapes the nature of the communication, which in turn shapes the distributed processes as they arise.

In a similar way we could view the case of $C$. In an interview with A I asked him in relation to his seeing problems what happens when they re-arrange in the grocery store, whereupon he quickly answers that "there is always someone that you can ask about the location of things". In the future detailed studies of situations where the social arena works as a resource can be of importance if we want to understand how individuals utilize this arena sufficiently.

## The smoothest possible performance

Part of understanding the ecology of cognitive phenomenon is to understand what a reasonable performance is for the particular subject or group. In the English Renaissance theatre it was the "smoothest possible performance" and not necessarily perfect recall (Tribble, 2011). In the case of $A$ above it is possible that the smoothest possible performance is not to perfectly recall all the groceries needed each day. For A, depending on the importance of the grocery, forgetting to buy something one day includes a new possibility to remember to purchase it the next day. A process-oriented view on memory deemphasizes the product of what to remember. To understand how humans remember we need to look on the process of remembering (c. f. Dixon, 1999). One important aspect of this is that this is from the perspective of the scientist conducting her research. The product from the subjective perspective in real-life settings can in a very true sense be the most important aspect. Consider the case of E .
" $E$ has an appointment at the podiatrist. She has a note from the podiatrist which she has posted on her fridge. She has turned the note around and written the date again, though bigger this time. She has also noted this in her calendar, located on the kitchen table. This calendar is always located on the kitchen table. For some unknown reason, the dates have gotten mixed up, and the wrong date has been transferred to her calendar." (Excerpt from E)

This is an interesting example since it shows the usage of different external sources for the same information. We can note that remembering appointments can be considered a highly important task to perform perfectly on since it is maneuvered with so many different resources. The smoothest possible performance is in this case, as in contrast
to the grocery shopping, perfect recall. The point here, similar to what Tribble (2011) noted, is that the social and cultural environment to some extent determines what "the smoothest possible performance" is. This is also an example of how the understanding of the mediated action gives insight to the nature of the purpose of the action (Wertsch, 1998).

Consider once again the case of A . What would happen if A would have a longer way to the grocery store? An apparent consequence would be that A:s physical limitations would be strained and therefore he may decide to not go to the store at all. But imagine that he still would manage despite the larger physical demand, and perhaps decide to walk there every second day. Would not his cognitive processes be composed in a different way? It would at least change what the smoothest possible performance would be. If one had a long road to the grocery store one would not as likely want to forget to buy something. Further, if the goal of the activity changes, the process will likely also change. Perhaps his loci-inspired remembering would be backed up with a shopping list despite his problems with seeing. This is of course an imagined world, but not an unlikely world.

## Cues of a diachronic process

As previously mentioned, an understudied part of cognitive ecologies is the diachronic perspective; that is how cognitive processes develop over time. The discussion of B shows how the study of the ecology can give insight into how cognitive processes develop. If one aspect of the ecology changes the process may also do so. Consider the next case of E :
"E demonstrates how to clean spoons discoloured by tea with the help of baking powder. E stands by the sink while the daughter and I are sitting by the kitchen table. [...] The daughter notices that $A$ uses the wet spoon in the powder container: "you can't do that, it will ferment". E answers quickly, and suggests that it will not ferment and will not be used for baking: "yes I can, because it is old baking powder". When E returns the container to the cupboard, the daughter remarks that she shouldn't place it next to the active baking powder. E rebels against her daughter's suggestion and places it next to the active container. She stops for a moment and lifts it a couple of times and says that she will anyway pay attention to and remember by the weight that it is the right one. The daughter remarks that at some point the containers will be of the same weight and they will be indistinguishable. E adds that anyway she always tests if the powder is active before baking."

We can view this from the perspective of cultural practice. E has learned to clean spoons in this way and (at least she claims) incorporated that knowledge into another activity, baking. She does not need an external memory aid to find the correct active baking powder. She instead remembers the practice of testing the powder, which appears to work instead of the daughter's suggested strategy. Understanding the practices of a group can predict development of cognitive strategies over time. Certain
ecologies of practices shape certain needs to develop certain kinds of cognitive processes. In the case of $E$ a cognitive process is used that can resist the process of cognitive aging rather efficiently.

Previously I have also discussed examples where we can predict that changes in cognitive ecologies such as suddenly being part of the home healthcare system constrain and alter the cognitive processes. Changing the social circumstances in general such as giving more structure or expectation of certain activities changes the cognitive processes involved, such as the use of an artifact for some purpose. The case of D previously is likely the clearest example of this, where the role of the envelope as an artifact is given two functions to serve different components of the activity. Understanding changes and ecological factors in people's lives can help us understand the diachronic aspect of cognitive processes and possibly also predict cognitive performance in new ecologies.

## Concluding remarks

Still there is a need to understand what the differences are between kinds of ecologies and what principles are at work in the shaping processes of cognitive processes in everyday life. It is still rather unexplored how distributed cognitive processes work in a less clear purpose-driven environment, in a less information dense environment, that are guided by a more or less clear socially structured environment, and that are more or less demanding for individuals. The importance of having a cognitive process adapted to the cognitive ecology can be different between these environments. It can be that the role of the individual is far more important in everyday life situations, and that the role of the ecology is more subtle in these environments since it is an ecology that do not shape, alter or constrain the cognitive process as much as other ecologies.

I have used the case of older adults to show that cognitive ecology is a useful term to understand cognitive processes in everyday life. But I do not believe that the points made throughout the second half of the paper are specific to older adults. Older adults are an interesting group for many reasons. One is that they have been investigated quite thoroughly in lab-settings and that we know that the prediction of lab-performance to the settings of their everyday life is low. Cognitive ecology is one way to understand this. But we all live in an everyday life where the social network and the length to the grocery store to some extent shape our cognitive processes. This paper shows that the ecology can shape how much effort we put into our cognitive processes, how we distribute them and how we create routines for them in everyday life environments.

# What Aspects of Cyber Cruelty are judged most distressing? An Adaptive Conjoint Study with Two Independent Samples 

Christina Kuhlmann (s1chkuhl@uni-trier.de)<br>Stephanie Pieschl (pieschl@uni-muenster.de)<br>Torsten Porsch (t.porsch@uni-muenster.de)<br>Department of Psychology, Westfälische Wilhelms-Universität Münster, Fliednerstraße 21, 48149 Münster, Germany

#### Abstract

Cyberbullying is defined as bullying via electronic means including the defining characteristics of repetition over time, intent to harm, and power imbalance. However, this normative top-down definition is discussed controversially. We argue that the term "cyberbullying" and the associated defining criteria might constrict our focus artificially. Therefore, we investigate bottom-up which aspects of cyber cruelty contribute to victims' distress in an adaptive conjoint design with two independent samples (sample 1: $n=131$; sample 2: $n=82$ ). Six potentially relevant factors were investigated, each with multiple attributes: number of incidents, perpetrator status, perpetrator motive, and type, medium, and publicity of cyber incident. Contrary to the definition of cyberbullying, number of incidents, publicity, and type of cyber cruelty emerged as most important factors. These results allow us to further map the cognitive representation of cyber cruelty and are practically relevant for the definition and measurement of cyberbullying.

Keywords: cyberbullying; electronic communication; emotional distress; cognitive representation; conjoint analysis.

## Theoretical Background

Cyberbullying - namely bullying via electronic means - is a prevalent problem among today's youth with mostly negative consequences (Tokunaga, 2010). In order to adequately research this phenomenon and to ultimately design effective prevention and intervention measures, a precise conceptualization of this construct is paramount (Ybarra, Boyd, Korchmaros, \& Oppenheim, 2012).

However, one area of controversy is the literal connotations of the composite term "bullying". Today most scientists agree that bullying denotes an "aggressive, intentional act or behavior that is carried out by a group or an individual repeatedly and over time against a victim who cannot easily defend him or herself" (Olweus, 1993; cited in Smith, Mahdavi, Carvalho, Fisher, Russell, \& Tippett, 2008, p. 376). Thus, repetition, power imbalance, and intent to harm are considered the key defining characteristics of bullying. But research shows that the understanding of "bullying" differs between historical eras, cultures or age groups (Smith \& Monks, 2008). For example, in cultural comparisons, one of the biggest challenges is finding translations of "bullying" with equivalent meaning. Most often, terms vary in breadth and cognitive connotations; "the social construction of meaning and its cultural and temporal variability become apparent" (ibid., p. 110).

With the advent of electronic communication and the first reported cases of online cruelty, the term "cyberbullying" was coined to refer to this new phenomenon. The definition of conventional bullying was transferred to cyberspace, and cyberbullying was defined as "an aggressive, intentional act carried out by a group or individual, using electronic forms of contact, repeatedly and over time against a victim who cannot easily defend him or herself" (Smith et al., 2008, p. 376). However, this theory-based top-down definition of cyberbullying has been discussed controversially ever since (e.g., Dooley, Pyzalski, \& Cross, 2009; Grigg, 2010; Menesini \& Nocentini, 2009; Pieschl et al., in press).

Recent empirical investigations about the connotations and cognitive representations of the term "cyberbullying" offer the possibility to shed further light onto this issue from a data-driven, bottom-up perspective. Results from a multidimensional scaling analysis with 2,257 adolescents from six European countries (Menesini et al., 2012) show that the most important dimension of cyberbullying is characterized by the imbalance of power and the second most important dimension is characterized by intentionality. When adolescents classify a scenario as cyberbullying, they seem to mainly consider the presence of these criteria. Focus-group interviews of 70 Italian, Spanish and German adolescents (Nocentini, Calmaestra, Schultze-Krumbholz, Scheithauer, Ortega, \& Menesini, 2010) on the other hand show that in some cases, subjects consider the publicity of an incident as a substitute of the criterion of repetition. Further, they consider victims' perceived level of distress more important than an existing imbalance of power and view victims' interpretation of an incident more critical than an existing intent to harm. These results seem to imply that the cyber-victims' experience is more important than the adherence to normative criteria. Adolescents from another focus group study go even one step further; they consider the term cyberbullying "vague, inadequate and restricted" (Grigg, 2010, p. 151) because of the broad and varied set of negative incidents that can happen on the internet but that are not covered by this term.

We argue that these investigations about subjects' interpretation of the term "cyberbullying" can only show one side of the coin: Subjects evaluate the normative criteria of cyberbullying. But generations of students have been taught the definition of "bullying" in school. Therefore, it is not surprising that they consider incidents as "cyberbullying" that are consistent with this learned
definition. Thus, the term "cyberbullying" might artificially constrict researchers' and practitioners' focus. Many hurtful online experiences do not fall into this narrow definition.

Therefore, we advocate a complementary route of investigation to also shed light onto the other side of the coin: We explore which aspects of cyber incidents are evaluated as most distressing and use these as cognitive criteria underlying a more inclusive definition of cyber cruelty. This approach is consistent with adolescents' views (Grigg, 2010; Nocentini et al., 2010). It is also consistent with the diagnosis of psychological disorders; only those disorders are considered that cause clinically significant distress or impairment in specific areas of functioning (American Psychiatric Association, 2000).
We assume that not only defining criteria of "cyberbullying" are relevant to the experience of distress but also cyber-specific factors (for an overview see Table 1). More specifically, the criterion of repetition can be captured in a straightforward way by investigating the impact of different number of incidents. Power imbalance, on the other hand, can have many facets, such as age, competence or intelligence; in this study we consider the social status of the perpetrator in terms of perceived popularity (Pieschl et al., in press) as well as anonymity (Dooley et al., 2009; Menesini et al., 2012) (perpetrator status). Besides intent to harm and the related motives of feeling superior and whish for appreciation (Olweus, 1996), we also consider that perpetrators might not be aware of the consequences of their behavior and instigate seemingly cruel incidents for fun (Twyman, Saylor, Taylor, \& Comeaux, 2010) or that they might seek retaliation (Vandebosch \& Van Cleemput, 2008) (perpetrator motive). For these criteria of (cyber-)bullying, we predict that those incidents including repetition, power imbalance and intent to harm will be more distressing than other incidents.

As first cyber-specific factor, we consider selected types of cyberbullying and cyber cruelty (Pieschl et al., in press; Willard, 2007): harassment (insults or threats), denigration (spreading rumors), outing (revelation of secrets), impersonation (passing off as someone else) and exclusion (from online groups and activities). The second cyberspecific factor is the medium. Because recently, hardware and software applications merge, we will consider the representational code as most relevant dimension; we predict that pictorial incidents will be more distressing than written / verbal ones (Pieschl et al., in press; Smith et al., 2008). Our third cyber-specific factor is the publicity of the incident; we predict that public incidents are more distressing than semi-public and private ones (Nocentini et al., 2010).

In the context of cyberbullying, distress has mainly been investigated on an emotional level, for example as feeling upset or stressed (Ortega, Elipe, Mora-Merchán, Calmaestra, \& Vega, 2009). But it also incorporates cognitive facets such as helpless cognitions, for example thoughts like "My situation is hopeless" (Pieschl et al., in press). Furthermore, previous research shows that
participants with a history of victimization consistently report higher levels of distress when confronted with bullying and cyberbullying scenarios (Bauman \& Newman, 2013). Thus, we also predict that previous cyber experience is relevant for the level of cognitive-emotional distress.

## Hypotheses

In this study we investigate two main hypotheses in an adaptive conjoint design: (1) Not all factors are equally important for the experience of distress as a result of cyber cruelty; the utility values of these factors differ significantly. More specifically, we predict that not all defining characteristics of (cyber-)bullying (number of incidents, perpetrator status, and perpetrator motive) are judged more important than cyber-specific factors (type, medium, and publicity of cyber incident). (2) The part-worth utility values of the attributes of each factor differ significantly (all attributes are given in Table 1). We predict more distress associated with more frequent cyber incidents (number of incidents), with popular perpetrators (perpetrator status indicating power imbalance) who have an intent to harm (perpetrator motive), and pictorial (medium) and public (publicity) cyber incidents. For type of cyber incident, this is an explorative research question. Furthermore, we explore two research questions about between-subject differences: (3) The results regarding (1) and (2) differ significantly according to previous cyber-experience; previous cybervictims report the highest level of distress, significantly more than previous cyber-perpetrators. (4) The results regarding (1) and (2) can be validated in two independent samples; in both samples we predict similar results.

## Method

## Samples

Sample 1 consists of 133 high school students. Data from 2 students had to be excluded because of missing data, thus the final sample size is $n=131$. These 43 boys ( $32.8 \%$ ) and 88 girls ( $67.2 \%$ ) are on average $17.47(S D=1.01)$ years old and spend on average 2.43 hours ( $S D=1.50$ ) on weekdays and 3.66 hours ( $S D=2.72$ ) on weekend days on the internet. Sample 2 consists of 91 young adults. Data from 9 young adults had to be excluded because of missing data, thus the final sample size is $n=82$. These 18 young men ( $22.0 \%$ ) and 64 young women ( $78.0 \%$ ) are on average 20.29 ( $\mathrm{SD}=1.14$ ) years old and spend on average 2.90 hours ( $S D=1.75$ ) on weekdays and 3.85 hours ( $S D=2.69$ ) on weekend days on the internet.

## Material

Adaptive Conjoint Analysis: Distress Measure An adaptive conjoint analysis (ACA; Gustafsson, Herrmann, \& Huber, 2007) was presented by the online survey system Unipark (© Questback). In this part of the study, participants had to imagine that they were cyberbullied and they had to rate their level of distress associated with multiple fictitious incidents that were described by
combinations of attributes. The relevant factors and attributes can be seen in Table 1. Because of the high number of factors and attributes in this study, we used a fractional factorial design. Yet the maximum gain of information was reached by using the adaptive conjoint design. The system automatically arranges the scenarios based on subjects' previous judgments by choosing those attributes whose comparison provides the maximum of new information.

Table 1: Factors (defining characteristics and cyberspecific) and corresponding attributes investigated in the adaptive conjoint analysis.

| Defining Characteristics | Attributes |
| :--- | :--- |
| number of incidents | once <br> $2-3$ times per month <br> weekly <br> multiple times per week |
| perpetrator status | anonymous <br> popular <br> unpopular |
| perpetrator motive | intent to harm <br> feeling superior <br> appreciation by others <br> retaliation <br> fun |
| Cyber-Specific Factors | Attributes |
| medium | written / verbal <br> pictorial |
| publicity | private <br> semi-public <br> public |
| type of cyber incident | harassment <br> denigration <br> outing <br> impersonation <br> exclusion |

In the preference for levels phase of the ACA, participants rated the level of distress associated with each attribute on a 6 -point scale ( $1=$ not upsetting $-6=$ very upsetting). In the attribute importance phase, the most and least distressing attributes of each factor were contrasted and participants had to judge on a 4-point scale if these were "equally upsetting" or "one is more upsetting than the other". In the phase of paired-comparison trade-off questions, we presented two fictitious cyber incidents, each consisting of 2 or 3 attributes of different factors. On a 5 -point scale with one situation located at each end, subjects had to decide which situation was more distressing. In the final calibrating concepts phase, participants had to rate the level of distress associated with cyber incidents consisting of a combination of 4 attributes of different factors on a scale from 0 (not at all distressing) to 100 (very distressing).

Based on participants' judgments, Unipark (© Questback) automatically computes part-worth utilities for each
attribute and utility values for each factor. High values indicate that a specific factor (or attribute) is relatively important for participants' judged distress while low values indicate relative unimportance.

Cyber Experiences Questionnaire We adapted the cyberbullying questionnaire of Riebel, Jäger and Fisher (2009) to include the following five of Willard's (2007) categories: harassment, denigration, impersonation, outing, and exclusion. Students were asked how often these incidents happened to them via cell phone or the internet (cyber-victim) and how often they instigated such incidents themselves (cyber-perpetrator) in the last two months. All answers were given on 5 -point scales with the categories "never", "once", "2-3 times per month", "weekly", and "multiple times per week". Cyber involvement was diagnosed if students gave at least once a different answer than "never" (cyber-victim and cyber-perpetrator). Participants who reported both cyber-victim and cyberperpetrator experiences were classified as cyber-perpetratorvictims. Note that we do not refer to these experiences as cyberbullying because some of the conventional criteria for bullying are not fulfilled, for example repetition over time.

## Procedure

Sample 1 was recruited at the Open Day of the Westfälische Wilhelms-Universität Münster, Germany. High school students visiting the Department of Psychology volunteered and their data was collected in group sessions in a computer lab. Sample 2 was recruited from a database of adult volunteers maintained by the same department of psychology; participants were sent the link to the online survey and answered at will. All participants answered the same electronic survey presented by Unipark (© Questback). It consists of demographic questions, the adaptive conjoint analysis, the cyber experience questionnaire and further questions ${ }^{1}$.

## Results

## Descriptive Results

Sample 1 and sample 2 differ significantly in age $(t(211)=-18.92, p<.001)$ and average internet use on weekdays $(t(211)=-2.11, p=.036)$. On average, sample 2 participants are older and spend more time on the internet on weekdays. Sample 1 and sample 2 also differ significantly in their cyber experience ( $X^{2}(3)=13.82$, $p=.003$ ). In sample 1 , only $37.4 \%$ of students were not involved in cyber incidents in the last two months, $22.9 \%$ were classified as cyber-victims, $15.3 \%$ as cyberperpetrators, and $24.5 \%$ as cyber-perpetrator-victims. In

[^319]sample 2, a total of $61.0 \%$ young adults were not involved in cyber incidents in the last two months, $18.3 \%$ were classified as cyber-victims, $12.2 \%$ as cyber-perpetrators, and $8.5 \%$ as cyber-perpetrator-victims. Therefore, the variables "sample" and "cyber-experience" will be included as between-subject factors in all subsequent analyses.

## Hypothesis 1: Factor Differences

To investigate hypothesis 1, we computed a repeatedmeasure ANOVA with the utility values of the six factors as repeated-measure dependent variable and cyber-experience and samples as between-subject factors. The results show a significant main effect of the repeated-measure factor $(F[4.5,921.7]=19.67, p<.001)$, but no significant differences between groups with different cyber-experiences $(F[3,205]=1.73, \quad p>.05)$ or between samples ( $F[1,205$ ] $=3.45, p>.05$; see Figure 1), and no significant interactions between these factors $(F[13.5,921.7]=0.5$, $p>.05$ ).

Figure 1: Utility values of the six factors extracted from the conjoint analysis; these values indicate distress.

As can be seen in Figure 1, publicity, number, and type of cyber incidents were assigned the highest utility values and these did not differ significantly from one another (publicity vs. number: $F[1,205]=0.75, p>.05$; number vs. type: $F[1,205]=0.96, p>.05)$. Perpetrator motive was judged significantly less important (type vs. motive: $F[1,205=12.42, p=.001)$, followed by perpetrator status (motive vs. status: $F[1,205]=8.72, p=.004$ ). Medium of incident was judged least important but did not differ significantly from perpetrator status $(F[1,205]=3.00$, $p>.05)$.

## Hypothesis 2: Attribute Differences

To investigate hypothesis 2 , we computed repeated-measure ANOVAs for the attributes of each factor separately. In each ANOVA the part-worth utility values of all attributes of one factor constitute the repeated-measure dependent variable, while cyber-experience and samples constitute the between-subject factors. We report only significant effects ordered by factor.

In all ANOVAs we found main effects of the repeatedmeasure variable: More frequent incidents were judged more distressing (number: $\quad F[2.1,432.4]=183.11$, $p<.001$ ), popular perpetrators were judged more distressing than anonymous ones, followed by unpopular ones (status: $F[1.9,389.7]=50.79, p<.001$ ), the intent to harm was judged more distressing than fun, followed by retaliation, appreciation by others, and feeling superior (motive: $F[3.6,731.7]=35.64, p<.001)$. Furthermore, pictorial incidents were judged more distressing than written / verbal ones (medium: $F[1,205]=123.00, p<.001$ ), more public incidents were judged most distressing, followed by semipublic ones and private ones (publicity: $F[1.5,306.7]=203.20, p<.001$ ), and outing was judged most distressing, followed by harassment, denigration, exclusion, and impersonation (type: $F[3.8,774.6]=7.51$, $p<.001$ ). To give one more specific example (number; see Figure 2): incidents "multiple times per week" were judged significantly more distressing than "weekly" incidents $(F[1,205]=11.90, p<.001)$ which were in turn judged significantly more distressing than incidents "2-3 times per month" ( $F[1,205]=72.36, \quad p<.001)$ and those were judged significantly more distressing than a single incident ("once": $F[1,205]=157.84, p<.001$ ).

Figure 2: Part worth utilities of the attributes for the factor number extracted from the conjoint analysis; these values indicate distress.

In all ANOVAs we also found main effects of the betweensubject factor cyber-experience. More specifically for number of incidents $(F[3,205]=3.21, p=.024)$, perpetrator status $(F[3,205]=3.21, p=.024)$, perpetrator motive $(F[3,205]=3.21, p=.024)$, and for medium $(F[3,205]=3.21, p=.024)$, publicity $(F[3,205]=3.21$, $p=.024)$, and type of cyber incident ( $F[3,205]=3.21$, $p=.024$ ). In all cases cyber-victims judged most attributes significantly more distressing than cyber-perpetrators. Additionally, we found significant interactions between the repeated-measure factor and cyber-experience for perpetrator motive ( $F$ [10.7, 731.7] $=1.87, p=.041$ ) and publicity $(F[4.48,306.7]=2.7, p=.025)$. To give one more specific example (number; see Figure 2): across all
frequencies of cyber incidents, cyber-victims judged level of distress was significantly higher than that of cyberperpetrators ( $M D=.11, p=.012$ ). Furthermore, the judged level of distress of non-involved participants did not differ significantly from that of cyber-victims ( $M D=.03, p>.05$ ) and the judged level of distress of cyber- perpetrator-victims did not differ significantly from that of cyber-perpetrators ( $M D=.01, p>.05$ ).

We found no significant main effects of the two samples in any of the ANOVAs.

## Discussion of Results

Our first hypothesis was confirmed: These results show that there are aspects of cyber cruelty that are perceived as significantly more distressing than others. As predicted, not all defining characteristics of cyberbullying were judged more important than cyber-specific factors. More specifically, while number of incidents was considered among the most important factors, status and motive of the perpetrator - indicative of power imbalance and intent to harm respectively - are considered significantly less important. On the other hand, the cyber-specific factors type of cyber incident and publicity are among the most important factors. Medium of cyber incident emerged as the least important factor.

Our second hypothesis was also confirmed: These results indicate that, for each factor, some of the associated attributes are perceived significantly more distressing than others. As predicted, more distress was associated with more frequent incidents (number), with popular bullies rather than with unpopular bullies (status), with intent to harm (motive), with pictorial rather than with written incidents (medium), and with more publicity. Furthermore, results regarding the perpetrator status indicate that anonymous perpetrators are perceived more distressing than unpopular ones but less distressing than popular ones. Additional results regarding perpetrator motives indicate that all other motives but intent to harm were judged significantly less distressing, more specifically retaliation, fun, appreciation by others and feeling superior. Finally, our explorative research question regarding types of cyber incidents indicates that outing was considered most distressing, followed (in order of descending importance) by harassment, denigration, exclusion, and impersonation. Consequently, the most distressing case of cyber cruelty would be the following one: several public incidents of outing per week, by a popular bully in form of pictures or videos, where the perpetrator wants to harm the victim.

Our third and fourth hypotheses were also (mostly) confirmed: We found no significant effects of the betweensubject factor cyber-experience regarding hypothesis one, but in all analyses regarding hypothesis two the results confirm our predictions (hypothesis 3): For all investigated factors, cyber-victims (and often non-involved participants) reported significantly more distress across all attributes than cyber-perpetrators (and often cyber-perpetrator-victims)
(main effects); further interactions indicate that these differences disappear for very distressing attributes.
Furthermore, the pattern of results in sample 1 and sample 2 did not differ significantly in any of our analyses, pointing to the validity of our findings (hypothesis 4).

On a theoretical level, these findings underline, on the one hand, that defining characteristics of conventional bullying are indeed relevant to the experience of cyberbullying. Repeated incidents with intent to harm and power imbalance are perceived more distressing than other incidents. On the other hand, these results also show that cyber-specific factors are just as or even more important for victims' experience of cyber cruelty. Especially the type of incident and its publicity seem to be important. Therefore, the experience of cyber cruelty seems not (only) to be determined by the (artificial) boundaries of a normative, theory-driven, top-down definition of cyberbullying. Rather, subjects' cognitive representation of such incidents (datadriven bottom-up approach) shows that all proximal factors that concern the content of the incident and thus also the cyber-victim directly - namely number of incidents, type of incident, and the incident's publicity - are judged more important for the experience of distress than more distal factors regarding the perpetrator or medium - namely status and motive of the perpetrator or medium.

## Limitations and Implications

The advantage of using the innovative approach of adaptive conjoint analysis to assess implicit judgments unfortunately goes hand in hand with a possible loss in external validity. Since the attributes needed to be suitable for every potential combination of attributes, they had to be expressed on a rather abstract level. Therefore, imagining concrete cyber incidents might have been complicated and the imagined situations might have been quite idiosyncratic. Additionally, we do not know if the results can be generalized since the experience of cyber cruelty presumably also depends on further personal and contextual factors, for example on previous cyber-experience as shown in this study. But we do not know if the effects of cyber-experience are due to the fact that previous cyber-victims are better able to take the victim perspective or if they point to a cumulative vulnerability as a result of cyber-victimization. Further research is needed. However, the fact that we could replicate our results with two independent samples points to the validity of our findings.

Despite these limitations these results have further theoretical and practical implications that are not only highly relevant for psychology, but might also have implications for other cognitive science disciplines such as linguistics or philosophy. For example, the question of how technical terms such as "cyberbullying" are conceptualized and might constrain human cognition clearly lies at the intersection of psychology and linguistics. On a more concrete theoretical level these results contribute to the controversial discussion within psychology about the definition of cyberbullying: We suggest that cyber-victims'
level of distress should be taken into account for the definition and diagnosis of cyberbullying. Such definitions and diagnosis criteria should not only be based on normative, theory-driven, top-down considerations but also on subjects' cognitive representations of cyber cruelty (datadriven bottom-up approach). We would like to propose the affected subjects' level of distress as potential defining criterion. However, because of the widely accepted criteria of "bullying", another more inclusive term for all kinds of cyber cruelty might be more useful. Further research regarding this issue is needed. However, we can still draw some practical conclusions: For example, the distress associated with outing indicates that adolescents need to be advised of the dangers of sharing private information online. Additionally, the distress associated with publicity indicates that education about data protection and privacy settings could also contribute to the prevention of cyber cruelty.

## Acknowledgments

The data was collected as part of the first author's Bachelor thesis requirement.

# Hierarchical Control and Sense of Agency: Differential Effects of Control on Implicit and Explicit measures of Agency 

Devpriya Kumar (devpriyak@cbcs.ac.in)<br>Centre of Behavioural and Cognitive Sciences, University of Allahabad<br>Allahabad 211002, India<br>Narayanan Srinivasan (nsrini@cbcs.ac.in)<br>Centre of Behavioural and Cognitive Sciences, University of Allahabad<br>Allahabad 211002, India

#### Abstract

While recent studies show dissociation between the implicit and explicit aspects of 'sense of agency', the mechanisms underlying these different aspects of agency are not yet clearly understood. We argue that the control achieved at different levels of hierarchy is important for different aspects of agency. In the current study, we investigate how changes in control at the perceptual-motor level and at goal level influence implicit and explicit measures of sense of agency. In a given trial, participants were first required to aim at a target in a noisy environment and then shoot at the target. After certain interval, a circle flashed at the location where participant aimed while pressing the trigger. Participants estimated the interval between action and presentation of the circle that acted as a measure of intentional binding, an implicit measure of agency and also rated an explicit sense of authorship. The results suggest that different aspects of agency and dissociation between implicit and explicit aspects of agency are mediated by control achieved at various levels.

Keywords: Sense of agency; event-control approach; intentional binding; control; hierarchical system; interval estimation.

## Introduction

With every action that we perform, we not only influence our environment but also modify our conscious mental state of being the agent of the action. This feeling is known as sense of agency (Pacherie, 2011). While elusive, this sense of agency (SoA) is central to our conscious experience and has recently gained popularity among philosophers as well as scientists (see Gallagher, 2006, for a review and insight on related issues).
Sense of agency is a complex, multifaceted, phenomenon (Pacherie, 2011). In general two aspects of SoA have been emphasized and studied in detail. Firstly, sense of Agency as first order experience, in which agency is generally linked to the intentional aspect of task. Here an action is considered to be self-generated when the effect of an action matches the intention of the participant (Moore, Lagando, Deal, \& Haggard, 2009; Farrer \& Frith, 2002), or when agency is linked to bodily movement as in the famous rubber hand illusion (Farrer, Frank, Georgieff, Frith, Decety, \& Jeannerod, 2003). This aspect of agency is also called pre-reflective or implicit sense of agency. Secondly, sense of agency as reflective attribution (or sense of
authorship), in which participant is asked to report his/her subjective sense of belief in causing an action (Ebert \& Wegner, 2010; Haggard \& Moore, 2010). Recent models of 'self' (Synofzik, Vosgerau, \& Newen, 2008) take into account these two aspects of agency.

An important measure of agency that has gained prominence in the last decade is intentional binding. Intentional binding refers to the finding that participants perceive the self-generated action and its effect to be temporally closer to each other (Haggard, Clark, \& Kalogeras, 2002b). The concept of intentional binding has been linked in the literature strongly to the sense of agency, that is, the experience of agency is greater when intentional binding is stronger. A recent review (Moore \& Obhi, 2012) suggests that intentional binding has been associated with implicit measures of agency like efference, sensory feedback, causal feedback, and intentionality. Haggard and Clark (2003) have suggested that when motor cortex is stimulated to produce a movement similar to a voluntary movement, intentional binding is not affected, suggesting that intentional binding does not depend on the sensory signals produced during movement, but rather it depends on the efference copy generated during action planning.

Desantis and colleagues (Desantis, Cedric, \& Waszack, 2011) showed that, when participant believes that he/she has control over the environment, intentional binding is stronger. In the original study showing intentional binding, (Haggard, Clark, \& Kalogeras, 2002b) the outcome of a participant generated action was manipulated in terms of intention (intended or unintended). Results indicate that intentional binding is stronger for the intended effect compared to the unintended effect. These and many more studies indicate a strong link between the implicit measures of agency and intentional binding, suggesting that intentional binding can be used as a reliable measure of implicit sense of agency.

In addition, researchers have investigated the relationship between intentional binding and explicit sense of agency or reflective sense of agency (Moore \& Obhi, 2012). In one such study (Ebert \& Wegner, 2010), participants were presented with a picture, which can either move congruent or incongruent to the direction participant moved the joystick. The delay between the participant's movement of the joystick and the movement of the object on the screen
was manipulated at three levels $(100 \mathrm{~ms}, 400 \mathrm{~ms}$, and 700 ms ). At the end of the trial participants were asked to perform a interval estimation task (to measure intentional binding) and give rating of authorship (explicit measure of agency). Authors reported dissociation between the two measures, with the congruency between action and effect, having a greater effect on intentional binding compared to the explicit measure of sense of authorship. The mechanisms underlying these two different measures and aspects of SoA are still not fully understood necessitating a study to understand the mechanisms involved in SoA. The current study investigates the mechanisms involved in determining the implicit and explicit measures of sense of agency and the way in which these two measures might be related to each other.
We argue that the concept of control exercised by the participant over perception-action events can provide us a basic framework to understand both explicit and implicit sense of agency. Recent studies have shown that control might play a crucial role in influencing sense of agency (Desantis, Cedric, \& Waszack, 2011; Moore, Lagando, Deal, \& Haggard, 2009; Jordan, 2003; Kumar \& Srinivasan, 2012; Kumar \& Srinivasan, under review). Studies based on event-control approach (Jordan, 2003; Kumar \& Srinivasan, 2012) suggest that all our interactions with the environment (which are in form of perceptual-action couplings) are constrained by multiple hierarchical control loops extending across organism and his environment (see Jordan, 2003 for details). Sense of agency, according to this framework is determined by the highest level of control loop at which participant is able to exercise control.
We used a modification of the paradigm used by Ebert and Wegner (Ebert \& Wegner, 2010). In the current experiment, the participant had to aim and shoot at a noisy target with the help of joystick and the noise in the environment was manipulated. By changing the amount of noise, we manipulated the perceptual-motor control that the participant can exercise. After the first task, the scenario was made static and a circle flashed at the location where subject aimed during the first task. The duration interval between the time when subject presses the trigger and when the circle is flashed was manipulated. Participant is later asked to estimate this interval and give a confidence rating for authorship of action. Estimated interval acted as a measure of intentional binding and confidence rating measured participant's subjective sense of authorship.
According to the event-control approach, sense of self depends upon the highest level at which control is exercised. In the current paradigm, control can be exercised at two levels; firstly, at the perceptual-motor level, that is the joystick level control and secondly, at the goal level, that is, whether or not participant is able to correctly aim at the target. We hypothesized that when participant misses the target, sense of agency would increase as a function of perceptual-motor control. When the participant hits the target, SoA would be independent of perceptual-motor control.

## Method

## Participants

Thirteen volunteers from University of Allahabad participated in the Experiment.

## Stimuli and Apparatus

Stimuli consisted of eleven natural scenes (resolution $3648 \times 2736$ ) from a custom database. Every scene contained a target region in the form of three concentric circles, placed randomly somewhere in the scene. Experiment was conducted on a 14 " monitor at a resolution of $800 \times 600$, with input from keyboard and joystick. The experiment was designed using MATLAB 2010b and psychophysics toolbox 3.

## Procedure

Participants were instructed that the experiment consists of two phases, practice phase and the main experiment. They were also told that they have to perform time interval estimation and were instructed about what millisecond stands for and an approximate idea of the concept (see Ebert and Wegner, 2010 for more details).

## Practice Session

In the practice session, a fixation cross was presented on the screen. Participants were instructed that they have to press a trigger to initiate trial and they can press the trigger when they feel like. After the trigger was pressed, the fixation cross on the screen turned blue in color indicating that the trigger has been pressed. After a random interval (out of $0 \mathrm{~ms}, 100 \mathrm{~ms}, 200 \mathrm{~ms}, \ldots, 900 \mathrm{~ms}$ ), a blue circle was flashed on screen. Participants were asked to estimate the time interval between trigger press and the circle flashing on the screen. Response was made using a ten point scale ( 0,100 , $200, \ldots, 900$ ). At the end of every trial, participant was given feedback about his/her estimate. The practice session served two purposes. Firstly, it helped improve interval estimation ability and also its assessment. Secondly, it made participants believe that the interval is manipulated at ten levels in the main session too. A total number of 200 practice trials were given with 20 trials for each of the ten intervals. Data from the practice session was used to perform preliminary analysis.

## Main Session

In the main session, for a particular trial, participants were instructed that they have to aim at a target, by moving the joystick and press the trigger, within 15 seconds. To manipulate the amount of control, a random movement was added to the scene. To decrease the amount of control that participant can exercise, amount of random movement was increased. This control varied from trial to trial. We manipulated control at three levels (low control, medium control, and full control). At a random interval after the participant pressed trigger, a blue circle was presented at the
location (always at the centre of the screen) where participant aimed while pressing the trigger. The SOA between the trigger press and the presentation of blue circle was manipulated at three levels $(100 \mathrm{~ms}, 400 \mathrm{~ms}$, and 700 ms ).

The circle remained on the screen for 500 ms , after which the participant was asked to report the interval between trigger press and appearance of circle, on a ten point scale similar to the practice session. In the main session participant was not given feedback regarding the interval estimated. This was followed by a second question, in which participant had to report the sense of authorship, on a seven point scale (similar to the questions used by Ebert \& Wegner, 2010). There were a total of 216 trials in the experiment, with 24 trials in each condition. We recorded estimated interval, rating of authorship, and whether or not the participant hit on the target in each trial. In the main session participants were not given feedback regarding the estimated interval.

## Results

## Preliminary Analysis

Data from the practice session suggest that participants in general are able to correctly estimate the time interval. Similar to Ebert and Wagner (2011), we calculated the mean correlation between actual time and estimated time (mean $r$ $=0.683$ ) that was significantly greater than zero $t(12)=$ $12.3489, p<.01$. Data from one participant that was beyond two standard deviations from the mean $(r=0.2112)$ was removed from further analysis. In the main experimental session, the outcome (target hit/miss) was not controlled or counterbalanced across SOA (given that this is completely dependent on the performance of the participant in a given trial). Hence, to remove bias due to the unbalanced aspect of target hit/miss, we performed a correlation between target accuracy and SOA. The correlation between accuracy and SOA was not significant (mean $r=-0.0129$ ) indicating a lack of relationship between them.

## Interval estimation task

Repeated measures ANOVA with SOA and control as factors on the estimated interval showed an expected significant main effect of SOA, $F(2,22)=23.46, p<.01$ indicating that participants' estimates increased as SOA increased. The effect of control as well the interaction between control and SOA was not significant. We categorized data further into two categories: (1) when participants hit the target and (2) when participants missed the target. For each category, we performed a two-way repeated measures ANOVA across three levels of SOA and three levels of control.
When participants were successful in hitting the target, there was a main effect of $\operatorname{SOA}, F(2,22)=27.17, p<.001$. Estimated interval for $100 \mathrm{~ms}, t(11)=7.76, p<.01$ and 400 ms SOA, $t(11)=4.21, p<.05$, was significantly different from that for 700 ms SOA. The main effect for control ( $p=$ 0.98 ) and interaction between control and SOA ( $p=0.26$ )
was not significant. When participants were not successful, there was a main effect of $\operatorname{SOA}, F(2,22)=34.01, p<.01$, with mean rating for 100 ms significantly different from rating for $400 \mathrm{~ms}, t(11)=7.55, p<.01$, and rating for 400 ms significantly less than rating for $700 \mathrm{~ms}, t(11)=8.6, p<.01$. The main effect of control was significant, $F(2,22)=6.86$, $p<.01$. Paired $t$-tests between different control conditions suggested a decrease in estimated interval with increase in control, with close to significance difference between, low control and medium control, $t(11)=1.619, p=.057$, and a significant difference between medium control condition and full control condition, $t(11)=3.14, p<.01$. The interaction between SOA and control was not significant ( $p$ $=0.7$ ).

(a)

(b)

Figure 1: Estimated intervals as a function of control and SOA (a) when goal was accomplished and (b) when goal was not accomplished

We used the interval estimation task to assess intentional binding between self-triggered event (cause) and a second perceptual event (effect). Results suggest that intentional binding is greater (estimated interval is less) as the amount of control increases, that is when higher level goal is not achieved. When higher level goal is achieved, intentional binding (interval estimate) is not influenced by the amount of control.

## Self-reported control

When subjects were successful in hitting the target, there was a main effect of control, $F(2,22)=35.57, p<.01$. There was an increase in self-reported control as amount of control was increased, from low to medium, $t(11)=3.91, p$ $<0.05$ and from medium to full, $t(11)=12.35, p<.05$. The
main effect of SOA ( $p=0.28$ ) and the interaction effect ( $p=$ 0.26 ) was not significant.

When subjects were not successful, there was a main effect of control, $F(2,22)=5.62, p<.05$. Post-hoc comparisons show a significant difference between low control and medium control conditions, $t(11)=4.5, p<.05$ as well as low control and high control conditions, $t(11)=$ $6.3, p<.01$. The main effect of SOA $(p=0.88)$ and the interaction ( $p=0.4$ ) was once again not significant.

Figure 2: Rating for the sense of Authorship as a function of control and SOA (a) when target is achieved and (b) when target is not achieved

Self-reported control was a measure of subjects' sense of control and authorship (Ebert \& Wegner, 2010). The results suggest that participant's sense of authorship depends on the amount of control and is independent of success or failure in achieving target.

## Relationship between the Two Measures

Results show dissociation between the sense of agency and sense of authorship with respect to various control levels. To further analyze how these dependent measures are related, we performed a correlational analysis between the measure of intentional binding (interval estimate) and authorship (self-reported control) for the two levels of control. When the target goal is not achieved, there was a significant positive correlation between the two measures ( $r$ $(108)=0.2, p<.05)$. When target goal is achieved, the
correlation between the two measures is not significant ( $r$ $(108)=0.13, p=.16)$ indicating differences between the two measures. Sense of authorship seems to depend on the amount of control that a participant exercises at the perceptual-motor level, whereas intentional binding depends on both lower joystick control level as well as the higher goal level control.

## Control \& SOA as Predictors

To further explore how control and SOA can be used to explain the differences in intentional binding as a function of goal, we performed two simultaneous multiple linear regressions for the estimated interval, treating target hit/miss as a dichotomous variable, with control and SOA as independent factors and intentional binding as the dependent measure.

In target miss condition, control ( $\beta_{1}=-92.3, t=-2.5$ ) and SOA ( $\beta_{2}=0.48, t=15.6$ ) were significant (adjusted- $\mathrm{R}^{2}=$ $0.19, F(2,1035)=124, p<.01)$. In target hit condition, SOA ( $\beta_{1}=0.49, t=18.65, p<.05$ ) was significant, but the $\beta$ value for Control ( $\beta_{2}=4.5, t=0.21, p=0.82$ ) was not significant (adjusted- $\left.R^{2}=0.24, F(2,1094)=174, p<.01\right)$. The analysis suggests that estimated interval decreased as the amount of control increases for the trials in which participants missed the target but control is not a significant predictor when the target goal was achieved.

## Discussion

In the current experiment, we investigated the role of control at multiple hierarchical levels in determining the sense of agency (both implicit, via measuring intentional binding and explicit, via rating on sense of authorship). There are a few important results that can be inferred from the data. Firstly, the high correlation between estimated and actual interval supports the idea of using interval estimation task as a valid measure of intentional binding (Ebert \& Wegner, 2010). Secondly, consistent with the findings from that study, our findings show dissociation between the two measures of agency. Thirdly, our study provides support to the hierarchical event-control framework in understanding self and sense of agency (Kumar \& Srinivasan, under review; 2012; Jordan, 2003).

## Control and Intentional Binding

The results for the measure of intentional binding support the hypothesis that sense of agency depends hierarchically on the amount of control at various levels. The results support to the framework provided by event-control approach (Jordan, 2003; Kumar \& Srinivasan, 2012) suggesting that control might play a key role in determining sense of agency. The results of the study are consistent with findings by Berberian and colleagues (Berberian, Sarrazin, Blaye \& Haggard, 2012), who showed the presence of intentional binding in a complex task and a decrease in intentional binding as a function of automaticity in control. A major difference between our study and that by Berberian et al. (2012) study was that although both studies
manipulated control at different levels, the manipulation of control in the two studies is different in nature. In their study, (Berberian et al., 2012), manipulated control along a single dimension (i.e. automaticity level). However, in the current study, control is varied at two different levels (at goal level, and at perceptual-motor level). A second difference is that, in their study, the authors report a strong correlation between the two measures of agency and we find dissociation between the two measures when subjects are able to achieve control at the goal level (hit the target). Both the studies, along with others (Jordan, 2003; Desantis, Cedric, \& Waszack, 2011; Kumar \& Srinivasan, under review) provide evidence that control is correlated to the amount of intentional binding and plays a key role in determining sense of agency.

## Control and Sense of Authorship

For the sense of authorship, our hypothesis was not completely supported by the results. Participants did show an increase in rating with control for the sense of authorship, when participants missed the target, thus supporting first part of our hypothesis. But, this increase in sense of authorship with control was also present when participants accurately hit the target indicating that the explicit measure of sense of agency is independent of control when participants hit the target. In combination, these results suggest dissociation between the intentional binding and sense of authorship. This dissociation has also been found in earlier studies (Ebert \& Wegner, 2010), but the underlying mechanisms are not yet clear (Haggard \& Moore, 2010; (Moore \& Obhi, 2012).

## Underlying Mechanism

Haggard and Moore (2010), commenting on the Ebert and Wegner (2010) study raised certain issues that remain unanswered from the study. Firstly, whether the exact mechanism of consistency is retrospective or prospective in nature? In the current study, control is predictive in nature, the control at perceptual-motor level was based on the prior expectation of participant when they moved joystick to aim at the target. At the goal level, participant's expectation of the outcome occurred prior to the event (as with congruency in the case of Ebert and Wegner. But, unlike congruency (Ebert \& Wegner, 2010), the effect at the goal level occurred immediately before (or at the time) they pressed the trigger. Hence, goal level control can also be assumed to be predictive in nature. This suggests that the mechanism linking control and intentional binding is influenced by predictive processes.
A second issue was the exact causal nature of the link between intentional binding and sense of authorship. Our results suggest that intentional binding is sensitive to the hierarchical levels of event-control. In comparison, the sense of authorship seems to be less sensitive to the eventcontrol hierarchy. Hence, we would like to suggest that intentional binding and sense of authorship are not causally linked to each other, but are rather mediated by amount of
control at different levels that can be exercised by participants.

## Conclusions

We have shown that the theory of event control provides a successful framework to understand sense of agency. We suggest that both implicit and explicit aspects of sense of agency are mediated by hierarchical levels of control, but differently. The dissociation between implicit and explicit aspects of agency can be attributed to a difference in the way hierarchical nested control at multiple levels mediate the different aspects of agency. We have also confirmed that interval estimation task can be used to successfully measure intentional binding.

If it is actually the case that these nested control loops mediate agency, what exactly causes these control loops to mediate various aspects of agency in a different fashion? Possible answers might lie in the nature of control and the potential perception-action interactions between the organism and the environment that are dependent on the control. The study provides a pathway to understanding differences in sense of agency and further experiments would enable to naturalize and understand self.

#### Abstract

Although many psychometric tests, like Raven's Progressive Matrices, are commonly evaluated according to total score, additional variables can lend insight into the underlying cognitive processes. We examine conceptual errors on the Raven's Standard Progressive Matrices (SPM) test. We present a complete classification of error types on the SPM using a two-kind coding scheme, yielding $\geq 95 \%$ inter-rater reliability. We also examine how to extract error data from a computational model, and we present a method for measuring errors through systematic ablation to create a "population" of models whose performance can be examined as a group. We present a preliminary analysis of error patterns on the SPM from typically developing individuals, individuals diagnosed with autism, and a computational model called ASTI. We discuss what the error patterns suggest regarding cognition on the SPM and routes towards improving the ASTI model.

Keywords: ablation experiments; computational modeling; error patterns; mental imagery; psychometrics; Raven's Progressive Matrices; visual representations.

## Introduction

Raven's Progressive Matrices (RPM) is a widely used series of intelligence tests that consist of multiple choice visual analogy problems, as in Fig. 1. Each problem contains a matrix of geometric figures with one figure missing; the correct missing figure that completes the matrix pattern must be selected from a set of answer choices.

Performance is generally measured in terms of overall score, i.e. number correct, which can then be used as an index into normative test data to determine an IQ score or percentile ranking for that individual. While total score is certainly an important variable, serving as a coarse measure of an individual's overall ability, there are alternative dimensions of performance that may provide a finer-grained view of an individual's cognitive processing:

1) Per-item accuracy, e.g. differential item functioning, takes into account potential variation even when individuals may obtain the same total score (Facon \& Nuchadee, 2010; Lynn, Alik, \& Irwing, 2004; Van Herwegen, Farran, and Annaz, 2011).
2) Reaction time can be used to understand the stages of processing in solving a single item (Bethell-Fox, Lohman, \& Snow, 1984) or to compare performance
across individuals or groups (Soulières et al., 2009).
3) Patterns of errors-for a problem answered incorrectly, which of the given distracters is selected?-have been studied as a window into cognitive strategy (Bromley, 1953; Gunn \& Jarrold, 2004; Miller \& Raven, 1939; Van Herwegen, Farran, and Annaz, 2011; Vodegel Matzen et al., 1994).
All of these dimensions represent measurable aspects of the "output" of a human cognitive system taking the RPM test. The "input" to such a system, in addition to the test itself, can be conceptualized as the set of cognitive functions drawn upon while solving the test. Unlike the output measures, it is difficult to directly measure cognitive functioning. Some studies have used eye-tracking as a measure of visual attention (Bethell-Fox, et al., 1984; Carpenter, Just, \& Shell, 1990), and some have used verbal reporting protocols (Carpenter et al., 1990) though verbal report may bias the cognitive strategies used by participants (DeShon, Chan, \& Weissbein, 1995).

Another way to elucidate these invisible cognitive mechanisms is to construct computational models of various aspects of RPM problem solving and then inspect these models in relation to human behavioral data. Aspects of RPM (or RPM-like) problem solving that have been investigated using computational models include:

Figure 1: Example of an RPM-like problem.

1) Knowledge representation, i.e. visual versus verbal representations of problem content (Hunt, 1974; Kunda, Goel, \& McGreggor, 2013; McGreggor, Kunda, \& Goel, 2011).
2) Goal-subgoal maintenance (Carpenter et al., 1990).
3) Problem-solving process, i.e. constructive matching (mentally constructing the answer and then selecting an answer choice) versus response elimination (inspecting each answer choice to find the best fit) (Bethell-Fox et al., 1984; Lovett \& Forbus, 2012).
4) Answer selection process in terms of confidence (McGreggor \& Goel, 2012) or probability (Little, Lewandowsky, \& Griffiths, 2012).
However, in the extant literature on computational models of the RPM, many models tend to focus on only one measure of output performance: total score. We believe it is not only valuable but critical that models examine the other dimensions of "output" that we have mentioned, in order to investigate how models relate to human cognition at increasingly fine-grained levels of resolution.

In this paper, we focus on one such "output" measureerror patterns-and one computational model-the ASTI model, described in detail in a previous publication (Kunda et al., 2013). We first present an operationalization of error patterns on the Raven's Standard Progressive Matrices (SPM) test, in the form of a two-kind classification of conceptual error types. Then, we briefly summarize the algorithms and performance of the ASTI model. Finally, we present a method for analyzing the errors made by a computational model, and we give preliminary results based on a comparison of the errors made by the ASTI model against human error data from typically developing individuals and individuals diagnosed with autism, along with an evaluation of what these differences in error patterns can tell us about cognitive processing on the RPM.

## Types of Conceptual Errors on the SPM

One way to examine errors on an RPM test is to look at which distracter is chosen in comparison to those most frequently chosen (Thissen, 1976; van der Ven \& Ellis, 2000). However, many studies have shown that errors can also be classified according to conceptual type, which may provide additional insight into what it means when a certain error is made (Forbes, 1964; Horner \& Nailling, 1980).

However, there is currently one significant barrier to the widespread analysis of error patterns on the SPM test; while the published manuals for two of the RPM tests, the Colored Progressive Matrices (CPM) and the Advanced Progressive Matrices (APM), include taxonomies of conceptual error types, the manual for the Standard Progressive Matrices (SPM) does not (Raven, Raven, \& Court, 2003). Vodegel Matzen et al. (1994) attempted to use the APM error type classifications on a portion of the SPM, but inter-coder reliability reached only about $70 \%$. The authors concluded that classification of SPM distracters seemed "problematic" in that there did not seem to be a systematic methodology used for constructing distracters.

The taxonomies given in the CPM and APM manuals (Raven et al., 2003), although having different labels, seem to represent the same four notions of error types. We now present a synthesized description of these four error types which, along with criteria used to classify a particular distracter, are also summarized in Table 1.

1) Incomplete correlate (IC) errors occur when the chosen distracter is almost, but not quite, correct. For example, some IC distracters have the correct shape but the wrong texture, as exemplified by distracter \#1 in Fig. 1. These kinds of errors are made when a test-taker more or less "gets" the problem, in terms of identifying the relevant matrix relationships, but then fails to fully account for all of the details when selecting an answer.
2) Repetition (R) errors occur when the chosen distracter copies a matrix entry adjacent to the blank space, as shown by distracters \#3 and \#8 in Fig. 1. The choice of an R distracter may represent perseveration or fixation on the matrix entries, in which an answer is selected via perceptual matching between the answer choices and the matrix entries closest to the blank space.
3) Difference (D) errors occur when the chosen distracter is qualitatively different in appearance from the other choices. D distracters include completely blank entries, as exemplified by distracter \#2 in Fig. 1, as well as those that have extraneous or complex shapes not found in the matrix. A D distracter might be chosen because it visually "pops" from among the other choices.
4) Wrong principle (WP) errors occur when the chosen distracter is a copy or composition of elements from various matrix entries, as exemplified by distracters \#4 and \#6 in Fig. 1. A WP distracter might be chosen if the test-taker fails to educe the correct relationship from the matrix and combines the entries according to some other rule or relationship to produce an answer.

## Two-Kind Taxonomy and Coding Results

The main difficulty we observed in coding SPM distracters is that the same distracter often seems to fall under multiple categories, e.g. it might represent a repetition as well as an incomplete correlate; this difficulty was shared by VodegelMatzen, et al. (1994). From this observation, we realized that the four error types listed above actually represent two orthogonal classifications of distracters:

Kind I: Relationship of distracter to matrix entries: Repetition, difference, and wrong principle errors all have to do with how a distracter is related to information in the matrix and in the other answer choices, without any regard to the content of the correct answer choice. In particular, errors of the first kind assume the participant is attending to irrelevant or erroneous aspects of the problem, and that they are not able to discover even a partial solution.

Kind II: Relationship of distracter to correct answer: Incomplete correlate errors have to do with how a particular distracter is related to the correct answer choice. These errors assume the participant correctly guesses some part of the solution but does not quite attain the correct answer.

Table 1: Criteria for classifying distracters on the SPM.

| Error type | $\#$ | Criteria |
| ---: | ---: | :--- |
| Kind I: | 1 | Repetition of matrix entry to left of blank space |
|  | 2 | Repetition of matrix entry above blank space |
|  | 3 | Repetition of matrix entry to top-left of blank space |
|  | 4 | Filled completely white or black |
| Kind I: | 5 | Union of matrix entries or aspects of them, so that union has more components than any single matrix entry |
| Difference | 6 | Maximizes some feature value or makes it more complex |
|  | 7 | Differs qualitatively from matrix and other answers, or contains information not found anywhere in matrix |
| Kind I: | 8 | Copy of matrix entry not adjacent to blank space |
| Wrong | 9 | Rotation/reflection of matrix entry |
| Principle | 10 | Other transformations or combinations of matrix entries or aspects of them, including negative images |
|  | 11 | Negative (color-inversion) of correct answer |
|  | 12 | Change only in fill, texture, or style |
| Kind II: | 13 | Rotation/reflection of correct answer |
| Incomplete | 14 | Change only in spatial layout of elements |
| Correlate | 15 | Change only in size or scale, in either or both dimensions (allowing for feature-wise scaling) |
|  | 16 | Change only in number of discrete elements (allowing for slight changes in layout) |
|  | 17 | Incomplete, with missing element or portion |

Using this two-kind taxonomy, two raters independently coded all 432 distracters on the $\mathrm{SPM}^{1}$ in two separate passes, first for Kind I and then for Kind II. Kind I classification used a copy of the test booklet in which no answers had been marked, and raters assigned every distracter to one of categories \#1-10 in Table 1. Kind II classification used another test booklet copy in which the correct answers had been marked and the matrix portions of each problem had been cut off, so only the answer choices were visible; raters assigned each distracter to one of categories \#11-17 in Table 1, or left it uncategorized.

Initial agreement between the two raters was $82 \%$ for Kind I errors and (coincidentally) $82 \%$ for Kind II errors. Kappa coefficients were calculated to test for independence between raters. The kappa values were 0.79 for Kind I errors and 0.67 for Kind II errors.

Discrepancies were resolved during a negotiation phase between the two raters. Each discrepancy was discussed, and each rater presented a rationale for the classification. It was found that there were several systematic discrepancies easily resolved by making the coding criteria more specific. For example, Criterion \#5 in Table 1 was modified to specify that this type of distracter had to have more elements in it than any entry in the matrix, which was not originally part of the criterion. Table 1 shows the final coding criteria, after these changes had been incorporated.

After the negotiation phase, rater agreement was recalculated. Post-negotiation agreement was $95 \%$ for Kind I errors and $98 \%$ for Kind II errors. Remaining differences were resolved by the primary rater based on consideration of the conceptual error type intended to be captured.

Fig. 2 shows the overall proportions of error types across all distracters of the SPM. Interestingly, there is roughly the same proportion of incomplete correlate distracters as

[^320]correct answers, and all remaining distracters are divided nearly evenly among the three remaining error types.

Figure 2: Proportions of each error type on the SPM.

## The ASTI Model

In previous work (Kunda et al., 2013), we presented a computational model of problem solving on the RPM, the Affine and Set Transformation Induction (ASTI) model. This model was constructed in order to investigate problem solving on the RPM using visual mental representations. All extant computational RPM models had previously relied on propositional forms of representation (e.g. Carpenter et al., 1990), despite a breadth of evidence from human studies suggesting that problem solving can proceed using either visual or verbal forms of representation (see Kunda et al., 2013, for a summary of these studies).

The ASTI model also has implications for a recent study of RPM performance in individuals diagnosed with autism, which found that these individuals seemed to use predominantly visual strategies (Soulières et al., 2009), in line with other empirical evidence showing a visual cognitive bias in autism (Kunda \& Goel, 2011).

The ASTI model uses purely visual representations in the form of pixel-based images along with affine and set transformations designed to emulate the types of operations observed in studies of human mental imagery. The model uses a constructive matching approach; first, it examines different subsets of the matrix entries (each an individual image), under each of these transforms to induce a "best-fit" overall transform. Then, the ASTI model applies this bestfit transformation to the remaining matrix entries to generate a predicted answer image. Finally, this predicted answer is compared to each answer choice to select the best match.

## Obtaining Error Data from the ASTI Model

The current version of the ASTI model correctly answers 50 out of 60 problems on the SPM. One difficulty with high performing computational models such as ASTI is that it is not immediately clear how errors made by the model might be analyzed in a meaningful way, as error data can only be collected on 10 of the 60 problems.

We use a method for obtaining error data from a computational RPM model through model ablation (Cohen \& Howe 1988). The ASTI model uses affine transforms (rectilinear rotations and reflections), as well as addition, subtraction, and pair-wise image composition (union,
intersection, etc.); the model also inspects the matrix according to rows, columns, and diagonals. By removing access to subsets of these mechanisms, we can observe the errors made by general classes of ASTI configurations.

Table 2 lists mechanisms used for $2 \times 2$ matrices (found in Sets A and B of the SPM) and $3 \times 3$ matrices (found in Sets C through E of the SPM). Ablating combinations of these mechanisms yields 96 different model configurations, whose total scores range from 15 to 50 correct.

Table 2: Mechanisms for Ablation in the ASTI Model

| Type | Image sets | Transforms |
| ---: | :--- | :--- |
| $\mathbf{2 \times 2}$ | 1. Rows | 1. Identity <br> matrices |
|  | 2. Columns | 2. Rotation/reflection <br> 3. Addition/subtraction |
| $3 \times 3$ | 1. Rows | 1. Identity |
|  | 2. Columns | 2. Rotation/reflection |
|  | 3. Diagonals | 3. Addition/subtraction <br> 4. Composition |

## Analysis of Error Patterns

Using the new classification of error types on the SPM that we described above, we conducted an analysis to compare the error patterns of typically developing individuals, individuals diagnosed with autism, and the ASTI model.

Human data were obtained from previous studies done at the Hôpital Rivière-des-Prairies in Montreal, Canada. Participants diagnosed with autism received a best-estimate multidisciplinary diagnosis after evaluation with standard diagnostic instruments, the ADOS and ADI-R (Lord et al., 1999; Rutter et al, 2003).

Using a cutoff of 17 years, participants were grouped into children and adults. Data included answer choices given for each SPM problem, including a few instances in which no answer was given. (One participant in the autism group was excluded from analyses, as he had selected answer choice " 1 " for more than half of the problems.)

Table 2 summarizes total SPM score, age, and Wechsler full-scale IQ information for these groups. While total SPM scores between TD and AUT groups are not significantly different, the ASTI SPM scores are significantly lower. This introduces a potential confound, if error types are dependent on overall ability. To address this issue, we conducted an analysis using three subgroups (TD children, AUT children, and the ASTI model) individually matched on total SPM score. Table 3 gives data on these subgroups.

We looked at the proportions of each error type that were made on the entire SPM test, averaged across participants in each group. Fig. 3 presents the results of these comparisons for the score-matched subgroups. Results for the full groups of children and adults were similar, and so we present detailed results of this first analysis only.

There is no significant difference in overall error distributions between the TD and AUT groups, $\chi^{2}(N=826)$
$=1.89, p=0.60$, whereas the error distribution from the ASTI model differs significantly from each of the human groups, $\chi^{2}(N=826)=91.62, p<0.001$ for TD, and $\chi^{2}(N=$ $826)=98.69, p<0.001$ for AUT.

A one-way ANOVA was used to test for differences in error proportions among the three groups. Proportions differed significantly for repetition, $F(2,111)=6.20, p=$ 0.003 , and difference errors, $F=32.03, p<0.001$, but did not differ significantly for incomplete correlate, $F=0.14, p$ $=0.87$, or wrong principle errors $F=1.61, p=0.20$.

Table 2: Demographic data for full participant groups. Values as shown as: mean (standard deviation).

|  | Children |  | Adults |  | Model |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | TD | AUT | TD | AUT | ASTI |
| N | 54 | 108 | 52 | 44 | 96 |
| SPM | 42.61 | 37.43 | 50.69 | 48.43 | 32.57 |
| score | $(9.79)$ | $(12.17)$ | $(5.38)$ | $(9.64)$ | $(9.74)$ |
| Age in | 11.96 | 11.02 | 22.98 | 26.80 | $\mathrm{n} / \mathrm{a}$ |
| years | $(3.40)$ | $(2.99)$ | $(4.28)$ | $(6.72)$ |  |
| IQ | 109.82 | 84.38 | 106.91 | 97.61 | $\mathrm{n} / \mathrm{a}$ |

Note: IQ data was not available for all participants.
Table 3: Demographic data for score-matched subgroups.

|  | Children |  | Model |
| :---: | :---: | :---: | :---: |
|  | TD | AUT | ASTI |
| N | 38 | 38 | 38 |
| SPM | 38.26 | 38.26 | 38.29 |
| score | $(8.07)$ | $(8.09)$ | $(8.07)$ |
| Age in | 11.11 | 10.76 | $\mathrm{n} / \mathrm{a}$ |
| years | $(3.30)$ | $(2.71)$ |  |
| IQ | 106.08 <br> $(9.08)$ | 88.83 <br> $(18.79)$ | $\mathrm{n} / \mathrm{a}$ |

Note: IQ data was not available for all participants.

Figure 3: Proportions of each error type made on the SPM by typically developing (TD) individuals, individuals diagnosed with autism (AUT), and the ASTI model.
(Error bars represent one standard deviation.)

## Discussion

We discuss results from two perspectives. First, what does this analysis tell us about the error patterns shown by the TD versus AUT groups? Second, what does this analysis tell us about the error patterns shown by the ASTI model?

First, we see that the distribution of conceptual errors made on the SPM does not seem to differ significantly between the TD and AUT groups. Following a prior study suggesting that individuals with autism tend to use visual strategies to solve these kinds of problems (Soulières et al., 2009), one interpretation may be that looking at error types of this kind does not by itself indicate potential differences in problem solving modality (i.e. visual/verbal). However, as TD individuals most likely use a combination of visual as well as verbal strategies on the SPM, another, currently unexplored, hypothesis is that differences in error types may only surface for problems solved verbally by the TD group and visually by the autism group. If this is the case, then detecting such differences would require a finer-grained analysis of error types on various subsets of SPM problems instead of across the entire test as a whole.
To address the latter question, comparisons of errors between human participants and the ASTI model show agreement on two types of errors (incomplete correlate and wrong principle) and discrepancies on the other two types (repetition and difference). Looking at these differences in error patterns lends valuable insight into how specific aspects of the ASTI model affect its overall behavior and simultaneously suggests concrete avenues for improving the cognitive fidelity of the ASTI model.

First, with regard to the relative increase in repetition errors, the ASTI model predicts answers based on the matrix entries adjacent to the blank space. Thus, it is likely that its prediction is visually similar to an adjacent matrix entry, leading to an error of repetition. While humans do often make repetition errors, they also likely draw upon more aspects of the matrix when selecting an answer, which the ASTI model could also be modified to do.

Second, regarding the relative scarcity of difference errors made by the ASTI model, recall that these errors are made according to how a particular distracter might seem different or more complex than the other answer choices. Making difference errors thus should only affect test-takers using a response elimination strategy, i.e. looking at the answer choices as a set at the start of or during problem-solving. Test-takers using a constructive matching strategy already have an answer in mind before moving to inspect the answer choices, and if this answer is constructed by examining and combining matrix entries, it would likely be similar to these entries and thus not be likely to lead to a difference error.

Difference errors may thus be considered a result of testtakers fixating on the visual salience of one particular answer choice over another. The ASTI model currently does not contain mechanisms to detect salience or perform response elimination; the addition of these mechanisms will improve the fidelity with which problem-solving strategies used by the ASTI model mirror those of humans.

## Conclusion

The main motivation for this work stems from the view that conceptual types of errors made on the Raven's tests can serve as an important additional measure of behavioral performance, above and beyond total score. To this end, this paper makes two primary contributions.

The first major contribution is the new classification of error types on the SPM using a two-kind approach that yielded $\geq 95 \%$ inter-rater reliability. This classification should have considerable utility for further studies of human or machine SPM performance, and it adds a significant new component of information for the RPM family of tests, as both the CPM and APM tests already have such error classifications, but the SPM previously did not. One area of future work is to examine the error patterns made by humans on different subsets of test problems, instead of across the test as a whole, to achieve a finer-grained analysis of what kinds of errors people make on certain problems.

The second major contribution is the methodology presented for measuring the conceptual errors made by a computational model on the RPM. Looking at the errors made by the ASTI model has led us to propose two modifications to improve its cognitive fidelity: first, the model should consider additional aspects of the matrix when generating answer predictions, in addition to just the adjacent entries, and the model should be able to adopt a response elimination strategy and also be susceptible to the visual salience of particular answer choices.

Neither of these observations would have been possible by looking at total score alone, or even at the pattern of correct vs. incorrect answers. Future work on test-taking by humans and computational models should continue to look at multiple performance measures, beyond just total score, to fully understand performance and cognitive implications.

## Acknowledgments

We are grateful to the US National Science Foundation for its support through NSF (RI) Grant \#1116541, "Addressing visual analogy problems on the Raven's intelligence test," and through a GRFP fellowship, and to the US Office of Naval Research for support through an NDSEG fellowship. # Experts' Explanations Engage Novices in Deep-Processing 

Andreas Lachner (andreas.lachner@ezw.uni-freiburg.de) Matthias Nückles (matthias.nueckles@ezw.uni-freiburg.de)

Department for Educational Science, University of Freiburg

Rempartstrasse 11, 79098 Freiburg, Germany

#### Abstract

Experts and intermediates fundamentally differ in the ways they explain subject matter to novices. Experts provide less details but in a highly coherent format, whereas intermediates provide many additional details but in a format with low coherency. In a recent study, we found that experts' explanations enabled novices to acquire more transferable and flexible knowledge as opposed to explanations by intermediates mainly due to the higher coherence of experts' explanations. In order to investigate more directly how experts' and intermediates' explanations differently triggered novices' processing of the explanations, we conducted a think-aloud study. Results indicated that novices learning with an expert's explanation processed the explanations deeper than novices with intermediates’ explanations. In line with this, deep processing was significantly related to novices' transfer. Thus, expertise can be regarded as an essential prerequisite for generating effective instructional explanations that engage novices to process the subject matter deeply and to generate transferable knowledge.

Keywords: expertise; processing; instructional explanations; transfer.

## Introduction

Experts and intermediate students fundamentally differ in the ways they explain subject matter to novices. Figure 1 shows two propositional representations, one intermediate student's explanation and one expert's explanation, taken from a study by Lachner, Gurlitt and Nückles (2012). These propositional representations about bacterial endocarditis, an inflammation of the heart valves, structurally differ in several important respects.

Figure 1: Graphical representation of an intermediate's explanation and an expert's explanation.

The typical expert's explanation consisted of only a few, mainly advanced, clinical concepts $(N=24)$. Beyond that, the expert's explanation was very coherent, as she related all
explanatory concepts to each other, resulting in a single very coherent chunk of knowledge. In marked contrast, the typical intermediate’s explanation provided many concepts ( $N=52$ ). Although there was one interrelated chunk about pathophysiological processes of bacterial endocarditis, the intermediate was less likely to relate basic pathophysiological concepts with advanced concepts, which resulted in many fragmented knowledge blocks $(N=8)$.

These two explanations nicely illustrate well-known differences between experts and intermediates. For instance, research on categorization shows that experts tend to organize their knowledge around abstract principles, which allows them to integrate their knowledge in a more coherent manner, whereas novices organize their knowledge around superficial features, which results in less coherent knowledge structures (Chi, Feltovich, \& Glaser, 1981; Rottman, Gentner, \& Goldwater, 2012).

In the same vein, in the medical domain, it has been shown that experts subsume basic medical concepts under advanced concepts, which results in very condensed schemata, whereas intermediates rather rely on detailed knowledge, as they have not yet acquired these advanced clinical principles. This subsumption process is also known as knowledge encapsulation (Boshuizen \& Schmidt, 1992, Rikers, Schmidt, \& Boshuizen, 2000; 2002).

Lachner et al. (2012) found that these effects for coherence and knowledge encapsulation also hold true for instructional explanations, specifically explanations written for novice medical students. Compared to intermediates, medical experts wrote more coherent and equally more encapsulated explanations, meaning that they omitted more details in their explanations. However, both intermediate students and experts used the same amount of advanced concepts. Apparently, experts adapted their choice of words, but not the way they would structure an explanation.

## Learning from Instructional Explanations

As explanations by experts and intermediates fundamentally differed on the level of coherence and encapsulation, explanations by experts and intermediates might also affect student learning differently. For instance, Hinds, Patterson and Pfeffer (2001) investigated how the instructor's domain expertise affected novices' learning in the domain of electrical engineering. More specifically, they examined how novices studying an intermediate's explanation differed from novices studying an expert's explanation with regard to their performance on near transfer and far transfer tasks. Results indicated an interaction effect. Although novices
with an intermediate's explanations outperformed novices with an expert's explanation on near transfer tasks, there was a clear benefit for novices with experts' explanations on far transfer tasks. In a related study, Boekhout, van Gog, van de Wiel, Gerards-Last, and Geraets (2010) showed that worked examples constructed by experts led to larger benefits for novices in transfer tasks than worked examples constructed by intermediates. However, with regard to the acquisition of factual knowledge, novices with experts’ worked examples did not differ from novices learning from intermediates' worked examples.

## Beneficial Features of Instructional Explanations

Bridging findings from expertise research and tutoring research, Lachner and Nückles (2013) investigated which expertise-related textual features of explanations accounted for the better transfer of novices learning with experts' explanations. Specifically, they examined how coherence and encapsulation of the instructors' explanations, as coherence and encapsulation were selective indicators for expertise (Lachner et al., 2012; Rikers et al., 2002; Rottman et al., 2012), affected novices’ learning outcomes. Similarly to Hinds et al. and Boekhout et al., Lachner and Nückles found that novices studying with experts' explanations significantly outperformed novices with intermediates' explanations on transfer tasks. At the same time, in line with Boekhout et al., they did not find a significant difference between experts’ and intermediates’ explanations regarding novices' factual knowledge.

More importantly, Lachner and Nückles (2013) conducted a mediation analysis to investigate whether encapsulation, as measured by the omission of detailed knowledge, or coherence, as measured by the number of isolated fragments (see Figure 1), accounted for novices’ transfer. Results indicated that the degree of encapsulation had no effect on novices' transfer, whereas explanatory coherence clearly mediated the effect of instructors' expertise on novices' transfer. Therefore, the authors could show that it was the coherence of experts' explanations that enabled novices to transfer their acquired knowledge to other medical tasks.

Nevertheless, although the Lachner et al. study suggests that explanatory coherence fostered novices' transfer, they did not examine which learning processes were provoked by experts' versus intermediates' explanations that could explain the transfer effect.

## Processing of Instructional Explanations

Bransford and Schwarz (1999) proclaimed that for flexible transfer, learning with "understanding" is necessary. Studies by Gilabert, Martinez and Vidal-Abarca (2005) and Linderholm et al. (2001) support this view, as they found that the high coherence of texts fostered students' active processing of the text material. As coherent explanations highlighted important causal relations between concepts, the coherence of explanations probably served as a valuable scaffold to engage students’ processing.

Text processing can be regarded as the construction and integration of multiple independent representations of a text (Kintsch, 1988; Kintsch, 2004). First, learners construct a text base which contains the essential meaning of the text, mainly by translating the text into propositions, or in other words, by paraphrasing the text and by bridging inferences to connect information within the text (Kintsch, 1988). Second, learners construct a situation model by doing selfexplanations to fill coherence gaps with their prior knowledge. Kintsch (2004) argued especially processing activities, that aim to enrich the situation model, are needed to develop a deep understanding.

In the study by Lachner and Nückles (2013), the mediating variable between instructors' expertise and novices' transfer was explanatory coherence. In the study described here, we examined whether the effect of expertise on novices' learning can be explained by novices' processing activities. In line with text comprehension research, (Gilabert et al., 2005; Linderholm et al., 2001), we assumed that experts' coherent explanations may better promote novices' deep processing and novices' acquisition of flexible knowledge compared to intermediates' less coherent explanations.

## Research Questions and Hypotheses

To investigate novices’ processing activities while learning with experts' and intermediates' explanations, we conducted a think-aloud study. The aims of our study were twofold. First, we wanted to replicate the findings by Lachner and Nückles (2013) that experts' explanations were better suited to foster novices' transfer compared to intermediates' explanations. Second, as we were interested in novices' processing activities, we examined how novices processed explanations by intermediates and experts using a thinkaloud procedure.

## Learning Hypotheses

In line with previous research (Boekhout et al., 2010; Hinds et al., 2001; Lachner \& Nückles, 2013), we hypothesized that novices would benefit more from experts' explanations as opposed to intermediates' explanations in transfer tasks. Experts' coherent explanations would better enable novices to construct an appropriate situation model of bacterial endocarditis and thus enable them to transfer their knowledge of bacterial endocarditis to other tasks (Kintsch, 2004).

For novices' factual knowledge gain, we refrained from making clear predictions, as Boekhout et al. (2010) and Lachner and Nückles (2013) did not find any significant differences between explanations by experts and intermediates. As coherence mainly accounted for the construction of a rich situation model and not for the generation of an adequate text base (Gilabert et al., 2005; Kintsch, 2004), novices with intermediates' explanations could perform just as well in a factual knowledge test as those with experts' explanations.

## Processing Hypotheses

As suggested by research on text comprehension (Gilabert et al., 2005; Linderholm et al., 2001), we assumed that experts' coherent explanations would encourage novices’ deep processing compared to intermediates’ explanations. Therefore, we expected that novices with experts' explanations would outperform novices with intermediates' explanations with regard to the proportion of bridging inferences and self-explanations, whereas intermediates' explanations would trigger novices' paraphrasing. For negative monitoring, we refrained from making clear predictions, as the fewer details in experts' explanations could trigger novices’ monitoring, as well as the lack of coherence of intermediates' explanations.

Beyond that, as Kintsch (2004) suggested, we assumed that novices' transfer was significantly related to novices’ deep processing.

## Method

## Participants

Sixty-eight novices from the University of Freiburg, Germany participated in the study. They were recruited from medicine ( 45 students) and biology programs (23 students). 70.60 \% were female; their mean age was 20.25 ( $S D=1.87$ ). Participants were on average in their first semester ( $S D=1.24$ ) and had not yet attended any courses in cardiology. Participants were financially compensated with 10 Euro for their participation.

## Design

Novices were randomly assigned to one of four explanations about bacterial endocarditis, an infection of the heart valves (two experts’ explanations and two intermediates' explanations). We used a pretest-posttest design with type of explanations, that is, experts' explanations or intermediates' explanations, as independent variables. There were two classes of dependent variables: We analyzed novices’ learning outcomes with both a factual knowledge test that measured novices' knowledge about central concepts and interdependencies of bacterial endocarditis, and with a transfer test that required the participants to apply their acquired knowledge of bacterial endocarditis to other medical phenomena. Additionally, we collected novices' processing activities by means of think-aloud-protocols (i.e. paraphrasing, bridging inferences, self-explanations, and negative monitoring) while studying the explanations.

## Materials

## Case description

We provided the participants with a general case description of a fictitious patient suffering from bacterial endocarditis. It included central findings of laboratory data, and descriptions of symptoms. The case description had been used in previous classical studies on the nature of expertise, as bacterial endocarditis can be regarded as a prototypical
heart disease that requires deep-level knowledge about embolisms, the structure of the heart, and the circulatory system (Boshuizen \& Schmidt, 1992).

## Explanations

We selected two experts' explanations and two intermediates’ explanations from a recent study by Lachner et al. (2012). We selected the explanations according to their degree of coherence, which can be regarded as the number of fragments in the explanation (see Figure 1). We chose the explanations of the two experts with the smallest number of fragments (Expert A: 1 fragment; Expert B: 3 fragments) and those of the two intermediates with the highest number of fragments (Intermediate A: 8 fragments; Intermediate B: 8 fragments).
In the Lachner et al. study, this structural feature of explanations mediated the effect of the instructors' expertise with regard to novices' transfer. The experts in that study were cardiologists who had at least 15 years of working experience. Intermediates were medical students in their fifth year of studying. The explanations were 157 words (SD $=36.03$ ) long on average. The explanations pointed out the biomedical processes and causes of bacterial endocarditis, and how the symptoms mentioned in the case description could be related to the underlying biomedical processes.

## Factual knowledge test

A factual knowledge test was used as pre- and posttest and measured novices' conceptual understanding of bacterial endocarditis. It consisted of nine multiple choice items with four answer possibilities and one correct solution (e.g. "What is the reason for the diastolic in cases of endocarditis?"). Participants received one point for each correct answer, yielding a total possible score of nine points.

## Transfer test

To measure novices' transfer, we constructed two complex questions that required novices to transfer their acquired knowledge of bacterial endocarditis to other complex medical phenomena ("Why can endocarditis result in a cardiogenic shock?", "Can endocarditis be the cause of a stroke?"). First, participants’ written answers to these questions were segmented into individual statements and then compared to reference answers constructed by a medical expert. A scorer who was blind to the participants’ treatment condition used a strict manual in which participants received 0.5 points for each unit of the reference answer. For each task, participants could obtain 4.5 points, which resulted in a maximum score of 9 points for both answers.

## Procedure

Participants were tested individually in a quiet room. They were randomly assigned to one of the four explanations. An experimental session lasted 60 minutes. During the experimental session, participants were not allowed to proceed before being signaled by the experimenter (exact time on task). First, participants answered the pretest (10 minutes). Then, in the learning phase, they received the case description and one of the randomly assigned explanations
( 25 minutes). Participants were instructed to think aloud while they studied the explanation. If participants did not think aloud for more than 5 seconds, the experimenter prompted them to continue talking. In the post-test phase, participants answered the factual knowledge test (10 minutes) and accomplished the two transfer tasks (15 minutes).

## Analyses and coding

For the analyses of novices' learning processes, their think aloud protocols were transcribed and segmented into idea units. Based on Chi (2000), each idea unit was categorized as paraphrasing, bridging inferences, self-explanation, and negative monitoring (see Table 1). Thirty percent of the protocols were co-rated by a second rater. In assigning verbalizations to categories, inter-rater agreement was very good ( $\kappa=.88$ ). Thus, only one rater coded the rest of the protocols.

Table 1: Categories to rate the think-aloud protocols.

| Category | Description |
| :--- | :--- |
| Paraphrase | Novice simply restated or <br> paraphrased a text segment from <br> the explanation. |
| Bridging inferences | Novice relates different text <br> passages of the explanation to <br> better understand relations <br> between sentences. |
| Negative | Novice connects new information <br> with prior knowledge by self- <br> explaining. Indicators are the <br> generation of examples or making <br> predictions. |
| monitoring | Novice utters his /her non- <br> comprehension |

## Results

We used an alpha level of .05 for all statistical analyses. As an effect size measure, we used partial $\eta^{2}$ qualifying values $<.06$ as small effect, values in the range between .06 and .14 as medium effect, and values > . 14 as large effect (see Cohen, 1988).

A series of ANOVAs and $\chi^{2}$ tests revealed no significant differences between the experimental conditions concerning age, $F(1,66)=1.22, p=.27$; gender, $\chi^{2}(1)=2.50, p=.11$; study programs, $\chi^{2}(1)=.59, p=.44$; prior knowledge, $F(1$, 66 ) $=1.16, p=.29$, and the number of processing activities, $F(1,66)=.84, p=.36$.

## Learning Hypotheses

Table 2 provides an overview of the means and standard deviations for the factual knowledge and the transfer test. To investigate differences in factual knowledge between novices who learned with an intermediate's explanation and novices learning with an expert's explanation, we performed
an ANCOVA with type of explanation as a fixed factor, novices' posttest scores as dependent variable and novices' prior knowledge as a covariate. There was no significant difference for type of explanation regarding novices' factual knowledge, $F(1,65)=1.90, p=.17, \eta^{2}=.03$. Thus, we could replicate the results from Lachner and Nückles (2013) that novices benefited from intermediates' and experts’ explanations to a similar extent.

With regard to the transfer hypothesis, we found that novices learning with an expert's explanation significantly outperformed novices learning with an intermediate's explanation on the transfer tasks, $F(1,65)=15.56, p=.00$, $\eta^{2}=.19$. Thus, as in the study by Lachner and Nückles, experts' explanations better supported novices in solving transfer tasks as opposed to intermediates' explanations.

Table 2: Means and standard deviations (in parentheses) for the learning outcome measures.

|  | Novices with <br> Intermediates’ <br> Explanations | Novices with <br> Experts’ <br> Explanations |
| :--- | :---: | :---: |
| Dependent variable | $3.29(1.34)$ | $3.71(1.78)$ |
| Factual knowledge | $4.18(1.73)$ | $4.76(1.30)$ |
| Transfer | $3.63(1.78)$ | $5.44(1.84)$ |

## Processing Hypotheses

Table 3 shows the mean proportions and standard deviations of novices' processing activities. With regard to our processing hypothesis, we conducted a MANCOVA with type of processing activities (paraphrase, bridging inferences, self-explanations and negative monitoring) as dependent variables, type of explanation as independent variable and novices’ prior knowledge as covariate. The MANCOVA revealed a significant effect for type of explanation, $F(3,63)=3.25, p=.03, \eta^{2}=.13$. Separate ANCOVAS showed that this effect was specifically due to the differences in the proportions of paraphrasing and selfexplanations (see Table 3).

Table 3: Mean proportions and standard deviations (in parentheses) of novices’ processing activities

|  | Explanations by |  | $F^{a}$ | $p$ | $\eta^{2}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | Intermediate | Expert |  |  |  |
| Paraphrases | . 51 (.24) | . 33 (.22) | 9.65 | . 00 | . 13 |
| Bridging inferences | . 22 (.12) | . 24 (.17) | 0.25 | . 62 | . 00 |
| Self- <br> Explanations | . 11 (.11) | . 20 (.22) | 4.79 | . 03 | . 07 |
| Negative monitoring | . 16 (.15) | . 22 (.21) | 2.17 | . 15 | . 03 |
| ${ }^{\text {a }} d f=1,65$ |  |  |  |  |  |

As expected, novices learning with intermediates' explanations used more shallow processing strategies directed at the construction of the text base (i.e. paraphrasing a text segment) as compared with novices’ learning with experts' explanations. In contrast, regarding the proportion of self-explanations, novices learning with experts' explanations used more deep-level processing strategies (i.e. self-explanations) as opposed to novices learning with intermediates' explanations.

However, there was no difference for type of explanation regarding the proportion of bridging inferences. Thus, novices used the same amount of bridging inferences to establish coherence within their text base regardless of which type of explanation they received. Additionally, we did not find any significant differences for type of explanation regarding negative monitoring, which suggests that intermediates' and experts' explanations entailed comprehension problems to a similar extent.

To test whether novices’ transfer was associated with the proportion of novices' deep processing of the explanations, we computed a Pearson's correlation. To obtain a single score for deep-processing of the explanations, we computed the proportion of deep processing learning activities (i.e. bridging inferences and self-explanations) that aimed at constructing a sufficient situation model for each participant. This was appropriate because the different values were significantly inter-correlated, $r(68)=.53, p=$ .00. Novices' deep processing activities were significantly correlated with novices' performance on transfer tasks, $r(68)=.30, p=.01$. Evidently, novices’ deep processing led novices to better transfer their knowledge to other tasks.

## Discussion

The main goal of the present study was to investigate how experts' and intermediates' explanations differently affected novices' processing and novices' learning outcomes.

For novices' performance on transfer tasks, we could replicate findings of previous studies (Boekhout et al., 2010; Hinds et al., 2001; Lachner \& Nückles, 2013) that experts’ explanations more effectively enabled novices to transfer their knowledge acquired from the explanations to other related medical phenomena. Similar to findings by Boekhout et al. and Lachner and Nückles, we did not find any significant differences between experts' and intermediates' explanations regarding novices' factual knowledge gain. Apparently, intermediates' and experts' explanations were comparably appropriate to establish a solid text base. However, it must be noted that the average factual knowledge gain was rather low (see Table 2), which can be mainly attributed to the brief text length of our instructional explanations.

With regard to novices' processing of the explanations, we can conclude that experts' explanations engaged novices in a deeper processing of the explanations as opposed to explanations generated by intermediates. Novices with experts' explanations made significantly more selfexplanations and less paraphrasing compared to novices
with intermediates’ explanations. However, in contrast to our assumptions, we did not find any differences for the proportions of bridging inferences and negative monitoring. Apparently, experts' omissions in their explanations and the lack of coherence in intermediates' explanations may have balanced each other out and therefore resulted in a trade-off in the novices' bridging inferences and negative monitoring.

Beyond that, we could show that novices' performance on transfer tasks was significantly related to novices’ deep processing. Apparently, intermediates' less coherent explanations triggered shallow processing activities that solely aimed at the construction of a solid text base. In contrast, experts’ explanations mainly triggered novices’ deep processing, which resulted in the construction of a better situation model and a better performance on the transfer test. As intermediates primarily relied on shallow processing, they probably constructed a less coherent and therefore less effective situation model that resulted in a lower performance on the transfer tasks (Kintsch, 2004). However, there was only a moderate correlation between novices' transfer and deep-processing activities. However, think-aloud protocols are less reliable to measure unconscious comprehension processes (Graesser et al., 1997). Therefore, in subsequent studies, behavioral measures should be included as a complementary measure to tap implicit processes of comprehension more directly (Holmqvist et al., 2011; Kaakinen \& Hyona, 2005).

What are the broader theoretical implications of our research? First, although research on the expert-blind spot (Hinds, 1999; Nathan \& Koedinger, 2000) suggests that experts sometimes have difficulties in taking a novice's perspective, their instructional explanations nevertheless effectively support novice students in acquiring deep and flexible knowledge due to the superior coherence of their explanations. Compared to intermediates, experts produce explanations that highlight central principles of the subject matter in a very coherent manner. This supports novices in processing the explanations deeply in order to establish coherent and flexible representations of the subject domain.

Second, we could show that the effect of coherence on novices' deep-processing and on novices' transfer performance also holds true in more naturalistic settings, such as in giving explanations. In our study, we used real instructional explanations by experts and intermediates, instead of constructing highly coherent vs. low-coherent explanations (e.g. Ainsworth \& Burcham, 2007; Gilabert et al., 2005; Linderholm et al., 2001). Despite the promising results of our study, there are also some limitations and open questions. One limitation of this experiment is the use of only one phenomenon of cardiology, namely bacterial endocarditis, which possibly restricts the generalizability of our experiment. However, bacterial endocarditis can be regarded as a classic disease, which requires fundamental knowledge about the circulatory system, the structure of the heart, and embolisms. In a similar vein, future studies should investigate whether the effect of the higher
coherence of experts' explanations on novices' processing and transfer also holds true for other subject-domains.

Overall, the present study shows that experts' explanations are an effective means to foster novices' deep processing of complex contents. Due to their highcoherence, experts' explanations prompt novices to process the explanations deeply by focusing on central principles, which results in more flexible knowledge structures and subsequently in a better transfer of knowledge to other tasks. In doing so, experts' explanations can be considered as a valuable scaffold for engaging novices in deep processing and in a meaningful construction of knowledge.

#### Abstract

We studied decision making in situations in which there is a monetary incentive to take risk, and in which the risk taking option sometimes involves deception. We conducted a within participant experiment in which we compared risk taking in deception conditions to pure (non-deceptive) gambles with equivalent risks and outcomes. We confirmed the fourfold pattern of risk attitudes in both conditions. We found that participants chose fewer risky options when the risky option was associated with deception, but that those who deceived more in the deception condition also took more risks in the gamble condition. We conclude that people who tend to take risks in gambles, also take them when it involves deception, although to a lesser extent.

Keywords: Decision making; risk attitudes; deception; incentives.

## Introduction

Despite being a fundamental construct in many economic theories, individual risk attitude does not exhibit the construct stability generally associated with personality traits. Many studies (e.g. Berg, Dickhaut, \& McCabe, 2005; Holt \& Laury, 2002; Isaac \& James, 2000) have shown that inconsistency in people's risk taking depends for instance on the nature (hypothetical vs. real) and magnitude of outcomes, the task and the situation they are facing (e.g., lottery vs. auction vs. game show), and the risk elicitation method (e.g., questionnaires vs. laboratory experiments).

Just as people are willing to take risk in certain situations and not in others, there are also situations in which people are willing to deceive and others in which they are not. We studied the interplay of these two tendencies in situations where deception was risky but the decision maker could choose not to deceive and not to take risk. In these situations there was, by design, no trade-off between risk-taking and deception.

Sakamoto, Laine, and Farber (forthcoming) found that perceived detection risk is one of the factors that determines whether people decide to deceive or not, and that it is evaluated differently in gain- and loss-facing situations. In the current study we sought to find out whether people's decisions to deceive are driven by their attitudes towards dishonest behavior or towards risk taking, and whether their non-deceptive risky choices can predict their decisions to deceive. Particularly, we were interested in if people's risk taking behavior in the deceptive domain also follows the four-fold pattern of risk attitudes (Tversky \& Kahneman, 1992), namely that on average people are risk averse when facing high probability gains and low probability losses (e.g., buying insurance) and
risk seeking when facing low probability gains (e.g., buying a lottery ticket) and high probability losses.

In the extensive decision making literature, few studies have addressed the four-fold pattern directly (Harbaugh, Krause, \& Vesterlund, 2009). Those that have, have not found convincing evidence in support of the pattern, supposedly due to methodological issues related to e.g. the elicitation method, usage of complicated or hypothetical prospects, or presence of low and high probability prospects in the gain domain only.

Often the number of participants and the number of decisions per participant have also been relatively small. In order to test the four-fold pattern of risk attitudes we designed a within participant study, and collected data from substantial number of individuals. We compared risk-taking decisions in two hypothetical situations, one of which was an abstract gamble and the other a real-life decision situation presumably familiar to many of our participants, namely filing a tax return. Using several analysis and modeling techniques we found support for the four-fold pattern of risk attitudes, as well as differences in risk-seeking vs. risk-avoiding behaviors in these two conditions. Despite differences in risk taking between participants who decided to deceive and those who did not, we found consistency in individual decisions across the two conditions.

## Risk attitudes when facing gain vs. loss

An abundance of empirical evidence has shown that people weight losses and gains asymmetrically, so that a loss is generally considered worse than an equivalent gain (Kahneman \& Tversky, 1979). This gain versus loss trade-off has been termed loss aversion. The principle of loss aversion is controversial since, as Gal (2006) points out, it is used in an ad hoc manner to explain a number of phenomena involving losses and gains, such as the sunk-cost effect, the endowment effect and status-quo bias (Harinck, Dijk, Beest, \& Mersmann, 2007); while at the same time, these phenomena have been presented as evidence for the existence of loss aversion. Tversky and Kahneman (1991) notwithstanding, it remains unclear how strong the experimental evidence is for loss aversion (Bateman, Kahneman, Munro, Starmer, \& Sugden, 2005; Novemsky \& Kahneman, 2005).

In general people prefer avoiding losses to making gains, and when facing gains they exhibit risk aversion, which is considered a fundamental element in theories of human decision making under risk (Holt \& Laury, 2002). Its true nature
is not well understood, for instance how its existence depends on the size of the risky outcomes (Holt \& Laury, 2002), as laboratory experiments usually use relatively low monetary incentives. The observed pattern of human risky behavior is more complex than briefly described above, and it relates not only to the magnitudes of gains and losses but also to their probabilities.

Markowitz (1952) proposed a value function, defined over gains and losses, that underweights small gains and small losses relative to large gains and large losses. This implies risk-seeking behavior for small gains and risk-avoiding behavior for large gains, whereas the reverse is true for losses (Haisley, Mostafa, \& Loewenstein, 2008). Kahneman and Tversky (1979) explain the equivalent risk preference pattern - dubbed the four-fold pattern of risk attitudes - with a probability weighting function that overweights low probabilities and underweights moderate and high probabilities.

## Lie aversion

We are interested in whether and how the risk preference changes when risk is associated with deceptive behavior that results in a better outcome than risk-avoiding behavior. Pure lie aversion would mean that the cost of lying is derived from the act of lying only. Even if there is evidence that lie aversion exists, it is not always pure, but is relative to the circumstances or linked to the consequences of lying (especially in repeated interactions where reputation is at stake) or beliefs about the outcomes and expectations of others (Erat \& Gneezy, 2012; Gneezy, 2005; Hurkens \& Kartik, 2009; López-Pérez \& Spiegelman, in press; Lundquist, Ellingsen, Gribbe, \& Johannesson, 2009).

López-Pérez and Spiegelman (in press) devise an experiment to isolate pure lie aversion. To rule out altruistic or guilt-avoidance motivations for truth-telling, none of their treatments induced loss for the receiver, but instead involved a slight increase in the sender's payoff if she decided to lie. Even if the majority of the participants lied, the number of participants (about one third) who never did was the same in each treatment. This led the authors to conclude that pure lie aversion does exist. Lundquist, Ellingsen, and Johannesson (2009) also find evidence for lie aversion, with the effect increasing with the size of the lie (people prefer not to stretch the truth too much), and with free communication as opposed to predefined messages.

Erat and Gneezy (2012) as well find strong evidence for lie aversion, but also convincing evidence that people are willing to lie, even at their own cost, if it significantly helps the other person, and even more so if their own payoff increases without increasing the other person's costs. Gneezy (2005) also finds that people tend to lie if there is no cost associated with lying itself, and if the lying benefits themselves without hurting others.

Hurkens and Kartvik (2009) argue that people can be categorized roughly into two kinds: to those who would never lie and to those who will always lie if the benefit from lying
exceeds the benefit from telling the truth. Gibson, Tanner and Wagner's results (2012) reject this static type-based model, but they argue that significant within and among individual heterogeneity exists in lie aversion and willingness to engage in deceptive behavior, providing evidence that intrinsic preferences are non-separable form economic incentives. In summary, people are sensitive to the outcomes attainable by lying, and aversion to lying cannot be explained solely by the negative (guilt) feeling from the act of lying itself, but rather must take some account of what can be achieved (benefits) or avoided (costs) by lying.

## Experiment

We designed an experiment to study how incentives, i.e, monetary gain vs. no-gain and monetary loss vs. no-loss, and the associated risks affect people's propensity to choose a deceptive risky option, in conditions where the risky option is associated with a better outcome (if successful) than the sure option. We compared risky choices in the deception condition to the pure gamble condition in which there was no deception. As the deception condition we chose a real-life scenario of filling in an annual income tax return. The risk in these scenarios was defined as the probability that the tax return would be audited and the information found to be in error.

Mainly supportive but also mixed evidence exists about the effectiveness of audit probability and fines as a deterrent for tax evasion. Maciejovsky, Schwarzenberger, and Kirchler (2012) review several studies that found a positive effect of audit probability on tax compliance, and also studies that failed to find any support for tax fines as effective deterrents for tax evasion. The authors suggest affect as a determinant of tax behavior, but other sources have also been suggested, such as trust, fairness, and social norms (Maciejovsky et al., 2012). We are not aware of any studies that have linked deception aversion to tax behavior or that have focused primarily on willingness to deceive in taxes across conditions of variable risk and outcome size.

## Method

Participants Using Amazon Mechanical Turk (MTurk, http://www.mturk.com/) we recruited 690 participants to complete an online questionnaire in Qualtrics software (http://www.qualtrics.com). After discarding data from participants who failed the attention check question we had 672 participants ( 362 women, 308 men, 2 unknown; median age 29 years, age range: 18-73 years). All participants were native English speakers, aged 18 or above, and residing in the US. Each participant received USD 1.00 for their participation.

Material We prepared 18 questions in two conditions that asked for choices between a sure and a risky option. The difference between the conditions was that one of them used simple monetary gambles, whereas the other used real-life scenarios of filling the tax return (deception scenario). In the deception condition risky outcome was always associated
with the deceptive option, and the sure outcome with the honest option. We chose this design because of the inherent risky nature of deception: there is always a chance, however minimal, that the deception is detected, leading to an adverse outcome. In other words, examples in which risk taking is associated with a sure outcome would have been, in our opinion, so artificial - especially the cases with sure losses - that we expected them to bias our participants' decision behavior.

We chose the tax return as our deception scenario since it has the extremely valuable feature of being usable symmetrically for the gain and loss domains, depending on whether the taxpayer is facing additional taxes or a tax refund. ${ }^{1}$

Four types of scenarios were prepared in both conditions: high probability gain, high probability loss, low probability gain, and low probability loss, so that for each outcome level (gain and loss) we created both a low probability and a high probability scenario. These types were designed to test the four-fold pattern of risk attitudes, and the value of the sure option was chosen to match the expected value of the risky option. For each type we created four outcome and probability variations, as shown in Table 1. ${ }^{2}$

Table 1: The money to gain or lose, and their probabilities.

| $p$ | 0.20 | 0.05 | 0.05 | 0.10 | 0.80 | 0.95 | 0.95 | 0.90 |
| :---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| Risky option \$ | 20 | 100 | 1000 | 5000 | 20 | 100 | 1000 | 5000 |
| Sure option \$ | 4 | 5 | 50 | 500 | 16 | 95 | 950 | 4500 |

Example scenarios in the gain condition are shown in Figure 1. The wording in the corresponding loss scenarios was "have to pay", instead of "get back" (deception), and "lose" instead of "win" (gamble). The choice options were presented horizontally next to each other, and their order was randomized.

Procedure After giving their informed consent the participants were asked to make their choices in 18 deception scenarios and 18 gamble scenarios (the order of sets was selected randomly for each participant). All participants answered all 36 questions, so the deception vs. gamble manipulation was within participant. After finishing the choice questionnaire they filled in optional background information, such as age, gender, and education. The questionnaire ended with a debriefing. It took them about 20 minutes to finish the whole experiment.

[^321]
#### Abstract

Deception scenario John is doing his yearly taxes. He has to answer a question about how many dependents he has. John is aware that only children under 19 years of age qualify as dependents for tax purposes; his son recently turned 19 , and so does not qualify. If he tells the truth, indicating he has zero dependents, he will get back $\$ 950$. Alternatively he could say he has one dependent, in which case he would instead get back $\$ 1000$. He knows that such mistakes are fairly common, and that he can relatively easily find an excuse for his "clerical error" if his tax return is audited. If in the audit his answer is found to be in error, however, he would get back $\$ 0$. He also knows that $5 \%$ of such errors are caught. If you were John, would you say [] You have zero dependents and get back $\$ 950$ for sure. [] You have one dependent, in which case you have a $95 \%$ chance of getting back $\$ 1000$, but also a $5 \%$ chance of getting back $\$ 0$.

Gamble scenario Imagine that you face the following two alternatives and you must choose one of them. Which one would you choose? [] Win \$950 for sure. [] $95 \%$ chance to win $\$ 1000, \$ 0$ otherwise.

Figure 1: Example questions.

## Results

We started by plotting the relative frequencies of risk takers in gains and losses for each question separately (Figure 2). When facing losses, clearly far more participants took risks in gamble scenarios than in deception scenarios across all probabilities of losing, and even more so for the higher probabilities. In gains, the risk taking varied with the amount to be gained in both conditions, but more so for gambles in which more participants took risk when facing small rather than large gains with low probabilities, whereas not much difference was seen between scenarios with high probabilities.

First we wanted to ensure that the concepts of gain/loss and gamble/deception really explain the variance in the data. Even if the overall frequency of risk taking is only $28.4 \%$, two-way repeated-measures ANOVA (2 scenario conditions $\times 2$ outcome conditions) found significant main effects both for gamble $(M=6.51)^{3}$ vs. deception ( $M=2.82$ ), $\mathrm{F}(1,671)=666.03, \mathrm{p}<0.01$, and for gain $(\mathrm{M}=3.19)$ vs. loss $(\mathrm{M}=5.78), \mathrm{F}(1,671)=651.43, \mathrm{p}<0.01$, as well as an interaction, $\mathrm{F}(1,672)=420.11, \mathrm{p}<0.01$. Pairwise t-tests with Bonferroni adjustment showed that all pairwise differences between these four conditions (i.e., deception gain, $\mathrm{M}=1.19$ (Risk taking score $\in[0,8]$ ); deception loss, $\mathrm{M}=1.64$; gamble gain, $\mathrm{M}=2.00$; and gamble loss, $\mathrm{M}=4.50$ ) were significantly different, $\mathrm{p}<0.001$.

Risk seeking and risk aversion To see if the data supports the concepts of risk seeking and risk aversion, we applied factor analysis that uses a multidimensional item response model

[^322]

Figure 2: Relative frequencies of risk takers; the larger the icon (G/D), the larger the associated outcome in that question.
for binary data. We chose solutions with the smallest number of factors that showed a meaningful structure: a one-factor solution for deception and a two-factor solution for gambles. The Promax rotated factor loadings are shown in Table 2.

For gambles the factor loadings clearly align with the fourfold pattern of risk attitudes, if we interpret the Factor 1 as "risk seeking" and Factor 2 as "risk aversion." Even though not shown in Table 2, a two-factor solution for deception also showed a similar pattern to the gamble data. It thus seems that our participants were driven by the risk attitude in both gamble and deception conditions.

However, as shown in Table 2, just one factor was enough to explain all responses in the deception condition, whereas no such meaningful pattern was detected in the gamble data. It thus seems that in the gamble condition our participants were driven by risk attitudes, but in the deception condition these attitudes were joined by other considerations.

On another note, unlike what would be suggested by the four-fold pattern of risk attitudes, the participants tended to choose the sure option in more than half of the low probability gain questions $(\mathrm{t}(671)=18.30, \mathrm{p}<0.01)$. More specifically, their risk taking in this condition was heavily affected by the value of the gamble, so that they were much more willing to trade off a sure $\$ 4$ for unsure $\$ 20$ than a sure $\$ 500$ for unsure $\$ 5000$, so they gambled in the former case but chose the sure option in the latter. This clearly contradicts what

one would expect from the four-fold pattern of risk attitudes, which predicts risk-seeking in all of these cases. We hypothesize that this may be an effect of our participant population, but more rigorous analysis of the difference the amount of money makes in risky and deceptive choices is a subject for future studies.
Risk aversion or deception aversion We have already established that the participants chose less risky options in the deception condition than in the pure gambling condition. However, the interesting question is whether their gambling behavior and deception behavior are statistically related.

We initially run $\chi^{2}$-analyses to find out if our participants' risk taking in the gamble scenarios and in the corresponding deception scenarios were correlated. For all questions the responses in these two conditions were not independent; the results were very or extremely significant for all questions except high probability loss with risky outcome of $\$ 20$ (for which it was still significant).

We also conducted another factor analysis for the whole dataset, i.e. gamble and deception responses combined. For the same reason as before, we chose a four-factor model. The Promax rotated factor loadings are shown in Table 3. For each question we chose the factor on which it loaded the strongest. We see Factor 1 appearing as a "deception aversion" factor, and Factor 3 as "risk aversion." Compared to the two-factor solution for gambles, in this solution the "risk seeking" factor is split into two, Factors 2 and 4. Also some questions in deception condition, which are expected to load the strongest on "deception aversion" load strongly on "risk aversion" factor.

We then considered the determinants of deceptive behav-

D?=deception condition(Yes)/gamble condition(No); OC=Outcome. $p=$ probability
ior by correlating factor scores of Factor 2 in the gamble data (which we interpreted as "pure" risk aversion) to the factor scores of the four factors in the combined data. The correlations are $0.46(\mathrm{p}<0.01), 0.04(\mathrm{p}=$ n.s.), $0.75(\mathrm{p}<0.01)$, and -0.11 ( $\mathrm{p}<0.01$ ) for combined factors $1,2,3$, and 4 , respectively. Note that the correlation to the combined Factor 1 is relatively high even though most questions highly associated with that factor are not highly associated with Factor 2 in gambles.

The factor pattern, together with the correlation of factor scores, suggests that deception aversion does not fully explain the reluctance to choose the risky option in the deception scenarios, but rather that something profound in the risk attitudes also plays a role.

As many as 279 (out of 672) participants never chose the
risky option in the deception condition, i.e. they never deceived. We wanted to see how these participants behaved in the gamble condition. The relative risk taking frequencies of non-deceptive and deceptive participants in the gamble questions are plotted in Figure 3 for gains and losses. Compared to the participants who never deceived, the participants who chose at least one risky option in the deception condition also more often chose a risky option in all gamble conditions.

Figure 3: Relative frequencies of risk takers; the larger the icon (H/D), the larger the associated outcome in that question.

To quantify the statistical significance of this observation, we conducted a mixed 2 (never deceived vs. sometimes deceived) $\times 4$ (four-fold pattern) ANOVA that showed a significant main effect of those who never deceived ( $\mathrm{M}=5.735$ ) (Score $\in[0,16]$ ) vs. those who deceived at least once $(\mathrm{M}=7.056), \mathrm{F}(1,672)=36.83, \mathrm{p}<0.001$. Non-deceiving participants also appeared to be risk averse in gambles.

The factor structure for non-deceiving participants' gamble responses follows the structure for the rest of the participants, shown in Table 2. As the above ANOVA shows, they took significantly fewer risks overall, and more specifically they chose significantly fewer risky options in low probability gain questions ( $\mathrm{M}=1.072$ ) (Score $\in[0,4]$ ), compared to the others $(\mathrm{M}=1.310), \mathrm{F}(1,614)=7.6308(\mathrm{p}<0.01)$. There is something particular in these participants and their responses, which is also reflected in the factor solution (see Table 3): the low probability gain questions are explained by their own factor, separate from the other supposedly risk seeking questions.

Zooming down to the individual question level, a 1 -sided proportion test showed a very significant reduction in risk taking for this participant group in all high probability gain questions ( $\mathrm{p}<0.001$ ), and also a significant reduction in all low probability loss questions ( $\mathrm{p}<0.01$ ). High probability loss and low probability gain groups both contained questions for which the test results were not significant. None of the questions in these groups showed statistically very significant ( $\mathrm{p}<0.01$ ) results.

In summary, honest participants chose less risky options in the gamble conditions in which one would expect risk aversion. Compared to the rest of the participants, the honest participants were more risk averse overall, and especially so in conditions in which one would expect risk avoidance.

## Discussion

Our central finding is that the participants who always chose the honest option in deception scenarios also displayed a distinctive pattern of behavior in non-deceptive gamble scenarios. They took fewer risks than normal in conditions that normally elicit risky responses, and were also more risk averse than other participants in conditions that normally elicit risk aversion. From this we conclude that it may not be pure lie aversion that determines the likelihood of risky deceptive behavior even in seemingly perfectly lie-averse people, but rather that risk attitude also plays a role. In other words, these "honest" participants may still be driven in part by an unusually strong aversion to risk, rather than purely by aversion to deception itself. Our results also support a (less surprising) generalization about risk-takers, namely that people who tend to take risks under normal conditions also tend to take them in deception context. Together, these results can be summed up as indicating that there is some within participant consistency in risk taking across conditions that do or do not involve deception. In other words, deception aversion cannot be regarded as a "pure" factor, and does not totally overrun risk seeking in the deception domain. However, the nature of our experimental design does not allow a fully conclusive distinction between these two forces. Future studies are planned to address this issue.

## Acknowledgments

We are grateful to Ilya Farber for the feedback and suggestions related to this work. We would also like to thank Wan Kum Seong for creating the Qualtrics survey for us, and managing the data collection.

# Maximizing learning from collaborative activities 

Rachel J. Lam (rachel.lam@asu.edu)<br>Arizona State University<br>Teachers College, 300 E. Lemon St.<br>Tempe, AZ 85281

#### Abstract

Utilizing a Preparation for Future Learning paradigm and the Interactive-Constructive-Active-Passive framework, this study examined how two different kinds of cognitively engaging activities prepared students to learn from collaborating. Findings show that preparing prior to collaborating improved learning, but a difference was not detected in the type of preparation. In addition, differences in learning outcomes were only present in measures of deep knowledge. Analyses used a multilevel method targeted to dyadic data. Discussion addresses designing collaborative classroom activities that are effective and efficient for deep learning, as well as the importance of aligning assessments to depth of learning.

Keywords: collaborative learning; preparation for future learning; cognitive engagement; classroom learning.

## Introduction

Collaborative learning has become a common instructional strategy in a variety of educational settings because of its potential to boost student learning. Through peer discussion, students can receive immediate feedback, ask questions, generate explanations, challenge each other, jointly construct understanding, and elaborate on each other's ideas, which are all behaviors that have been shown to improve learning outcomes in both the classroom and laboratory. However, despite the extensive research that has been conducted on collaborative learning, the literature is still unclear as to what factors lead to the best learning outcomes, in particular, for deep understanding of concepts. Thus, this work aimed to investigate two factors that may improve deep knowledge, in particular, in a conceptual (as opposed to a problem-solving) domain: (a) individually engaging in the learning material prior to collaborating and (b) "constructively" engaging, where students are generating (constructing) new knowledge beyond the learning material.

There are mixed results as to how collaboration affects student learning (Barron, 2003; Craig, Chi, \& VanLehn, 2009). In general, students do not always take advantage of the benefits collaboration affords, thus, researchers have searched for ways to help students collaborate more effectively. Methods such as training students in collaboration skills (Hausmann, 2006; Uesaka \& Manalo, 2011), providing structured guidance to students while interacting (Coleman, 1998; Walker, Rummel, \& Koedinger, 2011), and designing collaborative learning environments that elicit meaningful discussion (Engle \& Conant, 2002; Kapur \& Bielaczyc, 2012) have been found to improve learning from collaborating. However, there are also challenges and limitations to these methods.

One limitation to training students in specific skills before collaborating is that they often fail to retain those skills after time (Webb, Nemer, \& Ing, 2006). The challenge of structured guidance during collaboration is that too much can constrain creativity and flexible discussion, which can hinder learning (Cohen, 1994). Therefore, one question that remains is, does the effort and time that it takes to train or guide students in collaborative behaviors really pay off? Work that has investigated the design of collaborative activities to naturally elicit effective dialoguing addresses this challenge, showing that open-ended and flexible tasks can enrich discussion (Janssen, Erkens, Kirshner, \& Kanselaar, 2010; Van Boxtel, Van der Linden, \& Kanselaar, 2000). However, this only occurs when students have sufficient prior knowledge (Nokes-Malach, Meade, \& Morrow, 2012). Thus, a collaborative learning method that avoids the time and effort needed to train students in particular skills or structure their instance-by-instance dialogic behaviors, while providing the opportunities for students to acquire adequate prior knowledge is investigated in the current study.

## Cognitive theoretical models

Two cognitive theoretical models supported the design of the collaborative activities in this study. The Interactive-Constructive-Active-Passive (ICAP) framework and the Preparation for Future Learning (PFL) paradigm are described below.

## The ICAP framework

The ICAP framework differentiates student engagement in learning tasks by categorizing students' overt behaviors as Interactive, Constructive, Active, or Passive, and is founded on theoretical assumptions about how those behaviors link to different cognitive processes (Chi, 2009; Menekse, Stump, Krause, \& Chi, 2012). An Interactive behavior might be debating or extending a partner's idea and the cognitive process underlying Interactive engagement would be co-creating knowledge. Inventing a rule, self-explaining, or creating a concept map would be Constructive, the underlying cognitive process being creating new knowledge. Active behaviors include highlighting a textbook chapter or copying solutions steps from the board, and correspond to assimilating knowledge. Listening or watching would be considered Passive, corresponding to the process of storing knowledge. The ICAP hypothesis makes the prediction that Interactive activities will produce better learning outcomes than Constructive activities, which are better than Active
activities, which are all better than Passive activities: $\mathrm{I}>\mathrm{C}>\mathrm{A}>\mathrm{P}$. There is empirical support for the ICAP hypothesis, although the Interactive category carries several caveats (Menekse et al., 2012). One is that engagement should only be considered Interactive when both individuals in a dialogue are engaging constructively. This does not always occur (literature on the process of collaboration in learning settings attests to this claim). Thus, this current study will address the question of how learning is affected by interacting on a Constructively designed task or an Actively designed task.

## The PFL paradigm

This paradigm takes into account how earlier learning experiences can shape future learning, under the perspective that prior learning can activate a mental model to either facilitate or hinder the learning of a new concept (Schwartz, Sears, \& Chang, 2007). Although the PFL paradigm was introduced in the literature over two decades ago (Schwartz \& Bransford, 1998), more recent work has used this model to investigate learning outcomes in a variety of domains (Chin et al., 2010, in elementary school science; Gadgil \& Nokes-Malach, 2012, in cognitive psychology; Schwartz, Chase, Oppezzo, \& Chin, in press, in physics). This work has shown that invention-type tasks better prepare students to learn from a lecture (Schwartz \& Martin, 2004). In other words, tasks that are set up to cognitively engage students in a "constructive" way, by causing students to generate new knowledge (Chi, 2009), are those that best prepare students to learn in a future task. The majority of the work that has investigated the PFL paradigm uses some form of didactic instruction (i.e. lecture) as the future task, thus, little is known about the effects other forms of instruction as future tasks, such as collaboration. The current study utilizes the PFL model to structure collaborative learning activities for students, however, the future activity is peer discussion (instead of a lecture) and students individually (rather than collaboratively) engage in the preparation task.

## Measures of learning and mental models

In light of using the two aforementioned cognitive perspectives as the basis for this study, the measures of learning outcomes should be viewed as representing student mental models of the concepts being tested. Mental models can be assessed through externalizations such as selfgenerated concept maps, matrices, drawings, and freewriting (Janssen et al., 2010; Schwartz, 1995; Van Amelsvoort, Andriessen, \& Kanselaar, 2007). Multiplechoice or $\mathrm{T} / \mathrm{F}$ tests are often used to measure student learning with regard to accuracy or correctness of knowledge, however, these are not necessarily appropriate to fully assess a mental model (Bransford \& Schwartz, 1999; Schwartz et al., 2007). A more complete picture of student knowledge can be captured by combining these types of assessments. With respect to measuring depth of knowledge, shallow knowledge can be equated to the "surface features" of a mental model, while deep knowledge
lies in the "structure" of the model (Chi \& VanLehn, 2012). Surface features can be facets such as labels and definitions, physical characteristics, or other plain facts. Structural knowledge is much more complex, representing the relationships between the features of a concept and/or the process by which a concept occurs or functions. Thus, the current work used student-generated written responses to assess deep, structural-based learning, while T/F pre- and posttests were used to assess shallow, surface-feature learning.

## Method

The study used a $2 \times 2$ experimental design examining Preparation (No Prep and Prep) and Type of Task (Active and Constructive). The two dependent variables were shallow learning and deep learning. In order to preserve both internal validity and ecological validity, the study was conducted as a classroom study across four introductory psychology classes with equal representation of the four conditions in each classroom. The students participated in the study as a part of their "regular" classroom activity for the weekly topic of "concepts of memory."

## Participants

Ninety students from four Psych 101 courses at a large community college in a Southwestern city in the United States participated in this study. The mean age of students was 21 years and the sample represented an ethnically diverse population (46\% Hispanic, 37\% Caucasian, 10\% African American, and 7\% Asian, Native American, or Middle Eastern). Fifty six percent of the students were female, $44 \%$ were male.

## Materials

Regarding the topic of interest, prior research attests to the difficulty that students have in deeply understanding the differences between a variety of concepts of memory, in particular, for encoding- and schema-based concepts (Schwartz \& Bransford, 1998). Thus, all learning activity materials and assessments were based on Schwartz and Bransford's (1998) materials. These materials were the only form of instruction to students for the topic. Students received no other instructional material (lecture, textbook readings, etc.) prior to the study and, therefore, were assumed to have limited prior knowledge of the concepts.

The study used the following materials: (1) pretest and demographic survey, (2) four versions of learning materials based on condition, (3) posttest, and (4) scoring rubrics.
(1) The pretest consisted of T/F questions that were very slightly modified from Schwartz and Bransford's (1998) verification measure, which was used in several studies on concepts of memory.
(2) The materials used during the learning phase were equivalent in domain content, however, the specific task instructions varied according to the ICAP cognitive engagement definitions and whether or not the condition
included a preparation period. In Prep conditions, students were given a portion of the class time to individually work on the task prior to engaging with a partner, while students in the No Prep conditions worked with a partner for the entirety of the learning phase. Active tasks asked students to work within the existing learning materials (i.e. they did not have to generate inferences beyond the materials to complete the tasks), while the Constructive tasks required students to invent concepts. To provide an example, the Constructive task required students to answer questions such as, "Why do people remember certain kinds of information, but not other kinds?" after studying a memory experiment and its results. They had to generate ideas about the process of memory. The Active version of the task, on the other hand, instructed students to study a list of memory terms and their descriptions. They then applied the terms to the same memory experiment included in the Constructive version by writing the term next to the appropriate result of the experiment. These students had to "search and select," but did not necessarily have to generate any new knowledge. Since the Active tasks took much less time to complete (as shown in a prior pilot study of this work), they included a secondary memory experiment task that was identical in structure to the first, but with a different cover story. This was to control for time-on-task, which was equalized across the four conditions.
(3) The posttest included the same $T / F$ questions that were used in the pretest. To avoid a "testing effect" (i.e. learning solely attributed to the recognition of identical test questions at a later testing phase), the ordering of the questions was changed and there were four to five days inbetween the tests. (See work by Bjork and Storm, 2011, for details regarding the conditions under which testing influences learning.) Student gain scores from pre- to posttest served as the measure of shallow learning.

Two additional tasks were included on the posttest to obtain a measure of deep learning. These were "prediction" tasks, where students had to study novel experiments on memory (i.e. they did not appear in the learning materials) and synthesize their recently learned knowledge in order to apply it to new experimental conditions, generate new inferences about how memory works, predict the results of the experiments, and provide evidence of their reasoning for predictions. Students freely wrote their responses to a set of sub-questions that all corresponded to a basic question of, "Based on what you now know about memory, how do you think the results of these experiments will turn out?"

Because these types of prediction tasks are likely deeply cognitively engaging, there was concern that including any on the pretest might influence students to engage differently in the learning activity tasks. In particular, the Active conditions may have become contaminated if students were primed in a pretest task to think more deeply about the concepts. Thus, the pretest only included the shallow T/F questions. Although this prevented obtaining any measure of deep knowledge prior to the learning phase, this was of less concern since it was highly unlikely that students had
prior deep knowledge of memory concepts. As already mentioned, they not did have previous instruction on the topic in their classes and in addition, they produced low shallow knowledge scores at pretest ( $M=50.8 \%, S D=21.6$ ). Thus, rather than a gain score, the deep learning measure used only the posttest prediction task scores.
(4) Scoring rubrics were developed in order to quantify students' responses to these prediction tasks. Responses were coded by how well they represented any of the following eight concepts: elaboration, schema, gist, serial position effect, generation effect, obstacle recall, interference, and encoding failure. These concepts may have been explicitly learned in the Active conditions, through the "search and select" tasks, or may have been implicitly learned in the Constructive conditions, through the "invention of concepts" tasks. A code of "other" was used for responses that represented novel ideas about memory (i.e. ideas that were not taught through the activities). This coding translated to a score ranging from 0-3 points, based on a holistic-style rubric. A higher score indicated knowledge of a broader range of concepts, representing a more complete mental model of memory. A score was also given for the quality of students' reasoning supporting the relationship between their predictions and the concepts, also ranging from $0-3$ points. This score indicated knowledge of the relationships between the concepts and their applications to novel settings, thus, representing a better structured mental model. A total score of 0-6 was possible. Two raters scored a randomly selected $20 \%$ of the data and intraclass correlation was used to assess inter-rater reliability, $\operatorname{ICC}(2,1)=.76, \mathrm{p}<.001$. One rater scored the remaining tests.

## Procedure

The study took place over the course of a week. On the first day, students took the pretest and filled out the demographic survey. Students were given 15 minutes to complete the pretest.

Students completed the learning activity phase during the next class. They were randomly assigned to one of the four conditions: (a) No Prep-Active, (b) No Prep-Constructive, (c) Prep-Active, and (d) Prep-Constructive. For No Prep conditions, students were randomly assigned to a partner and told to follow the instructions on their packets. They were encouraged to share ideas, try come to agreement before writing down an answer, and not to worry about writing right or wrong answers. Instructions varied depending on whether students were completing the Active or Constructive version (described in the Materials section), but all students were told to try to contribute equally to the discussion. For Prep conditions, students first completed an individual packet. They were told not to worry about right or wrong answers and to do their best. They were informed that they would use this packet to work with a partner. After the individual work (ranging from 15-20 minutes), students were randomly paired and spent the remaining class period doing their collaborative packet (10-15 minutes). They were told to share their ideas, try to contribute equally to
discussion, and come to agreement before writing down their answers. At the end of class, all materials were collected (each pair turned in a jointly completed collaborative packet). Students spent 30-35 minutes on the learning task in all conditions.

The posttest was given in the following class and was completed individually. Students spent 35-50 minutes on the posttest. Any students who finished before 30 minutes passed were asked to go over their answers one more time.

## Results

To avoid violation of the assumption of independence of subjects (which traditional ANOVA assumes) (Kenny, Kashy, \& Cook, 2006), a dyadic multilevel model was used for all analyses. Figure 1 illustrates the model. The analytic technique was a linear mixed model with the Restricted Maximum Likelihood (REML) method, appropriate to cope with dependency between partners within dyads.

Figure 1: Multilevel dyadic design.

## Shallow learning

Analysis of the pre- and posttests compared learning gains across conditions. "Normalized change" calculations were used to adjust learning gains by accounting for influences of pretest scores, yielding a more sensitive measure of gains (Marx \& Cummings, 2007). When post>pre, the following formula was used: post-pre/1-pre. When post<pre, a different formula was used: post-pre/pre. Although students gained in all conditions, there was no reliable difference between conditions. Table 1 summarizes these results.

Table 1: Shallow learning mean scores

| Condition | $n$ | Pretest $\%$ | Posttest $\%$ | Adj. <br> Gain |
| :--- | :--- | :--- | :--- | :--- |
| No Prep-Active | 14 | 53.6 | 72.6 | .43 |
| No Prep- <br> $\quad$ Constructive | 18 | 49.1 | 61.1 | .21 |
| Prep-Active | 15 | 46.7 | 63.3 | .28 |
| Prep- <br> $\quad$Constructive <br> Total | 19 | 53.5 | 71.9 | .40 |

Note: Due to incompletion of the T/F questions at either pre- or posttest, the total sample was reduced from 90 to 66 students.

These results are not surprising because even the "lowest" condition (No Prep-Active) constitutes an effective teaching strategy in a number of ways. Students were provided terms and definitions, the opportunity to apply those to real-world examples, and the benefit of engaging in discussion. Because these pre- and posttests were used to assess the knowledge of the surface features of memory concepts, students were expected to gain in all conditions. The differences between conditions were only hypothesized for deep learning, attesting to the sensitivity of the manipulation of the conditions. The deep learning results are below.

## Deep learning

Ninety students completed the prediction task portion of the posttest. The prediction task posttest scores were reliably different across conditions. There was a main effect of Preparation $F(1,41.1)=5.79, p<.03$, but no effect of Type of Task, nor an interaction effect. Students who prepared in the task individually in either type of task before collaborating showed evidence of deeper learning. See Figure 2.

Figure 2: Prediction task results.
This result was not expected since prior work supports the notion that "constructively" engaging activities should produce improved learning above "actively" engaging activities. As shown in Figure 2, there is virtually no difference between the Active and Constructive conditions when students individually prepared prior to collaborating. One interpretation of these results is that the inclusion of preparation prior to discussion in a collaborative activity boosts learning such that it overrides any effects of type of task. It is possible that the inclusion of an individual preparation period increases the likelihood that students will engage constructively in a dialogue, regardless of whether the task itself requires generation of new knowledge. In other words, the preparation may have spontaneously impelled students to engage constructively even in Active tasks, thus, further exploratory analyses were conducted to check this.

## Preparation facilitates constructive engagement

To assess differences between how the No Prep-Active and Prep-Active students engaged in the tasks, the collaborative activity worksheets were examined. They were scored by student effort, rather than in correctness of responses, since these were never intended to measure learning. Support for such a strategy can be found in work on dynamic assessments (Bransford \& Schwartz, 1999; Schwartz et al., 2007), which measure readiness to learn, rather than learning outcomes. Thus, as related to the PFL paradigm, these learning tasks can be viewed as readiness tasks that prepared students to engage in collaboration, with the posttest prediction task measuring learning. It is possible that students from the Prep-Active condition developed an enhanced readiness for learning in discussion, accounting for the improved performance on the prediction tasks.

Each dyad that completed at least $94 \%$ ( 15 of 16 items) of the activity worksheet received an effort score of two; those that completed at least $75 \%$ received an effort score of one; zero points were given to any dyads that completed under $69 \%$ of the activity (only four dyads). Since amount of work completed is not a thorough indication of how deeply engaged students were in the activities, the number of times students within a pair disagreed was also taken into account. The worksheets included a line for each item that asked students if they agreed on the answer, and if not, they were instructed to explain their disagreements. (Work on argumentation shows that students benefit from talking through disagreements, Asterhan \& Schwarz, 2009.) Analysis of discourse could have provided a better measure of engagement, however, that was beyond the scope of this paper. Thus, activity effort and average number of disagreements per pair were used to measure engagement.

Results showed that dyads in the Prep-Active condition produced a higher activity score ( $M=1.71$ ) compared to those in the No Prep-Active condition ( $M=1.43$ ), and had a slightly higher average number of disagreements (.55 compared to .45 , respectively). Although none of these differences were significant, put together they provide some support that preparation may influence students to engage constructively in an activity, even when the activity in and of itself does not require such engagement.

## Discussion and future work

This study tested the effects of preparation and type of task on shallow and deep learning in a collaborative activity. Students engaged in either an Actively or Constructively designed task, and either worked individually during part of the learning phase, then collaborated (Prep), or worked jointly the entire time (No Prep). (Recall that time-on-task and domain content of the learning materials were the same across all conditions.) Results showed that preparation improved deep learning outcomes, but no difference was detected for type of task. The main effect of preparation on outcomes extends the PFL paradigm, showing that peer discussion can serve as a beneficial future learning task (i.e. the future task need not be lecture). Considering the learning
opportunities that peer discussion offers as compared to didactic forms of instruction, this is an important finding towards design of classroom activities, especially with regard to deep learning. Although this study cannot inform on the comparison between collaborative learning and didactic instruction as future learning tasks of a PFL model, it supports the need for more work in this area.

The ICAP framework was not necessarily supported as an effective tool for designing learning activities since, overall, there were no differences in type of task on learning. However, the ICAP hypothesis predicts outcomes based on student engagement, not on task instructions. Thus, the exploratory analysis showed that students in the Prep-Active condition might have engaged constructively, justifying a null effect. Additionally, one might argue that because all four conditions included collaborative activities, the level of engagement for all conditions was actually Interactive. What is of interest here is that there then should have been an overall null result, however, that did not occur in the deep learning outcomes. Chi (2009) discusses the idea that working in pairs does not automatically make engagement Interactive, and that to be truly Interactive, both students must at minimum be engaging constructively. Thus, with regard to design of learning tasks, one way to better ensure that students engage Interactively in collaborative tasks is to include an individual preparation task prior to discussion. Future work is examining discourse data from a sampling of pairs from this study to further inform on how discourse processes related to learning, within in the contexts of the ICAP framework and PFL paradigm.

This study draws concern toward prior work that has not used analytic techniques that account for dependency between partners within dyads. Future work in areas of collaborative learning should utilize dyadic or multilevel models to analyze data that includes individual student outcomes (such as individually completed posttests).

Regarding the learning assessments, this study shows the usefulness of distinguishing between deep and shallow learning, and that different kinds of measures are needed to evaluate learning of varying depths. By using a mental model perspective to understand outcomes, one can see that a measure of "surface feature" knowledge would have shown no effects across conditions. An appropriate measure of deep "structural" knowledge was needed to tease apart how learning was affected by the collaborative tasks.

To conclude, it appears that one way to maximize the benefits of collaboration on deep learning is to include a preparation task, which allows students to develop a readiness for learning in future discussion. Preparation also may elicit spontaneous constructive engagement in future discussion, and it may not be necessary to otherwise design collaborative activities to specifically engage constructive behaviors. In addition, students who prepared only spent half the amount of the time collaborating. Thus, using a PFL paradigm to structure collaborative activity is also efficient, in that students can make the most effective use of their time engaging in discussion.

## Acknowledgments

This work was partly funded by a GRSP grant from the Graduate \& Professional Student Association at Arizona State University. Thanks to Julie Morrison for feedback on materials, Ruth Wylie and Kasia Muldner for their mentorship, Micki Chi for her early influence on this work, and Kathy Nakagawa for her support and encouragement.

#### Abstract

Two experiments were conducted to examine how time-ontask (i.e., practice and fatigue) influences eye movements during visual search. In Experiment 1, we examined how practice influences eye movements during an extended visual search task. Results replicate the findings that over the course of a visual search task, performance improves and fixation duration increases. Yet changes in fixation duration did not correlate with changes in search performance. In Experiment 2, we examined how fatigue influences eye movements during an extended visual search task. To manipulate fatigue, participants either did or did not receive breaks. Those who did not receive breaks replicated the findings in Experiment 1. Critically, participants who did receive breaks showed no increase in fixation duration over the course of the visual search task. These results indicate that the increase in fixation duration with time-on-task reflects fatigue, and that this measure of fatigue can be derived independent of measures of performance improvements, such as shorter response times.

Keywords: Visual Search, Attention, Practice, Fatigue, Eye Movements.

Previous research (Horowitz, Cade, Wolfe \& Czeisler, 2003; Wolfe et al, 2007) has shown that after long passages of time, critical items are missed during visual search. Given that many studies have shown that fatigue negatively impacts the ability to allocate attention across a broad spectrum of tasks (Casagrande, Violani, Curcio \& Bertini, 1997; Dawson \& Reid, 1997; Drumer \& Dinges, 2005; Fairclough \& Graham, 1999; Lyznicki, Doege, Davis \& Williams, 1998; Marcus \& Loughlin, 1996; Williamson \& Feyer, 2000), it is reasonable to think that the fatigue which arises over time while engaging on a task contributes to search performance failures over time. Fatigue can be manifested in a number of different ways. For example, fatigue is considered to result from working (e.g., Winwood, Winefield, \& Lushington, 2006), mental stress (Baumeister, 2002), psychopathology (Berrios, 1990), boredom (Wyatt \&

Langdon, 1937), disease (Whitehead, 2009), and lack of sleep (Durmer, \& Dinges, 2005). In the present context, we refer to the fatigue that is associated with time-on-task (e.g., Neri, et al., 2002; Stern, et al., 1993; Wilkinson, 1961). Pinpointing the role of fatigue on search performance is inherently challenging, given that a) the negative effect of fatigue overlaps with the positive effect of practice on a task, and b) the same behavioural measures (e.g., response time, RT) are used to assess both the positive and negative effects of time on task. Further, several studies have found that RT measures are actually insensitive to fatigue (Baulk, Reyner \& Horne, 2001; Gillberg, Kecklund \& Akerstedt, 1996; Milosevic, 1997). Utilizing the fact that fatigue appears to influence oculomotor control (Bocca \& Denise, 2006; De Gennaro, Ferrara, Urbani \& Bertini, 2000; Galley 1989; Galley \& Galley, 1998; Hoffman, 1946; Luckiesh \& Moss, 1937; Morris \& Miller 1996; Saito, 1992; Schleicher, Galley, Briest \& Galley, 2008; Sirevaag \& Stern 2000; Stern, Boyer, \& Schroeder, 1994; Summala, Häkkänen, Mikkola, \& Sinkkonen, 1999), and could lead to an increase in fixation duration, the present paper investigated the intriguing possibility that fixation duration could provide an index of fatigue over time that is separable from the beneficial effects of practice on a task.

To achieve this aim, in two experiments the eye movements and performance of individuals were monitored as they performed a visual search task. Experiment 1 confirmed that changes in fixation duration are not correlated with the improvements in search that come from practice. Experiment 2 manipulated levels of fatigue, and showed that as fatigue levels increased, so did fixation duration, and that this could be separated and measured reliably from the positive effects that practice has on search performance. Collectively these data provide evidence that eye movements can be used as an indicator of fatigue that is
independent of other performance changes, in particular, the positive performance changes that accompany practice.

## Experiment 1

Participants performed a standard attentionally demanding visual search task, whereby search time increases with set size, and indicating that a target is absent takes longer than reporting a target's presence (Wolfe, 1998). An SR Research EyeLink 1000 desktop mount eye tracking system measured fixation duration.

## Method

Participants Twelve undergraduates (8 female) received course credit for participating.

Design A 2 (Target presence: present vs. absent) x 2 (Set size: 7 vs. 14 items) x 12 (Block: 1-12) within design was used.

Stimuli The stimulus displays were presented on a 24 -inch monitor set at a resolution of 1920 by 1200, with participants seated 80 cm from the screen. The visual search display consisted of target and distractor letters in an imaginary $6 \times 6$ grid, with cell-centres separated by 170 pixels horizontally and 128 pixels vertically. The only letters used as targets were " $E$ ", " $K$ ", " $P$ ", and " $Z$ ". Target letters never appeared as distractors in the visual search displays. All letters were presented in 36 -point Lucida Console font, measuring approximately 0.6 cm horizontally and 1.2 cm vertically, subtending 0.6 degrees of visual angle.

Procedure Each participant received 600 trials which were divided into 12 blocks of 50 trials. Eye tracking calibration was conducted before each block. Additionally, drift correction was conducted every 10 trials. Each target letter appeared in $25 \%$ of the target present displays. The displays were randomized for each participant. The visual search task consisted of the search for one of the target letters amongst either 6 or 13 distractor letters. Trials began with a 500 ms display indicating the target to be searched for on that trial, followed by a blank screen for 200 ms and then the search display. The participants were instructed to search for the target letter and press the right button on a gamepad if the target was present and the left button if the target was absent. The display remained on the screen until a response was made, at which point a blank screen was presented for 200 ms . The experiment took approximately 40 minutes.

## Results \& Discussion

Participants were encouraged to familiarize themselves with the task for the first 12 trials of the study, so those trials were removed from analysis. If the pupil was undetectable at any point during a trial (this includes blinks) then the trial was removed ( $8.4 \%$ of the trials). An error analysis was conducted on the remaining trials on which errors occurred
(4.5\%). The remaining analyses were conducted on the correct responses only. Each measure was analyzed using an Analysis of variance (ANOVA) with Target Presence (present vs. absent), Set Size (7 vs. 14 items), and Block (1 to 12 ) as within participant factors. We report all significant main effects and interactions. Because the focus of the study relates directly to time-on-task, we focus on the main effect of block and its interactions with other variables.

Performance Change in RT is plotted as a function of block (i.e., practice) in Figure 1. For RT, there was a main effect of Target Presence, $\mathrm{F}(1,11)=84.29$, MSE $=809646.70$, p .001, whereby responses were shorter on target present trials than target absent trials. There was a main effect of Set Size, $F(1,11)=190.71$, MSE $=303531.15, \mathrm{p}<.001$, with responses shorter on set size 7 trials than set size 14 trials. In addition, there was a Target Presence by Set Size interaction, $\mathrm{F}(1,11)=103.96, \mathrm{MSE}=147848.77, \mathrm{p}<.001$, indicating that the effect of target presence was greater on set size 14 trials than set size 7 trials. Critically, there was a main effect of Block, $\mathrm{F}(11,121)=5.18$, MSE $=31649.60$, p $<.001$, reflecting that responses became faster as block increased. No other main effects or interactions were significant. For errors, there was a main effect of Target Presence, F(1, 11) $=28.02$, MSE $=0.01, \mathrm{p}<.001$, whereby fewer errors were made on target absent than target present trials. No other main effects or interactions were significant.

Figure 1: Change in RT as a function of Block relative to the first Block in Experiment 1.

Eye Movements Change in fixation duration is plotted as a function of block (time-on-task) in Figure 2. Measurement of fixation duration revealed a main effect of Target Presence, $F(1,11)=40.60, M S E=1403.60, p<.001$, indicating that fixation durations were shorter on target absent than target present trials. There was a main effect of Set Size, $F(1,11)=8.40$, MSE $=350.20$, p $<.02$, with fixation durations being shorter on set size 14 trials than on set size 7 trials. Note that the average RT on trials without
targets and with 14 items was approximately 2-3 seconds, and our understanding of fatigue does not operate on this time scale. In other words, fatigue gradually increases throughout a task and, as such, is not measured over the course of a single trial. Critically, there was a main effect of Block, $F(11,110)=3.10, M S E=261.40, p<.002$, indicating that participants' average fixation duration increased as block increased.

Figure 2: Change in Fixation Duration as a function of Block relative to the first Block in Experiment 1.

Relation Between Performance and Eye Movements Finally, we calculated the change in both fixation duration and RT as a function of block for each participant. We then correlated these measures to examine the relationship between changes in RT and fixation duration over time. There was no correlation between the change in RT and the change in fixation duration as a function time on task, $\mathrm{r}(12)$ $=0.37, p=0.234$, demonstrating that the positive effect of practice on visual search is not driving the change in fixation duration ${ }^{1}$. Our working hypothesis is that this increase in fixation duration reflects an increase in fatigue a factor that increases with time-on-task, but is qualitatively distinct from those factors that benefit from time-on-task and lead to a performance improvement. Experiment 2 put this interpretation to a direct test.

## Experiment 2

As in Experiment 1, participants performed a standard attentionally demanding visual search task while their eye movements were monitored. Critically, half of the subjects received a three-minute break between each block of trials and the other half of the subjects did not. Fatigue is associated with time on task (Wilkinson, 1961; 1963; 1965).

[^323]As time-on-task increases the effect of fatigue on performance also increases. Providing subjects with a break reduces the amount of fatigue experienced throughout the task (Neri, et al., 2002; Stern, et al., 1993). If changes in fixation duration are related to fatigue, then we would not expect fixation duration to increase as a function of block in the Break group. However, in the No Break group, we would expect fixation duration to increase as a function of block as it did in Experiment 1.

## Method

Participants Thirty-two undergraduate students (14 female) received course credit for participating.

Design A 2 (Break condition: breaks vs. no breaks) x 2 (Target presence: present vs. absent) x 2 (Set size: 7 items vs. 14 items) x 12 (Block: 1-12) mixed design was used. The break condition was manipulated between participants; target presence, set size and block were manipulated within participants.

Stimuli and Procedure The stimuli and procedure were the same as those used in Experiment 1, except that each participant now received 576 trials which were divided into 12 blocks of 48 trials. The drift correction was now conducted every 12 trials. In addition, half of the participants now received breaks and half did not. Participants in the break condition received eleven 3 minute breaks, one at the end of each block of trials. Participants in the no break condition did not receive breaks throughout the task. The experiment was approximately 40 minutes in the no break condition and 75 minutes in the break condition.

## Results \& Discussion

Analysis was preceded by the same trial removal procedure used in Experiment 1 resulting in the removal of the first 12 trials and trials on which the pupil was undetectable (9.5\%) or errors occurred (3.1\%). Each measure was analyzed using a mixed ANOVA with Breaks (No Breaks vs. Breaks) as a between participant factor and Target Presence (present vs. absent), Set Size (7 vs. 14 items), and Block (1 to 12) as within participant factors.

Performance Change in RTs for the break and no break conditions are plotted as a function of block in Figure 3. For RT, there was a main effect of Target Presence, $F(1,30)=$ 219.84, MSE $=836634.27, \mathrm{p}<.001$, and Set Size, $\mathrm{F}(1,30)$ $=447.56$, MSE $=367483.96, \mathrm{p}<.001$. In addition, there was a Target Presence by Set Size interaction, F(1, 30) = 255.93, $\mathrm{MSE}=128222.02, \mathrm{p}<.001$, which indicates that search was more efficient when the target was present than when it was absent. Critically, there was a main effect of Block $\mathrm{F}(11,330)=12.94$, MSE $=78443.64, \mathrm{p}<.001$, whereby search became more efficient, that is, the time to determine whether a target was present or absent, became faster as block increased. This finding replicated the practice effect on performance observed in Experiment 1. There was
also a Block by Set Size interaction $F(11,330)=4.88$, MSE $=18439.20, \mathrm{p}<.001$, which indicates that search became more efficient over time. No other main effects or interactions were significant. For errors, there was a main effect of Target Presence, $\mathrm{F}(1,30)=43.16$, MSE $=166.03$, $\mathrm{p}<.001$, and Set Size, $\mathrm{F}(1,30)=16.14$, MSE $=29.59$, $\mathrm{p}<$ .001. In addition, there was a Target Presence by Set Size interaction, $\mathrm{F}(1,30)=14.15$, MSE $=30.30, \mathrm{p}<.001$, indicating that the effect of target presence was greater on set size 14 trials than set size 7 trials. No other main effects or interactions were significant.

## Block

Figure 3: Change in RT as a function of Block relative to the first Block in Experiment 2.

Eye Movements Change in fixation duration is plotted as a function of block (time-on-task) in Figure 4. Measurement of fixation duration revealed a main effect of Target Presence, $\mathrm{F}(1,30)=132.73$, MSE $=1739.87, \mathrm{p}<.001$, and a main effect of Break, $\mathrm{F}(1,31)=2.88$, MSE $=14847.77$, p $<0.01$, such that fixation durations were shorter in the no break condition than in the break condition. There was a Target Presence by Set Size interaction, $\mathrm{F}(1,30)=28.84$, MSE $=197.40, \mathrm{p}<.001$, and a Block by Target Presence interaction, $\mathrm{F}(11,330)=4.09$, $\mathrm{MSE}=161.66, \mathrm{p}<.001$, Most critically, there was a main effect of Block, F(11, 330) $=2.41, \mathrm{MSE}=289.61, \mathrm{p}<0.007$, whereby participants' average fixation duration increased as block increased and a Block by Break interaction, $\mathrm{F}(11,330)=1.87$, MSE $=$ 289.61, p < 0.042. No other main effects or interactions were significant.

To further assess the interaction of Block with Break, we calculated the slope relating Fixation Duration to Block. The effect of block was larger in the no break (1.14) condition than in the break condition (0.08), $t(30)=2.57, p$ < .015. The slopes were significantly different from zero in the no break condition, $t(15)=3.43, p<.005$, but not in the break condition, $t(15)=.32, p=.752$. This interaction confirms our hypothesis that the increases in fixation duration observed in Experiment 1, and in the No Break
group in Experiment 2, reflect increasing fatigue as a function of increased time-on-task ${ }^{2}$.

Figure 4: Change in Fixation Duration as a function of Block relative to the first Block in Experiment 2.

Relation Between Performance and Eye Movements in Experiment 1 and 2 Our argument that the increase in fixation duration reflects an increase in fatigue over the course of the task was based in part on the absence of a correlation between the changes in fixation duration and RT as a function of time observed in Experiment 1. Experiment 2 provides strong and convergent support for this argument by dissociating fixation duration and RT (i.e., a Block x Break interaction in fixation duration, and the lack of this interaction in RT). Finally, to increase the power of the original analysis in Experiment 1 we pooled the data from Experiment 1 and the no break condition of Experiment 2. There was a significant correlation, $\mathrm{r}(28)=0.386, p<0.04$, demonstrating that improvements in RT over time are related to decreases in fixation duration over time in individual subjects. As such, the positive effect of practice on visual search (i.e., shorter RTs) is not driving the increase in fixation duration, as individuals who improved the least or became slower over time also showed the greatest increase in fixation duration over the course of the task. This finding supports the notion that an increase in fixation duration is related to an increase in fatigue that results from an increase in time on task.

## General Discussion

Many everyday tasks require looking for objects over extended periods of time. For example, security officers may be required to conduct searches for the larger part of the workday. Given that performing even the most basic task for an extended period of time can lead to fatigue, and ultimately performance failures (Dawson \& Reid, 1997; Drumer \& Dinges, 2005; Williamson \& Feyer, 2000), the present study provides a measurement tool for assessing this change in state even when it is co-occurring with the positive effects of practice.

There are a number of reasons that fatigue might influence fixation duration. The increase in fixation duration may reflect an oculomotor disengage deficit. Bocca and Denise (2006) demonstrated that the effect of fatigue on saccadic latency was more pronounced when the fixation remained on the screen than when the fixation was removed prior to appearance of an eye movement target (see also Versace et al., 2006). This pattern of results has typically been interpreted as reflecting a difficulty in disengaging the oculomotor system from fixation (e.g., Kingstone \& Klein, 1993). Further, there is evidence that damage to the parietal lobe leads to problems disengaging attention (Olk, Hildebrandt \& Kingstone, 2009) and fatigue is known to disrupt parietal lobe function. Thus, fatigue may influence the ability to initiate an eye movement.

Another possibility is that fatigue influences the decision to move the eyes from one location to another. In the present context, the decision to move from one location to another is dependent on the decision that the target is not at the currently attended location. The ability to make this decision may be disrupted by fatigue induced as time-ontask increases. For example, a number of studies have demonstrated a selective impairment of frontal lobe function when an individual is fatigued (e.g., Harrison and Horne, 2000; Jones \& Harrison, 2001). The frontal lobe has also been associated with goal maintenance (e.g., Miller \& Cohen, 2001). Thus, activation of the goal "find the letter X" may decrease when individuals become fatigued as time-on-task increases. This decreased goal activation may lead to lapses resulting in longer fixation durations. Lapses have long been associated with fatigue and are thought to arise because of transient disruptions in cognitive control (e.g., Lim \& Dinges, 2008).

One important goal of future research will be to tease apart which of these mechanisms, or combination of mechanisms, drive the oculomotor mechanisms (e.g., fixation duration) that are sensitive to the effects of fatigue in search, even when it overlaps with the positive effects of practice on a task. This is a finding of potentially great importance because it means that one could use fixation duration as a means to detect the presence of fatigue well before its inevitable negative effects begin to override the positive benefits of time on task. For instance, security guards at airports might be performing their examinations of luggage x-rays quickly and effectively, but measures of fixation duration could determine that the searcher is
growing fatigued and a break would be well advised. Similarly, it is clear that driving requires one to constantly be searching the visual world and yet the dangers of fatigue are no less profound. In principle measures of fixation duration could be obtained noninvasively while one is driving, and when reliable increases in fixation duration are detected, a driver could be encouraged to take a small restbreak at the next opportunity, with the potential that lives on the roadways could be saved. In sum, while the ability to sustain attention in both fatigued and non-fatigued individuals has attracted a great deal of research recently (e.g., Lim and Dinges, 2008), the relations between indices of sustained attention and spatial attention (i.e., eye movements) have received little consideration. This is surprising given the importance of vision to the performance of everyday tasks. The present work represents an initial and significant step forward in understanding how oculomotor measures of sustained attention vis-a-vis fixation duration can be used to detect the presence of observer fatigue independent of the beneficial effects that time-on-task can have on visual search performance.

#### Abstract

In prior work, we have demonstrated that attention to the neural implementation of cognitive function is critical in creating models capable of simulating the physiological traces of those functions (e.g., Event-Related Potentials; ERPs). Here, we extend our Parallel Distributed Processing (PDP) model of ERP data elicited during the reading of single word forms to the simplest more temporally extended phenomenon: the ERP repetition effect. Simulations demonstrate that reproducing the dynamics of the ERP repetition effect can be accomplished by imposing the temporal envelope of post-synaptic potentials on individual units in the model.

Keywords: Parallel Distributed Processing; EventRelated Potentials; N400; Visual Word Recognition; Neural Computation

## Introduction

When PDP models were first introduced in the 1980s, part of the reason for their popularity was that they allowed the simulation of cognitive function with a computational architecture that was thematically similar to that employed by real neurons. In particular, the activation of a computational unit in a PDP model is determined by weighted summation of excitatory and inhibitory input-- similar to the manner in which the potential of a neuron is determined. However, especially in the domain of word reading, the neural metaphor introduced in the 1980s has made relatively little progress since that time. Instead of focusing on improving the neural metaphor, work has largely focused on increasing the number and sophistication of cognitive tasks that can be reproduced (e.g., Harm \& Seidenberg, 2004; Perry, Ziegler, \& Zorzi, 2007).

This situation is unfortunate for several reasons, two of which are particularly relevant to the present research. First, the incorporation of neural constraints in PDP models, in domains besides reading, has inspired significant theoretical progress. As a representative example, consider the manner in which models implementing the details of impaired dopaminergic gating in schizophrenia have been important in outlining a unified account of the
widespread cognitive impairments observed in that dysfunction (e.g., Braver, Barch, \& Cohen, 1999). As we attempt to demonstrate here, similar improvements in understanding could potentially be made in the domain of visual word recognition through models implementing relevant features of neural computation.

Second, though there is substantial disagreement between modeling groups about fundamental theoretical constructs (e.g., distributed versus local representation, importance of learned behavior, importance of computational homogeneity; see Seidenberg \& Plaut, 2006, for review), there is surprising agreement from many adherents of PDP models, dual-route models, and even Bayesian models, that improvement could be made to models of visual word recognition (and cognitive models more generally) by incorporating more neural constraint (Harm \& Seidenberg, 2004; Perry, et al., 2007; Griffiths, Chater, Kemp, Perfors, \& Tenenbaum, 2010). This agreement comes at a time when there exists a similar agreement that greater computational specificity is required in theories introduced to unify a voluminous ERP reading literature (e.g., Barber \& Kutas, 2007; Van Berkum, 2008; Laszlo \& Federmeier, 2011).

## The ERP Model

The ERP Model (Laszlo \& Plaut, 2012) improves contact between computational models of visual word recognition and the neural implementation of cognitive function in two principle ways. First, the ERP model's fundamental purpose is to simulate ERP waveforms, which are direct measurements of the activity of cortical neurons. This departs from traditional reading models, which instead focus on simulation of behavioral data. In particular, the ERP model simulates key effects on the N400 ERP component. The N400 is thought to represent the obligatory access of semantics in response to the presentation of an orthographic word form (for review, see Kutas \& Federmeier, 2011). This process has been explicitly couched in computational terms concordant with the PDP framework, such as

Figure 1: [Left] Architecture of the ERP model. INH stands for "inhibitory". [Right] Temporal dynamics of excitatory and inhibitory units.
parallelism and distributed representation (Laszlo \& Federmeier, 2011). The ERP model has demonstrated that PDP architecture can produce the critical effects on the N400 that led to its being considered the product of PDP architecture in the first place, such as a lack of sensitivity to lexicality as compared with a much larger effect of orthographic neighhorhood size (Laszlo \& Plaut, 2012).

Second, we have demonstrated that successful simulation of N 400 component effects requires implementation of an important constraining characteristic of neural computation: the separation of excitation and inhibition (Laszlo \& Plaut, 2012). In the ERP model, individual units have excitatory or inhibitory connections, never both. Further, inhibitory connections in the model are range-restricted, in that inhibitory connections are present only within a level of representation, never between, just as inhibitory neural projections are typically restricted to within a cortical area (this implementation is thematically similar to that in the TRACE model). Between-level connections in the ERP model are always excitatory. In addition to being range-restricted, inhibitory units in the ERP model are out-numbered by excitatory units: only one inhibitory unit is present at each level of representation. Finally, in the cortex, some populations of inhibitory units respond more quickly than others to input. In the model, this differential time course is simulated on the inhibitory units by means of the multi-linear "elbow" activation function, which produces unit activations that approximate the sum of "fast" and "slow" inhibitory
sub-populations. Figure 1 displays the architecture of the ERP model and the activation dynamics for excitatory and inhibitory units. Outside of the neural constraints just described, the ERP model is a typical PDP model that follows in the tradition of PDP word recognition models that have preceded it (most recently Harm \& Seidenberg, 2004). That is, its task is to associate a distributed pattern of orthographic input with a distributed pattern of semantic output, through non-linear (sigmoidal) transformation over several banks of hidden units. It accomplishes this task by acquiring connection weights over a training period of supervised learning with the back-propagation through time algorithm.

## ERP Repetition Effects

The ERP model successfully simulates important component effects elicited when participants read an unconnected list of text. This type of reading material, of course, does not resemble realistic reading material in numerous respects. Most importantly for the current research, realistic text comprehension pervasively relies on context for interpretation of individual word forms. Thus, to extend the ERP model's relevance to the processes involved in reading more realistic material, it is important to extend its sensitivity to context. The simplest type of context, and a type that produces robust modulations of the N 400 , is the immediate repetition of a word form (e.g., DOG DOG). This simple form of context requires that the processing of word, in a minimal fashion, be dependent on what has come before it, and is thus a reasonable first step in making the bridge between simulating the response to isolated items and simulating the response to items embedded in context.
Figure 2 displays canonical ERPs elicited when words (DOG), acronyms (DVD), pseudowords (GORK), and illegal strings of letters (XFQ) are repeated. Repetition effects on the N400 are characterized by a positivity in response to a $2^{\text {nd }}$ presentation, regardless of item type. The classic explanation of N400 repetition effects is that when an item is repeated in a short period of time ( $\sim 10$ seconds), its semantic features are still somewhat active from the prior presentation. Consequently, fewer-- unspecified-resources need be devoted to activating the same features a second time, resulting in a reduced N 400 . This interpretation has been essentially unchallenged since its formation (Rugg, 1985), but, as we will see, the model will suggest a subtly different account.
ERP repetition effects are prevalent enough in not only the reading literature, but also the memory and perception literatures, that their mechanics have been considered in computational models before (Huber,

Figure 2: Grand averaged ERPs elicited in response to first and second presentations of words, acronyms, pseudowords, and illegal strings, over the middle parietal electrode. The classic N400 repetition effect-reduced N400s for repeated items - is boxed. Note: negative is plotted upwards by convention.

Tian, Curran, O'Reilly, \& Woroch, 2008). This work, however, focused on early (i.e., pre-N400) repetition effects. An implemented computational account of N400 repetition effects, in contrast, is to our knowledge not present in the literature, and is a goal of the present simulations.

## Unit Fatigue, Post-Synaptic Potentials, and the Alpha Function

In the model, N400 activity is linked to mean activation in the semantic level of representation. Thus, in order to effect a simulated reduced N 400 in response to a repeated item, less activity must occur in semantics in the model when an item is repeated than when it is presented for the first time. In particular, specific units must become less active in response to an input when they have recently been active than when they have not; in other words, individual units must have the capacity to become selectively fatigued. Importantly, this fatigue must occur at the level of individual units-- not across the entire semantic level of representation-because units that have NOT recently been active must be free to activate to their maximum level (e.g., when a new item is presented instead of a repetition).

Thus, the desired dynamic for individual units in the model in the context of item repetition is one where an initial activation peak (in response to the first item in a pair) is followed by a subsequent decline in activation. Interestingly, this dynamic profile is similar to that of post-synaptic potentials (PSPs), as simulated in neural computation with the alpha function:

$$
\begin{equation*}
V=\alpha t e^{\frac{-t}{T}} \tag{1}
\end{equation*}
$$

Where $V$ is a measure of membrane potential, $\alpha$ is a scaling parameter that determines the maximum value of $V, t$ is the number of time steps since the unit became active, and $T$ is a free parameter that determines the time step at which $V$ peaks (see David, Kiebel,

Harrison, Mattout, Kilner, \& Friston, 2006). Figure 1 displays the shape of the alpha function.
Thus, in neural computation, PSPs are simulated with a function that resembles that desired for simulation of repetition effects. This is especially interesting in light of the fact that the source of the ERP signal is cortical post-synaptic potentials. Independent observations about 1) the dynamics of the function needed to implement repetition effects and 2) the source of ERPs thus converge to suggest a method for simulating ERP repetition effects: constraint of unit activation in the model with the alpha function.

As inhibitory units in the model are already constrained with the elbow function, to allow them to simulate the response of fast and slow inhibitory populations, we confine application of the alpha function to excitatory units. We aimed to determine whether imposing this profile would enable the model to simulate ERP repetition effects.

## Simulations

The architecture of the model is displayed in Figure 1, and is identical to that used in Laszlo \& Plaut (2012), with the exception that, now, excitatory unit activation is constrained by the alpha function. To understand how this is accomplished, think of the value of the alpha function at a particular time step as a scaling parameter. In simulations, the parameter $\alpha$ (see Equation 1) was set such that the permitted values of $V$ fell in $[0,1]$. Thus, when a unit activation is multiplied by $V$, that multiplication results in that unit's activation being scaled by $V$. When the alpha function is in its peak state, at $t=T, V$ is 1 , so multiplying unit activation by $V$ does not change the original unit activation. However, when the alpha function is in its fatigued state, when $t>T, V<1$, such that multiplying unit activations by $V$ reduces those activations, effecting unit fatigue.

Figure 3: Simulated ERPs elicited in response to repeated and non-repeated presentations of words, acronyms, pseudowords, and illegal strings. The dashed $y$-axis indicates stimulus onset. All units in the model data are arbitrary. In the simulated ERPs, as in the real ERPs, all item types produce reduced semantic activation when an item is repeated as compared to when it is not.

In the cortex, of course, not all neurons generate PSPs in response to all inputs. Thus, some neurons become fatigued in response to particular inputs, and some do not. In order to implement fatigue that mirrors the cortical situation, units in the model progress along the alpha function at different rates. Specifically, $t$ for purposes of calculating $V$ is not simply the total number of time steps that have elapsed since the presentation of the input. Instead, $V$ is calculated separately for each unit. In these by-unit calculations, $t$ is incremented not with every time step in the model, but only when a unit's activation on the prior time step exceeded a threshold. This threshold is a fixed parameter in the model. The result of this method for determining $t$ is that only units that respond to a particular input become fatigued. Units that do not respond to a particular input do not become activated above threshold, and therefore do not become fatigued.

## Training

Weights in the model were initialized to small, random values. The orthographic autoencoder was then trained via back-propagation through time for 20000 epochs to reproduce orthographic inputs on an identical output layer. Then, with the weights in the autoencoder and all inhibitory weights fixed, the remainder of the network was trained for 15000 epochs to associate input orthographies with output semantics. Each training pattern was presented for 16 time steps. Training items consisted of 62 words and 15 acronyms. Importantly, the entire network's activation was reset to its initial level after each item during training, meaning that each input during training was isolated from others. Thus, the model received no training on repeated items. The model's output dynamics in response to repeated items must therefore be an emergent characteristic of its architecture-- newly implemented to simulate PSPs-when extended to these novel input scenarios, not
simply the result of training it on the desired response to repetitions.

## Testing

The trained network was presented with input pairs either of the form AA (repetitions) or AB (nonrepetitions). Each item of the pair was presented for 16 time steps, with a single time step of blank input between each item of the pair. In testing, the network was not re-initialized between items in a pair (but was re-initialized between pairs). In non-repetitions, the B item was always of the same lexical type as the A item (i.e., words were followed by words, etc.).

In addition to trained items, the network was tested on repetitions and non-repetitions of pseudowords (85) and illegal strings (279)-- these comprised all possible nonwords in the model's orthography. The nonwords provide a particularly hard test for the model, since they were not presented to the model during training. When presented with nonword pairs, in order to, correctly, produce reduced activation on repetition but not nonrepetition trials, the model must produce dynamics it has never been trained on in response to items it has never been exposed to.

## ERPs

Target ERPs for simulation were drawn from the singleitem ERP corpus (for details, see Laszlo \& Federmeier, 2011). Briefly, it includes responses from participants who passively read an unconnected list including 75 each of words, pseudowords, acronyms, and illegal strings-- all of which repeated once-- while EEG was recorded. Figure 2 displays the target phenomenon for simulation: N400 amplitude is reduced on second presentation for all item types.

## Results <br> ERPs

Figure 4: Simulated ERPs elicited in response to repeated and non-repeated items in a model in which the alpha function is not applied. Simulated waveforms are essentially identical across presentations in these simulations, which is why only a single wave trace is visible in the figure: the second trace is directly beneath the first. Unlike the ERPs of the alpha function model, ERPs from this simulation do not display repetition effects for any item type.

Grand-averaged ERPs were computed over the middle parietal electrode site for each item type (words, pseudowords, acronyms, and illegal strings) on each presentation (first and second). N400 peak latency was measured from $250-450 \mathrm{~ms}$; N400 mean amplitude was then measured according to the full width at half max (FWHM) of that peak. This resulted in quantification of N400 mean amplitude over the $350-450 \mathrm{~ms}$ window. Using FWHM to determine the window of measurement allows for better consistency in measurements taken from real and simulated ERPs, as temporal units in the simulated ERPs are arbitrary (i.e., have no meaningful counterpart in milliseconds), but nevertheless have a peak and a FWHM of that peak.

The impact of repetition was assessed by analyzing the mean amplitude data for each item type using linear mixed effect regression, with item as a random factor and item type as a fixed factor. Markov Chain Monte Carlo sampling was used to generate $p$-values. These analyses replicated the standard finding: N400 mean amplitudes were reduced for all item types (all $p s<$ 0.0003 ).

## Simulations

Simulated ERPs were generated by averaging semantic activation for each time step in the model for the second item in each item pair; the time series of those averages across time steps is the simulated ERP. Figure 3 presents simulated ERPs for first and second presentations of each item type. As is evident from the Figure, simulated ERP amplitudes were reduced for each item type. Simulated N400 (sN400) peak latency was measured as simply the latency of the most positive peak in the simulated ERPs; since N400 activity is linked to mean semantic activation in the model, the peak of mean semantic activation in the model is transparently the peak of the sN400. Mean amplitude of the sN400 was then measured according to the FWHM of that peak, in analogy with measurement of the N400. Analysis identical to that described for the
human ERPs revealed a substantial sN400 amplitude reduction for all item types (all $p<0.005$ ).

To assess the degree to which the alpha function was responsible for the simulated repetition effects, we conducted a second simulation in which the only modification was the removal of the alpha function (essentially, this model was a replication of Laszlo \& Plaut, 2012). In what follows, we will refer to this simulation as the No-Alpha simulation, and the original simulation as the Alpha simulation. Figure 4 displays results of the No-Alpha simulation. As is evident in the Figure, the No-Alpha model did not exhibit a sN400 repetition effect, in contrast with both the empirical data and the Alpha simulation. Numerically, the difference between first and second presentation sN400 mean amplitude was not different than 0 to 5 degrees of decimal precision for any item type.

## Discussion

Our goal was to extend the original ERP model from being insensitive to context to being sensitive to the minimal context of whether an item has been repeated. We aimed to achieve this by improving the neural realism of the model. This improvement took the form of imposing the fatigue dynamic of PSPs on individual units in the model. The choice of this particular dynamic was motivated both by the empirical need to identify a fatiguing dynamic as well as the observation that the source of the ERP signal is cortical PSPs. Results indicated that, even when presented with a situation never encountered in training (item pairs) and items never encountered in training (pseudowords, illegal strings), a variant of the ERP model implementing unit fatigue reproduced the standard pattern observed in ERP studies: namely, that repeated orthographic items elicit reduced N400s. Importantly, reduced sN 400 s in response to repetition were not obtained in a version of the model without unit fatigue.
These results support the general conclusion that improving the neural realism of PDP models is a
strategy that can greatly extend the type of phenomena such models are able to explain. More importantly, however, this data provides a potential explicit mechanistic explanation of ERP repetition effects that subtly differs from that typically offered in the literature. As already discussed, the classic explanation of N400 repetition effects is that, when an item is first encountered, it invokes access of its associated semantics (or, in the case of nonwords, the semantics of visually similar items). Then, when the same item is repeated, there is less lexical-semantic processing required to re-activate the pre-activated semantics, resulting in a reduced N400 (see Rugg, 1985).

The source of N400 repetition effects in the model, in contrast, is not pre-activation of semantic features-- as is visible in Figure 3, network activity drops back almost to zero between items in a pair, before the onset of the simulated N400. Instead, semantic activity is reduced due to the fatigue of individual semantic units. While the traditional view of N 400 repetition effects is based on unspecified principles of cognitive resource, the simulations suggest a view based on explicit mechanistic principles of the underlying neural system.

More exploration-- both empirical and computational-- of fatigue as an explanation of repetition effects is clearly needed: for example, it has been demonstrated in the ERP literature that additional repetitions of word forms (i.e., third, fourth, or more presentations) do not further diminish the N400 response (Young \& Rugg, 2007), and it is not clear that the ERP model would exhibit this pattern. Similarly, in the present simulations words were considered a monolithic group, but it is well known that N400 repetition effects are strongly influenced by lexical factors such as word frequency (e.g., Young \& Rugg, 2007), and it is again not clear that the ERP model would respond similarly. Thus, although the current work suggests an interesting alternative explanation of N400 repetition effects, based on realistic neural mechanisms and processing dynamics, clearly there is significant additional work to be done to explore this explanation further. The explicit simulation implemented here is hoped to provide a foundation for this future work.

#### Abstract

It has been demonstrated that brief exposure to behavioral information is sufficient for making accurate social judgments. Movement coordination during social interaction, is one potential cue. Although coordination between individuals has been identified, our ability to perceive it when making judgments regarding affiliation (friends vs. strangers) is unknown. In the present studies, we investigated how correlated movement contributes to observers' accuracy when judging affiliation. Using correlation map analysis to quantify coordination, we showed that individuals familiar with each other correlated their movements more frequently. Observers were able to use coordination as a cue, but only when the information presented was restricted to movement related to speech (i.e. while only viewing faces). These results suggest that observed movement coordination is influenced by speech-related movements. We suggest that social perception is multi-faceted and cues may be prioritized differentially based on availability.

Keywords: social perception; social interaction \& conversation; movement correlation

## Introduction

Humans are constantly immersed in social interaction and conversation. It is not surprising that we have mechanisms to facilitate these interactions, both while engaging in and observing them. One mechanism is our ability to create a rich representation of social cues from very brief exposures as short as a few seconds. These short exposures or "thin slices" of behavioral and linguistic information are sufficient for making remarkably accurate judgments regarding social situations. Research has demonstrated great accuracy in judgments in a variety of domains including personality, social status and mental states (Ambady \& Rosenthal, 1993). However, little known about how specific cues contribute to our accuracy in social perception.

Understanding how we use available social cues is important to human behavior because monitoring others' intentions and actions is a prerequisite for modulating and guiding our own behavior, interactions, and relationship formation (Foulsham et al., 2010). In addition, using social cues is often impaired in many social and psychological disorders such as autism spectrum disorder and
schizophrenia leading to difficulty in successful interaction (Klin et al., 2002).

Previous research has looked at specific motion patterns that occur during interpersonal communication. Studies have demonstrated that individuals unintentionally synchronize and coordinate their movements and converge in linguistic properties during conversation (Richardson, Dale \& Shockley, 2008; Richardson \& Dale, 2005; Chartrand \& van Baaren, 2009; Pardo, 2006). This has been shown with different attributes of conversation such as facial expression, postures and accents (Capella \& Planalp, 1981; McHugo, Lanzetta, Sullivan, Masters \& Englis, 1985). Individuals even unintentionally coordinate their movements without visual information from their partner (Shockley et al., 2003). Coordination without visual information suggests that convergence in behavior can be directly influenced by vocal information exchanged during conversation. Further, studies examining social-cognitive variables in convergence have shown through subjective observation that individuals with good rapport coordinate their movements (Grahe \& Bernieri, 1999). Also, friends converge more in linguistic properties than strangers (Dunne $\& \mathrm{Ng}, 2002$ ). Coordination may occur because of inherent biological and behavioral rhythms as well as a coupling of conversation-engaged individuals' mental representation of their perceptions of each other (Richardson \& Dale, 2005; Meltzoff \& Prinz, 2002).

Although the presence of convergence in nonverbal and linguistic properties has been examined, our ability to perceive this convergence has not been investigated. In particular, the contribution of correlated movements has not been examined objectively in the perception of affiliation (i.e. whether individuals engaged in conversation are friends or strangers). The current studies use movement and coordination quantification methods to examine convergence between interacting individuals. These methods allowed us to investigate whether the amount of coordination differs as a function of affiliation and whether it contributes to the accuracy of affiliation judgments made by an external observer.

## Experiment 1: Movement Analysis

This experiment investigated if there was an observable variation in coordination between individuals as a result of known affiliation differences.

## Methods

Participants Sixty-two undergraduates (Mean Age $=21.2$, 36 females) from Queen's University were recruited in pairs to engage in video-recorded conversation. Thirty-one dyads were either recruited as friend pairs or were experimentally paired. Conversations from 15 same gender friend pairs (10 female), 12 same gender stranger pairs ( 6 female) and two mixed friend and stranger pairs were video recorded.

Stimulus Collection Stimuli were collected by video recording, unstructured conversation between two participants, using a single camera aimed to capture both individuals ${ }^{1}$. Individuals sat on fixed chairs and were left to converse without an experimenter present for approximately 10 minutes.

Stimulus Analysis An algorithm computing spatiotemporal coordination was used on the video clips. In these experiments, only the visual information was examined using this algorithm. The algorithm developed by Barbosa et al. (2012) first computes optical flow using a standard image processing technique where velocities of brightness patterns in an image are calculated within a region of pixels and summed to give a global value for a particular cluster of pixels (Horn \& Shunck, 1981). Then, a correlation analysis is used to compute instantaneous correlation between movement signals within a specified region of interest.

Using the optical flow analysis, the Barbosa et al. (2012) algorithm computes total motion in an identified region of interest by summing the optical flow in that region. Regions of interest were drawn around each individual engaged in conversation, for a gross estimate of their total body motion. Correlation Map Analysis (CMA) was then used to quantify the coordination between the two speakers' movements. A key characteristic of CMA is that it computes the correlation between a pair of signals as a function of both time and the lag between the signals. This not only allows us to characterize the correlation throughout the duration of the signals, but also to capture correlations between events that are not perfectly aligned in time. Therefore, CMA is able to capture coordination between signals, where events in the signals are related to each other but do not necessarily happen at exactly the same time; rather, they fluctuate around some specific lag between the signals as the signals evolve through time. Capturing coordination at a time lag allows for alternating behavior, such as that seen in social interaction, to be captured. This kind of mechanism is ideal for biological rhythms that are rarely synchronous and allows for convergence in social

[^325]interaction to be quantified (Winfree, 1980, Barbosa et al, 2012).

Correlation Data Analysis Average distributions of correlation were created for each of the friends and strangers groups. For statistical comparison, a resampling nonparametric technique was used to create null distributions. The correlations for friends and strangers were compared to a null distribution. The distributions were simplified to look only at the positive lags $(0-+0.5 \mathrm{~s})$. Because of the rhythmical structure of conversation, the positive and negative lags tend to be redundant and we included only the positive lags in all analyses. This resulted in distributions looking at 16 lags in total, including 0 lag (i.e. completely synchronous correlation; Frame rate $=30 \mathrm{fps} ; 0.5 \mathrm{~s}=15$ frames plus one 0 lag frame).

Motion Magnitude Analysis To control for the magnitude of motion when looking at the correlation, distributions of all motion magnitudes from the friends and strangers pairs were generated. The two distributions were compared to determine differences in total motion.

## Results

Correlation Analysis The probability distributions of each of the friend and stranger correlations at each lag were compared with a null distribution representing the correlations computed between the motions of all subjects who were not actually in a conversation together. The means for the correlations at lags closest to synchronous were significantly different $(\mathrm{p}<0.05)$ from the null distribution for both friends and strangers. These results are displayed in Figure 1 where the first half of both the friend and stranger distributions (first 8 lags/frames) displays higher mean correlations than observed for the random pairings. Correlations significantly different at time-points closest to synchronous indicates that individuals engaged in conversation are highly sensitive to their partner's movements and coordination occurs within moments of the movement first being initiated. Thus, the data indicate that engaging in a face-to-face conversation produces correlations greatly exceeding what would be produced by chance pairings of motion signals.

To determine how correlation differed based on affiliation, the friends and strangers distributions were subtracted from each other to create a difference distribution. This was compared with two null difference distributions: One looked at correlation differences between randomly paired individual's movements and randomly assigned affiliation categories and the second distribution looked at correlation differences between real pairs that actually conversed but who were arbitrarily categorized as a particular affiliation for this analysis. Both the overall difference as well as the mean difference per lag was significantly different when compared to both null distributions where friends had more correlated events than
strangers. ( $\mathrm{p}<0.05$ ) (See Figure 3). Although comparisons to both these null distributions is interesting in that they suggest that friends' and strangers' conversation contain content unique to their affiliation categorization, the comparison to the null containing real pairs is more informative. The real-pair null contains motion that can be attributed to conversational motion in general as opposed to random motion. These results support our hypothesis that affiliation results in correlational variation, and that friends correlate more frequently than strangers.

Figure 2. (Top to Bottom) Distributions of average correlation for the null, friend and strangers. Lighter colors indicate larger proportion of events occurring at correlation values plotted along the $x$-axis. Lag counts (in frames) indicate 16 temporal points between 0 and 0.5 s where average correlation was computed. Here, both friends and strangers had correlation value greater than the null but only significant in the first few frames.

Motion Magnitude Analysis A distribution of magnitudes of motion for the friends and strangers was created to determine any differences in motion present within the groups. Results indicated that friend pairs contained more motion (Mean=0.88 pixels/frame, $\mathrm{SE}=5.79 \mathrm{e}-04$ ) than stranger pairs (Mean=0.84 pixels/frame, $\mathrm{SE}=5.38 \mathrm{e}-04$ ). This analysis was carried in preparation for Experiment 2. We wanted to be able to control the amount of motion presented to observers making perceptual judgments so that judgments about accuracy were not being affected by motion differences.

Results from Experiment 1 demonstrated in a quantified manner that correlation was an inherent part of conversational movement and that friends coordinated more

Figure 3. (Top to Bottom) Three-dimensional average correlation difference distributions for friends-strangers, random-pair subtractions and real-pair random subtractions. Lighter colors indicate higher correlation differences along the x -axis with height indicating frequency of events. Lag counts (in frames) indicate 16 temporal points between 0 and 0.5 s where average correlation was computed. Greater positive peaks indicate more correlated events for friends in comparison to strangers.
than strangers. This supported our hypothesis and previous studies that indicated that familiarity and good rapport resulted in linguistic and behavioral coordination. The correlation data from this study were used to identify stimuli for a perceptual judgment task in Experiment 2.

## Experiment 2: Perceptual Judgment

The previous experiment demonstrated that affiliation led to differences in movement correlation. This experiment investigated whether observers were attuned to the correlational differences and if perception of correlation was influencing accuracy of affiliation judgments. In this study, we varied amount of correlation while controlling for the amount of motion in the perception of thin-slices of conversation

## Methods

Stimuli The analysis of motion magnitudes from Experiment 1 was used to control the amount of motion so that differences in perception of clips could be attributed to correlation differences rather than confounded by motion
differences. Clips were selected from a window that was centered at half a standard deviation around the mean of the sum of the motion distributions for friends and strangers. Clips and their corresponding correlation values were extracted if they were contained within a 5 s continuous ${ }^{2}$ clip that contained average motion from within our defined thresholds. Correlations were re-computed using the same procedure as Experiment 1 for only those clips that were controlled for motion magnitude to ensure that the friend/stranger correlation results were true for our perception stimuli.

All possible clips were sorted from lowest to highest average correlation. Six of the lowest and six of the highest correlated clips were selected for each of the friends and strangers groups ( $\mathrm{n}=24 \mathrm{clips}$ ) such that each conversing pair was only presented once. The final clips contained ten same gender friend pairs, ten same gender stranger pairs and two mixed-gender pairs for each group.

Procedure Twenty undergraduates (Mean age $=20.8,16$ females) from Queen's University participated for monetary compensation. A within-subjects design was used where all participants viewed both high and low correlated friend and stranger clips. The 24 five-second clips were presented and participants were asked to perform a social judgment rating using a Likert scale. On a scale of 1-7, participants indicated whether the two individuals engaged in conversation had just met (1) or were friends (7). Following the experiment, each participant was asked to record the kind of information they used to make their judgments.

## Results

Correlation Analysis Average correlations and correlation difference patterns seen in Experiment 1 were also observed in the 24 stimulus clips, confirming that the restricted magnitude of motion was not influencing correlations.

Social Perception Accuracy The accuracy of affiliation perception was determined by computing the average score for all videos presented as a function of their correlation and affiliation. Figure 3 displays the perceptual rating results. A factorial ANOVA was performed and results indicated that although participants could accurately discriminate between friends and strangers $(\mathrm{F}(1,20)=4.28, \mathrm{p}=0.05)$, correlation did not seem to affect perceptual judgments. In addition, scores were analyzed using an extreme groups analysis (Preacher, Rucker, MacCallum \& Nicewander, 2005) where neutral responses were eliminated and a factorial ANOVA was

[^326]

Figure 3. Average score for affiliation rating. A greater score represents a preference towards a judgment of 'friends' and a lower score represents preference towards a 'strangers' rating.
performed. Results demonstrated the same effect as the simple analysis.

The perceptual judgment results in this experiment demonstrated that observers could clearly make affiliation judgments. However, our results showed no evidence that degree of correlation between pairs influenced perceptual judgments. Subjective responses of reported cues used by participants indicated that subtle movements such as those of the hands and the mouth were given precedence. A high correlation between speech and face/head motion related to speech has been demonstrated in previous studies (Barbosa et al, 2008); perhaps these smaller gestures of speech were not contributing to our correlation measures as much as larger body motions. Experiment 3 was conducted to investigate whether the correlational structure of smaller speech related movements, such as face/head motion, might better account for the perceptual data.

## Experiment 3: Selected Perceptual Judgment

In this experiment, we looked at whether an observer's ability to make perceptual judgments of affiliation altered when the social information presented was restricted to more subtle, speech related correlations within the face/head region.

## Methods

Stimuli All video recordings from Experiment 1 were cropped at participants' shoulders to include only head and facial movement. Correlation and motion analysis was performed in the same manner as Experiment 1. Motion thresholds and clip selection criteria were created using the same procedure as Experiment 2. Twenty-four clips were selected to include 12 same gender friends and 12 same gender strangers. ${ }^{3}$ These included six of the highest and six of the lowest correlated clips in each category.

[^327]Procedure Twenty undergraduates from Queen's University (Mean Age=20.1, 16 females) participated in this experiment. The perceptual judgment task used the same procedure as that used in Experiment 2.

## Results

Correlation Analysis Overall, average correlations and correlation differences reflected the same pattern as Experiments 1 and 2 confirming that movement correlation was influenced by affiliation, independent of amount of motion.

Social Perception Accuracy Analysis of affiliation perception accuracy was performed as in Experiment 2. Average score for all videos as a function of correlation and affiliation was computed and a factorial ANOVA was performed. Results showed that there was a significant effect of correlation indicating observers provided a higher proportion of 'friends' responses for highly correlated clips $(\mathrm{F}(1,20)=7.78, \mathrm{p}=0.01)$. There was no significant effect for affiliation indicating that scores were not dependent on the true affiliation between conversing individuals. Results are presented in Figure 4. Observers were more likely to misperceive high-correlation pairs as friends and lowcorrelation individuals as strangers. These results demonstrated that movement correlation was a significantly influencing cue when perceiving subtle, speech-related movement.

Figure 5. Average score for affiliation rating when viewing only faces. A greater score represents a preference towards a judgment of 'friends' and a lower score represents preference towards a 'strangers' rating.

## General Discussion

In these studies, we were interested in examining how affiliation between two individuals resulted in variation in movement and coordination. Additionally, we were interested in determining whether this variation influenced the accuracy of observers making rapid judgments regarding that affiliation. Based on previous studies on convergence in linguistic and behavioral properties, we predicted that familiarity would result in greater coordination which would influence judgments of affiliation by external observers.

The results of these studies demonstrated that there was indeed variation in motion and coordination resulting from affiliation. In general, movement correlation was present during social interaction, regardless of affiliation, although higher correlations were present for friend pairs. This was supported by studies that suggest that we interactively align our representations of conversation content (Garrod \& Pickering, 2004). But, is this correlation used as information when making social judgments?

The observation that participants were not sensitive to the correlation differences presented in Experiment 2 suggests that other cues in the full body stimuli such as static postural cues as well as motion cues might have influenced the way participants attributed affiliation. The correlational structure of the larger body movements used to select stimuli clearly was not the major determinant of participant responses. Observers reported that they prioritized more subtle movements related to speech when producing their judgments. Experiment 3 tested this by restricting visible motion to the head and face area to minimize the contribution of other possible cues and showed that coordination was a determinant of affiliation judgments. Observing a clear decrease in accuracy by eliciting use of coordination cues indicates that integration of many cues, including movement correlation, contributes to our remarkable ability to make accurate social judgments.

These studies provided us with two important conclusions regarding movement coordination in social perception: 1) Perception of unintentional coordination observed during social interaction in previous studies is directly influenced by speech-related movement and 2) Multiple factors contribute to social perception however, observers can use coordination as their basis of their affiliation judgments.

Previous studies have shown individuals engaged in conversation become mutually entrained in their movements and this coordination persists even when individuals are interacting verbally without visual input from the other individual. Even when facing an individual with whom participants were not conversing, coordinated movements persisted with the direct conversation partner (Shockley et al., 2003). These findings can be explained by the fact that speech-related movement of the head and face is directly correlated with the auditory signal of speech (Barbosa et al., 2008). Our studies have demonstrated that coordination occurred between individuals actively involved in the conversation but also that third-party observers were sensitive to the speech-related correlation between talkers. The complete explanation for participants' performance in Experiment 2 and 3 warrants further research. We know that full body information provides additional information contributing to greater accuracy but the exact nature of this information has yet to be identified.

Human communication provides a rich information set for making judgments and many cues can contribute to perceptual decisions. The perceptual strength of cues will vary with the context and the observer's history with a
judgment and the manner in which multiple social cues are integrated is still unknown. As in the study of the general visual world (Gibson, 1968), we need to identify potential sources of information in the social world.

Future work examining where observers visually fixate when making affiliation judgments is necessary since the distribution of attention will be a window into the perceptual cues observers use. Information about the allocation of attention may explain individual differences in performance as well as accuracy differences in different social contexts.

These studies aimed to investigate social perception in a less arbitrary and more objective manner. We used motoric correlation to address how judgments of affiliation could be affected by nonverbal factors. We demonstrated that affiliation influenced coordination of movement during social interaction. Further, we showed that observers used this correlation information as a cue, at the expense of accuracy, when making judgments but only when the rich social information set present in human communication was restricted. This broad area of research will continue informing us about our sensitivity to information used for the successful social interactions we encounter everyday.

#### Abstract

Metacognitive monitoring that accompanies a learning task reflects the predicted achievements at test during and at the end of studying the materials. Monitoring reliability is strongly associated with the quality of study regulation and with ultimate performance at test, because it is by this subjective assessment that people decide whether and how to invest more time. Previous studies that compared learning texts on screen to learning from printed texts found that screen learners performed worse and were overconfident about their success. The present research examined two methods for overcoming screen inferiority in these respects. Gaining experience with the study-test task with six different texts allowed improvement. Writing keywords after a delay from learning already eliminated screen inferiority from the first studied texts. In both methods, predictions of performance did not reflect changes in test scores. The two methods clearly affected screen and paper learners differently. This study outlines directions for overcoming screen inferiority, but also calls attention to the effects of context on cognitive and metacognitive processes, beyond the mere interaction between the person and the task content.

Keywords: Reading comprehension; e-learning; humancomputer interaction; metacognitive monitoring; overconfidence.

## Introduction

Learning from texts is a central task in many daily situations. Models of self-regulated learning (Dunlosky \& Hertzog, 1998; Nelson \& Narens, 1990) suggest that reliable subjective assessment of knowledge, or metacognitive monitoring, is essential for effective regulation of learning (Metcalfe \& Finn, 2008; Thiede, Anderson, \& Therriault, 2003). Worryingly, the typical finding in metacognitive studies is that monitoring accuracy regarding comprehension of texts is quite poor (see Maki, 1998). Research suggests that learners use heuristic cues to assess their knowledge (Koriat, 1997). Low monitoring accuracy might be a result of using non-predictive cues. In the case of text learning, such cues may be ease of processing (Dunlosky \& Rawson, 2005) or domain familiarity (Glenberg, Sanocki, Epstein, \& Morris, 1987).

Kintsch (1998) proposed a model of representation levels. According to this model, reading comprehension is constructed from three levels of text representation: words
and signs, sentences, and inference level. It can be derived from this theory that when high-order comprehension is tested, prediction of performance should be more accurate when it relies on the highest representation level of the text. Indeed, studies that demonstrated improvements in monitoring accuracy in text learning often used methods for increasing in-depth processing of the studied materials. In particular, Thiede and his colleagues used writing keywords or writing a summary of the text after a delay (Anderson \& Thiede, 2008; Thiede, Dunlosky, Griffin, \& Wiley, 2005). In another study they made sure to instill appropriate test expectancy for directing participants to the level of processing required for the test (Thiede, Wiley, \& Griffin, 2011). Monitoring reliability is measured in the literature in two respects, resolution and calibration. Resolution is the extent to which predictions of performance at test discriminate between better and lesser known items studied. Calibration is the gap between the predicted performance and actual score at test, and reflects the extent of over- or under-confidence. The above mentioned methods had benefits for performance at test and for resolution. Calibration was not the focus of the mentioned studies that examined the effects of in-depth processing, but is the focus of the present study, as detailed below.

Nowadays, text learning in computerized environments is widespread in numerous domains. For example, reading in depth is required for lawyers using computerized repositories of forensic precedents and for higher education candidates when they face the reading sections in online screening exams such as the Graduate Management Admission Test (GMAT). Thus, it is worthwhile considering whether performance and monitoring accuracy are affected by the reading media of screen versus paper.

Previous studies indicated that people process data more shallowly in computerized environments than they do when studying from print (e.g., Liu, 2005; Morineau, Blanche, Tobin, \& Guéguen, 2005). Ackerman and Goldsmith (2011) addressed these questions by comparing learning texts on screen to learning the same texts from paper, and took the metacognitive processes into account. They found that screen learners performed worse and were overconfident about their success. Overall, people tend to prefer reading texts in depth from print rather than from computerized environments, including modern e-books (Jamali, Nicholas,
\& Rowlands, 2009; Olsen, Kleivset, \& Langseth, 2013; Woody, Daniel, \& Baker, 2010). So a question is raised whether the observed screen inferiority depends on the reluctance of the participants regarding studying texts on screen. Indeed, the results of Ackerman and Goldsmith (2011) were obtained from students who strongly prefer print over computerized learning. However, Ackerman and Lauterman (2012) recently found similar outcomes among engineering students, but only under mild time pressure. Importantly, these students are used to reading from screen and have only a moderate preference for print.

As explained above, overconfidence reflects a calibration bias. This aspect was neglected in studies that attempted to improve monitoring reliability by increasing depth of processing. The present study examined whether methods found effective for improving resolution are also effective for reducing overconfidence. However, notably, most of the previous improvements in monitoring accuracy were achieved in computerized conduction of the experiments (e. g., Anderson \& Thiede, 2008). The present study examined whether such methods are particularly effective on screen, where processing is hypothesized to be shallower even for people experienced in reading from screen. This hypothesis is important in two respects. First, it may point to practical directions for reducing screen inferiority. Second, it has theoretical significance in pointing out that the extent of improvement depends on study context, beyond variables related to the learners and/or to the task content.

## Experiment

The first method we used for reducing screen inferiority relative to paper learning was gaining experience with the task. Multiple study-test cycles were used for providing the participants with appropriate test expectancy for allowing adjustment of their processing level to the requirements and improving the correspondence between the cues used for monitoring and the gained knowledge (Thiede et al., 2011).

The participants of the first group worked on six texts, all on screen or all on paper. The present sample was drawn from the same population used by Ackerman and Lauterman (2012). Following on from them, the participants learned each text under mild time pressure, predicted their performance at test, and answered multiple-choice test questions before moving to the next text.

For the second group, we attempted to direct the participants to a high level of text representation. We did it by asking them to write keywords for each text. It was found effective by Thiede et al. (2005) for improvement of monitoring resolution, but only when there was a delay between text learning and keywords writing. This group studied two texts consecutively. They then wrote keywords, predicted their success at test, and were tested on each of the two texts by their study order. Because of the delay and the study of two texts in a row, test performance for the whole second group was expected to be lower than for the first group that was tested on each test immediately after studying it. The question is whether the delayed keyword
writing reduces screen inferiority because it helps participants who naturally process the information more shallowly on screen, to process it more deeply and therefore eliminate screen inferiority.

## Method

Participants. Eighty undergraduate students from the Faculty of Industrial Engineering at the Technion with no learning disabilities participated in the study. Mean age was 25.8 years old and $48 \%$ were women.

Materials. The six texts, 1000-1200 words (2-4 pages) each, dealt with various topics (e.g., the advantages of coalbased power compared to other energy sources; adult initiation ceremonies in various cultures). An additional, shorter text ( 200 words) was used for familiarizing the participants with the procedure. The texts were taken from web sites intended for reading on screen. Each text formed the basis for a multiple-choice test including five questions testing memory of details and five questions testing higherorder comprehension.

Procedure. The experiment was administered in groups of up to eight participants in a small computer lab. Each group was randomly assigned to read from screen or from paper and for the immediate-test or the delayed keywords conditions. The procedure for the immediate-test group was identical to that used by Ackerman and Lauterman (2012) and was the same for screen and for paper. The participants read each text for seven minutes and were directed to study it for a multiple-choice test. Immediately after reading they provided their predictions of performance (POPs) on two scales (25-100\%), one for memory for details and one for higher-order comprehension, and then answered the test questions. The mean of the two ratings was used for the analyses. This procedure was repeated six times.

For the delayed keywords condition, the participants read two texts consecutively. After reading both, they wrote four keywords for the first text, filled in their POPs, and took the test for the first text. The same procedure (keywords, POPs, test) was done then for the second text. This procedure was repeated for two more text pairs, which were not included in the present analyses. The entire procedure was explained to the participants in advance and the order of the texts was counterbalanced across participants.

## Results

We started our analysis by examining whether the first two texts of the immediate-test group replicate the screen inferiority in performance and overconfidence found by Ackerman and Lauterman (2012) under the same conditions. Figure 1 panel A presents the results. A two-way Analysis of Variance (ANOVA) with Measure (POP vs. test score) $\times$ Medium (screen vs. paper) revealed a main effect of the measure, $F(1,38)=54.64, M S E=101.80, p<.0001$, suggesting a general overconfidence. There was also a

Figure 1: Predictions of performance (POP) and test scores for the first and the last two texts studied for an immediate test are presented in panel A and panel B, respectively. Panel C presents the results for the two texts for which the test took place after a delay and after providing keywords. The error bars represent the standard error of the means.
significant interactive effect, $F(1,38)=12.83, M S E=$ $101.80, p=.001$. As can be seen in the figure, test scores were lower on screen than on paper, $t(38)=2.76, p<.01$, while POP showed the opposite direction, though insignificantly, $t(38)=1.69, p<.10$. Overconfidence was measured as the mean gap between POPs and test scores. The opposite direction of changes - lower test scores and higher POPs on screen - yielded a higher overconfidence level than on paper, $t(38)=3.58, p=.001$. These findings replicate the findings of Ackerman and Lauterman (2012) and form the starting point for our attempts to reduce screen inferiority.

In comparison to the first two texts, a similar ANOVA on the last two texts of the immediate-test group showed only the main effect of the measure, $F(1,38)=11.79, M S E=$ 121.91, $p=.001$, which reflected general overconfidence. There was no interactive effect, $F<1$. A three-way ANOVA of Pair Order (first vs. last) $\times$ Measure (POP vs. test score) $\times$ Medium (screen vs. paper) revealed a triple interactive effect, $F(1,38)=9.42, M S E=68.73, p<.005$. Test scores improved on screen, $t(38)=3.87, p=.001$, but not on paper, $t<1$, and there were no differences in the POPs, both $t \mathrm{~s}<1.2$. Thus, by gaining experience with the task, screen learners improved their test scores, but did not acknowledge this improvement. The outcome was a reduction in their overconfidence, $t(38)=4.08, p=.001$.

The first two texts of the delayed-keywords group also showed a significant overconfidence, $F(1,76)=89.57, M S E$ $=132.80, p<.0001$, but resulted in an elimination of screen inferiority relative to paper, with no interactive effect of measure and media, $F<1$. The triple interaction when comparing the two conditions was significant here as well, $F(1,76)=7.53, M S E=132.80, p<.01$. In this case, the difference stemmed from a near significant reduction in performance after the delay on paper only, $t(39)=1.86, p=$ .07. Screen learners, in contrast, scored similarly in immediate tests without keywords as after a delay but with writing keywords. As in the immediate-test, POPs did not mirror the performance changes found on paper. Thus, the delayed keywords procedure eliminated screen inferiority
relative to paper learning in both performance and overconfidence.

## Discussion

In light of previous findings of screen inferiority relative to paper learning in both performance and overconfidence (Ackerman \& Goldsmith, 2011; Ackerman \& Lauterman, 2012), the present study examined whether students learning from texts presented on screen benefit from using methods that were found in previous studies to contribute to the resolution of metacognitive judgments. As expected, media differences in both performance and overconfidence were eliminated. One group eliminated the media effect by gaining experience with the task and the other group eliminated it by writing keywords and being tested after a delay.

Although predicted, the findings of differences between the media in the effects of the two methods on performance are striking. In the group that gained experience with the task, performance improved for screen learners only. In the group that provided keywords and was tested after a delay, performance was not lower relative to immediate testing for screen learners only. We interpret these findings to suggest that participants who studied on paper spontaneously engaged in effective in-depth learning. Thus, the two methods did not change the effectiveness of their processing. This made experience with the task unnecessary. The keywords provided upon delay also could not increase depth of processing, and thus the delayed test took its toll. For the screen learners, in contrast, spontaneous learning was less effective, so experience with the task led them to improve learning regulation. The delayed keywords led them to overcome the toll of the delayed test. Clearly, this explanation is speculative and requires further research; however, it accords the particular effective regulation found by Ackerman and Lauterman (2012) on paper only with the same population.

Another striking finding is the mismatch between changes in performance and POPs. In all cases, the POPs were
almost constant, while performance was affected by the manipulations and the media used. Thus, overconfidence differences stemmed almost solely from differences in performance. These findings correspond to the wellestablished literature, which suggested that metacognitive judgments are more affected by the materials' internal characteristics than by the external conditions in which the task is performed. For example, while people take into account the a-priori difficulty of paired associates (e.g., related vs. unrelated word pairs), they do not sufficiently appreciate the benefit of repeated memorization of the same list of items (Koriat, Sheffer, \& Ma'ayan, 2002). Similarly, when guided to engage in imagery for elaborated processing of paired associates, although performance improved, it was not appreciated in recall predictions (Rabinowitz, Ackerman, Craik, \& Hinchley, 1982). However, in contrast to this low sensitivity of the metacognitive judgments to knowledge variations, in the previous studies with the same materials (Ackerman \& Goldsmith, 2011; Ackerman \& Lauterman, 2012) POPs did show sensitivity to time conditions, freely allocated, time pressure, and unexpected interruption of the learning. This sensitivity to time conditions, exhibited some correspondence with performance, in particular when studying on paper. The comparison between the previous studies and the present one highlights the dissociation found here between POPs and performance at the tests. The screen participants in the present study did not acknowledge knowledge improvement, even when it was pronounced (last two texts of the immediate test condition). The present line of research examined media and time frames. It will be interesting for future studies to further examine these factors and others that affect POPs' sensitivity to changes in performance.

To sum up, the consistent screen inferiority in performance and overconfidence can be overcome by simple methods, such as experience with task and guidance for in-depth processing, to the extent of being as good as learning on paper. The findings have clear implications. First, software designers and policy makers in numerous contexts should take into account the differences between the media in the quality of monitoring and regulation of learning. Second, the principle of improving the reliability of the cues used for monitoring, which guided us in choosing the methods for improvement, should be taken into account when designing training towards using computerized environments that involve extensive textual sections. However, the observed media differences in the effectiveness of the methods should draw attention to the fact that some methods reported in the literature were examined only on one medium, either screen or paper. From the theoretical perspective, the media effects draw attention to the effects of the context on learning regulation and outcomes, beyond the interaction between a person, with his or her given learning skills, and the study materials (see also Morineau et al., 2005).

# Effects of Explicit Abstract Knowledge and Simple Associations in Sequence Learning 

Jessica C. Lee (jlee4128@uni.sydney.edu.au)<br>Evan J. Livesey (evan.livesey@sydney.edu.au)

School of Psychology, University of Sydney
Sydney, NSW 2006 Australia

#### Abstract

This study examined the effect of an explicit relational rule on sequence learning in a 3 -choice serial reaction time task. Simple probabilistic contingencies between pairs of response cues were used in such a way that the sequence of cues moved predominantly in one direction (i.e. either clockwise or counterclockwise). Performance on cued and miscued responses was compared for a group given a hint about the abstract rule describing the relationship between the response cues, and a group given no information about this relationship. Experiment 1A demonstrated that XYZ and XYX subsequences showed performance differences when the location of the target on each trial was random. Experiment 1B showed that giving participants the explicit hint affected XYZ subsequences more than XYX subsequences. Implications for sequence learning and, specifically, the interaction between rule and instance learning are discussed.

Keywords: serial reaction time; awareness; motor learning; volitional control; sequence learning; rule vs. instance learning

## Introduction

Humans are remarkably capable at learning about sequential material, such as the underlying sequence of locations of a target in a serial reaction time (SRT) task (Nissen \& Bullemer, 1987). A typical paradigm involves participants pressing keys corresponding to the location of a target as it appears in positions on a computer screen. Speed and accuracy of responses are emphasized. Unbeknownst to participants, some or all of the positions can be predicted using deterministic or probabilistic rules. Participants exposed to this structured material generally show a reduction in reaction times ( RTs ) for predicted locations, relative to unpredicted (random) locations, suggesting that they have learned about the underlying sequence. The SRT task is an example of an implicit learning paradigm that appears to show robust learning in the absence of verbalizable knowledge (e.g. Destrebecqz \& Cleeremans, 2001; Willingham, Nissen \& Bullemer, 1989) and intention to learn (Jiménez, Méndez, \& Cleeremans, 1996; Jones \& McLaren, 2009). Since implicit learning is, according to some definitions, unconscious (Reber, 1993), this classification implies that learning is independent of explicit knowledge, and should not be susceptible to cognitive influences (Lewicki, 1986).

However, the implicit status of sequence learning has been challenged by later studies showing that sequence knowledge is reportable when appropriate tests are used (e.g. Jimenez, Mendez, \& Cleeremans, 1996; Perruchet \& Amorim, 1992). The results from several studies (e.g.

Dominey, Lelekov, Ventre-Dominey, \& Jeannerod, 1998; Jimenez, Vaquero, \& Lupianez, 2006; Jones \& McLaren, 2009) suggest that while learning is generally automatic (in that it does not require an intention to learn and occurs under a variety of learning conditions), giving participants knowledge about the sequence or instructions to search for an underlying rule can change what is learned, implying that learning is under some degree of volitional control. Conflicting results and ongoing disagreement about appropriate methodology has meant that no firm conclusions can be made about the status of implicit learning and what learning mechanisms it embodies (Shanks \& St. John, 1994).

A corollary of the implicit/explicit distinction made by several researchers is between the learning of rules and instances. Explicit learning is assumed by some to involve knowledge in the form of symbolic propositions that are apt for describing abstract relations between events (Mitchell, De Houwer, \& Lovibond, 2009). In contrast, implicit learning can be seen as the accumulation of statistical information in an incremental fashion, and many have argued is better suited for learning the surface structure or physical properties of events in a sequence rather than abstract relations (McLaren, Green, \& Mackintosh, 1994; Perruchet \& Amorim, 1992). Conceptualizing implicit learning in this way allows it to be explained using the same simple associative learning mechanisms that have been postulated to explain animal learning (McLaren, Green, \& Mackintosh, 1994). In support of this conceptualization, models such as Elman's (1990) Serial Recurrent Network (SRN) have been quite successful in modeling human performance in the SRT task using associative mechanisms (e.g. Cleeremans \& McClelland, 1991). The SRN captures statistical regularities in the pattern of responses and allows predictions to be made based on a limited temporal context of responses. However, models such as these presuppose that explicit representation of sequence knowledge is limited, and assume rule learning to be a separate, higherorder process. While it seems obvious that humans are capable of rule learning and hypothesis testing, the question of interest is whether these explicit processes have any place in sequence learning.

Where abstract relations between events can be described in ways that do not depend on the physical properties of those events, the content of rule learning often differs from that of instance learning (e.g. Natal, McLaren, \& Livesey, 2013; Livesey \& McLaren, 2009; Shanks \& Darby, 1998;). It is possible to derive evidence for both rule and instance
learning in an SRT task with appropriately constructed sequences. For example, Dominey et al. (1998) found that participants under implicit and explicit learning conditions were able to learn about surface contingencies in an SRT task, but only those in the explicit condition were able to learn about, and transfer their knowledge of, the underlying abstract rule. This study shows that what is learned in an SRT task depends on the learning conditions imposed, and while rule learning requires appropriate learning conditions (sufficient cognitive resources, or in this case, explicit instructions to search for a rule), instance learning can occur automatically.

In Dominey et al.'s (1998) study, evidence of a dissociation between the learning of abstract and surface structure was sought by testing transfer to sequences containing different surface features but the same abstract rule. An alternative approach used by Jones and McLaren (2009) is to allow participants to make a prediction about the target's location before the onset of the target, with the assumption that some sequences will benefit from an intentional search for sequences more than others. In a twochoice (X,Y) SRT task, Jones and McLaren found that participants given incidental learning conditions showed the strongest evidence of learning for subsequences containing an alternation (e.g. YYX, YXY) and the least evidence of learning for subsequences consisting of runs of the same response (XXX). However, when participants were presented with two cue positions and given instructions to predict what would happen on the next trial, this pattern of results was reversed, with the best learning occurring for the more salient XXX subsequences. This study shows that the effect of explicit instructions can differentially affect certain subsequences. Giving participants the intention to learn or alluding to the existence of sequences does not entail that all subsequences will benefit from these manipulations. However, the fact that learning in the SRT task is even affected by these manipulations suggests that sequence learning cannot be considered implicit in the traditional sense.

The translation of abstract rules to the performance of a concrete action is not necessarily a straightforward task, even when the rule is explicitly identified. Many researchers have assumed that it requires intentional mental effort (Gick \& Holyoak, 1983; Gomez, 1997; Shanks \& St. John, 1994). Although the rules used in the studies by Dominey et al. (1998) and Jones and McLaren (2009) could be explained verbally and symbolically, they were relatively complex. Once known, implementation of the rule involved retention of at least two items in working memory in order to use the abstract relationship to determine the next response.

In contrast, in this study a relatively simple rule was used; the sequence of response cues moved clockwise most of the time for some participants, and moved counterclockwise most of the time for others. This rule can be applied purely on the basis of the preceding response but was still abstract in the sense that it involved a relationship between at least two events and can be applied flexibly to any of the
response cues in the sequence. Although the rule was probabilistic in nature and not necessarily obvious to participants performing the task, it was easy to describe and (we assumed) easy to implement once recognized explicitly. Thus the primary aim of current study was to explore the degree to which learning in an SRT task could be affected by explicit knowledge of an abstract rule describing the probabilistic contingencies in the task.

## Experiment 1

Experiment 1 used a simplified version of the SRT task with three response locations (A, B and C, see Figure 1) and probabilistic contingencies to minimize hypothesis-testing strategies and the development of explicit sequence knowledge during training (see Jiménez \& Méndez, 2001). The target never appeared in the same location twice in a row, meaning that each set of three consecutive responses in the sequence contained either three unique responses (XYZ, e.g. $\mathrm{ACB}, \mathrm{ABC}$ ) or a repetition of one response as the first and third in the set (XYX, e.g. ABA, ACA).

Figure 1. Illustration of the target positions (A, B, C) and an example of the contingencies arranged between them (in this case, resulting in a predominantly clockwise direction of motion). Curved, bold lines indicate cued trials ( $p=.75$ ) and dotted straight lines indicate miscued trials ( $\mathrm{p}=.25$ ).

Experiment 1A sought to establish performance differences on these two subsequences using a single control group that performed the SRT task with a randomly generated sequence. Experiment 1 B compared learning between two groups: a group given a hint before the experiment about the nature of the contingencies embedded within the target locations (hint group), and a group who did not receive a hint (no hint group). The contingencies were arranged such that most of the time, the target appeared to be moving in one direction (clockwise or counterclockwise), with the direction of motion randomly chosen for each participant. If the target was moving clockwise, for example, there was a .75 probability that the next location would be the next clockwise position (cued trials), and a . 25 probability that the next location would be the next
counterclockwise direction (miscued trials, and vice versa for counterclockwise, see Figure 1).

Since the contingencies were probabilistic, an explicit hint about the direction of motion would still mean that the location of the target on any given trial could not be predicted with complete accuracy. We expected that both groups in Experiment 1B would learn the sequence, but the group given the hint would show both better overall learning (a larger cueing effect) and higher levels of awareness in subsequent tests. Furthermore, we hypothesized that even with a simple abstract rule its application on each trial would not be straightforward. Since responses are made rapidly, there is little time to prepare for the next response based on the direction of motion. Thus, although the directional rule is applicable to every response, we expected that the effectiveness of the hint when applied to specific instances would be greater on the more salient XYZ subsequences than the XYX subsequences because the presence of a consistent direction of motion for several responses would facilitate the use of the rule.

## Method

Participants and Apparatus In Experiment 1A, fifteen University of Sydney staff and students participated. In Experiment 1B, forty-six University of Sydney first year Psychology students participated in exchange for course credit. The experiment was programmed using PsychToolbox for Matlab (Brainard, 1997; Pelli, 1997) and run on Apple Mac Mini desktop computers connected to 17 inch CRT monitors, refreshed at a rate of 85 Hz . Participants made responses using a standard Apple keyboard and mouse. Testing was conducted in individual cubicles in groups of up to six.

Procedure For both experiments, participants performed a SRT task where they were asked to respond to a series of targets appearing in one of three positions (on the left, top and right) on the computer screen by pressing corresponding arrow keys. Training in both experiments was presented to participants in one continuous block of 720 responses. In Experiment 1 A , the position of the target was completely random, such that no learning could occur. In Experiment 1B, the sequence of locations followed a probabilistic rule such that the sequence of response locations usually moved in a clockwise or counterclockwise direction around the screen, and each trial was either cued ( $75 \%$ of the time) or miscued ( $25 \%$ of the time, see Table 1). The direction of motion was randomly chosen for each participant.

Participants in Experiment 1B were allocated to either a hint or no hint group. The hint group received written instructions at the beginning of the experiment that stated that the target moved in either a clockwise or counterclockwise direction most of the time, and that their task was to work out which direction it went. The no hint group did not receive any explicit instructions about the possibility of an underlying sequence, nor did the control group in Experiment 1A. All participants were informed that
they would have to respond as quickly and as accurately as possible to the targets appearing around the screen.

After the training phase, both groups in Experiment 1B were told that there was a pattern in the sequence of locations in the training phase, and they would now be asked questions about the sequence. Participants completed a recognition test and a prediction test, in counterbalanced order. Participants in Experiment 1A did not complete any awareness tests, as there were no contingencies to assess.

Table 1. Probability of occurrence for each triplet type and conditional probability of the last response cue (cue t) in each triplet given the preceding сие (сие $t-1$ ).

|  | $p($ triplet $)$ | $p($ cue $t \mid$ cue $t-1)$ |
| :--- | :---: | :---: |
| XYZ - Cued | 0.5625 | 0.75 |
| XYZ - Miscued | 0.0625 | 0.25 |
| XYX - Cued | 0.1875 | 0.75 |
| XYX - Miscued | 0.1875 | 0.25 |

Recognition Test On each trial in the recognition test, participants were presented with two sequences in which they had to respond to the target in the same way as in training. One of the two sequences was the same sequence they saw in training, and the other sequence was the opposite (the direction of motion was reversed). Each sequence contained 12 response cues and participants completed 10 trials. After responding to the two sequences, participants were asked to press a key to indicate which of the two sequences they thought was most similar to their training sequence.

Prediction Test The prediction test simply presented participants with the target in one of the three positions and asked which of the remaining two positions they would predict the next position to be. This test consisted of 3 trials (one for each of the target positions).

## Results

All of the following RT analyses refer to response times on correct trials only, excluding responses $>1$ second.

Experiment 1A Participants in Experiment 1A took on average 317 ms to respond on XYZ trials (with $98 \%$ accuracy), and 363 ms to respond on XYX trials (with $94 \%$ accuracy). Thus participants were both faster, $F(1,14)=$ 119.91, $p<.001$, and more accurate, $F(1,14)=21.81, p<.001$, on XYZ trials, relative to XYX trials. These performance differences indicated that the repetition of a recentlyperformed response on XYX trials interfered with fast and accurate responding, or conversely that performing all three responses without repetition facilitated responding. This effect was not based on differential contingencies (after each response, the remaining two cues were equally likely) and is similar to alternation effects found in other choice response tasks, which are most likely not based on sequence learning effects (e.g. see Barrett \& Livesey, 2010). In any
case, performance differences provided further impetus for examining the XYX and XYZ subsequences separately.

Experiment 1B: Training All trials were classified as being either cued or miscued, and the cueing effect taken as the difference between the cued and miscued trials.

Figure 2 shows the mean RTs for cued and miscued trials in Experiment 1B for both the hint $(n=23)$ and no hint ( $n=23$ ) groups, and the mean RTs for the control group ( $n=15$ ) in Experiment 1A, across the 4 training quarters. It is evident that in both the hint and no hint groups, participants were slower to make a response on miscued trials, and faster to make a response on cued trials, relative to what would be expected without any contingencies (the control group). An ANOVA with group (hint x no hint) as a between-subjects factor, and cueing (cued x miscued) and quarter (1-4) as within-subjects factor revealed an overall cueing effect, $F(1,44)=344.15, p<.001$, and a marginal interaction with group, $F(1,44)=3.99, p=.05$, with the hint group exhibiting a larger cueing effect overall. There was also a significant linear trend in the cueing effect, $F(1,44)=74.17, p<.001$, which did not interact with group, $F<1$, indicating that the cueing effect increased during training.

Figure 2. Mean reaction times for the hint and no hint groups in Experiment 1B, and mean reaction times for the control group in Experiment 1A.

To examine whether the effect of the hint differed between the two subsequences, a repeated measures ANOVA with cueing (cued $x$ miscued), subsequence type (XYZ x XYX) and quarter (1-4) as within-group factors and group (hint x no hint) as a between-subjects factor was performed. As hypothesized, a significant 4-way interaction was found $F(3,132)=3.37, p=.02$. The cueing effect for both
subsequence types and for both groups is shown in Figure 3. It is evident that while both the hint and no hint groups obtain similar cueing effects for the XYX subsequences across training, the hint group's cueing effect increased sharply in the $3^{\text {rd }}$ quarter. This may be because it took participants in the hint group some time to translate the hint given at the start of the SRT task into confident knowledge about the direction of motion, and therefore for this knowledge to affect their performance.

There was a significant group difference for XYZ cueing, $F(1,44)=7.29, p=.001$, but not for XYX cueing, $\mathrm{F}<1$. Thus it appears that the effect of the hint increased cueing for XYZ subsequences but not for XYX subsequences, relative to the no hint group.

Figure 3. Cuing effect by training quarter in Experiment 1B, for both groups and subsequence types, showing a significant difference between hint and no hint groups for XYZ cuing, but not for XYX cuing.

Recognition Test The hint group showed a recognition score (61.1\%) that was statistically above chance, $F(1,21)=8.56, p=.008$, while the no hint group did not (55.2\%, $F<1$ ).

Prediction Test Mirroring the recognition test, the hint group showed a level of performance (65.4\%) that was statistically higher than chance, $F(1,21)=8.06, p=.01$, and the no hint group did not $(59.4 \%, F(1,21)=1.58, p=.22)$.

Cueing and Awareness To examine the relationship between awareness and cuing, each participant's recognition score was correlated with their cuing effect for XYZ and XYX sequences separately (Figure 4). There was a significant correlation between recognition and cuing for the

XYZ subsequences in the hint group only, $r(23)=.45, p=.03$. Comparing the correlation coefficients between groups, there was a stronger relationship between awareness and cuing in the hint group for XYZ subsequences ( $r(22)=.45$ ) than the no hint group $(r(22)=.2), z=2.2, p=.028$.

Figure 4. Scatterplots of the cuing effect (in seconds) as a function of recognition accuracy for each subsequence type
(XYX and XYZ) and each group (Hint and No Hint) in Experiment 1B.

## General Discussion

In this study, we observed a robust sequence learning effect using probabilistic contingencies arranged between 3 target locations in both a group given an explicit hint about an abstract rule underlying the contingencies and a no hint
group who performed the task as usual. The hint group exhibited a marginally larger cuing effect overall and produced above-chance results on both a recognition and prediction test.

Experiment 1A demonstrated that participants were both faster and more accurate to respond on XYZ subsequences (consisting of 3 unique responses) than on XYX subsequences (when the response on the current trial is the same as the response 2 trials back) when there were no contingencies present. Closer inspection of the different subsequences indicated that the benefit of the hint group over the control group in Experiment 1B was only evident on subsequences that did not contain a repetition (XYZ), and that participants in both groups learned about subsequences with a repetition (XYX) equally well. While the hint group were able to produce results on the awareness tests at a level greater than chance, there was a significant correlation between cueing and recognition on XYZ subsequences only.

The results from this study suggest that the relationship between explicit abstract knowledge and performance in sequence learning tasks is complex. The SRT task utilized in this experiment shows a strong dissociation between two subsequence types - participants given an explicit hint about the underlying contingencies could use this knowledge to produce a larger cueing effect (relative to those given no hint) on XYZ subsequences, and the amount of cueing was related to how well those in the hint group performed in the recognition test. On the other hand, whether or not participants received the hint did not make any difference to the magnitude of the cueing effect on XYX trials, and the cueing effect was not correlated with recognition performance.

These results indicate that while the hint may have been successful in helping participants to discover the abstract rule amongst the contingencies, this knowledge could only be applied to XYZ trials and not XYX trials. One potential reason for this may be that certain subsequences are learned better in intentional learning conditions because they are more salient (see Jones \& McLaren, 2009). The repetition of two clockwise or counterclockwise positions in the XYZ subsequences may be particularly salient if participants are searching for the correct direction of the target. This is in line with our initial prediction that the abstract information provided by the hint would be easier to implement (and thus produce a greater facilitatory effect) on trials where the direction of motion was consistent for several cues. An alternative reason may be simply that XYX subsequences are harder to respond to in general, and therefore applying explicit knowledge on these trials may also be more difficult. According to this explanation, whatever property of the XYX subsequences that produced the slower reaction time and lower accuracy in Experiment 1A might also be responsible for interfering with the expression of any knowledge of the sequence that participants had acquired.

While Experiment 1B demonstrated that giving participants explicit knowledge did affect their SRT
performance, it is also obvious that this knowledge is not necessary to display a cueing effect. In fact, very robust cueing effects were evident in the no hint group, along with poor performance (not differing significantly from chance) on awareness tests. However, the fact that giving participants an explicit hint about the underlying sequence affected performance suggests that there is some degree of volitional control in sequence learning, and that learning is not impervious to cognitive influences such as intention to learn. However, whether or not explicit knowledge about an abstract rule can be expressed in sequence learning seems to be dependent on the properties of the subsequences to be learned.

In summary, this experiment demonstrates that sequence learning does not appear to be independent of explicit knowledge of the abstract relations between the cues in the sequence. However, participants are not able to apply their knowledge equally to all subsequences even when, in principle, the abstract relation applies to all instances. These results are most consistent with an explanation in which simple associations between events are learned and expressed relatively automatically, but explicit symbolic knowledge has a strong influence on performance only when specific conditions permit its use.

## Acknowledgments

This research was supported by a University of Sydney Bridging Support Grant to EJL. The authors would like to thank Lauren Shone and Dorothy Kwok for helpful comments on an earlier version of this manuscript.

# Learning and representation of causative motor actions: a neural network model and its use in an embodied theory of language 

Jeremy Lee-Hand (leehandjeremy@gmail.com) and Alistair Knott (alik@cs.otago.ac.nz) Department of Computer Science, University of Otago, New Zealand

#### Abstract

In this paper we present a neural network model of motor learning structured around circuits which associate motor actions with their sensory effects, as proposed by Hommel et al. (2001). The network implements a novel model of causative actions, which bring about specified distal movements in manipulated target objects (e.g. bending a lever). It also serves as the basis for a novel embodied account of the syntax of causative sentences such as John bent the lever.

Keywords: motor control, neural networks, embodied models of language

## Effect-based action representations in neuroscience and language

A common idea in models of action representation is that an agent's actions (also known as motor programs) are encoded in a way which makes reference to the sensory effects they bring about. This idea has a long history, but in recent research it is most strongly associated with Prinz's (1997) theory of 'common coding' and Hommel et al.'s theory of 'event codes' (Hommel et al., 2001). The key idea uniting these models is that motor programs are not defined purely within the motor domain: their neural representation includes a specification of the sensory effects they bring about, in one or more sensory modalities. This position can be supported both on theoretical grounds and through experiments; we will give brief examples of each kind of argument.

Theoretically, a strong argument for this view of action representation comes from considerations about how actions are learned. It is uncontroversial that an agent's repertoire of motor programs is learned through some kind of reinforcement. A reinforcing signal is a sensory signal. When an agent executes a motor program and generates a rewarding signal, an association is made between the sensory signal and this particular program. After a certain amount of training, if all goes well, the sensory signal will become associated with a range of related motor movements, which bring it about in different ways or under different circumstances, perhaps in ways which are parameterised or organised by features of the sensory stimulus. At this point, if the agent activates the sensory signal, this will bring about one of these movements, and result in reward. But equally importantly, the group of motor movements associated with the sensory signal can now be thought of as comprising an action category, in virtue of their shared ability to evoke the stimulus. Categories are defined around central concepts or prototypes, and in this case the unifying concept is a sensory one. For this reason, it makes sense to talk about action categories as being defined by the sensory effects they bring about.

Experimentally, the idea that actions are defined by their effects has been suported in several ways. For instance, there have been many studies exploring variations on the wellknown stimulus-response compatibility effect (Simon, 1969). A good example is a study by Hommel (1993). Here subjects had to respond to an auditory stimulus by pressing a button, either with the left or right hand. The tone of the auditory stimulus indicated which button the subject should press. But as a distracting factor, the stimulus was also presented either on the left or the right. The classical stimulus-response compatibility effect is that subjects are slower to respond if the spatial location of the stimulus is incompatible with the hand which must respond. In Hommel's experiment, button presses generated a reafferent visual stimulus whose location could be decoupled from the location of the hand pressing the button, to explore whether the compatibility effect operates in the domain of motor movements or that of their sensory consequences. Button presses consistently produced a visual stimulus: illumination of a light. In one condition the light appeared on the same side as the hand (e.g. left button presses illuminated a light on the left), while in another it appeared on the opposite side (e.g. left button presses illuminated a light on the right). Hommel found that the stimulus-response compatibility effect depended on compatibility with the perceptual effects of button-presses, rather than on the hand which was used. This shows that the way subjects encode actions does make some reference to their sensory consequencesat least enough to interfere with stimulus-response mappings. Effect-based representations of motor actions are also supported by several studies of the neural representation of actions; see for instance Umiltà et al. (2008); Matsumoto et al. (2003).

Another interesting piece of evidence for effect-based action representations comes from a completely different area of cognitive science: linguistics. The evidence comes from a phenomenon called the 'causative alternation'. This is found in many languages, but we will illustrate with English. Consider the following two sentences:
(1) John bent the lever.
(2) The lever bent.

As these show, the verb bend can be used in a transitive sentence, where the lever appears as the object (Example 1) or in an intransitive sentence, where it appears as the subject (e.g. Example 2). On the face of it, a syntactician would have to assume two different senses of the word bend: one which describes the lever as an agent and one as a patient. But this is counterintuitive, since what happens to the lever is the same
'Underlying' syntactic structure
John CAUSED the lever bent
'Surface' syntactic structure
John bent the lever $\square$

Figure 1: Derivation of John bent the lever by movement from an underlying syntactic structure

Figure 2: (a) The hand/arm (b) detail of a single finger pad
in each case. A way to avoid assuming this implausible ambiguity in the verb bend is to argue that the transitive sentence John bent the lever really means John caused [the lever to bend]. This analysis can be neatly expressed in syntactic theories which posit that sentences have an 'underlying' syntactic structure which is distinct from their surface form: an idea associated with Chomskan accounts of syntax (see e.g. Chomsky, 1995). In a Chomskyan framework, we can argue that the underlying structure of Example 1 is John caused [the lever bent], as shown on the left of Figure 1. At this level of analysis, 'the lever' is the subject of bend, just as it is in Example 2. In a Chomskyan model, the surface structure of Example 1 is produced by moving the lower verb bent into the position of the higher verb caused, as shown on the right of Figure 1.

In this paper we have two aims. We will first introduce a computational model of the learning and control of causative actions, which implements a particular take on Hommel et al.'s conception of event codes. The model has several interesting features as an account of action representation, which we will briefly discuss. But our other main aim is to juxtapose an account of processing in the motor control network with the syntactic analysis of causative verbs just sketched above. We will argue that the network may provide a framework that allows the syntactic analysis to be expressed in terms of neural mechanisms.

## A platform for learning and control of simulated actions

Our computational model was implemented in a software environment for simulating hand/arm actions called GraspProject (Lee-Hand et al., 2012; for details see Neumegen, 2013). The environment is built on top of the JMonkey games engine, which uses the Bullet physics engine to define objects made up of linked rigid bodies, and OpenGL to render graphical views of these. GraspProject provides a simple model of the hand and arm, with three degrees of freedom in the arm

Figure 3: Architecture of the motor control network
(two at the shoulder and one at the elbow) and one in the hand controlling grip aperture (see Figure 2a). It also provides a fairly rich model of the touch sensors in the fingers. Finger pads are modelled as deformable grids of rigid bodies connected by springs. (A single finger pad in light contact with a solid surface is shown in Figure 2b.) Information about light touches is provided by collision detectors on each pad, and information about stronger touches which deform the surface of the skin is read from the joint angles between adjacent pads.

## Architecture of the motor control network

Our model of the motor system is a neural network for learning hand actions directed at target objects. It provides a simple model of some aspects of infant motor development.

The general architecture of the network is shown in Figure 3. It consists of three sub-networks arranged in sequence. These are assumed to be trained at three successive developmental stages, by reward signals of different degrees of complexity. In this scheme, the system is initially rewarded by very simple sensory signals, which train a simple motor circuit, but as learning takes place in this circuit, more complex reward signals become available, which in turn train higherorder circuits. The first two networks are described in detail in Lee-Hand et al. (2012), and their interaction with the third network is described in Lee-Hand (2013).

The first network to be trained is called the reach network (see the lower part of Figure 3). This network learns a function which maps a visual representation of a target object onto
a goal motor state of the hand and arm. (The visual representation has two components, one relating to the position of the target, the other to its shape. The former representation maps to a goal arm state; the latter to a goal hand state.) During training, the agent visually attends to objects in its perispace, and executes hand/arm actions at random. Sometimes these actions result in its hand touching the target, evoking a touch signal (the simple touch signal). This signal is intrinsically rewarding (as in Oztop et al., 2004). The touch signal has two functions. First, it allows a proprioceptive representation of the agent's current motor state to be copied into the medium holding its goal motor state (see the upper arrow leading from the simple tactile signal). Second, it allows the reach network to be trained, so that the current visual representation of the target object is associated with this newly specified goal motor state, and similar presentations of the target in the future will automatically elicit an appropriate motor goal.

This simple circuit implements a particular version of Hommel et al.'s model of event codes. Learning in the circuit creates what can be thought of as a single simple action category, associated with the sensory representation of a touch to the hand: a network which maps visual stimuli onto motor goals which will bring about this representation. Motor goals in the circuit are associated with sensory stimuli in three ways. Any representation in the motor goal medium is implicitly associated with one particular reward stimulus (a simple touch sensation). Specific motor goals are associated axiomatically with specific motor states (sensed proprioceptively) when the reward stimulus is evoked. And specific motor goals are also associated through learning with arbitrary sensory stimuli (in this case visual), which carry information about the motor states associated with reward signals. Again this happens at the time the reward stimulus is evoked. The key devices in the circuit are reward-gated learning and copy operations. These devices will be replicated in the other two networks.

The reach network generates a motor goal-but of course there must also be a mechanism which achieves this goal. At the first developmental stage, we assume this mechanism is a simple feedback motor controller. This device takes the current motor state and the goal motor state and generates a motor signal proportional to the difference between them, in a direction which reduces this difference. (The controller is not shown in Figure 3.) A feedback controller does not need to be trained; it can be assumed to be present at birth. (We use a PID controller; see e.g. Araki, 2006). However, mature motor control involves a mixture of feedback control and feedforward control (see e.g. Kawato et al., 1987). Feedforward control exploits learning about the properties of the agent's motor system to optimise action trajectories. If we think of the feedforward controller in sufficiently general terms, we can say that it is through learning in this controller that an agent can acquire a repertoire of different action categories. Different actions (like grabbing or punching or slapping) have different characteristic trajectories of the
hand and fingers; the feedforward control system somehow learns about the distinct effects of particular trajectories and creates action categories associated with each. However, it is not clear how different trajectories are represented in the biological motor control system. There is good evidence that agents do not compute detailed trajectories in advance; these are only generated 'on the fly', as an action is actually underway (see e.g. Cisek, 2005). Our network implements a particular idea about how trajectories are represented. We assume that the agent evoking a goal motor state can generate learned perturbations of this goal state as an action is under way, which deviate the hand from the normal course it would take under simple feedback control. For instance, to generate a trajectory bringing the hand onto the target from above, the goal state could be temporarily perturbed to a point above the target, so the hand initially moves higher than it would normally do. This idea is discussed in more detail and evaluated in Lee-Hand et al. (2012). This kind of learning takes place in the second network in our model, the motor program network (see the middle of Figure 3).

The motor program network learns to map a goal motor state onto a perturbed goal motor state, which is applied at the start of a reach action and removed when the hand is at a specified distance from the target. Learning in this network begins when the reach network reliably generates actions that lead to reward signals. During training, random perturbations are applied to the goal motor state produced by the reach network. From time to time, these perturbations result in richer tactile reward signals than those used to train the reach network. There are several different signals, which result from particular perturbations. Some perturbations result in a grasp or near-grasp, which generates a characteristic rich tactile stimulus. Others result in a slap movement, which generates another, different, tactile stimulus. (These rich stimuli are almost never generated through pure feedback control, because they result from special trajectories.) When a rich tactile stimulus is generated, copy and learning operations take place in the motor program circuit which are analogous to those in the reach circuit. First, the tactile stimulus is copied to an area holding 'motor programs'. Second, the motor program network is trained to map the current goal motor state, plus the currently active motor program, onto the perturbation which resulted in the reward. After this learning, activating a specific motor program will generate an action with a characteristic trajectory. We envisage motor programmes competing with one another, with the winner being selected.

Note that the motor program network must execute in parallel with the simple reach network. It basically modulates the behaviour of the simple network, in a manner reminiscent of Brooks' (1991) subsumption architecture. In order to execute a motor program, it is important that the whole motor program circuit is enabled, or turned on. Accordingly, while different motor programs provide different input to the motor program network, they also uniformly generate a control signal to enable the network they provide input to.

The final network to be trained is the causative action network (see the top of Figure 3). Our assumption here is that there is a higher level of motor control where sensory reward signals are generated within a perceptual module whose primary function is to classify actions observed occurring in the external world. There is a well-studied perceptual module of this kind in the brain, implemented in a pathway from sensory cortices (in particular visual cortex) through the superior temporal sulcus (STS) and inferior parietal cortex to the premotor cortex (see e.g. Keysers and Perrett, 2004). When an agent allocates attention to an external object, representations in this pathway encode the actions of this object in various ways. Canonically, the action recognition pathway is active when an agent is passively observing the external world. But consider what happens when the agent is attending to an external object as a target, while directing a hand action towards it. Any actions evoked in the action recognition pathway in this scenario are potentially actions brought about by the hand action. We propose that during action execution, action signals evoked in the action recognition pathway function as reward signals, which train the causative action network to bring about particular distal actions in the world.

Training in this higher-level motor circuit again proceeds by random generation of perturbations to the goal motor state delivered by the reach network. In this circuit, sequences of perturbations are applied, to generate still more complex trajectories. (This is depicted in the diagram by a recurrent input, though in our implementation we 'unroll' this recurrence and generate exactly two perturbations.) Some of these sequences cause particular patterns of movement in the target object, which are interpreted as external actions by the action recognition system. Activation of an action representation in the action recognition system when performing an action on a target object is hard-wired to generate a reward signal. This signal has two effects. First, the observed action is copied to a specialised motor medium: specifically, a medium in which action plans are held. Second, the causative action network is trained to map the basic goal motor state delivered by the reach network onto the sequence of perturbations which led to reward. Note that the network also takes representations in the action planning system as input. After training, the causative action network can take a simple goal motor state, plus an action representation in the action planning system, and generate a sequence of perturbations which will lead to observation of a specific action on the attended target. And different patterns in the action planning system will lead to different observed actions.

This network enables a rich repertoire of actions to be learned. It preserves Hommel et al.'s idea that action representations are organised around their perceptual effects. But since the action recognition network generates rich, highlevel percptual signals, a correspondingly rich set of motor programs can be established. At the same time, the basic mechanisms through which learning happens are the same as in much simpler motor learning systems.

Part of the design of the causative action circuit is that 'cause' is motor program in its own right, which competes within the motor program selection system against regular motor programs like 'grasp' and 'slap'. One important difference is that the 'cause' action enables the causative actions network rather than the motor program network, but other than that it counts as a regular motor program. This raises some important questions about how causative actions are planned and executed. When an agent decides to perform a causative action, presumably he has some particular caused action in mind. But at the time of planning, this caused action is in the future: minimally, the agent must bring his hand into contact with the target object before he can cause it to move in any way. Moreover, there is hardly ever a clear way of decomposing a causative action into a simple reach action and a subsequent manipulation. In order to cause a particular action in a target object, the trajectory of the hand towards the object must typically be biased from the very start: for instance, to cause an object to squash, the hand must approach the target from a particular direction, and with particular force. So the movements which bring about the caused action must be initiated some time before the action is perceived.

Our way of addressing this issue in the network is to activate the motor correlates of perceived actions in a medium holding planned actions, rather than in the medium of regular motor programs like 'grasp' and 'slap'. An underlying assumption in our model is that an agent brings about actions through planned sequences of sensory or motor operations (for details see Knott, 2012). We also assume that planned sequences are selected as wholes, and that the component actions in a planned action sequence are active in parallel in the working memory medium where actions are planned. (This assumption is well supported by single-cell recordings in monkeys; see e.g. Averbeck et al., 2002). When the causative actions network is exploring causative actions, it will activate the 'cause' motor programme experimentally, and choose a random sequence of perturbations. In some cases, this results some time later in activation of an action in the action recognition system: say 'squash'. This observed action activates a corresponding planned action; additionally the sequenceplanning system will learn that the sequence 'cause', 'squash' is a good one to execute in the current context, so that when a similar context occurs in the future, it will activate this planned sequence. Now consider what happens when the planned sequence is executed. The agent first executes the motor programme 'cause'. This enables the causative action network, which generates a sequence of perturbations. Crucially, the causative action network also takes input from the planning medium in which the caused action ('squash') is active as part of the planned sequence. So as soon as it is initiated, the network is configured to generate the perturbation sequence which led to the caused action, even before this action actually occurs.

The key mechanism enabling causative actions to be executed is one which activates a sensory representation (the
squash action) as a goal some time before it is evoked as a sensory stimulus. Note that something very similar happens in the other networks; for instance in the reach network the actual motor state where the touch sensation occurs is activated as a goal motor state. In the simple network this activation is possible because visual perception provides information about reward-associated motor states. In the higher-level causative actions network, the advance notification of reward comes from the working memory system which stores prepared actions. But the effect is much the same.

## Experiments learning causative actions

We built two objects in the simulation environment which could undergo specialised kinds of action. One comprised two horizontal planes connected by a spring; this object could be 'squashed' by pushing down on it. The other was a lever which could pivot around a joint; this object could be bent. Our action recognition system consulted the states defined in the physics engine directly; we did not attempt to simulate the action recognition module (though we did simulate the visual inputs to the reach network in a simple way). Each training trial involved the presentation of a single object (either the bendable target, the squashable target or a rigid object) in one of several possible positions. This led to activity in the nework and a motor action. If the rigid object was presented, 'grasp' was activated in the motor program circuit, so that this circuit could be trained; otherwise the activated program was always 'cause', the operation activating the causative action network. This network always generated two perturbations in sequence. At the start of training, perturbations were annealed with noise; this was gradually reduced as the network learned. If the action recognition system detected an action $A$, it generated a reward, and the sensed action activated a corresponding unit in the action planning system, resulting in the sequence ['cause', A]. This sequence plan was also associated with the visual target shape, so subsequent presentation of this target would activate the plan. As training progressed, the system learned perturbations which brought about particular perceived actions, and also learned to map visual target representations onto appropriate sequence plans. Details of the network's training and testing are given in LeeHand (2013).

## A syntactic analysis of causative actions, and a sensorimotor interpretation

It is interesting to compare the structures used by our network to learn and generate causative actions with the syntactic structure of sentences reporting causative actions. As discussed at the start, a Chomskyan analysis posits an underlying level of syntactic representation at which the sentence John bent the lever contains an explicit 'cause' action as its main verb, which takes as its argument a nested action ('The lever bent'). The network model also contains an explicit 'cause' operation (the 'cause' motor programme), and a nested action (the action delivered by the action recognition system).

An emerging school of thought in cognitive science is that concrete sentences get their meanings by evoking embodied representations in the sensorimotor system (see e.g. Glenberg and Kaschak, 2002; Barsalou, 2008). The network model of causative actions presented above may support an interesting 'embodied' account of the semantics of causative transitives like John bent the lever. We will conclude by discussing this possibility.

The underlying structure of sentences in Chomsky's (1995) Minimalist model is called 'logical form' (LF). The LF of John bent the lever is shown in Figure 4. LF represen-

Figure 4: LF of John bent the lever, including head-raising operation
tations have a right-branching recursive structure: the units of recursion, called X-bar schemas (XPs), are indicated with boxes in the figure. (Details of the higher two XPs are omitted for simplicity.) Knott (2012) uses Minimalist LF structures to express a strong claim about the embodied nature of sentence meanings. In his proposal, the LF of any sentence reporting a concrete episode in the world can be interpreted as a description of the sensorimotor processes through which this episode is experienced. Knott assumes Ballard et al.'s (1997) account of sensorimotor processing, which posits that this processing is organised into well-defined sequences of attentional or motor operations called 'deictic operations'. The key idea in Knott's proposal is that the LF structure of a concrete sentence describes a sequence of deictic operationsspecifically, that each XP in the structure describes a single operation. The sensorimotor denotations of XPs are shown in red in Figure 4.

This general proposal makes a specific prediction about the sequential structure of a causative action. As shown in Figure 4 , the XP introducing CAUSE immediately dominates the XP presenting the nested action. Knott's proposal thus predicts that a causative action involves two stages: activation of a 'cause' operation, followed by experience of the 'bend' action. And indeed, execution of causative actions in our network model has this sequential character. So the recursive structure of LF has the right general form.

However, an additional neat correspondence can be drawn
between the structure of LF and the structure of the sensorimotor routine. As discussed above, the hand movement initiated by the 'cause' motor program must follow different trajectories to the target to achieve different causal effects on it. In the network model we catered for this by having the causative actions network take input from a medium representing a casual effect as it is planned, rather than as it is later observed. We assumed that this medium holds the entire sequence of actions being executed by the agent, as a sustained signal, so as soon as the causative network is engaged, its output is influenced by the planned action to be brought about. Now note that in the LF structure in Figure 4, the lower verb bent raises to the position of the higher verb CAUSE (as shown by the arrow) so that it can be pronounced in this higher position, giving the surface form John bent the cup. We propose to explain the Minimalist device of verb raising in sensorimotor terms by assuming in general that surface verbs describe motor actions as they are planned rather than as they actually occur. The reason why the verb bent can be pronounced at the higher verb position is that it denotes a signal in the planning medium, which is tonically active through the whole executed routine. In fact, this account of verb raising follows naturally from a wider sensorimotor account of verb raising which was proposed by Knott (2012) and is implemented in a neural network model of sentence generation described in Takac et al. (2012). But in the current context, the key point is that the sensorimotor interpretation of LF explains both the structural relationship between the CAUSE verb and its complement VP and the extended syntactic domain of the nested verb bend at LF which allows it to appear in the position of the CAUSE verb in surface structure.

## Summary

In this paper we presented a neural network model of the learning and execution of causative actions. The model embodies a particular take on Hommel et al.'s proposal that actions are defined in terms of their effects: a basic circuit implementing this principle is replicated in three different components of the network, at different levels of abstraction. At the same time, the network provides the basis for an interesting account of the syntactic structure of causative sentencesspecifically, of the relation between a cause predicate and the action which this predicate introduces.

# Coordinate-free Thinking 

Joop Leo (joop.leo@phil.uu.nl)<br>Department of Philosophy, Utrecht University, P.O. Box 80126<br>3508 TC Utrecht, The Netherlands

#### Abstract

Thinking outside the box is a nice metaphor, but we are so used to putting things in boxes that it may seem essential to our way of thinking. This idea is enforced by the standard view of relations that says that relata always come in a certain order. There is, however, an alternative view on relations, the antipositionalist view, according to which the constituents of the complexes of a relation neither come in a certain order, nor do they occupy positions. Instead, a relation is conceived as a network of interrelated complexes. We show that this view facilitates a coordinate-free way of thinking and that it may thus have a heuristic value.

Keywords: Antipositionalism; relational complex; relation; substitution.

## Introduction

Consider the following state 'out there':

According to the standard view on relations, we have two distinct complexes here: the cat's being on top of the mat and the mat's being under the cat. So, in the first complex the cat comes first and in the second complex the mat comes first. However, in the state itself, there is no such order. This makes the standard view weak.

A better view on relations is the positionalist view. According to this view, each relation comes with a number of positions to which objects can be assigned. The state above can be expressed in a neutral way by assigning the cat to the position Top and the mat to the position Bottom. But for symmetric relations like the adjacency relation, we would get two indistinguishable complexes for a single state. ${ }^{1}$ This makes also this view objectionable.

Kit Fine developed a radically different view on relations, the so-called antipositionalist view (Fine, 2000). In this view,

[^328]the objects of a complex neither come in a certain order, nor are objects assigned to positions. Instead, a relation consist of a network of the complexes interrelated by substitutions. We may illustrate this as follows.

If we substitute in the complex of the cat on the mat a dog for the cat and a table for the mat, we get the complex of the dog on the table. Furthermore, substituting in the last complex a caterpillar for the dog and a mushroom for the table gives the same result as substituting in the original complex the caterpillar for the cat and the mushroom for the mat.

Since the antipositionalist view rejects order and positions as fundamental, it is in fact a coordinate-free view on relations.

A detailed comparison of mathematical models for the different views on relations provide strong support for the claim that antipositionalism is the superior view on relations (Leo, 2008, 2010, 2013b). Nevertheless, the view does not seem to be in line with our ordinary way of thinking and of expressing ourselves. Our natural languages are linear and in many languages we exploit the linear order to our advantage to express factual situations concisely. We say, for example, "the cat is on the mat" and we know that by mentioning the cat first that he or she is on top. We may, however, be misled into thinking that the order is essential for the underlying relation.

This misconception is reinforced by standard logic, which also imposes an order that is not present in the represented states 'out there' in reality. In fact, standard logic functions like a distorting mirror. It does not faithfully represent reality. However, of an impeccable logic we expect that it can represent reality in a very pure and natural way. Only, such a logic does not yet exist.

In this paper a sketch will be given of a new logic of relations that matches well with a coordinate-free way of thinking. Furthermore some ideas will be given for utilization of the new logic.

## A coordinate-free view of the world

Suppose you had to make clear that a block $a$ is on top of another block $b$, but that you were not allowed to use expressions in which the order $a$ and $b$ are mentioned is relevant for
the meaning, and also that you are not allowed to use positions like Top and Bottom. In other words, you would have to give a coordinate-free account of the state.

Then what you could do is point at a situation where $a$ is indeed on top of $b$. Now there is a big chance that someone else will not directly know what kind of relationship you mean between $a$ and $b$. It might, for example, be thought that you wanted to express that $a$ and $b$ are close to each other. But it would help if you would point at a lot of other situations and in case there is a vertical placement between two objects you would say "This is another state of the same relation that can be obtained from the original state by substituting this object for $a$ and that object for $b$, ," and for dissimilar situations you would say "This state is not of the same relation."

The relation could in this way be grasped without using a specific order for the objects and also without using positions. In this setting, we understand the relation by explicitly using the notion of substitution. A very interesting question is how much of the world we could understand in terms of substitutions.

I consider substitution as a primitive kind of operation. We have, for example, a clear understanding of what it means to substitute Romeo for Adam in Adam's loving Eve. What is less clear, however, is how important the notion of substitution is for our understanding of the world.

When you think about Adam's loving Eve and of Romeo's loving Juliet, you probably do not think explicitly in terms of substitutions. Rather, you think in terms of the love relation applied in a certain way to the persons involved. This is in line with the standard view and the positionalist view on relations, which considers a relation as something with 'holes' in which things can be put.

As I argued before, the standard view and the positionalist view on relations are wrong. ${ }^{2}$ But this does not mean that the views are also harmful. In Leo (2010), an explicit justification was given for using positional representations. Moreover, positional representations are very practical.

Nevertheless, realizing that on a fundamental level there are no positions in relations is a liberating thought. It opens the door to explore new ways of learning and of looking at the world.

Because substitution may be an essential ingredient for any truly intelligent system, the insights are likely also relevant for the field of artificial intelligence. One of the challenges will be to investigate whether and how a general notion of substitution can be implemented in artificial systems.

## Developing a logic of relations

The motivation for developing a logic of relations is that we like to have a formal framework that captures the essence of 'real' relations. In this section, a short description is given of a new logic in which we can reason about relations in a coordinate-free way. Although the technical details are kept

[^329]to a minimum, some basic knowledge of predicate logic will be assumed.

Let us start with the love relation. In predicate logic this relation is represented by a binary predicate symbol, say $L$, and the state of Adam's loving Eve is represented by a formula like $L(a, e)$. The order of the arguments $a$ and $e$ play a role for the interpretation. But it makes no sense to say that in the state itself Adam comes first. The key question is: How can we get rid of the order?

## The main idea

As in predicate logic, the new logic also has terms and formulas, where the terms represent entities in the world (or in our domain of discourse) and the formulas represent assertions about these entities. For example, a term may represent Adam and a formula may represent the assertion that Adam loves Eve.

To prevent problems with the order, we will in our new logic not accept terms $F\left(x_{1}, \ldots, x_{n}\right)$ and formulas $P\left(x_{1}, \ldots, x_{n}\right)$ for any $n \geq 2$. At the same time we do not want to loose anything of the expressive power of predicate logic. Fortunately this is possible.

The main idea for a new logic of relations is to use terms to represent not only individuals, but also all kinds of complex entities 'out there' and to build formulas from the terms only with equality and normal logical connectives and quantifiers. So, we will get rid of predicates altogether-with the exception of equality.

The terms may, for example, not only represent persons like Adam and Eve, but also complexes like Adam's loving Eve and they may even represent substitutions like the one from Adam's loving Eve to Romeo's loving Juliet. Formally, for these entities the terms might look like:

$$
a, e, L_{a e}, s
$$

In addition, we have terms like $\operatorname{src}(s)$, representing the source of the substitution $s$, i.e. the complex of Adam's loving Eve, $\operatorname{tgt}(s)$, representing its target, i.e. Romeo's loving Juliet, and $s(r)$, representing the substitution of Adam by Romeo in the original complex.

As we said, the formulas represent assertions about the terms. To express in a formula that Adam loves Eve we could say

$$
L_{a e}=L_{a e}
$$

This might look as something that is trivially true, but this is not the case since we do not assume that all terms have an interpretation. It is similar to what we have in natural languages with non-referring terms like 'Vulcan', 'ether', 'Santa Claus', and ' 5 loves Eve', and in arithmetic with terms like ' $\frac{1}{0}$ '. The way equations are interpreted in our logic guarantees that if $t=t^{\prime}$, then both $t$ and $t^{\prime}$ have an interpretation. In other words, for an equality assertion to be true, the existence of the interpretation of the terms is required.

Because we need existence assertions so often, we abbreviate the formula above as

$$
\mathrm{E}!L_{a e}
$$

Now if we would like to express that Eve loves Adam as well, then this might require a much larger formula involving src, tgt, $=$, logical connectives and quantifiers. For this reason, it is convenient to introduce abbreviations like:

$$
E!L_{a e}[a \mapsto e, e \mapsto a]
$$

Here $L_{a e}[a \mapsto e, e \mapsto a]$ stands for the result of substituting $e$ for $a$ and $a$ for $e$ in the complex $L_{a e}$.

What I presented here is only an example. It is just to give an impression of the logic of relations. In Leo (2013a) a more detailed and formal description of the syntax and semantics of the logic is given.

## Axiomatization

For the logic of relations, a rather straightforward axiomatization can be given. Here, we do not give the more general axioms, but only axioms that say something specific about complexes and substitutions.

The logic has two constants:
src, tgt

The constants will be interpreted as partial functions that give the source and the target of a substitution.

For convenience, we give a few definitions:

$$
\begin{array}{ll}
\mathrm{E}!t: & t=t \\
t \simeq t^{\prime}: & \mathrm{E}!t \vee \mathrm{E}!t^{\prime} \rightarrow t=t^{\prime} \\
t \text { is a complex : } & \exists s(t=\operatorname{src}(s)) \\
t \text { in } t^{\prime}: & \exists s\left(\operatorname{src}(s)=t^{\prime} \wedge \mathrm{E}!s(t)\right)
\end{array}
$$

The first formula, E! $t$, says that (the interpretation of) the term $t$ is defined. The formula $t \simeq t^{\prime}$ expresses weak equality between the terms $t$ and $t^{\prime}$, i.e. if either $t$ or $t^{\prime}$ is defined, then so is the other and their contents are the same. The formula ' $t$ is a complex' is true if and only if $t$ is the source of a substitution. And the last formula, $t$ in $t^{\prime}$, expresses that $t$ is an object that belongs to $t^{\prime}$, which is the case if $t^{\prime}$ is the source of a substitution for which $s(t)$ is defined.

The axioms are as follows :

## Source and target axioms

Any substitution has a source and a target:

$$
\forall s(\mathrm{E}!\operatorname{src}(s) \leftrightarrow \mathrm{E}!\operatorname{tgt}(s))
$$

The target of a substitution is a complex as well:

$$
\forall s(\mathrm{E}!\operatorname{tgt}(s) \rightarrow \operatorname{tgt}(s) \text { is a complex })
$$

## Constituents axiom

For any complex, all substitutions are defined for the same objects:

$$
\forall x \forall s(x \text { in } \operatorname{src}(s) \rightarrow \mathrm{E}!s(x))
$$

## Extensionality of substitutions axiom

A substitution is uniquely determined by what objects are substituted for the constituents of a complex:

$$
\forall s, s^{\prime}\left(\operatorname{src}(s)=\operatorname{src}\left(s^{\prime}\right) \wedge \forall u\left(s(u) \simeq s^{\prime}(u)\right) \rightarrow s=s^{\prime}\right)
$$

## Identity of substitutions axiom

Substituting for each object of a complex the same object results in the same complex:

$$
\begin{aligned}
& \forall x(x \text { is a complex } \rightarrow \exists s(\operatorname{src}(s)=x \wedge \operatorname{tgt}(s)=x \wedge \\
& \forall u(u \text { in } x \rightarrow s(u)=u))
\end{aligned}
$$

## Composition of substitutions axiom

Substitutions can be composed like partial functions:

$$
\begin{aligned}
\forall s, s^{\prime}(\operatorname{tgt}(s) & =\operatorname{src}\left(s^{\prime}\right) \rightarrow \exists s^{\prime \prime}\left(\operatorname{src}\left(s^{\prime \prime}\right)=\operatorname{src}(s) \wedge\right. \\
& \left.\left.\operatorname{tgt}\left(s^{\prime \prime}\right)=\operatorname{tgt}\left(s^{\prime}\right) \wedge \forall u\left(s^{\prime \prime}(u) \simeq s^{\prime}(s(u))\right)\right)\right)
\end{aligned}
$$

Furthermore, to make deductions we use modus ponens as our single rule of inference:

$$
\text { from } \varphi \text { and } \varphi \rightarrow \psi, \text { infer } \psi
$$

With these axioms and this rule of inference we have a powerful system to reason about all kinds of relational structures in a natural way.

## Advantages of the logic of relations

With this design of the new logic we get the same expressive power as that of first-order predicate logic. In addition, it has some significant advantages compared to predicate logic:

1. We got rid of the artificial order of the arguments of a relation. The logic allows us to express relations in a neutral way. This applies not only to everyday relations like the love relation, but to mathematical relations as well. We speak of the less-than relation and the greater-than relation, but it would be more natural and correct to say that there is just a single strict ordering relation. In the logic of relations this single relation can be formulated in a convincing way.
2. The logic of relations seems conceptually simpler than predicate logic. The formulas only make use of terms, logical connectives, quantifiers and equality. Predicate symbols do not occur at all-except equality. I consider this a significant advantage. The logic allows us to talk in a purely 'logical' way about the things that are 'out there'.
3. Substitution-the basic operation of the new logic-is a very intuitive notion. In my view it is more elementary than assuming that arguments of a relation come in a specific order or that relations have fixed positions to which arguments can be assigned.
4. In the logic of relations, certain complex properties of objects can be expressed very concisely. For example, that objects $a$ and $b$ have exactly the same relations can be expressed as

$$
\forall x(x \text { is a complex } \rightarrow \mathrm{E}!x[a \mapsto b, b \mapsto a])
$$

In predicate logic we need in some cases an infinite number of formulas for this.
5. In principle, the logic of relations allow complexes to have any number of objects, including infinitely many. This is not the case for normal predicate logic.

What might seem a disadvantage of the logic of relations is that the formulas can be relatively long. However, using abbreviations like $t\left[u_{1} \mapsto v_{1}, \ldots, u_{n} \mapsto v_{n}\right]$ may solve this problem. We might even go a step further and let certain formulas look exactly like formulas of ordinary predicate logic, for example by writing $L(x, y)$ for $E!L_{a e}[a \mapsto x, e \mapsto y]$.

In conclusion, the logic of relations has the potential to represent reality more adequately than predicate logic.

## Learning relations

The new logic of relations may influence the way we look at the world. But how do we normally 'learn' relations? Is it by substitution, by abstraction, by positional representations or via processes with a completely different logic? And what is the role of language in learning relations?

A psychological investigation of the way we learn relations would be extremely useful. It might, however, not be easy to develop experiments to determine how we learn all kinds of relations. It will require experts in cognitive psychology to design appropriate tests and experiments.

And there are also more questions to be asked, for example, how small children and animals learn relations. Answers to these questions might deepen our insight in fundamental aspects of the way we understand and represent the world. In addition, they might suggest new learning programs.

Some theoretical research has been done in this field. For example, in Tomlinson and Love (2006) a model of relational learning has been developed. But as far as I know, the role that the notion of substitution may play in learning relations has never been explicitly considered. A more explicit investigation could fit in nicely with the research field of the way we reason. Interesting research in this more general field has been done in Johnson-Laird (1983); Evans, Newstead, and Byrne (1993); Gentner and Smith (2012). In particular, work on analogical reasoning seems to be most relevant.

A related question is what is the best way for artificial intelligence systems to learn relations. There is encouraging re-
search with respect to developing algorithms for learning relations (Richards \& Mooney, 1992; Heyer, Läuter, Quasthoff, Wittig, \& Wolff, 2001; Katrenko \& Adriaans, 2007). In some cases the goal is to build systems that 'discover' relations, and in other cases to find instances for which a given relation holds.

As we saw, the basic operation of the new logic is substitution. If we will be able to implement a general notion of substitution in an AI system, then it might perhaps be possible for such a system to learn a variety of relations by feeding it large sets of samples. As a result we might get sophisticated systems that are able to discover all kinds of subtle regularities in the world.

## Impact of a coordinate-free view

The introduction of a coordinate system in the 17 th century by René Descartes marked a major step forward for mathematics and physics. The idea is quite simple: to each point in the plane a pair of numbers is assigned. This made it possible to describe geometric shapes by algebraic equations. However, in the twentieth century coordinate-free treatments of certain geometric topics turned out to be simpler and more elegant. In particular this is the case for vector analysis and differential geometry.

The choice of a particular coordinate system often turns out to be irrelevant. In physics, this may have an underlying reason; around 1910, Albert Einstein introduced the principle of general covariance, according to which the basic laws of physics remain invariant under changes in frames of reference. From this, one should not immediately conclude that a completely coordinate-free formulation of the laws is always possible. It would also be misleading to call the coordinates used in physics artefacts.

For relations the situation is different. According to the antipositionalist view-the superior view on relations-a relation has on a fundamental level no positions and no order for the relata. The view is genuinely coordinate-free. We do not have the problem of having to deal with irrelevant details like choosing an order, since such details are simply lacking.

This observation may not immediately have an effect on how we perceive the world around us. However, I expect an impact in the longer term:

1. Becoming more acquainted with the new logic of relations may make us more familiar with the idea that relations around us are indeed networks of interrelated complexes. This may help us to 'discover' new relations and instances of relations in an easier way.
2. An interesting application of the new logic presented in this paper will be the development of a philosophically driven alternative for set theory-the standard foundation of mathematics. There is a substantial need for this, since we do not live in a world of sets, but in a world of things with relations between them. Although almost everything
can be coded in set theory, the coding is in some cases quite artificial. ${ }^{3}$
3. The new logic may be useful for developing a new programming language in which complexes and substitutions play a central role. Programs written in such complexoriented programming languages may have a simpler internal structure. This would be of great interest.
4. Finally, I can imagine that some day an effect of this research may be found in websites, shops, airports, and cities: innovations in the design of such places may be inspired by what is for us the most logical way to relate things.

It will be obvious that to accomplish the goals mentioned above, more innovative and interdisciplinary research needs to be done-in particular by computer scientists, linguists, logicians, philosophers, and psychologists. But the results so far are promising.

## Acknowledgments

This research was supported by a VENI grant from the Netherlands Organization for Scientific Research (NWO). I thank Niels van Miltenburg, Vincent van Oostrom, and Albert Visser for their comments on the paper.

# Categorization and Abstract Similarity in Chess 

Pablo León-Villagrá (pleonvil@uos.de) Frank Jäkel (fjaekel@uos.de)<br>Institute of Cognitive Science, University of Osnabrück<br>49069 Osnabrück, Germany

#### Abstract

Chess experts remember meaningful chess positions better than novices (de Groot, 1978; Chase \& Simon, 1973). This can be explained with a larger number of chunks in experts' long-term memory (Gobet \& Simon, 1998). These chunks are mainly based on visual representations-that is, pieces on squares. However, a recent experiment highlighted that experts prefer to group chess positions by abstract similarities that cannot be explained purely visually (Linhares \& Brum, 2007). Based on these data it was claimed that chess expertise, in addition to chunks, crucially relies on abstraction and analogies. These data and the conclusions were heavily criticized because the instructions strongly biased the participants to group positions in a certain way (Bilalić \& Gobet, 2009). Here, we successfully replicated this experiment with less explicit instructions. In addition, we collected category labels for the groupings that allowed us to explore the abstract principles that participants used.

Keywords: Analogy, Categorization, Chess, Expertise, Pattern Recognition, Representations, Similarity

## Introduction

After a match strong chess players often comment that aspects of their game were similar to well-known classical games. For example, after his win against Aronian in January 2013 world champion Viswanathan Anand stated at the press conference: "It was the same concept [...], Rubinstein's version was even Rook takes c3 and Rook to h3, but essentially [it was] the same idea [...]." Or take another example, Rosentalis commented on one of his games: "When playing Qa3 the game Smyslov-Reshevsky came to my mind" (Rowson, 2001). The left panel of Figure 1 shows the position in Rosentalis' game which made him remember the position from Smyslov-Reshevsky (right panel). The two positions share no obvious visual similarity and differ considerably with regard to the pieces and their arrangement on the board. Nevertheless, Rosentalis perceived both positions to share some crucial aspects and based on this similarity he considered the move Qa3 (which allowed an exchange of queens). How do chess players represent chess positions and what kind of similarity do expert chess players perceive in positions that are visually very different?

The classical conception of expertise in chess is based on the idea that finding the right move is a process of recognition and association (Gobet \& Simon, 1998). There are convincing data indicating that experienced chess players have access to a large database of stored patterns, called chunks, and these chunks are associated with plausible plans and ideas (de Groot, 1978; Chase

Figure 1: The left panel shows the game RosentalisAppel before white played Qa3. The right panel shows the game Smyslov-Reshevsky, World Championship 1948. Rosentalis commented that his game was similar to Smyslov-Reshevsky although there are few obvious visual similarities (Rowson, 2001).
\& Simon, 1973). A chunk in chess is, hence, defined as a unit of information in long-term memory containing a meaningful grouping of pieces on squares, plus associated moves and ideas. Each chunk consists of up to five pieces and the size of the stored chunks is positively correlated with skill. Furthermore, under the assumption that experts and novices can both retain $7 \pm 2$ chunks in short-term memory, more skilled players can make better use of their short-term memory because they have the right chunks available. Hence, differences in skill are, to a great part, based on differences in the number and the size of the chunks stored in long-term memory. In order to accommodate various findings that were inconsistent with the original chunking theory the concept of a chunk was later expanded to more complex structures, so-called templates. Templates are formed if positions reoccur frequently and in addition to the template core (which is a classical chunk) can contain free variables (Gobet \& Simon, 1996, 1998). Even though this notion expands classical chunking, in actual implementations of the theory templates are still accessed via discrimination nets and thus patterns of specific pieces on squares are fundamental for recognition.

In the anecdotal examples mentioned above strong players did not seem to rely on purely visual information, such as pieces on squares, to retrieve relevant information from memory. Linhares (2008) has argued forcefully that chess research should not focus too strongly on the visual aspects of the game. According to him, although visual similarities between stored chunks and
presented positions surely play a role in chess expertise, abstract-level relations and analogies are more important for understanding expert performance (Linhares \& Brum, 2007). Chess experts excel because their representations are on a high level of abstraction and these representations are not explainable by chunking alone.

In other areas of expertise it is well established that experts rely on abstract representations while novices concentrate on superficial aspects. Chi, Feltovich, and Glaser (1981) asked experts and novices to sort physics problems into groups. They found that the novices grouped problems based on superficial similarities (problems with pulleys vs problems with springs) whereas experts grouped problems based on physical, non-obvious principles (conservation of energy vs conservation of momentum). Inspired by this work, Linhares and Brum (2007) constructed a set of chess positions that could be grouped either by superficial, visual similarity or based on abstract principles. In their experiment they showed subjects 20 positions that formed 10 pairs based on 10 abstract ideas, like "material gain due to a double attack" or "endgame with bishops of the same color." These pairs are fairly natural as they consist of wellestablished categories in chess. Importantly, they constructed the material in a way that there were also 5 obvious pairings based on purely visual similarity. That is, the pieces and their respective positions on the board were extremely similar. But these 5 pairs were strategically or tactically very different situations due to small, but crucial, differences. Figure 2 shows an example of positions that can be grouped either visually or abstractly.

Linhares and Brum (2007) then asked chess players of varying strengths, from relatively strong masters to unrated amateurs, to pair their 20 chess positions based on strategical similarity. The expert players almost exclusively grouped the positions into abstract pairs while the novices only matched about half of the abstract pairs. Almost no visual pairs were chosen by the experts whereas novices often paired by visual similarity. Linhares and Brum concluded that multiple levels of encoding of chess positions exist, from surface representations of concrete piece relations to abstract semantic or conceptual representations consisting of abstract roles of pieces. Expert chess players perceive positions as global semantic arrangements and associate them with future developments and plans. Therefore, what differentiates experts and novices is the level of abstraction at which positions can be represented.

Bilalić and Gobet (2009) reproduced the study by Linhares and Brum introducing a condition in which participants were not asked to pair positions based on abstract similarity but on visual similarity. They did this because in the original study the instructions explicitly encouraged grouping by abstract similarity and discour-

Figure 2: Four of the positions presented in the experiment by Linhares and Brum (2007). While positions 14 and 15 and positions 17 and 18 are visually almost identical they differ considerably in their abstract essence. On the other hand, positions 14 and 17 and positions 15 and 18 are very similar on an abstract level. Positions 14 and 17 are examples of endgames with opposite-colored bishops in which no side can make progress as the opponents pawns are fixed on the wrong color. In contrast, positions 15 and 18 consist of endgames with bishops of the same color and are easily winning for white because the black pawns are attackable. For example, in position 18 white can immediately win the pawn on d6 and proceed to win the game.
aged grouping by visual similarity. They argued that this is a big methodological flaw of the original study and wanted to demonstrate that the explicit instructions simply biased the subjects to respond as the experimenter wished. In the abstract-similarity condition Bilalić and Gobet could replicate the original resultsexperts paired more than twice as many abstract pairs as novices. In the visual-similarity condition, in which players were instructed to group positions together based on visual similarity, both groups matched an equally low number of abstract pairs and a high number of visual pairs. The point that Bilalić and Gobet wanted to make with this experiment is that experts will group the material in any way they are instructed to. Hence, the strong conclusions that Linhares and Brum drew from their data are not warranted. Bilalić and Gobet argued
that the original experiment did not show any evidence that analogical reasoning or abstract similarity play an important role in chess expertise. According to them, experts did not group abstract pairs because they thought that was the natural thing to do but because they were explicitly instructed to do so.

Linhares and Brum (2009) responded to this criticism by stating that experts can of course behave like novices if told to do so. But there is an important asymmetry: "Novices cannot behave as experts." (Linhares \& Brum, 2009, p. 750) The original experiment was meant to demonstrate that experts can group the stimuli by abstract similarity whereas the novices have to rely on superficial similarity, just like in the study by Chi et al. (1981). We agree with this observation but still think that Bilalić and Gobet had a valid point. The original experiment just shows that expert chess players can group by abstract similarity if told to do so, but this in itself does not show that noticing abstract similarities and making analogies is as crucial for chess expertise as Linhares and Brum claim. As participants were explicitly discouraged to pair by visual similarity we don't know whether expert players considered visual similarity relevant at all-however unlikely this may seem. Visual similarity, in any case, might still play the dominant role in memory retrieval during a game (despite the anecdotal evidence mentioned in the introduction). We think that even if the link between real-world expert performance and subjects' pairings in the experiment by Linhares and Brum is unclear, it is still interesting to try and directly probe experts and novices for their intuitions about the similarity of positions. This was also the first step in the work of Chi et al. (1981). But similarity is a difficult notion. Unless the "respects for similarity" (Medin, Goldstone, \& Gentner, 1993) are precisely specified neither subject nor experimenter can be sure about what is meant by "similarity." The pairing experiment was cleverly designed to compare abstract and visual similarity against each other and thus the material probably biased the subjects to focus on these two aspects. In an actual chess game there might be even more respects for similarity than the two (abstract vs visual) that Linhares and Brum had in mind for their pairs. However, even in their experiment participants might perceive several notions of similarity in conflict with each other-but because of the clear instructions they use the one that was intended by the experimenters.

The present paper tried to replicate Linhares' and Brum's study once again. In our experiment less explicit instructions about the nature of pairs were provided. Therefore, every participant was able to pair the positions based on his or her individual, intuitive understanding of similarity in chess. We think that this is the "missing condition" in the debate. As we didn't give the subjects any obvious instructions on what we meant
by similarity, potentially there could be other notions of similarity that participants might consider relevant or in conflict with the abstract similarities that Linhares and Brum had constructed. Visual surface similarity could be one of them - but not the only one. Hence, if participants, even under our fuzzy instructions, grouped the stimuli mainly as predicted by Linhares and Brum this would be somewhat stronger evidence for their claims. But if the experts spontaneously grouped by visual similarity or in any other way this would show that Bilalic's and Gobet's methodological concerns are indeed important. In addition, we decided to go beyond Linhares' and Brum's original study by also asking participants to provide a category label for each pairing. In the study by Chi et al. (1981) the category labels proved to be very helpful for understanding the difference in the representations of experts and novices. These category labels will allow us to see more directly what the participants deemed relevant for the task.

## Methods

The design was based to a large extent on the original experiment and the same set of stimuli was used (Linhares \& Brum, 2007). In contrast to the original experiment, the present study changed the instruction given to the participants and permitted a more differentiated evaluation of the positions in the orientation phase.

## Participants

32 participants were recruited at local chess clubs, of which two participants aborted the experiment due to fatigue. The remaining 30 participants were all at least familiar with the rules of chess and basic strategies. The participants' skill is reflected in their DWZ rating. The DWZ rating system is an adaptation of the Elo rating system for the German national chess federation. Like the Elo scale the DWZ rating allows a fine differentiation of skill based on the players performance at chess tournaments. The mean DWZ rating was 1395.5 ( $\mathrm{SD}=$ $750.3, \min =0, \max =2461$ ), 5 players had no official rating. On average each player had performed about 2-3 hours of chess-practice per week in the last year. The mean age was 32.7 years ( $\mathrm{SD}=15.5$, min $=12$, max $=74$ ). Only two participants were female and both female participants were unrated. The participants were divided into an expert and a novice group according to the mean playing strength of all registered German players $(\mathrm{M}=1518)$. The expert group was composed of 16 participants with a mean DWZ of $1945.9(\mathrm{SD}=268.2$, $\min =1569, \max =2461$ ). The novice group had 14 members, with a mean DWZ of 766.4 ( $\mathrm{SD}=611.3$, min $=0, \max =1490)$. Splitting the participants in this way is not ideal since both groups now contain players that are around the German average. This will blur the differences between novices and experts, making it harder to find an effect if there is one. However, this
grouping is consistent with the grouping that was used in previous studies and allows for a better comparison with these studies (Bilalić \& Gobet, 2009; Linhares \& Brum, 2007). In addition we also calculated and report correlations here.

## Procedure

At the beginning of the experiment verbal instructions explaining the basic procedure of the survey were provided. The participants received a form of consent and after signing it proceeded to the first part of the experiment. Each participant received a questionnaire that asked for gender, age, and chess rating (DWZ). The final question asked for the amount of chess practice the subject had performed per week in the last year (Scale: 0-1 hours per week, 1-2 hours per week, 2-3 hours per week, 3-4 hours per week, more than 4 hours per week).

Familiarization Phase After these general questions the main experiment started. Participants received a short instruction on how to perform the survey. The twenty chess positions were presented in random order. The task consisted in giving an evaluation of the position and checking the particular response ("White has a winning advantage", "White has a minor advantage", "The position is equal", "Black has a winning advantage", "Black has a minor advantage", "No evaluation is possible"). For each position white was to move and unlimited time was granted to perform the task. Nevertheless, the participants were instructed to perform like in an over-the-board chess game and to use a reasonable time investment per position. After evaluating a position participants had to write down the next move for white. The familiarization phase served the purpose of activating, for each stimulus, the representations that would also be relevant in an actual game.
Pairing Phase The task in the second part of the experiment was to group the twenty chess positions from the familiarization phase into pairs. Participants received overview-sheets in which the twenty positions were displayed. The sheets were placed in front of the participants so that they could inspect all position simultaneously. There were three types of overview-sheets with different random arrangements of the positions. Positions were labeled with successive numbers (from 1 to 20) and each participant received one type of randomized overview-sheet. Instructions were to pair together positions which "intuitively seemed similar." Additionally, participants should perform "as if they were thinking about similar positions in a chess game." It can be argued that this additional instruction biased participants more than necessary. However, we decided to include it so that subjects understand that they should use the representations that they would use in an actual game.

Participants had to fill the position pairs into a designated table. Several of the expert players asked for
clarification of the instructions, indicating that our instruction was indeed vague, as intended. They asked in what regard they were to interpret the similarity and were told that this was up to them and they should follow their intuitions.

Labels and Features The final part of the survey consisted of ten sheets with questions about the chosen pairs. Participants were instructed to use the overviewsheet and their response table as an aid. First of all, participants were asked to name a headline or topic for each chosen pair. After that, participants had to name attributes or features which made them select the pair. Finally, they had to rate the similarity of both positions and the prototypicality for each of the two positions for the chosen headline. The ratings are not easily interpretable as the labels were highly idiosyncratic and we usually did not have enough identical pairings for a statistical analysis. We still performed an exploratory and qualitative analysis (which had unclear results) but omit it here due to space limitations.

## Stimulus Material

The twenty chess positions in the present study were the same as in the original study (Linhares \& Brum, 2007). The positions were constructed in a way that 10 abstract pairs (i.e., all 20 positions) could be selected. At the same time, five control pairs (i.e., 10 positions out of 20) consisted of visually almost identical positions. The positions with a high visual similarity were very different on an abstract level, while the abstract pairs had no similarity on a visual level. An example is shown in Figure 2. All positions displayed a middlegame or endgame position and in all positions white was to move. Most positions were relatively easy to solve.

## Results

## Pairings and Evaluations

The two groups differed significantly in the number of abstract and control pairs that they chose. The expert group chose a significantly higher number of abstract pairs ( $\mathrm{M}=5.5, \mathrm{SE}=.62$ ) than the novice group ( M $=3.1, \mathrm{SE}=.54, t(28)=-2.9, p=.007)$. The novice group matched significantly more visual pairs ( $\mathrm{M}=3.4$, $\mathrm{SE}=.37)$ than the expert group $(\mathrm{M}=1.7, \mathrm{SE}=.38$, $t(28)=3.1, p=.004)$. As mentioned above, grouping participants in this way is not ideal, therefore we also calculated the correlation between DWZ rating and the choices, excluding the five unrated participants. DWZ rating correlated positively with the number of abstract pairs, $r=.52, p=.007$ and negatively with the number of control pairs, $r=-.49, p=.014$ (Figure 3). Not surprisingly, there was also a positive relationship between rating and correct evaluation of the position, $r=.77$, $p<10^{-5}$.

Figure 3: Number of chosen abstract pairs (left) and visual pairs (right) as a function of skill.

## Category Labels

In order to compare the labels given by each participant to the labels of the other participants, the first author came up with a hierarchical classification scheme for the labels based on the abstract categories given in the original design of the material (Linhares \& Brum, 2007). He then assigned the participants' labels to these classes. Some additional classes were added later based on labels that were given by several participants, for example "last pairing(s)" (the participant could not match all positions and some pairs had to be chosen randomly from the remaining material). One other unexpected label occurred relatively frequently: Situations described as deadlocked, stuck, or impenetrable were summarized in one label ("deadlocked"). This classification resulted in the hierarchical system of labels shown in Table 1.

The most common label for the novice group was "visual similarity" ( 34 out of 140 labels), followed by "last pairing" (12). This is in stark contrast to the experts who chose these labels rarely $(5,1)$. The most common labels for the expert group were "checkmate in one" (15 out of 160 labels), "endgame with opposite colored bishops" (13), "pawn endgame" (13), "passed pawn in the pawn endgame" (13) and "endgame with bishops of the same color" (12). Those labels were chosen much less frequently by the novices.

Overall, novices chose a higher number of pairs based on visual characteristics and often gave purely visual descriptions. In addition, novices often chose general levels of description ("check", "endgames" or "bishop endgame") while most experts used more specific labels (e.g., "passed pawn in the pawn endgame", "bishop endgame with bishops of the same color"). Finally, various unexpected labels were given which in many cases could not be classified using the descriptions (or more general instances of these descriptions) of the categories by Linhares and Brum (17 idiosyncratic labels in the novice group and 11 in the expert group).

## Label-based Reanalysis of Pairing

The material consisted of pairs of visually very similar positions that could also be interpreted as clear and well-established instances of abstract categories. Even

1. Visual Similarity [Novices: 34, Experts: 5]

## 2. Tactics

(a) Material Gain [N: 1, E: 3]
i. Double Attack [N: 7, E: 11]
ii. Discovered Attack [N: 2, E: 1]
(b) Check [N: 6, E: 1]
i. Checkmate [N: 4, E: 9]

- Checkmate in One [N: 5, E: 15]
- Discovered Checkmate [N: 1, E: 6]
- Smothered Checkmate [N: 2, E: 10]

3. Endgames [N: 3, E: 0]
(a) Pawn Endgame [N: 7, E: 13]
i. Pawn Chain [N: 2, E: 6]
ii. Passed Pawn [N: 2, E: 13]
iii. Opposition [N: 6, E: 10]
(b) Bishop Endgame $[\mathrm{N}: 8, \mathrm{E}: 6]$
i. Bishops of the same color $[\mathrm{N}: 1, \mathrm{E}: 12]$
ii. Bishops of different color [ $\mathrm{N}: 1, \mathrm{E}: 13$ ]
4. Other Labels
(a) Last Pairing [ $\mathrm{N}: 12, \mathrm{E}: 1]$
(b) No Label [N: 0, E: 2]
(c) Incomprehensible Label [N: 5, E: 1]
(d) Deadlocked [N: 7, E: 9]
(e) Advantageous Positions [N: 4, E: 2]
(f) Drawish Positions [N: 3, E: 0]
(g) Idiosyncratic Labels [ $\mathrm{N}: 17$, E: 11]

Table 1: Hierarchical classification scheme used for participants' category labels.
though the results in preceding studies (Linhares \& Brum, 2007; Bilalić \& Gobet, 2009) were very clear, in our study several unexpected pairings could be observed. Analysis of the labels given by the participants for particular pairings showed that unexpected abstract relations existed in the material. Therefore, several pairs originally designed as visual pairs allowed for a plausible and consistent abstract classification. One of the most striking examples of such an underlying unexpected abstract similarity was the pair consisting of positions 3 and 6 (not shown). Although designed as a visual pair, this pair was perceived as abstract by two of the strongest participants in this study, stating that both positions share similarity with the abstract concept of a fortress. Also, some abstract pairs were chosen for the wrong reasons. For example, if a participant chose an abstract pair but gave the label "last pairing without similarity" it is very improbable that the abstract pair had been chosen
based on abstract similarity.
The labeling task we used in this study allows us to reconsider for each pair whether it should be considered as an abstract pairing or not, independent of the intended pairings by Linhares and Brum. In total, about half of the labels for abstract pairs in the novice group did not contain any sort of abstract information and most explicitly stated that they were not selected due to abstract similarity. A reevaluation of the pairings chosen by the subjects based on their labels resulted in a slightly higher number of abstract pairs for the expert group but did not change the general difference considerably (M expert abstract $=6.3, \mathrm{SE}=.67, \mathrm{M}$ novice abstract $=1.8, \mathrm{SE}=$ .55). The reanalysis did increase the correlation between rating and number of abstract pairs ( $r=.66, p=.0003$ ) considerably, while it did not change the correlation between rating and the number of visual pairs $(r=-.49$, $p=.01$ ).

## Discussion

The present study replicated the results obtained by Linhares and Brum (2007) and Bilalić and Gobet (2009). On average experienced chess players chose considerably more abstract pairs than the novice group. On the other hand, novice players selected about twice as many visual pairs than the expert group.

As in our experiment no explicit instruction about the nature of expected pairs was given, the number of chosen abstract pairs was smaller than in the previous studies. The results obtained in this study weaken the methodological concerns raised by Bilalić and Gobet (2009). Experts did not simply do what they were instructed to do, but in our experiment freely chose to pair positions based on abstract similarity. Even though the material contained a considerable amount of visually almost identical positions, these possible pairings were not interpreted as relevant for the task by the experts.

As we have the category labels for the pairings as well, we have very direct evidence for what the participants deemed relevant for each pairing. The labels clearly show that novices very often spontaneously grouped by visual similarity whereas experts did not and preferred wellestablished abstract chess categories that, probably, simply weren't available to many of the novices. Furthermore, even though novices sometimes also used abstract categories, we could see that there was a tendency for experts to use better differentiated categories. This is a common finding in the study of expertise (Johnson \& Mervis, 1997).

The present study showed that the categorization behavior observed in Linhares' and Brum's study was not simply based on the instruction but was a genuine, asymmetric characteristic of expert players. However, we still agree with the conclusion of Bilalić and Gobet that "it may well be that analogy is central to expert cognition
[...]. This cannot, however, be demonstrated by asking experts to look for analogy in problems." (Bilalić \& Gobet, 2009, p. 746). Future research should therefore follow more closely the example of Chi et al. (1981). While the stimuli that Linhares and Brum (2007) used were cleverly designed to contrast abstract and visual similarity, they may have biased participants to consider mostly these two aspects. The next step should be to have subjects group a representative selection of stimuli to avoid this bias. In addition, it remains to be demonstrated beyond anecdotal evidence that abstract similarity is important for actual chess playing. One way forward could be to look for abstract categories and analogical processes in think-aloud protocols that were collected during actual games.

# Prior Linguistic Knowledge Influences Implicit Language Learning 

Janny H.C. Leung (jannyleung@hku.hk)<br>School of English, The University of Hong Kong, 735 Run Run Shaw Tower, Centennial Campus, The University of Hong Kong, Hong Kong

#### Abstract

We report three experiments that explore the effect of prior linguistic knowledge on implicit language learning. Native speakers of English and native speakers of Cantonese participated in implicit learning (IL) experiments that involved different learning materials. In Experiment 1, both participant groups showed evidence of learning a mapping between articles and noun animacy. In Experiment 2, neither group showed learning of the mapping between articles and a linguistically anomalous concept (the number of capital letters in an English word or the number of strokes in a Chinese character). In Experiment 3, the Chinese group, but not the English group, showed evidence of learning a mapping between articles and a concept derived from the Chinese classifier system. It was concluded that first language knowledge affected implicit language learning, and that IL, at least when natural language learning is concerned, is not a completely unconstrained domain-general mechanism.

Keywords: implicit learning; form-meaning connections; vocabulary learning; second language acquisition; cross-linguistic influence

## Introduction

Traditional implicit learning (IL) (as contrasted with explicit learning, EL) research has sought to minimise the effect of prior knowledge, either by using artificial grammars (e.g., Reber, 1967) or artificial event sequences (e.g., serial reaction time experiments; e.g., Nissen \& Bullemer, 1987). Perruchet and Pacton (2006: 237) suggest that even arbitrary materials may not be "neutral" enough, for they may interact with related situational knowledge. It is typically assumed that domain general mechanisms underlie IL, but in many real life situations the learner may bring relevant domainspecific prior knowledge or dispositions, so the question arises as to whether, or how, these impact upon the IL process.

Natural language learning is a case in point - some believe that linguistic universals constrain both first and second language acquisition (Chomsky, 2006; Hawkins, 2004) and that in both cases the theoretically interesting learning processes operate at the implicit level. Even those who dispute the nature of such linguistic universals would accept that second language acquisition (SLA) is heavily influenced by first language (L1) knowledge, or L1-based processing strategies (MacWhinney, 2008; Ellis \& Sagarra, 2011). Second language (L2) learners approach SLA with existing linguistic knowledge and habits they have gathered from their first language acquisition experience. Cross-linguistic influence is well documented in the SLA literature, much of which is concerned with identifying the ways in which elements from one language get incorporated into another, accounting for errors, contrastive analysis, and interaction of transfer effects with other factors. Ellis (1994/2001: 300) argues that no theory of SLA "can be considered complete" if it ignores the learner's prior linguistic knowledge. In a similar vein, if IL is posited as an underlying mechanism of language acquisition, one must also consider whether and how the influences of prior linguistic experience on learning take place implicitly. In the SLA literature, cross-linguistic influences are sometimes thought of in terms of hypothesis testing and learner strategies (Corder, 1981; Tomasello \& Herron, 1989), implying a certain degree of intention and awareness in the process. Although it is difficult to imagine that such influences involve only explicit processes, there does not seem to be empirical effort to demonstrate such influences operating at the implicit level during learning. Moreover, cross-linguistic influence is found to be subject to general constraints such as language proficiency, sociolinguistic factors, markedness, prototypicality, language distance and psychotypology, and developmental factors (Ellis, 1994/2001). The interaction of such constraints with domain general learning mechanisms begs for research.

Our earlier work has begun to show that learning processes supporting implicit language learning
effects are not completely unconstrained. Leung and Williams (2012) used an efficiency measure (Seger 1994) to measure learning of a semi-artificial article system comprising the pseudowords gi, ul, ro, ne. Participants were told that the use of the articles depended on the distance of the object described by the accompanying noun ( $g i$ and $u l$ were used with an accompanying noun which referred to a near object; ro and ne were used if it referred to a far object). Unbeknownst to them, article use also depended on noun animacy ( gi and ro were used with animate objects and $u l$ and ne with inanimate objects). Objects were pictorially presented, along with an audio presentation of the corresponding noun phrase. The task for the participants was to respond as quickly as possible whether the noun referred to a living or a non-living thing ${ }^{1}$. Learning was measured by an increase in reaction time when the hidden regularity was violated (Violation trials) compared with reaction time in grammatical trials (Control trials). After performing 272 training trials in the task, native speakers of English who claimed to be unaware of the hidden regularity (as revealed in a standardised verbal report) nevertheless slowed down significantly in animacy decisions when the correlation between article use and noun animacy was reversed. In contrast, in a second experiment article use correlated with the relative size of objects rather than their animacy. This time there was no significant change in relative size decision times when the mapping between article use and relative size of the objects described by the nouns was reversed. The findings suggest that some meanings are more amenable to the IL of form-meaning connections than others. One possible explanation for this is the availability of grammatical processes and representations based on participants' existing linguistic knowledge, but to probe into this issue, comparisons between participants with different first languages have to be made.

The present study aims to consolidate and extend our earlier work by further exploring potential first language influences on IL of a semi-artificial grammatical system. We report below three experiments involving different learning materials and two language groups (native Chinese and native English speakers).

[^331]
## Experiment 1

## Objective

To test whether animacy, a conceptually salient feature, may be implicitly mapped onto articles by native speakers of English and Chinese.

## Participants

Thirty native speakers of English from the University of Cambridge and 27 native speakers of Cantonese Chinese from the University of Hong Kong, with a varied second language background. All Hong Kong participants spoke English as an L2, and some also knew other second/foreign languages.

## Materials and Procedure

All experimental materials were digitalized and presented with E-Prime software.

Participants were told that they would be introduced to a miniature article system from a language not known to them (Table 1). They were told that the articles ${ }^{2}$ were used to encode the distance between the speaker and the object ( $g i$ and ro for near objects and $u l$ and $n e$ for far objects). Therefore gi dog may be read as 'the near dog', ro table as 'the near table', ul mouse as 'the far mouse', and ne car as 'the far car'. Participants could spend as much time as they needed to remember the mapping between the articles and the distance system. Participants were however not told that the use of these articles also depended on the animacy of the accompanying noun ( $g i$ and $u l$ for animate objects and ro and ne for inanimate objects).

Table 1 The miniature article system in Experiment 1

| Miniature article <br> system |  | Participants not told |  |
| :---: | :---: | :---: | :---: |
|  | animate | inanimate |  |
| Participants <br> were told | near | gi | ro |
|  | far | ul | ne |

A total of 176 animate and inanimate nouns were used for the experiment, each appearing twice (once with each possible article). In the training phase, participants were exposed to visually presented noun phrases (article and noun combinations). While the same article system was used for all participants, the nouns were presented in each participant group's first

[^332]language（i．e．，English or Chinese；see table 2）．For instance，an English subject may see gi fox and a
Chinese subject may see $g i$ 狐狸（＇fox＇）on the screen． The task for the participants was first to make a decision about the animacy of the object（living or non－living，M or C key）described by the noun．The noun phrase then disappeared and was replaced by the prompt＂N／F＂．Participants had to indicate the distance meaning of the article（ $\mathrm{M}=$ near， $\mathrm{K}=\mathrm{far}$ ）． Both decisions had to be made as quickly as possible and reaction time was recorded．Response buttons were configured such that the near／far buttons were in a logical arrangement－one above the other，which also helped reduce interference with the other decision which is in a horizontal arrangement；see figure 1 for visualisation．Reaction time for the animacy decision was measured from the onset of the noun phrase；reaction time for the near／far decision was measured from the onset of the N／F（near／far） prompt，which appeared immediately after the animacy response．Feedback was provided；if participants gave a wrong response，the display did not change．Eight practice trials were provided before the experiment started．A total of 204 grammatical trials were presented in the training phase，with equal numbers of trials presented with each article．These trials were divided into four blocks，although no division between blocks was apparent to the participants．The first block consisted of 84 trials， which were made up of 84 nouns used in combination with an equal number of one of the two grammatically possible articles for each noun．Block 2 contained 60 trials，comprising 60 new nouns， again in combination with an equal number of appropriate articles．In Block 3， 28 of these nouns were repeated with a correct article of opposite distance from Block 2 （e．g．if gi pig had occurred in Block 2，then ul pig occurred in Block 3）．Within Blocks 1 to 3 the trials were divided into fixed groups of four，with each article occurring once．For each participant the order of trials within groups was randomised as was the order of groups．This procedure meant that no more than two successive trials would involve the same article．In Block 4 the remaining 32 nouns from Block 2 were repeated． Half of them occurred with an article of different distance from Block 2，but correct animacy（e．g．，if $u l$ parrot had occurred in Block 2 then gi parrot occurred in Block 4）．These were Control trials．The other half of the Block 4 trials occurred with the article of opposite distance and animacy（e．g．if ro tent had occurred in Block 2，then ul tent occurred in Block 4）．These were Violation trials．Control and Violation trials were randomly intermixed，and the nouns were rotated around conditions across subjects，
resulting in two presentation lists．Note that although nouns were repeated from Block 2 to Blocks 3 and 4， no article－noun combination was repeated throughout the experiment．After Block 4 participants filled out a questionnaire which probed awareness of the relevance of animacy to article usage，awareness of violations，and at what point in the experiment awareness of the regularity developed．Participants who reported no awareness were then encouraged to guess what factors（apart from near／far）determined when the articles were used．The whole experiment took about 45 minutes to complete．

Table 2．Sample animate and inanimate nouns used in Experiment 1

| $\mathrm{gi} / \mathrm{ul}$ |  | ro／ne |  |
| :---: | :---: | :---: | :---: |
| English <br> version | Chinese <br> version | English <br> version | Chinese <br> version |
| fox | 狐狸 | piano | 鋼琴 |
| buffalo | 水牛 | microscope | 㪚微鏡 |
| gorilla | 大猩猩 | telescope | 望遠鏡 |
| seal | 海豹 | kettle | 水壺 |

Figure 1．Configuration of response buttons on millisecond accurate keyboard／response box．

## Results

In the post－experiment debriefing，two levels of unawareness were assessed：a failure to report knowledge of the hidden regularity，and a failure to suggest any relevance of the target concept to article use when prompted to guess．Data from participants who failed to report knowledge are reported below； data from participants who failed to guess were found to show a pattern consistent with the summarized findings and are not reported here．

Outlying response times，at cutoff limits at $\pm 2.5$ standard deviations from each subject＇s mean in the Control and Violation blocks respectively were removed．In addition，data were excluded from any participant whose mean response time for the first decision over the two critical conditions was more than 2.5 standard deviations from the group mean．

Considerable variability in response times was observed，possibly because participants varied in how they distributed processing time over the two decisions and so inordinately slow participants were excluded on the basis that they may have been approaching the task in a different way from the majority．

Evidence of learning is based on the difference in reaction time across Control and Violation trials，as tested by a paired－sample t－test．Only data for the first（in this case animacy）decision are reported（no effects in any experiment were obtained for the second，near／far，decision）．

Twenty native English and 20 native Chinese did not report relevant knowledge of the regularity in response to the first debriefing question（awareness rates $33 \%$ and $26 \%$ respectively）．One Chinese participant was excluded due to slow overall animacy decision response times．Response times to make animacy decisions were significantly slower for Violation than Control trials even for participants who showed no awareness of the relevance of animacy，or related concepts，to article usage（see fig． 2，＇English animacy＇and＇Chinese animacy＇）， indicating that the animacy rule has been learned implicitly．The combination of alphabetical articles with characters is orthographically odd for the Chinese，but this did not seem to have affected their learning．

Figure 2．Reaction times（RT）in milliseconds（ms） for unaware participants in all three experiments， ＊ $\mathrm{p}<0.05,{ }^{* *} \mathrm{p}<0.01$ for difference between control and violation conditions

The question that follows is whether anyone with any language background will learn any regularity．A
linguistically unnatural learning target is adopted in the following experiment to investigate this．

## Experiment 2

## Objective

To test whether a linguistically anomalous，form－ based，distinction may be implicitly mapped onto articles by native speakers of English and Chinese．

## Participants

Twenty three native speakers of English from the University of Cambridge and 29 native speakers of Chinese from the University of Hong Kong，with a varied second language background，participated in the study．

## Materials and Procedure

The experiment shares a similar design with Experiment 1．The animacy system was now replaced by a non－semantic distinction for each participant group．In the English version，the hidden regularity was that the choice of article depended on whether the word had one capital letter or two．In the Chinese version，the hidden regularly was whether the first character in a two－character noun has more strokes than the second and vice versa，with a strokes difference between the characters being big enough that no counting would be necessary（see Table 3 below）．

Table 3．Sample nouns used in Experiment 2

| gi／ro |  | ul／ne |  |
| :---: | :---: | :---: | :---: |
| English <br> version <br> （case） | Chinese <br> version <br> （stroke） | English <br> version <br> （case） | Chinese <br> version <br> （stroke） |
| foX | 天鵝 | goRillA | 獅子 |
| piAno | 月餅 | TelesCope | 剪刀 |
| buffaLo | 牙醫 | sEAl | 學生 |
| miCroscope | 天橋 | kEttlE | 瀑布 |

The design and procedure were the same as Experiment 1 except that here participants had to indicate，as their first decision，whether the noun contained one or two capital letters（ M and Z keys respectively）or whether there were more strokes in the second or first character（ M and Z keys respectively）．The second decision indicated whether the article meant＇near＇$(\mathrm{M})$ or＇far＇$(\mathrm{K})$ ，as before．

## Results

Twenty native English and 28 native Chinese did not report relevant knowledge of the regularity in response to the first debriefing question（awareness rates $13 \%$ and $3 \%$ respectively）．One slow English unaware participant was excluded．

In both language groups，the reaction times across Control and Violation trials for unaware participants were not significantly different（see fig．2），indicating that implicit language learning in this domain does not occur for a linguistically unnatural，and non－ semantic，distinction．The next experiment examines whether learning occurs for any linguistically natural semantic distinction，regardless of whether it is reflected in the first language．

## Experiment 3

## Objective

To test whether a concept derived from the Chinese classifier system，which is not grammaticised in English，may be implicitly mapped onto articles by native speakers of English and Chinese．

## Participants

Twenty seven native speakers of English from the University of Cambridge and 32 native speakers of Chinese from the University of Hong Kong，with a varied second language background，participated in the study．

## Materials and Procedure

The learning target in this experiment is derived from a shape distinction in the Chinese classifier system． The Chinese classifier 張（zoengl in Cantonese）is generally used with thin flat objects（e．g．，sheets of paper，photos，blankets），and the counter 條（tiu4 in Cantonese）is generally used with long thin objects （e．g．，rivers，straws，ties）${ }^{3}$ ．Both classifiers frequently occur in daily usage．

The same design as the above experiments was adopted，except that the long／flat distinction became the hidden regularity governing article use in this experiment．The same article system was used with the two participant groups；nouns were presented in the first language of the participants．For example， one may find items such as gi shoelace and ro envelope in the English version，and their equivalents in the Chinese version（e．g．，gi 鞋帶 and ro 信封）．

[^333]The design and procedure were the same as in previous experiments except that here participants had to indicate，as their first decision，whether the noun referred to an object that was long（M key）or flat（Z key）．The second decision indicated whether the article meant＇near＇（M）or＇far＇（K），as before．

## Results

Twenty four native English and 26 native Chinese did not report relevant knowledge of the regularity in response to the first debriefing question（awareness rates $11 \%$ and $19 \%$ respectively）．One slow English and two slow Chinese unaware participants were excluded．A significant slowdown in Violation trials when compared with the Control trials was obtain among the unaware Chinese participants but not the unaware English participants（see fig．2），suggesting that implicit language learning is sensitive to prior linguistic knowledge．

## Discussion

One might imagine that in this paradigm participants merely learn associations between articles and patterns of keystrokes，e．g．，that＇gi＇is associated with the sequence M （living）－ M （near），or＇ne＇with Z（non－living）－K（far）．Control trials respect these patterns，but Violation trials break them，e．g．＇gi＇ would occur with the sequence Z （non－living）－ M （near）．However，if this were the case，then the nature of the categorization being performed on the noun should have made no difference whatsoever．The fact that it did suggests that the learning effects were due to learning associations between the articles and conceptual categories．

It is important to note that in all of the experiments the relevant＇hidden＇conceptual distinction had to be attended and computed in order to perform the task． But this did not guarantee that the association with the articles would be learned．Some equate statistical learning with IL（e．g．，Conway \＆Christiansen，2006）， but statistical computations should not be sensitive to the nature of the data（Perruchet \＆Pacton，2006）．

The finding that IL effects are sensitive to the nature of the concepts involved points to an interaction between the domain general learning mechanism and linguistic knowledge，which，according to many linguists，is domain specific．Semantic IL in natural language is constrained by the availability of conceptual distinctions to grammaticisation，which varies cross－linguistically．

Where no evidence of learning was obtained，it is possible that measurable learning would develop over
time. This is to say that linguistically unnatural or unfamiliar semantic categories may not be unlearnable. However, the variable amount of learning obtained after equivalent exposure shows that implicit language learning is sensitive to prior linguistic knowledge. The present study thus extends the existing literature and is congruent with studies which show that cross cultural processing biases also apply to unconscious knowledge (such as a preference for local versus global perspectives in Kiyokawa et al., 2012), and can help explain SLA studies which find L1 semantic structures in L2 processing (e.g., Jiang 2004).

We provide evidence that cross-linguistic influences may take place implicitly, and caution against a presumption that L1 transfer is based on hypothesis testing or learner strategy. It remains unclear to what degree such influences take place implicitly, or explicitly, or both implicitly and explicitly, in different SLA settings, and it seems likely that individual differences exist. A better understanding of the mechanism underlying cross-linguistic influences has obvious theoretical and pedagogical implications. Theoretically it sheds light on debates in language acquisition on domain specificity and linguistic universals; pedagogically it informs teaching/learning methodologies that aim to promote or discourage different kinds of influences.

But the kind of cross-linguistic influence that we have demonstrated may have gone beyond simple transfer. In our experiments, English participants were only sensitive to animacy - a fundamental conceptual distinction, even though it is only subtly marked in English, and there is no article-noun agreement. Chinese participants were sensitive to all semantic (but not non-semantic) distinctions, presumably through experience of their classifier system, but generalizing to novel distinctions.

Although many assume that first language acquisition is essentially implicit, it is only recently that research has shown possibilities of adult SLA taking place implicitly. Apart from further exploring the mechanisms of crosslinguistic influence, which are pertinent to SLA research, future research into implicit language learning may also inform IL research as to its nature and constraints.

## Reading Motor Intentions

Lewkowicz Daniel (daniel.lewkowicz@etu.univ-lille3.fr)<br>URECA laboratory, Univ Lille Nord de France, F-59000 Lille, France

#### Abstract

Some evidence in very recent psychological studies have demonstrated that motor simulation ability is crucial for the correct understanding of social intentions. The present study was conducted first to confirm that the nature of the motor intention leads to early modulations of movement kinematics. Then, we tested whether humans could read an agent's intention when observing the very first element of a complex action sequence. Results revealed early variations in movement kinematics and further showed that human agents can use these deviants to distinguish above chance level between three different social actions. Similar performance levels were found using an artificial classifier (Neural Network) and this procedure demonstrated furthermore that decisions could be taken on the basis of information contained in the first 500 ms of movement kinematics. Taken together these results confirm the importance of motor simulation for adapted social interaction, and suggest how robotic adaptive controllers may use as input low-level motor information (e.g. kinematics) to afford biologically inspired social behaviors.

Keywords: Classifier; kinematics; sequences; motor control; intentionality: social interaction; internal models; prediction; motor planning; biological movement.

## Introduction

In everyday activities, the grasping of an object might be performed with different prior intentions: e.g. touch, move, throw or pass. Ansuini et al. (2008) have measured the prior-to-contact grasping kinematics for reach-to-grasp movements performed toward a bottle filled with water. By comparing hand shaping across tasks involving different subsequent actions - pour the water into a container; throw the bottle; move the bottle from one spatial location to another - the authors demonstrated how the prior intention in grasping the object strongly affected the positioning of the fingers during the reaching and the contact phase of the action (Ansuini, Giosa, Turella, Altoè, \& Castiello, 2008). In another series of studies, Becchio and collaborators investigated the effects of social context on reach-to-grasp actions. They found initial adjustments reflecting specific planning strategies (Becchio, Sartori, Bulgheroni, \& Castiello, 2008a) as well as online adjustments (Sartori, Becchio, Bulgheroni, \& Castiello, 2009) when performing under social context (see : Becchio et al., 2010 for a review).

More recently, researchers have gone one step further to suggest that not only end-point constraints and social
contexts affect movement kinematics, but that these deviants may be used to read motor intention. For example, when observing actions performed under social context or not, Castiello and collaborators demonstrated that humans can successfully use kinematic cues of reach-to-grasp movements to predict the final goal of the action (Sartori, Becchio, \& Castiello, 2011). Similar results were also found using point-light displays of simple reach to grasp movements (Manera, Becchio, Cavallo, Sartori, \& Castiello, 2011). However, in these studies, the classification rates were obtained under a forced two-choice paradigm, and for the most subtle differences (cooperative vs individual preferred speed or competitive vs fast speed) the classification rates were very small (near 50\%).

In the present work, we wanted to study the capacity of humans to read motor intention in a sequence of 2 motor elements. One novelty of this study is that the sequences were performed entirely during an interactive situation with a con-specific, without any interruption or verbal instruction between the sequences. As such, we recorded sequential actions during an ecologically inspired task (Jungle Speed), a simple face-to-face game using a unique manipulated object. Our main focus was to compare human and artificial categorization performances for three different sequential actions that took part during the game. To test the hypothesis that kinematics alone is sufficient to read social intention, we fed the artificial classifier with movement kinematics only.

Confronting Jacob \& Jeannerod's (2005) reading motor intention hypothesis, we hypothesized that human agents are able to read motor intention through the simple observation of arm kinematics of the first element of a 2-sequence action. This is possible due to the fact that arm kinematics of the reach to grasp movements reveal specific deviants in function of goal intention from an ideal optimized trajectory. Finally, if motor simulation is sufficient, then an artificial neural network should be able to learn from the deviants and predict as well as humans, the motor intention of an observed agent. In the following section, we first describe the methods we used to make the observation videos (Part A), which were then played to human agents (Part B) and used as input parameters to an artificial neural network (Part C).

## Creating Stimuli

Two adults participated in the study, one experimenter and the other as subject. Both participants were right handed
as verified with the Handedness questionnaire (Oldfield, 1971). They had no prior knowledge of the experiment and provided informed consent before participating in the experimental session that lasted approximately 90 minutes. The subjects' movements were recorded using a (1) a video camera (Sony Handycam) and (2) 4 Oqus infrared cameras (Qualysis). 5 infrared reflective markers were placed on the thumb (tip), index (base and tip) and the wrist (scaphoïd and pisiform). Cameras were calibrated before each session, allowing the system to reach a standard deviation smaller than 0.2 mm , with a 200 Hz sampling rate

Figure 1. Schematic representation of the experimental setup.
The game. The object that was to be manipulated by the subject was a wooden dowel of width 2 cm and height of 4 cm that was placed precisely 20 cm in front of the starting position ('pick' position). The subject started each trial by pinching index and thumb together at the starting position (see Figure 1). Each trial, the subject's task was to reach and grasp the dowel between thumb and index finger in order to move it from the initial position to one of the three 'place' positions during an adapted version of the jungle-speed game. The game consisted in 4 blocks of approximately 40 rounds. First, the subject's task was to pick and place the dowel at the 'Play' position in order to set the initial condition of the game. Then, at the 'go' signal (high pitch) both participants reached for the dowel as quickly as possible. The competitive move was not recorded and is not part of this study, although, this was indeed intentionally omitted during instructions given to the subject. During competitive move, the first who have grasped the dowel, won the round and scored a point. The second phase consisted in a rewarding phase. The dowel was first always repositioned at pick position and the subject wait at starting position for the next audio tone (low pitch). During the rewarding phase just after the competitive move, the subject has to reach to grasp the dowel and place it either at the 'You' position if the experimenter scored during competitive move, or at the 'Me' Position if the participant scored during competitive move. The game went on until one of the two players reached 20 points. Thus, we recorded twice as much 'Play' moves than 'You' or 'Me' moves during the game. Nonetheless, after 5 rounds of training to
set up the game rules, no other verbal instructions were given during the blocks. The three different positions ('Play'; 'Me'; 'You') where the dowel had to be placed were delimited by visual marks directly placed on the tabletop.

The recordings. The best 16 recordings of each category ('Play', 'Me' and 'You') were extracted using VirtualDub and kept for future use as stimuli. Each sequence was delimited with a 1 -second pre-trial, i.e., before the initial movement onset, and was cut exactly one frame before the index finger contacted the object. Movies were compressed with FFdshow codec (MJPEG) at 50 frames per seconds with a screen resolution of $720 \times 576$. Video clips were coupled with the recordings of the arm kinematics using 4 Oqus infrared Cameras (Qualisys). Infrared reflective markers were placed on the index (base and tip), the thumb (tip), the wrist (scaphoïd and pisiform) of each participant, as well as on the object. Cameras were calibrated before each recording session, allowing the system to reach a standard deviation smaller than 0.2 mm for all three absolute positions at a 200 Hz sampling frequency. Care was taken as to provide no contextual information within the video clips (torso, gaze, face expression), i.e., only the hand and the target object were fully in view. Velocity profiles are presented in Figure 2 and show that play, me or you sequences show deviations during both first and second motor element (amplitude and the width of the bell-shaped curves, first and second peaks of velocity, time position for local minima).

Figure 2. Mean velocity profiles for the three categories of sequences. Each bell-shape curve corresponds to a motor element. The first is the reach to grasp element, and the second bell-shape curve is placing element. The local minima are used to segment the two motor elements and compute movement times.

## Human Categorization Performance

The short video clips were presented to a panel of human subjects to test whether human agents were able to predict
the goal of a sequential action when shown only the first sub-element of a sequence, i.e., the reach movement.

Participants, Apparatus and Software. Twenty-six young adults (mean age: $21.82 \pm 2.76$ years, range $=18-29$ years) participated in the study. All subjects were right handed (Oldfield, 1971) and had no prior knowledge of the experiment. Subjects provided informed consent before participating in the experimental session that lasted approximately 45 minutes. Participants were seated comfortably facing a table in a dark and silent room. For each trial, participants started by placing their hand on response keys that were delimited by tape placed directly on the keyboard keys. Stimuli were presented on a laptop computer with MATLAB software (Mathworks) with the PsychToolbox environment.

Experimental Procedure. The participants' task was to answer on the keypad after each video clip presentation whether the social intention of the sequence was 'let's Play' (5 key), 'for Me' (2 key) or 'for You' (8 key). A 1-second blank screen was displayed in between two trials. Participants were instructed to give their answers as fast and as accurately as possible. They were obliged to provide an answer within a 4-second time window otherwise the trial was cancelled and presented at the end of the block. A feedback message was given to tell participants if their response was too slow. Each block consisted in the random presentation of a series of 48 stimuli, i.e., 16 different video clips for each of the three categories (Play; Me; You). After a 5-minute pause, the next block of 48 video clips was presented.

Dependent variables and statistical analyses. The number of correct responses (correct prediction of the ongoing action) and the response times were calculated for each category. The dependent measures were submitted to a repeated-measure ANOVA with Block and Category (Play; Me; You) as within factors. The participants' scores for each category were compared using a Chi-square between the observed scores and the random distribution between categories corrected by total the number of answer of that category. In other term, because the total amount of answer is not exactly the same between categories, we consider the guessing base-rate of each category separately. The alpha level of significance was set to 0.05 .

Response times. Results showed no effect of Block on response time, $\mathrm{F}(2,50)=1.401, \mathrm{p}=.256$, indicating that participants answered with a similar response time in the first ( $\mathrm{M}=878$, $\mathrm{SD}=382 \mathrm{~ms}$ ), the second $(\mathrm{M}=$ $848, S D=315 \mathrm{~ms})$, and in the third block $(\mathrm{M}=944, \mathrm{SD}=$ 316 ms ). No effects of Category were found on response time, $\mathrm{F}(2,50)=2.621, \mathrm{p}=.083$, indicating that participants answered within the same delay both for 'Play' ( $\mathrm{M}=900$, SD $=294 \mathrm{~ms})$, 'Me' $(\mathrm{M}=866, \mathrm{SD}=294 \mathrm{~ms})$, and 'You' categories ( $\mathrm{M}=905$, $\mathrm{SD}=300 \mathrm{~ms}$ ).

Number of correct responses. There was an absence of Block effect on classification performances, $\mathrm{F}(2,50)=$ $0.102, p=.903$. However, a main effect of Category was obtained, $\mathrm{F}(2,50)=16.022, \mathrm{p}<.001, \eta_{\mathrm{p}}^{2}=.39$. Post-hoc Scheffé analyses further showed that participants were more accurate for trials in the 'Me' category ( $\mathrm{M}=57.53$, $\mathrm{SD}=$ 13.02 \%) than in the 'You' ( $\mathrm{M}=40.87, \mathrm{SD}=12.12 \%)$ and in the 'Play' category ( $\mathrm{M}=47.27, \mathrm{SD}=13.04 \%$ ). More importantly, Chi-squared tests showed highly significant difference between observed frequencies and random guessing baselines for the 'Me' (guess rate $=36.98$, $\mathrm{p}<.001$ ), 'Play' (guess rate $=36.12, \mathrm{p}<.001$ ) or 'You' (guess rate $=26.90, \mathrm{p}<.001$ ). These results confirmed that performance was significantly greater than chance level.

## Categorization with Artificial Neural Networks

In the following section, we present the simple feedforward neural network that was developed to demonstrate the possibility to categorize on the only basis of motor kinematics.

Architecture and Learning procedure. A simple classification Neural Network was constructed with N neurons (1-23 neurons) as inputs, 3 hidden layers and 3 output neurons (one for each category). The N size is the sub-selection of the total movement duration. Activation functions for the output layers were symmetrical and sigmoid, between -1 and 1 .

With this NN, the instantaneous velocity in 3D was calculated between the recorded positions of the wrist for two subsequent frames. A threshold of $20 \mathrm{~mm} . \mathrm{s}^{-1}$ was then determined to compute the reaction time (RT) delay between the start of the recording and the actual beginning of the movement. Second, a sampling parameter was used to compute the average velocity across 10 frames. Third, the mean velocity values were converted from $\mathrm{mm} . \mathrm{s}^{-1}$ to $\mathrm{m} . \mathrm{s}^{-1}$ in order to get data within an overall range of 0 to 1 . Finally, a training set (25\%) and a test set (75\%) were randomly picked from the 144 different kinematic recordings. 20 different networks were trained to obtain the classification performance for every specific target time widow (i.e. time window for kinematic recognition). The mean response and variance across the 20 networks are described in the result section as the NN success rate (this value is always lower than the best performing network). By varying the amount of data fed as input, we computed the classification performance from multiple time windows. The learning procedure was a back-propagation algorithm using the FANN library (Nissen, 2003). Target error (to stop the learning) was set to MeanStandardError < 0.001 with a maximum number of epochs set to 10000 , and 300 iterations between each test (evaluation of target global error.

Classification results in function of time. Results revealed that the simple artificial classifier was able to converge in most cases. The classifier succeeded in
discriminating between categories for input sizes above 9, i.e. with a time window of 450 ms . For the input size of 9 , single sample $t$-tests confirmed that all categories were above chance level, $\mathrm{p}<.001$ : 'Play' ( $\mathrm{M}=55.70 \mathrm{SD}=8.08$ \%); 'Me' category ( $\mathrm{M}=56.70 \mathrm{SD}=4.16 \%$ ), and 'You' category ( $\mathrm{M}=50.33 \mathrm{SD}=5.63 \%$ ). Figure 3 presents the detailed results for 12 different input sizes, between 50 ms to 1150 ms with a step of 100 ms . From the input size of 5 ( 250 ms ) to 9 ( 450 ms ), only 2 categories were successfully recognized while the other remained below chance level; Below 250 ms , only one category was correctly classified. The crucial point to note here is nevertheless the fact that by 450 ms all categories are classified above chance level; a point in time that occurs before the end of the first subelement of movement sequence confirming the capacity of a simple network to predict motor intention by the use of lowlevel kinematics early on during motor execution.

Artificial Neural Network (Classifier)

Figure 3. Results obtained with the ANN. Note that with an input size of 450 ms , most of the networks classify the movements with a higher rate than chance level and before the end of the first motor element (vertical grey bar).

## Discussion

In the present contribution, we report experimental data confirming that motor intention can be read through the simple observation of movement kinematics. More specifically, we first showed that the three different motor intentions that were used in a simplified version of the Jungle Speed game (Asmodee eds.) modified the kinematics of the first (reach) sub-element of the sequential action. Second, human agents were able to classify rapidly ( $<1$ s) and above chance level ( $>40 \%$ ), the trial category when observing a video-clip of the reaching movement only of the sequence. Third, a classic feedforward neural network was also able to categorize motor intention through the use of low-level kinematic information of, once again, the reaching sub-element only. In the following section, we discuss these findings in more detail and describe how this work can help
advance the development of future cybernetic systems that will afford true human-robot interactivity.

Kinematics reflecting motor intention. In the abundant literature of manipulating actions, the effects of end-point constraints on the early parts of movement kinematics have been investigated extensively in experimental psychology. In individualistic situations, multiple sources have been reported to modify and shape hand trajectory in two-element sequences such as second-target distance (Gentilucci, Negrotti, \& Gangitano, 1997), end-target orientation (Haggard, 1998; Hesse \& Deubel, 2010) or second-action type (Armbrüster \& Spijkers, 2006; Marteniuk, MacKenzie, Jeannerod, Athenes, \& Dugas, 1987). In social interactive manipulative tasks, final-goals have also been reported as having an effect on reach-to-grasp kinematics such as giving vs. placing an object (Becchio et al., 2008a), cooperative vs. competitive actions (Becchio, Sartori, Bulgheroni, \& Castiello, 2008b; Georgiou, Becchio, Glover, \& Castiello, 2007), absence vs. presence of social request (Ferri, Campione, Dalla Volta, Gianelli, \& Gentilucci, 2011), verbal communicative vs. non-communicative intentions (Sartori, Becchio, Bara, \& Castiello, 2009). The kinematic effects reported here are consistent with this literature and suggest that when planning a sequential action with multiple sub-elements, the requirements of the endpoint element are back-propagated to constrain the way the very first element of the sequence will be planned and performed. Thus, it is possible to suggest that low-level motor components may contain early indices that reflect the end-point motor intention of an agent.

Reading intentions. In the present study, the first part of each movement was identical, i.e., the agents initiated their move with their hand placed on the starting pad of the playing area, and reached for and grasped the wooden-peg that was always at the same position on the table. However, the second part of the move was specific and directly related to the game intention: lift the wooden peg to take it ('Me' category), to give it ('You' category) or to place it on the table ('Play' category). Thus, any kinematic deviants observed on the first part of the sequence may be related to the social intention of the second part. By measuring two basic motor parameters (peak velocity and movement duration), we showed that it was possible to dissociate the three types of social interaction categories (Figure 2). We then tested the fact that human observers could use these deviants to classify observed actions above chance level. The video clips were created in order to show the first subelement only, without any contextual cues; care was also taken to cut the end of the reaching action, one frame before object contact, in order to avoid providing any cues on movement direction of the second part of the sequence. Our findings demonstrate that classification is possible and that in certain cases, the participants' performance can be extremely precise (up to $67 \%$ of correct classification for the best of participants). But how is this possible?

An alternative low-level hypothesis. It is nevertheless possible that the understanding of motor intention is based on more low-level cue readings. As suggested by the work of Perrett and al. (Perrett et al., 1989), the visual system definitely contribute to action recognition and the performance showed by humans could be interpreted as the resolution of an "inverse" problem (goal attribution) with a simple bayesian inference about which goal explain the best which action (Csibra, 2008). Indeed, despite a total absence of contextual cues within the video clips (body, head, eyes), we demonstrated in the present study that participants were able to read motor intention significantly above chance level. Hence, the subjects' responses could be guided by the slight deviances from the optimal strategy (i.e. to grasp without any subsequent action) in the low-level motor kinematics. This confirms recent results presented by Stapel et al. (2012) who showed that in absence of contextual cues, kinematics could be a key source of information to predict intentions of ongoing actions. To go further in this low-level hypothesis, we conducted a second work for which we used a very simple artificial neural network classifier and we showed that this simple classifier performed as well as our human subjects in categorizing the three different socialintended video-clips. Further studies, namely brain imaging, are needed in order to determine whether the good performance reached in our human individuals was due to direct coding of the low-level kinematic parameters or whether the kinematics deviants are simple by products and that even for simple actions, human performances engage in a cognitive motor simulation to read motor intention (see e.g. Kilner, Friston, \& Frith, 2007; Kilner \& Frith, 2008).

It is to note that correct classification of the three social categories was far from being perfect, reaching in the best of cases $60 \%$ of correct identification. Hence, kinematics can be used for predicting ongoing actions but cannot be the only source, used by human agents to judge motor intention. It has been shown that during natural sequential task (i.e. preparing a sandwich), eye movements are stereotyped and predictive (Hayhoe, Shrivastava, Mruczek, \& Pelz, 2003). During the task, the eye precedes the hand movements in systematic way ensuring a good coding of object position for accurate planning of arm (Johansson, Westling, Bäckström, \& Flanagan, 2001). This coordination between eye and hand movements during manipulative tasks have extensively been tested in experimental psychology and have demonstrated that e.g., eye movement onset is always faster than hand movement onset, and the peak velocity of both eye and hand movements are strongly correlated, suggesting that they possess a coupled function. It is thus possible that using both gaze position and the hand movements kinematics, an observer would be able to increase the efficiency of intention reading (see also : (Bekkering \& Neggers, 2002).

## Perspectives for interactive and social robotics.

The application of our work would be to develop
robots that afford true interaction, i.e., being able (1) to read motor intention in human kinematics in order to adapt but also (2) to move with biological realistic kinematics, in order allow others to understand the intention of the robot. Following the data presented here, we hypothesize that a humanoid robot could become interactive if it moved following the laws of biological movement with action sequences that integrate back propagation of terminal intention. Such a phenomenon would provide the means for human agents to read intentionality and thus, gain in understanding the goal of the robot's movements. Furthermore, including social deviants in the motor kinematics within early steps of motor sequences would also allow safe interaction with large industrial robots by affording humans the possibility of anticipating false moves in joint actions that share similar work spaces.

Implementing robots with the architecture necessary to "afford intentionality" would need to integrate the different brain regions that are known to play a role in motor planning and motor-sensory predictive mapping. De Rengervé et collaborators (de Rengervé, Hirel, Andry, Quoy, \& Gaussier, 2011) have recently reported on such an architecture, which included amongst other areas, the cerebellum and the basal ganglia. Tested on both software and hardware, this neural architecture has demonstrated its efficiency on data collected in a hydraulic robotic arm. With a series of imitation trials, this system demonstrated the capacity to learn how to perform sequential actions that respected biological laws, i.e., to perform movements with kinematics that mirror those performed by human agents. As such, this robot arm has demonstrated increased interactivity with human agents affording augmented interaction both in time and in space (none published results). Ongoing studies are now being conducted to assess whether this interactivity is associated to an increase in the capacity of human collaborators to read the robot's intention.

## Conclusion

We have here described experimental findings in humans demonstrating that it is possible to read motor intention through the simple observation of kinematic deviants. Classification capacities were significantly above chance level and provided human subjects the means to dissociate between three different socially oriented actions. We argue in the present study that reading intentionality may not depend on a high-level cognitive function as suggested in the psychological literature. Internal simulations may not be systematically required and understanding other intentions may in certain cases relate to a direct coding of those kinematic deviants that back propagate from end-point to early on during sequence execution; this direct coding would emerge through years of joint-action experiences, during interactions with adult con-specifics. As a first step to support this hypothesis, we report in the present study simple neural networks that were able, after learning the meaning of kinematic deviants, to classify the three categories of actions to the same degree of accuracy than
our human participants. These preliminary results stresses the importance of further developing the optimal theories of motor control in order to include the effects on sequential actions such as, back propagation phenomena of social context.

# The Influence of Collective Opinion on True-False Judgment and Information-Sharing Decision 

Huaye Li (hli21@stevens.edu)<br>Yasuaki Sakamoto (ysakamot@stevens.edu)<br>Howe School of Technology Management, Stevens Institute of Technology<br>Hoboken, NJ 07030 USA

#### Abstract

The purpose of the current work is to examine when and how knowing collective opinion influences people's judgments and decisions in social media environments. In particular, the present work focuses on people's true-false judgment of statements found on websites and the likelihood of sharing these statements. The results from Experiment 1 revealed that, for false statements, collective opinion had little influence on people's true-false judgments, but, for true and debatable statements, their judgments were biased toward collective opinion. The results from Experiment 2 indicated that the likelihood of sharing the true, debatable, and false statements followed the collective opinion, and that people were less likely to share false statements than debatable or true ones without collective opinion. These findings extend past work on social influence and advance understanding of how people make judgments and decisions in social media websites.

Keywords: Collective opinion, true-false judgment, information-sharing decision, social media, social influence

## Introduction

Social media technologies, such as Twitter and Facebook, have become part of many people's everyday lives. Using these technologies, people not only acquire new information but also generate content and influence trends. Given the growing use and participatory nature of social media, better understanding of how people behave in such an environment is essential.

The objective of the current paper is to contribute to this need by reporting the results from two experiments that examine how people make true-false judgments on statements found on websites and how they make decisions about whether or not to share these statements in a social media environment. In the current work, sharing of a statement means passing of the statement to others. In particular, the work presented here focuses on how social influence plays a role in people's true-false judgments and sharing decisions in a social media context.

## Collective Opinion

One of the main functions of social media is to share opinions with others and collectively make decisions (e.g., Glushko et al., 2008). Collective opinion, such as how many people have liked or shared a message, is part of social media technologies. In Twitter, an example of collective opinion is the number of re-tweets, or the number of people
who re-tweeted a particular message. Re-tweeting is a kind of sharing, in which an original tweet, a brief message of 140 characters or less, is broadcast to the re-tweeter's followers through a simple clicking of a re-tweet button. The re-tweeted messages become available to the public as well, and the number of re-tweets associated with a tweet signifies the popularity of the tweet. The more ret-tweets, the more popular. Facebook uses 'like' to indicate the popularity of photos, stories, communities, and so on. Many review websites allow users to indicate their opinion about the usefulness of a particular review.

Despite the abundance of collective opinion in social media websites, when and how it affects people's judgments and decisions in such an environment is not well understood. However, there are classic studies on social influence in face-to-face environments, and more recent work on social influence in online environments, whose findings indicate that people use collective opinion to make their judgments and decisions in various situations.

## Social Influence

Past research in face-to-face environments has shown that people have a strong motivation to compare their opinions with others (Festinger, 1954), and they often adopt the decisions of others (e.g., Cialdini \& Goldstein, 2004; Deutsch \& Gerard, 1995; Gureckis \& Goldstone, 2006) due to their desire to make correct responses under uncertainty (Sherif, 1935) or their desire to be liked by others (Asch, 1955). By relying on others' opinions, individuals can learn and entertain solutions that they would not have even considered otherwise (Bandura, 1965).

More recent work has shown that knowing other's decisions also influences people's decisions in online environments. In an online market experiment, whereas good music was always downloaded by many and bad music was always unpopular, the popularities of the pieces in between varied depending on whether or not people knew the number of downloads the pieces had (Salganik, Dodds, \& Watts, 2006). In another set of online experiments, subjects liked the same online news stories more when the stories had many existing supporters than when the stories had only a few supporters (Sakamoto et al., 2009). Subjects even switched their preferences when the experimenter flipped the assumed numbers of previous supporters (Sakamoto, 2010; Salganik \& Watts, 2008). These past studies on social influence suggest that people's liking and rating can follow collective opinion in social media
environments. The current research extends this past work on social influence to true-false judgments and sharing decisions in a social media environment.

## Hypotheses

Social influence may be especially strong in social media environments, as people experience a lot of information whose factual accuracy is unclear, and they rely on collective opinion in an attempt to reduce uncertainty. During crises, for example, uncertainty is high and people are under pressure mentally. People generate a large amount of information in an attempt to make sense of the situation, and they readily share this information without verifying its factual accuracy, resulting in the dissemination of false rumors (e.g., Allport \& Postman, 1947; DiFonzo \& Bordia, 2007). Consequently, a large amount of debatable information appears during responses to disasters.

In relation to debatable information, one focus of the current work is to examine how collective opinion influences people's judgment about whether a statement is true, false, or debatable. The statements used in the current research were related to health advice. A statement is true when the advice in the statement is supported by clear evidence according to health professionals. A statement is false when it contains information identified as incorrect by health professionals. A statement is debatable when health professionals cannot verify its factual accuracy because evidence is mixed or missing. The first hypothesis is that the true-false judgment of debatable statements will be most prone to social influence because their factual accuracy is unclear; people will adopt collective opinion in an attempt to make a correct decision when they encounter debatable statements. In contrast, people's perceptions of true and false statements are relatively strong and hard to change, just as good and poor pieces of music were immune to social influence in Salganik et al.'s (2006) research.

Another focus of the present work is to examine how collective opinion influences people's intention to share a statement differently depending on whether the statement is true, debatable, or false. Because it is unlikely that people strongly feel that they should or should not share the healthrelated statements used in the present work, they will rely on collective opinion to make their decision. The second hypothesis is that social influence takes place for true, debatable, and false statements; people's decision will follow the collective opinion. If this is the case, there will be a positive social influence, in which increasing the value of collective opinion increases the likelihood of sharing.

An alternative account is that people want to share information that others have not shared. There is evidence in consumer research that some people want to be unique and differentiate themselves from others (Berger \& Heath 2007; Snyder \& Fromkin 1980; Tian, Bearden, \& Hunter 2001). According to this view, in deciding whether or not to share a statement in social media, people will go against the information about the number of people who already shared the statement. This leads to a negative social influence.

It is unclear whether positive or negative social influence takes place in information sharing decisions. In the information transmission literature, researchers focus mainly on how factors such as valence and source credibility relate to the spread of information (e.g., Fragale \& Heath 2004; Ha \& Ahn 2011; Heath 1996; Rene et al. 2012). Those who study social dimensions tend to examine how social network structures, including the number of followers and position in the social network, affect information diffusion (e.g., Cha et al. 2010; Huberman et al. 2009; Kwak et al. 2010; Xin et al. 2012) and how to maximize the spread of influence through online social networks and the extent to which one could predict online popularity (Kempe, Kleinberg and Tardos, 2003; Kim, Kim \& Cho, 2011). Social influences on sharing decisions are not well studied.

Another important question the current work can address is whether people are more likely to share true, debatable, or false information, without knowing collective opinion. Although this question does not involve the main topic of social influence, the answer will be useful. Here, we borrow an idea from the rumor psychology literature. The third hypothesis is that debatable statements result in a higher likelihood of sharing than false and true statements because debatable statements will induce informational ambiguity and anxiety by being disputable. Ambiguity and anxiety are proposed to be strong predictors of rumor spread (Anthony 1973; Shibutani 1966).

## Experiment 1

The main purpose of Experiment 1 is to examine how collective opinion influences people's judgment about whether a statement is true, false, or debatable.

## Method

Participants In return for a nominal fee, 227 workers of Amazon's Mechanical Turk (https://www.mturk.com) completed the experiment. The mean age was 36 . Using Mechanical Turk, a few research groups have replicated classic psychological phenomena and have shown that researchers can collect high-quality data (e.g., Buhrmester, Kwang, \& Gosling, 2011; Mason \& Suri, 2011; Paolacci, Chandler, \& Ipeirotis, 2010). We followed their recommendations.
Materials From Discovery, Food Networks and National Institute of Health (NIH), 120 statements about health advice were selected with two constrains: each statement was clearly identified by health professionals as true, debatable, or false, and the information carried by each statement was familiar to most people. Of 120 statements, 40 were true, 40 were debatable, and 40 were false.
Design and Procedure Subjects were instructed to read a health-related statement online, and to rate the extent to which the statement was true using a 7 -point scale, where 1 was definitely false and 7 was definitely true. A response
around the middle of the scale indicated debatable. The 120 statements were presented sequentially in a random order.

There were three conditions.

1. Control: Statements were presented with no social information. Fifty unique subjects rated each statement. Figure 1 shows an example of the actual screen used in the control condition.
2. Real: Each statement was presented with real collective opinion, which was the mode of the 50 ratings from the control condition. We used the mode because it preserved extreme ratings. With mean and median, the ratings tended to go toward the middle of the scale. Figure 2 shows an example.
3. Invented: Each statement was presented with invented collective opinion. We transformed the observed mode as follows: $1 \rightarrow$ (became) $7,2 \rightarrow 6,3 \rightarrow 5,4 \rightarrow 7$ if the mean was smaller than $4,4 \rightarrow 1$ if the mean was larger than $4,5 \rightarrow 3,6 \rightarrow 2$, and $7 \rightarrow 1$. Figure 3 shows an example.
```
Background: People are bombarded with more informaton than they can process in social media, such as Twitter and Facebook. Although people can find a lot of useful information in social media, they also encounter a significant amount of unverified information. Please help us improve social media environments. Your responses are valuable!
Question A: Does the statement below contain the word fiber? Yes No
Oatmeal contains soluble fiber, which rectuces your low.density lipoprotein
LDL), the "bad" cholesterol.
Question B: Imagine that you are reading the statement above in social media, such as Twitter and Facebook. To what extent do you think this statement is true or false? 1234567
definitely false \(\circ \circ \rho \circ \circ \circ \circ\) definitely true

\section*{Results and Discussion}

All participants were included in the analyses. The main interest of Experiment 1 was whether and how collective opinion might influence people's true-false judgments. Figure 4 shows the overall pattern of the results.

A 3 (statement: true, false, debatable) by 3 (condition: control, real, invented) analysis of variance (ANOVA), with true-false ratings as a dependent measure, revealed a significant main effect of statement, \(F(2,117)=33.95, p<\) .001. Collapsing across condition, the true-false ratings for true (5.05), debatable (4.72), and false statements (3.62) differed significantly. There was also a significant main effect of condition, \(F(2,396)=26.65, p<.001\). Collapsing across different types of statements, the true-false ratings in the control (4.97), real (5.53), and fake conditions (4.64) conditions differed significantly, indicating that there might be some sort of social influence. The statement by condition interaction was significant, \(F(2,234)=11.28, p<.001\), indicating that the pattern of social influence differed depending on the statement type.

Given the significant interaction between statement and condition, we further analyzed social influence within each statement type using a one-way ANOVA with condition as independent variable and true-false ratings as a dependent measure. Within true and debatable statements, the control, real, and invented conditions differed significantly in the true-false ratings, \(F(2,117)=18.29, p<.001\), and \(F(2,117)\) \(=5.601, p<.001\), respectively. However, within false statements, there was no significant difference across the three conditions, \(F<1\).

Experiment 1 tested the first hypothesis that the true-false judgment of debatable statements would be most prone to social influence. This hypothesis was partially supported. Although, as predicted, people adopted the collective opinion when making true-false judgments for debatable statements, the judgments of true statements resulted in the same pattern. As predicted, there was little social influence for the true-false judgments for false statements. As figure 4 shows, for true and debatable statements, the ratings increased in the real condition and decreased in the inverted
condition relative to the ratings in the control condition, indicating a positive social influence. The true-false judgments followed the collective opinion for true and debatable statements.

Figure 4. Results of Experiment 1 are shown. Error bars represent \(95 \%\) confidence intervals.

\section*{Experiment 2}

The focus of Experiment 1 was on the effect of collective opinion on people's true-false judgments. The main purpose of Experiment 2 is to examine how collective opinion affects people's likelihood of sharing information in a social media environment. The results from Experiment 2 will also address the question of whether people are more likely to share true, debatable, or false information, without knowing collective opinion.

\section*{Method}

Participants In Experiment 2, 220 workers of Amazon's Mechanical Turk completed the experiment for a nominal fee. Their mean age was 28 .
Materials The same as Experiment 1.
Design and Procedure The same as Experiment 1 except that, in Experiment 2, the question asked how likely it is that subjects will share the information, and the collective opinion indicated information regarding collective likelihood. Figures 5, 6, and 7 show an example of the screen presented to the subjects in Experiment 2's control, real, or invented condition, respectively.

Background: People are bombarded with more information than they can process in social media, such as Twitter and Facebook. Although people can find a lot of useful information in social media, they also encounter a significant amount of unverified information. Please help us improve social media environments. Your responses are valuable!

density lipoprotein (LDL), the "bad" cholesterol.
Question B: Imagine that you are reading the statement above in social media, such as Twitter and Facebook. How likely is it that you will share this information? Likelihood of sharing by majory of others like you: 3

Figure 7. Example of Experiment 2's invented condition

\section*{Results and Discussion}

All participants were included in the analyses. The main interest of Experiment 2 was whether and how collective opinion might influence people's sharing decisions. Figure 8 shows the overall pattern of the results in Experiment 2.

A 3 (statement: true, false, debatable) by 3 (condition: control, real, invented) ANOVA, with people's likelihood of sharing as a dependent measure revealed a significant main effect of statement, \(F(2,117)=12.99, p<.001\). Collapsing across condition, the likelihood of sharing true (4.27), debatable (4.39), and false statements (3.96) differed significantly. There was also a significant main effect of condition, \(F(2,396)=10.55, p<.001\). Collapsing across statement, the likelihood of sharing in the control (4.29), real (4.46), and invented conditions (3.87) differed significantly, indicating the presence of social influence. Moreover, there was a significant statement by condition interaction, \(F(2,234)=11.16, p<.000\). The pattern of social influence differed depending on the type of statement.

We analyzed social influence within each type of statement using a one-way ANOVA with condition as independent variable and the likelihood of sharing as a dependent measure. Within true, debatable, and false statements, the control, real, and invented conditions differed significantly in the likelihood of sharing, \(F(2,156)\) \(=13.92, p<.001\), and \(F(2,156)=10.58, p<.001\), and \(F(2\), \(156)=4.399, p=0.005\), respectively.

The results from Experiment 2 show that collective opinion affects people's likelihood of sharing information, and support the hypothesis that a positive social influence takes place for true, debatable, and false statements. In Experiment 2, people's intention to share information followed the collective opinion. In addition, Experiment 2's results partially supported the third hypothesis that debatable statements would result in a higher likelihood of sharing than false and true statements. Although people were more likely to share debatable statements than false statements in the control condition, the likelihood of sharing debatable and true statements did not differ significantly, as can be seen in Figure 8.

Figure 8. Results of Experiment 2 are shown. Error bars represent \(95 \%\) confidence intervals.

\section*{General Discussion and Implication}

In the current paper, we reported results from two experiments that examined how collective opinion might influence people's true-false judgments and information sharing decisions. In Experiment 1, we found that, for false statements, collective opinion had little influence on people's true-false judgments, but, for true and debatable statements, their judgments were biased toward collective opinion. In Experiment 2, we learned that the likelihood of sharing the true, debatable, and false statements followed the collective opinion, and that people were less likely to
share false statements than debatable or true ones without collective opinion. The current results reveal that whether or not people adopt collective opinion in social media contexts depends on the type of judgment they make and the type of information they evaluate.

In the real social media environments, collective opinion is updated constantly. Future research may examine several iterations of the current experiments, in which collective opinion is updated after each run based on the ratings of the previous run. By doing so, we can study the evolution of people's ratings and collective opinion. Do the ratings converge or diverge after several iterations? The ratings might diverge when using mode as collective opinion as in the current work, but they might converge when collective opinion takes the form of median or mean.

Another characteristic of social media is that there are diverse kinds of information. The focus in the current work was information related to health advice. Future work should extend the current findings to other kinds of statements. We are currently examining the role collective opinion plays in sharing information related to natural disasters, such as Hurricane Sandy in 2012 and the Great East Japan Earthquake in 2011.

Finally, although we used rating scales in the current work, people's information sharing decisions in social media environments are binary. For example, there is a retweet button in Twitter. One extension of the current work might be to measure actual behavior by creating a 'share' button that sends a message to an associated email account when pressed. We can create a button and a Gmail account for each condition in an experiment, and ask subjects to click the button if they want to share the message. Although the measure of intent using a rating scale can provide us information about the strength of intent, it may or may not translate to actual behavior. When stimuli are tweets, one can examine whether or not there is a positive correlation between the likelihood of sharing and the actual re-tweeting number in Twitter. On the other hand, clicking of a share button cannot capture information about how much people want to share.

In conclusion, better understanding of how people make judgment and decision in social media contexts is important. People use social media technologies to share information everyday, even during responses to disasters. More research along this line can help the development of a set of recommendations for enhancing people's social media literacy and for improving the design of socialcomputational systems to improve the quality of information in social media, and more generally, to increase the productivity and wellbeing of our society. We hope that the present work can stimulate further investigation of social influence in social media environments.

\begin{abstract}
Neural correlate of human inductive reasoning process is still unclear. Number series and letter series completion are two typical inductive reasoning tasks, and with common core component of rule induction. Previous studies have demonstrated that different strategies are adopted in number series and letter series completion tasks even the underlying rules are identical. In the present study, we examined cortical activation as a function of two different reasoning strategies for solving series completion tasks. The retrieval strategy, used in number series completion tasks, involves direct retrieving of arithmetic knowledge to get the relations between items. The procedural strategy, used in letter series completion tasks, requires counting a certain number of times to detect the relations linking two items. The two strategies require essentially the equivalent cognitive processes, but have different working memory demands (the procedural strategy incurs greater demands). The procedural strategy produced significant greater activity in areas involved in memory retrieval (dorsolateral prefrontal cortex, DLPFC) and mental representation/maintenance (posterior parietal cortex, PPC). An ACT-R model of the tasks successfully predicted behavioral performance and BOLD responses in DLPFC and PPC. The present findings support a general-purpose dualprocess theory of inductive reasoning regarding the cognitive architecture.
\end{abstract}

Keywords: Number series; Letter series; Inductive reasoning; Adpative control of thought-rational (ACT-R)

\section*{Introduction}

Inductive reasoning, defined as inferring a general rule or relation from specific elements, is traditionally considered as one of the most important constitutes of human intelligence (Spearman, 1923). Several studies were performed to investigate the neural underpinnings of human inductive reasoning using different types of tasks, including sentential (e.g., House cats have 32 teeth; Lions have 32 teeth; therefore, all felines have 32 teeth. Was the given conclusion plausible given the premises? Goel et al., 1997; 2004), figural (e.g., infer the rule underlying the figural
stimuli consisting of novel animals. Goel et al., 2000) and numerical (e.g., number series completion tasks. Liang et al., 2007; Yang et al., 2009; Zhong et al., 2011; Jia et al., 2011) tasks. The recruitment of fronto-parietal regions together with their left lateralization are convergent reported in most of these studies, however, the detailed activation patterns are modulated by the heterogeneousness of the experimental task. Neural correlate of human inductive reasoning process is still unclear, and needs more experimental studies.

The series completion problem, including letter series (e.g., c e g ?) and number series (e.g., 357 ?), is a kind of typical inductive reasoning task (Pelligrino, 1985; Thurstone, 1938; Thorndike et al., 1986) and always used in general fluid intelligence (Gf) test (Cattel, 1963; Hayslip et al., 1995; Johnston et al., 2010; Redick et al., 2012). However, number series and letter series completion tasks are solved differently. Evidences demonstrated that different strategies (by definition, a strategy is a goal-directed procedure under the deliberate control of the participant (Rosenberg-Lee and Anderson, 2009)) were employed in number series and letter series completion tasks, in which each item in one has a same-rule counterpart in the other (Quereshi, 2001), and number series tasks are easier and more familiar than letter series tasks (Quereshi \& Seitz, 1993; Quereshi \& Smith, 1998). This has been confirmed by a recent pilot study with post-test oral report in our group, in which subjects are required to solve the two kinds of series completion tasks comprising items based on identical rules. A "retrieval" strategy is used in solving number series tasks, in which the relation between two adjacent items can be directly attained by retrieving the corresponding arithmetic fact from long-term memory (e.g., \(1113: 11+2=13\), thus, the rule is +2 ). As to letter series tasks, a "procedural" strategy is adopted, in which participants require to step-wise count the corresponding adjacent letter of an item in order to find the relation linking two items (e.g., k n: k ... l ... m ... n; thus, the rule is +3 ). The investigation of strategies using imaging has the potential to enrich our understanding the
neural substrates of inductive reasoning, in terms of locus, level, and duration of activity.

The retrieval and procedural strategy involve performing equivalent cognitive processes (retrieving of declarative memory to detect the relation between the adjacent two items, internal representation and maintenance, and response output), thus engage the same brain areas. However, the working memory demands differ between the two strategies. In the retrieval strategy (e.g., 11 13), participants directly get the relation (e.g., +2 ) between the adjacent two items by retrieving once the corresponding arithmetic fact (e.g., \(11+2=13\) ); While in the procedural strategy (e.g., k m), participants require to perform twice retrieval step by step (e.g., l is next to k , and m is next to l ) and twice internal maintaining/updating a counter, and then the rule can be determined according to the counter. In this way, the procedural strategy incurs many more working memory demands than the retrieval strategy. Thus, the two strategies should differentially engage brain areas that are sensitive to working memory load. It is predicted that the two strategies can be differentiated by the extent of activity within the same brain areas, including the left prefrontal cortex, recruited in memory retrieval, and posterior parietal cortex, involved in mental representation (see a summarization in Anderson et al., 2008).

The goal of the current study was to employ computational cognitive modeling to make specific predictions about the strategy differences. Specifically, based on the aforementioned specification, we expect to demonstrate that the strategy difference can be distinguished neurally by differential engagement of the same brain areas. To make our predictions more precise (in terms of the timing and level of activity), we plan to build computational models of the experimental tasks using the adaptive control of thought-rational (ACT-R) cognitive architecture (Anderson, 2007). ACT-R proposes that cognitive process is the result of the independent activity of distinct modules which are coordinated by a central production system. The ACT-R models automatically generate predictions for activity in the ACT-R modules, which we could then compare with activity in the brain areas of interest. For the tasks in the present study, the differential engagement was mainly due to the differences in retrieval and maintenance demands between the two strategies. Two modules were thus of particular interest in this study: the retrieval module, which is responsible for the retrieval of declarative memories and linked to the lateral inferior prefrontal cortex (LIPFC) and the imaginal module, which is responsible for the encoding and maintenance of internal representation of the problems and linked to the posterior parietal cortex (PPC) (Anderson, 2007; Qin et al., 2004). As the procedural strategy incurs more demands of retrieval and maintenance, thus, we expected LIPFC and PPC have a greater response to the procedural strategy (used in letter series tasks) than the retrieval strategy (used in number series tasks). Together, we will test the two competitive theories empirically and computationally.

\section*{Materials and Methods}

\section*{Subjects}

Twenty-three paid healthy undergraduate and postgraduate students (11 females; \(24.1 \pm 3.7\) years old) participated in the experiment. Writhen informed consent was obtained from each participant and this study was approved by the Ethics committee of Xuanwu Hospital, Capital Medical University.

\section*{Stimuli and experimental design}

Four kinds of tasks were organized into a \(2 \times 2\) factorial design (Table 1). The first factor was Content, consisting of two levels, number-related (24 inductions and 24 baselines) and letter-related ( 24 inductions and 24 baselines) tasks. The second factor was Task in which the first level was the induction condition consisting of series completion tasks (24 number series inductions and 24 letter series inductions) and the second level was the baseline condition (24 number judgment baselines and 24 letter judgment baselines). This yielded four types of tasks: number series induction (NumIR), letter series induction (LetIR), number judgment baseline (Is10) and letter judgment baseline (IsJ). In particular, interferential tasks, which are identical in pattern to inductions but without common rules (e.g., "1 38 " or "a c f"), were included into NumIR and LetIR tasks based on a pilot study. There were twelve interferential tasks within 60 induction tasks in the current study, with six in NumIR tasks and another six in LetIR tasks.

For all kinds of tasks, there were three sequentially presented numbers or letters (e.g., "1 35 " or "a c e"). Number-related tasks and letter-related tasks were matched for magnitudes and operations. All the letters involved were lowercase and within the range of a-z. Correspondingly, all the numbers involved were within the range of 1-26. Half of NumIR and LetIR tasks was forward (e.g., "1 35 " or "a c e"; the rule is: +2 ) while another half was backward (e.g., "13 9 5 " or "m i e"; the rule is: -4). In the answer options of NumIR and LetIR tasks, the distances between the correct and the false answer were less than 3. Half of Is10 and IsJ tasks were with the answer of "yes" while another half were with the answer of "no".

Table 1: Examples of experimental tasks.
\begin{tabular}{llllc}
\hline & Task & \multicolumn{3}{c}{ Options } \\
NumIR & 111315 & A. 18 & B. 17 & B \\
LetIR & t s r & A. q & B. p & A \\
Is10 & 142310 & A. yes & B. no & A \\
IsJ & n w j & A. no & B. yes & B \\
\hline
\end{tabular}

\section*{Stimuli Presentation}

Stimuli from all conditions were organized into three sessions and presented randomly in an event related design. The order of sessions was counterbalanced among subjects. The beginning of a trial was signaled by a cue of the task type ("Finding a rule" for NumIR and LetIR tasks, "Is there
' 10 '" for Is10 tasks and "Is there ' J '" for IsJ tasks) for 2 s. The numbers/letters then appeared on the screen with the first number/letter appearing at 2 s , the second at 2.6 s , and the last at 3.4 s . After the appearance of the third number/letter, subjects were instructed to press the left or right button (counterbalanced among subjects) when the answer was acquired. Three numbers/letters would remain on the screen for at most 6.6 s (since the presentation of the third number/letter), or the button-pressing response within 6.6 s would stop it. Subsequently, two answer options were displayed and subjects were asked to choose the correct answer by pressing the corresponding buttons (left button for "A"). Subjects were instructed to respond as accurately and quickly as possible and move to the next trial if the stimuli advanced before they could respond. The interstimulus interval (ISI) was 8 s and quick responses would leave more rest time within the trial. Thus, reaction times (RT) were recorded based on the first button response and accuracies were acquired based on the second button response.

\section*{MRI data acquisition}

Scanning was performed on a 3.0 Tesla MRI system (Siemens Trio Tim; Siemens Medical System, Erlangen, Germany) with a 12 -channel phased array head coil (see details in Liang et al., (2007)). This acquisition sequence generated 364 volumes for each session. The scanner was synchronized with the presentation of every trial.

\section*{Data Analysis}

\section*{Data preprocessing}

Data were analyzed using SPM5 software (http://www.fil.ion.ucl.ac.uk) and the preprocessing steps are identical to Jia et al. (2011).

\section*{FMRI analysis}

Only correct response trials were included in data analysis (wrong response trials and interferential trials were not included). The epoch of interest is the duration between the presentations of the first number/letter to the first button response. The BOLD signal was modeled using the canonical HRF with time derivative and the RT as duration trial by trial.

For confirmatory analysis, region of interest (ROI) analyses focused on two predefined functional regions in ACT-R, LIPFC (TAL., -43, 23, 24) and PPC (TAL., -23, 63, 40) (Anderson, 2007). The statistical results were based on the beta-values (of general linear model implemented in SPM5) averaged within the two ROIs.

For exploratory analysis, we are primarily interested in the conjunction analysis to explore activations common to both strategies [(NumIR-Is10) and (LetRI-IsJ)]. The Task by Content interaction comparisons ([(NumIR-Is10)-(LetIRIsJ)] and [(LetIR-IsJ)-(NumIR-Is10)]) were also executed to reveal the areas specific to each strategy. The activation
reported survived a voxel-level intensity threshold of p < 0.05 corrected for multiple comparisons.

\section*{Results}

\section*{Behavioral performance}

We carried out analyses of variance for two factors: Content (number vs. letter) and Task (induction vs. baseline) on both RT and accuracy. Behavioral scores indicated that subjects performed the task in the expected manner. The main effects of Content and Task were significant for RT and accuracy: Response to induction tasks was significantly longer ( \(\mathrm{F}(1,22\) ) \(=70.10, \mathrm{p}<0.001\) ) and less accurate \((\mathrm{F}(1,22)=61.56, \mathrm{p}<\) 0.001 ) than that of baseline tasks; Response to letter tasks was significantly longer \((\mathrm{F}(1,22)=68.38, \mathrm{p}<0.001)\) and less accurate \((\mathrm{F}(1,22)=69.94, \mathrm{p}<0.001)\) than that of number tasks. The interaction effect between Task and Content was significant for RT \((\mathrm{F}(1,22)=69.24, \mathrm{p}<0.001)\) and accuracy \((\mathrm{F}(1,22)=66.75, \mathrm{p}<0.001)\) : The difference between LetIR and IsJ (i.e., LetIR-IsJ) (RT: \(\mathrm{F}(1,22)=30.59\), \(p<0.001\); accuracy: \(F(1,22)=73.81, p<0.001)\) than the difference between NumIR and Is10 (i.e., NumIR-Is10) (RT: \(F(1,22)=6.39, p<0.05\); accuracy: \(F(1,22)=2.89, p=0.10)\). This indicated that the significant interaction effect is primarily driven by the strategy difference, i.e., the difference between LetIR and NumIR.

\section*{Imaging results}

Confirmatory analysis We performed repeated measures Task by Content for the two ROIs. The two ROIs showed the identical patterns. The main effect of Content \((F(1,22)=\) 35.46, \(p<0.001\) for LIPFC and \(F(1,22)=14.23, p<0.001\) for PPC), Task \((F(1,22)=67.10, p<0.001\) for LIPFC and \(F(1,22)=35.45, p<0.001\) for PPC) and the Task by Content interaction effect \((F(1,22)=29.64, p<0.001\) for LIPFC and \(F(1,22)=4.60, p<0.001\) for PPC) were all significant. The post-hoc multiple comparisons showed that the interaction effect was driven by the strategy difference, i.e., the difference between letter series reasoning tasks and number series reasoning tasks \((F(1,22)=46.58, p<0.001\) for LIPFC and \(F(1,22)=13.51, p<0.001\) for PPC). There were no significant difference between the two kinds of baselines (i.e., IsJ versus Is10; \(F(1,22)=3.98, p=0.06\) for LIPFC and \(F(1,22)=1.85, p=0.19\) for PPC).
Exploratory analysis Conjunction analysis indicated that both strategies showed common activation in the left dorsolateral prefrontal cortex (DLPFC, BA 46, 9) and bilateral superior parietal lobe (SPL, BA 7) extending to left inferior parietal lobe (IPL, BA 40) (Figure 1). Regions specific to LetIR [(LetIR-IsJ)-(NumIR-Is10)] were found in the left middle frontal gyrus (BA 9, 46), bilateral superior frontal gyrus extending into anterior cingulate cortex/medial frontal gyrus (BA 6, 8, 9, 32), inferior frontal gyrus/insula (BA 13, 45, 47), and bilateral superior parietal cortex (BA 7). No significant activations were found specific to NumIR [(NumIR-Is10) - (LetIR-IsJ)].

Figure 1: Activations common to both strategies.

\section*{The model}

Having now reviewed the result of the experiment, we come to the question whether we can understand them in the frame work of the ACT-R theory. The model we constructed primarily depends on the visual module to perceive the stimuli, the manual module to respond, the retrieval module to retrieve a fact from memory, and the imaginal module to encode and update its stored representation. Figure 2 presents the sequences of activity in the four modules, for a " +2 " NumIR problem or a "backward next" relation LetIR problem solved by each of the strategies. Specifically, the underlying productions driving these modules are not shown. As the fronto-parietal network plays an important role in inductive reasoning, the retrieval and imaginal module are of special interest in the present study, in the following, we would illustrate the prediction of BOLD responses in the two modules.

The fit of the predictions of the model to the RT and ACC data are presented in Figure 3. The parameters were estimated to fit the behavioral data: a factor that scaled the time to retrieve a declarative memory fact ( 0.3 sec ) and the time to modify the contents of the imaginal module (i.e., 0.2 sec ). This leads to a predicted effect size ( 605.42 ms for NumIR, 2116.17 ms for LetIR, 551.25 ms for baseline conditions) that is highly similar to the observed effect size ( 586.4 ms for NumIR, 2221.4 ms for LetIR, 530.4 ms for Is10, and 606.1 ms for IsJ). Only the deviation of data is presented because the model makes identical predictions. It can be seen that the model produced a reasonable fit to the behavioral data.

In order to generate BOLD predictions, we convolved the module activity with a gamma function. As is typical (e.g., Boyton et al., 1996; Glover, 1999), if the module is engaged, it will produce a BOLD response \(t\) time units later according to the function:
\[
H(t)=m(t / s)^{\alpha} e^{-(t / s)}
\]

The parameter \(m\) is the magnitude parameter and determines the height of the function; the parameter \(s\) is the scale parameter and determines the time scale, and the parameter is the shape parameter and determines the narrowness of the function. The cumulative BOLD responses in a particular module is the sum of the individual BOLD responses driven by a module's activities. This can be modeled by convolving the hemodynamic response, \(H(t)\), with a demand
function, \(D(\mathrm{t})\), which has a value of 1 when the module associated with that region is active, and 0 otherwise:
\[
B(\mathrm{t})=\int_{0}^{t} D(x) H(t-x) d x
\]

Once the timings of buffers actions are all set, we can predict the BOLD functions by estimating the magnitude parameter \(m\), the exponent \(\alpha\), and the latency scale \(s\) for each brain region. The estimates of these parameters and measurement of the quality of the prediction are given in Table 2. Figure 4 displays percent change of BOLD response (relative to the baseline defined by the average BOLD response of the first two scans and the last two scans), along with the prediction of the ACT-R model to be presented.

Table 2: ACT-R parameters and the BOLD predictions.
\begin{tabular}{lcc}
\hline & Imaginal & Retrieval \\
\hline Exponent \((\boldsymbol{\alpha})\) & 3 & 3 \\
Scale \((s)\) & 2.2 & 1.8 \\
Magnitude & & \\
\(\quad M \Gamma(\alpha+1)^{*}\) & 5.6 & 5.5 \\
Correlation \((r)\) & 0.94 & 0.92 \\
\hline
\end{tabular}

Figure 2: A schematic representation of the ACT-R model's solution to the number- and letter-series problem of "11 1315 " and "t s r", solved by retrieval strategy and procedural strategy, respectively.

\section*{Discussion}

The primary purpose of the current study was to investigate the neural correlates of the two cognitive strategies in series completion inductive reasoning tasks. Both confirmatory and exploratory analysis indicated that DLPFC (L.>R.) and PPC (bilaterally) were commonly recruited in the two kinds of tasks, but with different extent. Additionally, the exploratory analyses identified additional regions in dorsomedial prefrontal cortex (DMPFC) and ventrolateral prefrontal cortex (VLPFC) was active for the procedural strategy but not for the retrieval one. These results suggest that some aspects of the behavioral signatures of strategies may be recovered from imaging data. We constructed the computational model to simulate participants' behavior. The results showed that there was reasonable fitness between the model prediction and the empirical data.

Figure 3: Data (red solid lines) and model fits (black dashed lines) for NumIR, LetIR, Is10, and IsJ.

In the current study, the significant co-activation of the left DLPFC and bilateral PPC is identified to be strategyindependent. These results replicated a recent fMRI study of number series completion task in our group (Jia, et al., 2011), and were consistent with previous studies of sentential inductive reasoning task (Goel and Dolan 2004) and figural inductive reasoning tasks (Induction minus Perceptual baseline; Goeland Dolan, 2000). This implies that these two regions may be the key regions involved in inductive reasoning. Moreover, the left DLPFC is more specific to sentential induction, as contrast to deduction (Goel and Dolan, 2004). The activity of the DLPFC is right lateralized in Goel et al. (2000), but is left lateralized in the other studies (Jia, et al., 2011; Goel and Dolan, 2004) and the current study, which may be ascribed to the different kinds of experimental materials (figure versus number, sentences).

As to the functional role of DLPFC and PPC, different interpretations were proposed. In the domain of inductive reasoning, the left DLPFC was related to the use of world
knowledge in the generation and evaluation of hypotheses (Goel and Dolan, 2004), rule identification and extrapolations (Jia, et al., 2011), and the fronto-parietal network was more specific to rule identification (Jia, et al., 2011). (Note: In Goel and Dolan (2000), the authors are interested in bilateral hippocampus, which is specifically associated with rule inference, and right lateral orbital prefrontal cortex, which is associated with the task by difficulty interaction. The former is interpreted in terms of semantic encoding of novel stimuli, and the latter in terms of hypothesis selection. While the DLPFC (R.>L.) and bilateral PPC, identified in Rule Induction minus Perceptual Baseline, is not explained of their functional roles.) It is not surprise of these different explanations, as different domain and context were situated in.

Figure 4: The BOLD signals obtained for the prefrontal and parietal regions for NumIR and LetIR condition and the prediction of the ACT-R model of the task.

In this study, with the help of computational modeling, we made a more general account. The DLPFC and PPC regions identified in the exploratory analysis, are largely overlapped the regions involved in the ACT-R LIPFC and ACT-R PPC. Therefore, consistent with the explanation in ACT-R theory, it was inferred that the left DLPFC is associated with memory retrieval of semantic information/knowledge and PPC is associated with mental representation of problem states (Anderson, 2007; Danker \& Anderson, 2007). In the current study, although the procedural strategy and the retrieval strategy commonly recruited the left DLPFC and bilateral PPC, the strategy variation can be distinguished by the extent of cortical activity within these regions. The procedural strategy incurs more working memory demands (both the retrieval and maintenance demands) than the retrieval strategy. The ACTR model fitted well with the experimental behavioral and imaging data, which demonstrated the validity of this general account.

In summary, by coupling this empirical work with computational modeling, we have deepened our understanding of what constitute the strategy variation (the retrieval strategy versus the procedural strategy) and quantify their predictions. These results support the generalpurpose dual-process theory of inductive reasoning.

\begin{abstract}
This study examined the hypothesis that individuals with obsessive-compulsive disorder (OCD) show a selective deficit in inductive reasoning but are unimpaired in their ability to make deductive inferences. 100 participants from an analog sample made inductive or deductive inferences about arguments that differed according to causal consistency and validity. They also completed a task examining sensitivity to the implications of diverse evidence in induction. Participants who were high or low on obsessivecompulsive symptoms showed similar patterns of induction based on causal knowledge and similar patterns of deduction. However, those with the highest level of OCD symptoms showed less of a preference for diverse evidence when evaluating inductive arguments, compared to those with the lowest level of symptoms. This difference was found across both OCD-relevant and OCDneutral items, and persisted when the effects of group differences in general ability were controlled. These results indicate that both inductive reasoning based on background knowledge and deductive reasoning are intact in individuals with high OCD-traits but the use of inductive heuristics such as evidence diversity is impaired.
\end{abstract}

Keywords: inductive reasoning, deductive reasoning, psychopathology, cognitive neuropsychiatry

\section*{Introduction}

Obsessive-compulsive disorder (OCD) is characterized by the experience of unwanted, repetitive intrusions in the form of thoughts, impulses or images. These obsessions are often accompanied by compulsions (repetitive behaviors or mental acts) that represent attempts to reduce or neutralize the marked distress that the obsessions cause.

A variety of biological, cognitive and social factors affect the onset and maintenance of OCD symptoms (Riggs \& Foa, 1993). Recently, a number of theoretical accounts have suggested that deficits in reasoning contribute to OCD symptomatology. Some of these accounts suggest that people with OCD have difficulty in reasoning about uncertain or probabilistic information (O’Connor, 2002; Pélissier \& O'Connor, 2002); that is, they show a deficit in some forms of inductive reasoning. These accounts suggest that this is a global deficit, such that people with OCD show poorer inductive reasoning compared to controls across a range of stimulus materials and content domains. Moreover, this impairment in inductive reasoning is thought to be found together with a relatively intact ability to reason deductively. Unlike induction, deduction involves the evaluation of arguments that are certain to be either valid or
invalid on the basis of logical rules (Heit, Rotello, \& Hayes, 2012).

A review of the empirical evidence however, reveals only mixed support for this "impaired induction but spared deduction" account of OCD. In support of this account, Pélissier and O'Connor (2002) found that individuals with OCD had more difficulty than controls in drawing plausible probabilistic conclusions from a set of verbal statements about everyday situations. This impairment in inductive reasoning was found together with apparently intact deductive reasoning, as measured by performance on the Wason Selection Task and ability to discriminate between valid and invalid verbal syllogisms. Moreover, this pattern was found with stimulus materials that had little connection with the content of OCD patients' obsessions.

Other work however, has suggested that the reasoning deficit in OCD extends to deduction as well as induction. For example, Simpson, Cove, Fineberg, Msetfi, and Ball (2007) found that people with OCD were poorer than controls at discriminating between logically valid and logically invalid syllogisms with OCD-neutral content.

This mixed pattern of evidence reflects, at least in part, a general problem with the methods used in previous attempts to examine inductive and deductive reasoning in people with OCD. These studies have made little attempt to match tasks that ostensibly assess inductive and deductive reasoning on dimensions such as overall task difficulty, stimulus content and task familiarity. Hence, differences in performance between nominally inductive and deductive tasks may actually reflect task-specific characteristics rather than in the cognitive processes that underlie inductive and deductive reasoning.

A major aim of the current studies was to re-examine inductive and deductive reasoning in those with OCDrelated traits and controls, using a method that addressed this major limitation of previous work. The general approach is patterned after Rips (2001) and Heit and Rotello (2010) who asked university undergraduates to evaluate a set of verbal arguments that varied in both logical validity and inductive plausibility. Crucially, different groups evaluated the set of arguments on the basis of logical necessity (deduction condition) or the overall plausibility (induction condition) of the conclusions.

Another important aim was to carry out a more exhaustive examination of possible deficits in inductive reasoning in those with OCD-related traits. A review of
research on induction in people without OCD (typically university undergraduates) suggests that such reasoning is influenced by at least two distinct factors (cf. see Hayes, Heit, \& Swendsen, 2010 for a detailed review). On the one hand, people often evaluate inductive arguments using their prior knowledge of causal or taxonomic relations between argument premises and conclusions (Medin, Coley, Storms, \& Hayes, 2003). For example, Rips (2001) found that participants were more likely to accept conclusions in inductive arguments when these were consistent with background causal knowledge (e.g. see the top right cell of Table 1), than when they were causally inconsistent (e.g. see the bottom right cell of Table 2), even though neither conclusion is logically entailed by the premise.

A second factor influencing induction is the use of general heuristics for assessing probabilistic evidence (Heit, Hahn, \& Feeney, 2005; Osherson, Smith, Wilkie, López, \& Shafir, 1990). Such heuristics include the sample size (or "monotonicity") principle in which the strength or plausibility of an inductive conclusion tends to increase with the number of instances of positive evidence observed (Osherson et al., 1990). Another important heuristic is premise diversity. All things being equal, more diverse evidence (e.g., cows and mice have property \(X\) ) is usually seen as a stronger basis for inductive generalizations (e.g., mammals have property \(X\) ) than less diverse evidence (e.g., cows and horses have property \(X\) ). Although there is some debate about the normativity of this principle (e.g., Lo, Sides, Rozelle, \& Osherson, 2002), a large body of evidence shows that most reasoners use this heuristic when evaluating inductive evidence (see Heit et al., 2005 for a review).

Previous work on inductive reasoning deficits in OCD has blurred this distinction, with some researchers examining induction based on background knowledge (e.g., Pélissier \& O'Connor, 2002), while others have examined the use of domain-general heuristics in probabilistic and inductive reasoning (e.g., Fear \& Healy, 1997). We sought to clarify the nature of inductive deficits in people with OCD by assessing those with low and high levels of OCDrelated traits on each of these two types of inductive tasks.

\section*{The Current Study}

To re-examine inductive and deductive reasoning in individuals high and individuals low on OCD symptoms, we administered two tasks. The first examined inductive and deductive reasoning using a common set of stimulus materials. Following Rips (2001), participants were asked to judge either the inductive strength or deductive validity of four types of arguments. Table 1 illustrates this design with arguments that vary in logical validity and consistency with causal knowledge. Crucially, different groups were instructed to evaluate the same set of arguments on the basis of either deductive validity or inductive plausibility.

Previous work with undergraduates (e.g., Heit \& Rotello, 2010; Rips, 2001) has found that this instructional manipulation interacts with argument type. In particular, Rips (2001) found that under deduction conditions, binary
judgments of argument strength were primarily affected by validity, regardless of causal consistency. In contrast, those given induction instructions were highly sensitive to causal consistency. In this condition, causally-consistent but logically invalid arguments (e.g., arguments like those in the top right cell of Table 1) were judged to have similar argument strength to logically valid arguments. According to Rips (2001), this pattern shows that people use qualitatively different criteria for evaluating arguments when doing induction and deduction.

If those with OCD-symptomology exhibit spared deductive reasoning but impaired inductive reasoning, then they should show a different pattern of performance on the Rips induction-deduction task. Specifically, they may show sensitivity to logical validity under deduction instructions but may not show the same sensitivity to causal consistency as controls, when given induction instructions.

Table 1: Examples of the argument types used in the Rips induction - deduction task. Participants were asked to evaluate the conclusion (below the line in italics) assuming the premises (above the line in normal font) to be true.
\begin{tabular}{|c|c|c|}
\hline \multirow[b]{2}{*}{Causal status} & \multicolumn{2}{|c|}{Validity} \\
\hline & Valid & Invalid \\
\hline \multirow[t]{2}{*}{Causally Consistent} & If Jill rolls in the mud, & Jill rolls in the mud. \\
\hline & Jill rolls in the mud. & \\
\hline \multirow{4}{*}{Causally Inconsistent} & Jill gets dirty. & Jill gets dirty. \\
\hline & If Jill rolls in the mud, & Jill rolls in the mud. \\
\hline & \begin{tabular}{l}
Jill gets clean. \\
Jill rolls in the mud.
\end{tabular} & \\
\hline & Jill gets clean. & Jill gets clean. \\
\hline
\end{tabular}

Note that the Rips task examines induction based on background causal knowledge. With the aim of providing a more comprehensive examination of possible inductive deficits in OCD, we also administered an inductive reasoning task which tested sensitivity to the diversity heuristic. In the diversity task, participants were asked to make judgments about which of two pairs of premises would provide better evidence for a more general inductive conclusion (see Table 2 for an example). One premise pair (non-diverse set) contained two very similar premises, while another (diverse set) contained premises that were less similar (but still nested within the conclusion category).

Those with no OCD-symptomology were expected to show a robust preference for the diverse set (cf. Heit et al., 2005; Osherson et al., 1990). However, if inductive reasoning is impaired in people with OCD, then we would expect to see less evidence of the diversity heuristic in those with OCD symptoms. Indirect support for this prediction comes from the finding that relative to controls, individuals with OCD often make repeated observations of the same or similar items before making a probability judgment (e.g., Fear \& Healy, 1997; Volans, 1976). As shown in Table 2, the prediction about differences between diversity-based reasoning in those low or high in OCD traits was examined
using "OCD-neutral" arguments as well as arguments with content relevant to common obsessions (OCD-relevant).

Table 2: Examples of the four argument types used in the Diversity task. The premises are given in normal font above the line and are assumed to be true. Conclusions are given in italics below the line.
\begin{tabular}{lllll}
\hline \begin{tabular}{c}

\end{tabular} \\
\hline
\end{tabular}

It is important to note that unlike many previous studies (e.g., Pélissier \& O'Connor, 2002; Simpson et al., 2007), we did not test patients who had received a formal diagnosis of OCD. Instead we employed an "analog-sample" of undergraduates who showed relatively low or high levels of OCD symptomology as measured by a widely used selfreport screening questionnaire. This approach is justifiable given that non-treatment seeking individuals who score highly on self-report measures of obsessive-compulsive symptoms often do meet diagnostic criteria for OCD (Burns, Formea, Keortge, \& Sternberger, 1995).

\section*{Method}

Participants. One-hundred undergraduate students who spoke English as their primary language participated for course credit.

These participants were all assessed using the Obsessive-Compulsive Inventory-Revised (Foa et al., 2002). This is an 18 -item self-report measure that assesses subjective experience of OCD symptoms in the past month. Item ratings are made on a 5 -point Likert scale ( \(0=\) not at all distressing, \(4=\) extremely distressing). The OCI-R has been shown to reliably distinguish between individuals with OCD and non-OCD controls, and to have high internal consistency and test-retest reliability (Foa et al. 2002). Individuals high on obsessive-compulsive symptoms were defined as those scoring equal to or greater than 21 on the

OCI-R ( \(n=44, M=29.95, S D=7.19\) ), which is consistent with the cut-off used for distinguishing between nonanxious controls and those with OCD (Foa et al., 2002). Of these participants, the majority were female \((n=30)\) and the mean age was 18.75 years ( \(S D=1.64\) ). Low-OCD individuals were defined as those scoring less than 21 on the OCI-R ( \(n=56, M=10.85, S D=5.42\) ); the majority of these participants were female ( \(n=30\) ) and the mean age was 20.46 years ( \(S D=6.67\) ).

\section*{Design and Procedure.}

All participants were tested individually in the UNSW Cognition and Reasoning lab. All were administered a Rips induction-deduction task and a premise diversity task, with order of task presentation counterbalanced across participants. After completion of the reasoning tasks, all participants also completed a test of general ability (the twosubtest short-form of the Wechsler Abbreviated Scale of Intelligence) (WASI; Wechsler, 1999), and the OCI-R. The general ability test was included so that possible group differences in reasoning performance could be differentiated from group differences in overall cognitive ability.

Rips induction-deduction task. The Rips inductiondeduction task consisted of 16 arguments that varied factorially in logical validity (valid vs. invalid) or causal consistency (consistent vs. inconsistent) (see Table 1 for examples), such that there were four argument types. The valid items were based on either the inference form modus ponens (If \(p\) then \(q, p\) therefore \(q\) ) (as in the Table 1 example) or conjunctive syllogism (not ( \(p\) and \(q\) ), p therefore not \(q\) ), such that valid items followed an acceptable logical structure but invalid items did not. Item content for 12 of the arguments was taken from Rips (2001), and the remaining four arguments were generated by the researchers.

Instructions for evaluating these arguments (deduction vs. induction) were manipulated between subjects, with approximately equal numbers allocated to each condition. Those in the induction condition were told that strong arguments are those for which "assuming the information above the line is true, this makes the sentence below the line plausible", whilst those in the deduction condition were told that valid arguments are those for which "assuming the information above the line is true, this necessarily makes the sentence below the line true". They were instructed to examine each argument and make a binary judgment about the conclusion ("strong" or "weak" in the induction condition; "valid" or "invalid" in the deduction condition). Arguments were presented one at a time on a computer screen in random order, and responses were made via onscreen buttons. There was no time limit on responding.

Premise Diversity task. This consisted of 30 items, each made up of two pairs of premises (one diverse, one nondiverse) and a general conclusion (see Table 2 for examples). Assignment of premises to the diverse or nondiverse set was based on pre-test ratings of the similarity
between the categories mentioned in the premises (e.g., cows and horses) by an independent group of participants who took no part in the main experiment. This pre-test established that diverse premise pairs ( \(M=4.52, S D=1.31\) ) were reliably perceived as less similar to one another than the non-diverse pairs ( \(M=7.94, S D=.54\) ), \(t(10)=11.75\), \(p<.01\). Premise and conclusion categories (e.g., cows, horses, mammals; gold coins, silver coins, money) were selected so that they would be familiar to participants, but the properties attached to each (e.g., "have an ileal vein", "are contaminated by hemonasella coli") were unfamiliar (cf. Osherson et al., 1990). For each item, participants had to choose which of the premise pairs provided stronger evidence for the conclusion, as illustrated in Table 2.

Half the diversity items were content-neutral (related to animals), whilst the other half were OCD-relevant (containing emotional content related to common OCDrelated concerns, such as washing and checking). The leftright positioning of diverse and non-diverse premises was randomized, as was item order. The full set of items is available from the authors.

\section*{Results}

Preliminary Analyses. A one-way ANOVA analysis of general ability scores between OCD-high and OCD-low groups indicated that the groups did not differ in estimates of general ability, \(F(1,98)=3.36, p=.07\). However, general ability estimates for those scoring in the highest quartile on the OCI-R ( \(M=105.37, S D=11.62\) ) were lower than those in the lowest quartile \((M=112.4, S D=7.55), F(1,98)=\) 298.04, \(p<.01\). As there were general ability differences in the lowest and highest quartiles of OCD symptoms, general ability was controlled in all analyses.

Rips Induction-deduction task - Proportion of positive responses. The proportion of trials in which OCD-high and OCD-low participants judged an argument as "valid" in the deduction condition or "strong" in the induction condition is given in Figure 1. As Figure 1 indicates, the proportion of positive responses across item types is clearly affected by argument consistency, \(F(1,98)=261.94, p<.01\), and validity, \(F(1,98)=223.33, p<.01\).

The key question however, is whether responses to valid-inconsistent (V-I) and invalid-consistent (Inv-C) items differ as a function of instruction and OCD-group status. Crucially, as in Rips (2001), we found a crossover interaction between the relative likelihood of making a positive response to V-I and Inv-C and the instruction manipulation, \(F(1,96)=10.82, p<.01\). Figure 1 shows that under deduction instructions, there was a higher rate of positive responding to V-I items than to Inv-C items, but that this pattern reverses under induction instructions. This suggests that people applied qualitatively different criteria to evaluating argument strength in the induction and deduction conditions. Notably, as is clear from Figure 2, this effect was found in both OCD-low and OCD-high groups (i.e. there was no significant group x item x instruction
interaction, \(p=.595\) ). All of these results remained robust when group comparisons were restricted to the highest and lowest quartile groups on the OCI-R (OCD-low, \(\mathrm{n}=24\); OCD-high, \(\mathrm{n}=27\) ). These results challenge the view that induction involving the use of background causal knowledge is selectively impaired in OCD.

Figure 1. Proportion of positive responses ('strong' or 'valid') for each item type, by instruction condition and group. V-C = Valid + causally consistent items; V-I = Valid + causally inconsistent items; Inv-C = Invalid + causally consistent items; Inv-I = Invalid + causally inconsistent items.

A further analysis of the deduction data was carried out by calculating an "interaction index", which measures the influence of causal consistency on positive responding for valid and invalid problems, whilst correcting for response bias (see Dube, Rotello, \& Heit, 2010). The interaction index was calculated using the formula;
\[
\begin{equation*}
\text { Interaction index }=\left(\mathrm{H}_{I}-\mathrm{F}_{I}\right)-\left(\mathrm{H}_{C}-\mathrm{F}_{C}\right) \tag{1}
\end{equation*}
\]

H denotes the rate of hits (responding "valid" to a logically valid item). F denotes false alarms (responding "valid" to a logically invalid item), and \(C\) and \(I\) denote causally consistent and causally inconsistent arguments respectively. The index is scaled such that a positive index suggests that people find it easier to discriminate between valid and invalid items with unbelievable conclusions. An interaction index score was calculated for each participant and mean scores were compared between the OCD-low ( \(M=0.39, S D\) \(=.05)\) and OCD-high ( \(M=0.34, S D=.07\) ) groups. Consistent with previous work, the interaction index calculated for the OCD-low group was positive (Dube et al., 2010), as was the index calculated for the OCD-high group. The interaction index scores did not differ between these groups, \(F(1,95)=.38, p=.54\). In other words, there were no OCD-group differences in the impact of causal consistency on judgments of logical validity. Again it appears that OCD-low and OCD-high show similar patterns of reasoning based on background causal knowledge.

Proportion of Diverse Pairs Chosen. Overall, both OCDhigh and OCD-low groups were more likely to choose the diverse premise pairs as providing stronger evidence for inductive generalization than would be expected by chance, (OCD-low, \(t(55)=7.98, p<.01\); OCD-high, \(t(42)=4.05\), \(p<.01)\). The relative preference for diverse pairs in OCDhigh and OCD-low groups was compared. There was no effect of OCD status for overall proportion of diverse pairs chosen, \(F(1,106)=1.35, p=.25\). Participants showed a reliable diversity effect (i.e. selection of diverse pairs above chance) for both OCD-neutral, \(t(99)=7.27, p<.01\), and OCD-relevant items, \(t(99)=9.24, p<.01\).

We again reanalyzed these data restricting group comparisons to those individuals showing the most extreme scores on the OCI-R (i.e. the lowest and highest quartiles). As can be seen in Figure 2, individuals exhibiting the highest OCD symptoms shows reduced preference for diverse evidence in induction than those with low levels of OCD symptoms, \(F(1,51)=7.41, p<.01, d=1.09\). Individuals with high scores on the OCI-R were less likely to show a preference for diverse evidence, regardless of whether item content was neutral, \(F(1,51)=5.95, p<.05\), \(d=1.06\), or emotionally relevant, \(F(1,51)=7.89, p<.01\), \(d=1.01\). Moreover, this difference persisted when group differences in general ability were controlled by using individual scores on the ability test as a covariate. \({ }^{1}\)

Figure 2. Proportion of Diverse Pairs Chosen by Lowest and Highest Quartiles on the OCI-R.

Overall, these data suggest that non-clinical adults with the highest levels of OCD symptoms were less likely to make use of the diversity heuristic in inductive reasoning than those who show low levels of symptomatology.

\footnotetext{
\({ }^{1}\) Moreover, linear regression analyses showed that scores on the OCI-R explained a significant amount of variance in the proportion of diverse pairs chosen overall after the common variance explained by general ability had been controlled (i.e. when OCI-R scores were entered into the equation after general ability), \(\mathrm{R}^{2}=\) \(.33, F(1,97)=5.95, p<.01\), and for both neutral items, \(\mathrm{R}^{2}=.35\), \(F(1,97)=6.77, p<.01\), and OCD relevant items, \(\mathrm{R}^{2}=.29, F(1,97)\) \(=4.42, p<.05\).
}

\section*{General Discussion}

Previous work (e.g. Pélissier \& O’Connor, 2002) has suggested that people with OCD show a selective deficit in inductive reasoning but unimpaired ability to reason deductively. This study tested this hypothesis in two ways. First, we compared the inductive and deductive performance of those with low or high levels of OCD-related traits using a common stimulus set for both tasks. Second, we examined the performance of these two groups on two types of inductive problems; one based on the use of background knowledge to determine inductive validity and another examining the inductive heuristic of evidence diversity.

Overall there was mixed support for the hypothesis of a selective inductive deficit in people with OCD-related traits. Results from the Rips induction-deduction task replicated the main findings of other comparisons of inductive and deductive reasoning in nonclinical populations (e.g, Heit \& Rotello, 2010; Rips, 2001). Induction and deduction instructions led participants to evaluate arguments in qualitatively different ways. Evaluations of inductive strength were based on consistency with prior knowledge. Evaluations of deductive validity were evaluated according to logical necessity. Crucially, there were no differences between OCD-low and OCD-high groups in patterns of inductive and deductive reasoning. These data provide little support for a selective deficit in inductive reasoning based on background knowledge in people with OCD.

An important finding however is that those who showed the highest level of OCD symptomatology exhibited an atypical pattern of induction based on the diversity heuristic. Those in the highest OCD symptom quartile were less likely to see diverse premise pairs as a stronger basis for inductive generalization than those in the lowest quartile. This difference persisted when the effects of general ability were factored out. This suggests that although inductive reasoning based on consistency with background knowledge may be intact in people with high-OCD symptoms, this group does show an impaired understanding of the implications of evidence diversity. Moreover, this appears to be a global impairment, affecting inductive reasoning about both OCD-related and OCD-neutral items.

Further work is needed to identify the specific source of this inductive impairment. It is notable that although sensitivity to evidence diversity is robust in nonclinical groups (Heit et al., 2005), there are some cases where this heuristic interacts with other factors, such as property knowledge. When diverse premises share a highly specific or idiosyncratic property, inductive generalizations based on diverse premises may actually be weaker than those based on non-diverse premises (Feeney \& Heit, 2011). For example, Medin et al., (2003) found that people were less likely to generalize a property shared by camels and desert rats to other mammals, than a property shared by camels and rhinos, even though the first set of premises was rated as more diverse. It seems unlikely however, that this type of mechanism could explain the weakening of the diversity effect in people with OCD-symptoms. If this effect was
driven by the high OCD group inferring more specific or idiosyncratic relations between diverse premise pairs, one could reasonably expect that this effect would be stronger in items with OCD-relevant content. However, the weakening of the diversity effect in people with OCD symptoms was found across both OCD-relevant and neutral items.

A more likely explanation of reduced sensitivity to diversity in the OCD-high group relates to preservative tendencies observed in other studies of probabilistic and inductive reasoning in OCD patients (e.g. Fear \& Healy, 1997; Volans, 1976). Such studies have found that when asked to evaluate evidence for an uncertain conclusion, people with OCD-related traits often repeatedly choose to examine similar or redundant types of evidence.

Overall, we found some evidence for impaired inductive reasoning in people with OCD-related traits, but only when a general inductive heuristic was involved. By contrast, high-OCD individuals did not differ from controls in induction based on background knowledge or in deductive reasoning. Clearly, given the analog nature of our samples, we must be cautious in generalizing the deficit in the use of the diversity heuristic to clinical populations. However, given that the level of OCD symptomology is likely to be more severe in those seeking or undergoing treatment, it seems reasonable to speculate that such individuals will also show impairment in diversity-based inductive reasoning.

This study is one of the first to apply contemporary methods and theories of induction and deduction to examine reasoning deficits related to a specific clinical condition. Our view is that a careful examination of patterns of spared and impaired reasoning in such groups can contribute to the understanding of reasoning in both clinical and non-clinical populations (cf. Caramazza \& Coltheart, 2006). For example, the finding that OCD-related symptoms are associated with impairments in some forms of induction but not others suggests that more than one underlying cognitive process drives inductive reasoning.

\begin{abstract}
The processing of incoming sensory information relies on interacting mechanisms of sustained attention (the ability to focus attention and ignore irrelevant stimuli) and attentional capture (the ability of certain stimuli to reflexively attract one's attention). Being able to precisely predict what can capture attention when it is engaged in a demanding task is important both for understanding the nature of attention as a cognitive system and also for practical applications. While evidence indicates that exogenous capture, a mechanism previously understood to be automatic, can be eliminated while concurrently performing a demanding task, we reframe this phenomena within the theoretical framework of the 'attention set' (Most et al., 2005). Consequently, the specific prediction that cuing effects should reappear when dimensions of the cue overlap with those in the attention set (i.e., elements of the demanding task) was empirically tested and confirmed. Suggestions for further theoretical refinement and empirical testing are discussed.
\end{abstract}

Keywords: Theories of attention; attention set; exogenous cuing; orienting; attentional capture; perceptual load

\section*{Introduction}

As an information processing mechanism, one of the characteristic dichotomies of attention is how it must have the capacity to be both focused and distractible at the same time. The ability to ignore irrelevant stimuli and closely attend to a specific task at hand is fundamental to goal directed behavior. Conversely, the ability to be distracted by potentially dangerous events or to be drawn towards relevant information outside the current task or area of focus can be crucial for avoiding harm and responding effectively to the environment. In fact, neurological evidence has demonstrated that these dissociable mechanisms are underpinned by distinct and interactive neural networks (Corbetta, Patel, \& Shulman, 2008; Corbetta \& Shulman, 2002).

Many of the attentional mechanisms that we use on a daily basis can be characterized by the way in which they enable goal-directed and top-down control of behavior. Indeed, top-down attentional control has been observed to play a role in visual search (Wolfe, 2007), endogenous (participant directed) orienting of attention to spatial locations (Posner, 1980), and even feature integration (Treisman \& Gelade, 1980), to name but a few. Although
the environment may contain stimuli that actively compete for and capture attention, what ultimately becomes selected for subsequent processing can be influenced by "top-down signals" that filter for behaviorally relevant objects (Desimone \& Duncan, 1995).

Considering the importance of responding effectively to changes in the environment, the attentional system allows for stimuli to 'reflexively' capture attention, in a 'bottomup' environmentally triggered fashion. It has been shown that this aspect of attention can be dependent on the particular nature of the stimuli and environmental circumstances at hand. Such factors may include the role of stimulus saliency (Jonides \& Yantis, 1988) and relevancy to behavioral goals (Yantis \& Egeth, 1999), for example.

Of direct interest to the current study, recent research has suggested that the reflexive orienting of attention can, at times, be interrupted when an observer is undergoing a difficult and demanding task (Santangelo, Belardinelli, \& Spence, 2007). In other words, where such exogenous, or stimulus-driven, mechanisms were previously thought to be automatic (Müller \& Rabbitt, 1989), more recent evidence has suggested that these effects may be eliminated in a state of focused attention. For example, several recent studies have demonstrated that requiring participants to perform a concurrent demanding task can effectively eliminate the ability of exogenous cues to capture attention (Santangelo et al., 2007; Santangelo, Finoia, Raffone, Olivetti Belardinelli, \& Spence, 2008; Santangelo \& Spence, 2008; Theeuwes, 1991; Yantis \& Jonides, 1990). Two of these studies, for instance, employed central-arrows as \(100 \%\) predictive cues in a target detection task, while also deploying abrupt visual onsets as exogenous cues (Theeuwes, 1991; Yantis \& Jonides, 1990), and found that the abrupt visual onsets had no effect on performance. Yet a different study by Van der Lubbe and Postma (2005) used more eccentric (peripheral) exogenous cues and obtained evidence to the contrary, where effects of the abrupt visual onsets were observed even when attention was engaged.

Thus, there appears to be evidence indicating that under some circumstances exogenous cuing effects remain, while under others these effects are eliminated. While these experiments often employ a demanding central task, the question remains as to why opposing findings have been observed. Importantly, the answer to this question should
provide insight as to how the sustained attentional system interacts with the attentional capture system.

Although it is inherently difficult to formulate theories of attention that are both broad in scope (encompassing several classes of phenomena) while concurrently possessing predictive power for detailed behavioral outcomes, there are frameworks that could provide initial scaffolding towards such comprehensive theories. One such general framework for combining aspects of both inattentional blindness (i.e., an indirect measure of sustained focus) and attentional capture has been proposed by Most, Scholl, Clifford, and Simons (2005). Central to their theoretical framework, is the idea of an 'attention set' that is synonymous with the current task at hand or state of mind. The authors postulate that this 'attention set' should be the most influential factor in determining what captures attention. Incidentally, the idea that the current frame of mind determines how attention is allocated has also been proposed by Neisser's construct of the perceptual cycle (1976). While Most and colleagues' formulation provides an explanatory construct for both sustained attention and attentional capture, their emphasis on the attention set can be used to infer precise predictions. Specifically, Most et al. (2005, p. 218) proposed that:
> "Although some stimulus properties (e.g., uniqueness) can affect noticing, to a larger extent the unexpected objects that people consciously see depend on the ways in which they 'tune' their attention for processing of specific types of stimuli-that is, on the attentional set that they adopt."

Consequently, this leads to the prediction that irrelevant events that are within the same attentional set should be capable of capturing attention (i.e., irrelevant events that are similar to the targets used in a separate and attended to task), whereas events that fall outside of the attention set should go unnoticed (e.g., a gorilla walking amidst a group of people passing a basketball while counting passes, see for example Simons \& Chabris, 1999).

Most and colleagues’ (2005; 2001) predictions regarding the influence of the attention set were supported by a series of empirical studies centered around a paradigm in which participants counted the number of bounces of a subset of items moving within a display. Crucially, an unexpected object entered the display after several trials and detection rates for these objects were used as a measure of attentional capture. In this way, Most et al. were able to manipulate the composition of the attention set (the items moving and bouncing within the display), and observe the subsequent effects on attentional capture. Of critical importance to their theory, the findings suggest that the capture of awareness is influenced both by top-down and bottom-up interactions, where the most influential factor is ultimately the attention set adopted (although certain bottom-up factors such as stimulus salience can increase the chance that objects will be noticed). In general, when unexpected items possessed features that overlapped with those in the attentional set, participants consistently noticed them, whereas when the items were outside the attention set, participants rarely
noticed them. Bearing in mind that Most and colleagues' (2005; 2001) experiments were adaptations of an inattentional blindness paradigm where participants were tested on their awareness and processing of an unexpected event, the question remains as to whether the same predictions would generalize to a different task setting where attention is focused on a central area (rather than across the experimental display), and attentional capture is measured through exogenous cuing rather than conscious detection.

To recall a related example that was mentioned earlier in more detail, Santangelo and colleagues devised a paradigm involving both a demanding central task and an exogenously cued target detection task, and found that exogenous orienting does not capture attention in a mandatory fashion when undergoing a demanding central task (see Santangelo et al., 2007; Santangelo \& Spence, 2007, 2008). That is, when one's attention is engaged in performing a perceptually or attentionally demanding task, the automatic effects of exogenous cues seemingly disappear. This finding is especially important considering that previous accounts of exogenous cuing suggest that peripheral cues automatically capture attention (Jonides, 1981; Müller \& Rabbitt, 1989; Van der Lubbe \& Postma, 2005).

While it is possible that the elimination of the cuing effect could be related to an increase in perceptual load and a concomitant reduction in available attentional resources, as suggested by Santangelo et al. (2007), Most et al.'s (2005) theoretical framework could equally predict the same result. That is, Most et al. would predict that the elimination of the cuing effect would be related to the fact that the peripheral cues were not contained in the 'attention set' (i.e., the cue was not a part of, nor was it related to, anything in the central task). This was precisely the case in the paradigm used by Santagelo and colleagues (2007; 2008). Specifically, participants were required to detect a number amongst a rapid serial presentation of letters and numbers, while the peripheral cue was a geometric shape (i.e., not a letter or number). Adopting Most et al.'s logic, the peripheral cue was task irrelevant and not related to anything in the attention set (letters or numbers), therefore it is not surprising that it failed to capture attention. Accordingly, one can predict that if the irrelevant peripheral cues were to be manipulated such that they overlapped with the current attention set (i.e., the peripheral cues and central targets come from the same category or share the same features), they should successfully capture attention despite being completely irrelevant to the task at hand. In the present study, our goal was to investigate the relationship between central processing and the peripheral capture of attention (exogenous orienting), and how this relationship is mediated by the attention set.

Using a within subjects design, participants performed a difficult central task requiring them to detect numbers that were presented within a stream of rapidly presented letters. On a subset of trials participants responded to the location of a peripherally presented target (above or below) that was
orthogonally cued. Critically, we presented different types of peripheral cues to each participant, such that the cue was either of the same content as the central task or different. Note that the cue itself was completely irrelevant to the task and in theory would be outside of the attention set if it did not share any stimulus characteristics with items in the attention set (i.e., the central task in this case). If Most et al.'s (2005) prediction holds, exogenous cuing effects should be eliminated when peripheral cues are different from stimuli in the central stream. However, if peripheral cues are related to (or were even subsets of) the central task, then an exogenous cuing effect (i.e., attentional capture) should emerge.

\section*{Methods}

\section*{Participants}

Twenty-three participants (mean age \(=22 \pm 4 ; 13\) females) were recruited from undergraduate courses at the University of Hawaii at Manoa, and offered course credit for their participation. All participants were naïve as to the purpose of the experiment and had normal or corrected to normal vision. Ethical approval was obtained from the University's Committee on Human Subjects.

\section*{Stimuli}

All stimuli were presented on a 20 ", iMac using Bootcamp and DMDX software (Forster \& Forster, 2003). Observers sat approximately 60 cm from the display. Stimuli in the central rapid serial visual presentation (RSVP) stream was constructed from randomly chosen non-repeated letters (11 selected from set of 17: B, C, D, E, F, J, K, L, M, N, P, R, S, \(\mathrm{T}, \mathrm{Y}, \mathrm{X}, \mathrm{Z}\) ), each presented for 100 ms with a 16.7 ms interstimulus interval (ISI). For digit detection trials, numbers were selected from a set of six: \(2,3,4,5,6,9\). Visual targets were black circles (subtending \(2^{\circ}\) ) and cues were either black rectangles \(\left(2.5^{\circ} \times 1.7^{\circ}\right)\) or numbers of comparable size (i.e., outside or in the attention set of the primary task, respectively; see Figures 1 and 2). Aside from the use of number cues on half of the trials, all stimuli, presentation times, and counterbalancing were constructed to be similar to the unimodal visual condition used in Santangelo et al.'s experiment (2007).

\section*{Procedure}

All participants were presented with written instructions for the task on the computer screen. Next they were presented with practice trials and given accuracy and reaction time feedback after the end of each trial. The participants had the option of repeating the instructions, repeating the practice trials, or continuing with the experiment. The experimenter also monitored participants during the practice trials to ensure their understanding of the task.

For the actual task, participants were required to monitor the RSVP stream presented in the center of the display, and to respond to the occurrence of a numerical digit. A digit occurred on the majority of trials ( \(67 \%\) ). On the remaining
trials (33\%) the digit was not presented and instead, participants responded to the location of a spatial target that could have occurred in one of the four corners of the screen. A peripheral cue was presented on all trials, but was irrelevant to either task. The cue could have validly predicted the side of the spatial target or not (note, a spatial target was not present on digit trials). Responses were made using one of three keys following detection of either 1) a number, 2) an upward spatial target, or 3) a downward spatial target.

Figure 1: Schematic representation of the task. See text for details.

Figure 2: The two different cue types used in the task.
Each trial began with a fixation cross ( 1000 ms ) followed by the RSVP stream of 11 items. On digit detection trials, the numbers randomly occurred in either the third, sixth, or ninth position in the stream (see also, Santangelo et al., 2007). A spatial cue was also presented on each trial (for 100 ms , identical to item duration), occurring in the third or sixth position on either the right or left side of the display equiprobably. When spatial targets occurred a number was not presented in the stream, and the spatial target appeared two positions after the cue ( \(5^{\text {th }}\) or \(8^{\text {th }}\) position). The two
types of cues, rectangles or numbers, also occurred equiprobably (see Figure 2). Each experimental session consisted of 196 randomized trials, 132 of which were the digit detection task, and 64 of which were target detection (Santangelo et al., 2007). Cue combinations and trial repetitions were counterbalanced. Participants were instructed to respond as soon as targets were detected.

\section*{Results}

Mean reaction times (RTs) and error rates were analyzed using three repeated measures ANOVAs (analysis of variance): one for the overall experiment and two separate ANOVAs for the digit and spatial target detection conditions. Assumptions of sphericity were tested on all analyses, with Huyn-Feldt corrections being applied to \(p\) values where appropriate.

Figure 3: Mean error rates across tasks and cue types. Error bars indicate standard error values.

The first ANOVA was performed on the RT data with factors of task type (digit or target) and cue type (rectangle or number). There was no main effect of task type, \(F(1,22)\) \(=1.2, p=.3\), indicating that there were no overall differences in RTs across digit ( \(M=594 \mathrm{~ms}\) ) and target ( \(M\) \(=556 \mathrm{~ms}\) ) detection tasks. There was, however, a main effect of cue type, \(F(1,22)=8.4, p=.008\), indicating that, overall, RTs were slower when number cues ( \(M=589 \mathrm{~ms}\) ) occurred compared to rectangle cues \((M=563 \mathrm{~ms})\). There was no interaction between task and cue types, \(F(1,22)<1\), \(n s\), indicating no differences in RT patterns across the two tasks. In examining the error data, there was a main effect of task type, \(F(1,22)=36.2, p<.001\), with lower error rates for the digit task ( \(2 \%\) ) compared to the target task ( \(15 \%\) ). Error rates were also higher on trials with number cues ( \(10 \%\) ) than on those with rectangle cues ( \(7 \%\) ), \(F(1,22\) ) = \(4.5, p=.045\), indicating that on average the task was more difficult when number cues were present. Notably, the analysis revealed a marginally significant interaction between task and cue types, \(F(1,22)=3.5, p=.07\), indicating that number cues tended to be more distracting
than rectangle cues ( \(18 \%\) vs \(13 \%\), respectively) during spatial target detection, but not during digit detection ( \(3 \%\) vs \(2 \%\), see Figure 3).

A second three way ANOVA performed on the digit detection condition with factors of digit position (3), cue position (2), and cue type (2) revealed that participants detected the digits significantly faster when they were presented in the ninth ( \(M=455 \mathrm{~ms}\) ) position than when presented in the sixth ( \(M=584 \mathrm{~ms}\) ) or third ( \(M=736 \mathrm{~ms}\) ) positions respectively, \(F(2,44)=25.6, p<.001\). Reaction times were also faster when cues were presented in the third position \((M=574 \mathrm{~ms})\) than in the sixth position \((M=613\) \(\mathrm{ms}), F(1,22)=13.0, p<.01\). There was also a significant interaction between digit position and cue position, \(F(2,44)\) \(=5.4, p=.008\), suggesting that performance was worse when the cue occurred at the same time as the digit. Although there was no main effect in mean RTs between trials with number cues compared to trials with rectangle cues \(F(1,22)<1, n s\), there was a significant three-way interaction, \(F(2,44)=4.1, p=.04\), indicating a different pattern of RTs between rectangle and number cues. Specifically, when the target and cue both occur in the third position the number cue adversely affected performance whereas the rectangle cue did not (see Figure 4). No significant differences were found in the error rate data.

Figure 4: Interaction between target position, cue position in temporal stream, and cue type. Graph A shows trials with rectangle cues, whereas Graph \(B\) shows those with number cues.

The third, and most important, two way ANOVA was performed on the spatial target detection condition with factors of cue validity (2) and cue type (2). While there were no main effects of cue validity on reaction times, \(F(1,22)=\) \(3.0, p=.1\), there was a main effect of cue type, \(F(1,22)=\) \(11.0, p=.003\), where reaction times were slower when the target preceding cues were numbers \((M=570 \mathrm{~ms})\) compared to when they were rectangles \((M=543 \mathrm{~ms})\). Paramount to this study, the interaction between cue validity and cue type was also significant, \(F(1,22)=4.7, p=.04\), indicating the presence of cuing effects for number cues on the one hand ( 554 ms for valid cues, and 587 ms for invalid cues), and the lack of cuing effects for rectangle cues on the other hand ( 539 ms for valid cues, and 547 ms for invalid cues, see Figure 5). No significant differences were found in the error rates across cue type or validity.

Figure 5: Interaction of cuing effects within the spatial target detection condition. Cue validity: \(0=\) invalid cue, and \(1=\) valid cue.

\section*{Discussion}

The main purpose of this experiment was to test Most et al.'s (2005) theoretical framework on attention. To this end, our findings unequivocally support the prediction that irrelevant items that fall within the attentional set are capable of capturing attention while irrelevant items that fall outside of the attention set do not. That is, as was predicted, peripheral cues that were in the same category, or had overlapping features with the central task (numbers) had a cuing effect ( 33 ms ) on spatial target detection, while items outside the category (rectangles) did not (i.e., the cuing effect was eliminated). Not only was a cueing effect observed for peripheral number distractors, but this type of cue also led to a general increase in RTs for spatial trials. This indicates that despite being irrelevant to the task, the number cues were nevertheless processed, and served as more effective distractors when compared with the rectangles.

Although valid number cues effectively captured attention, they did not facilitate overall faster reaction times. That is, the mean reaction time for trials with rectangle cues was in fact faster than for number cues, despite the lack of a
cuing effect within this condition. This may possibly be due to the interaction of the number cues with the requirements of the central task. That is, any potential facilitating effects on performance of the valid number cues were probably offset by the overlap and interference with the digit detection task. The effects of this interference were also observed in the higher error rates for trials with number cues when compared to rectangle cues for spatial target detection (Figure 3).

Reaction times on the digit detection trials also point towards greater interference from the number cues. The interaction indicates that performance was worse on trials when the cue occurred at the same time as the digit, with more interference occurring from number cues when presented in the third frame. It is worth noting here that the lack of clearly distinguished differences between the effects of the rectangle and number cues on digit detection may be due to a more general distracting effect of the number cues. That is, the number cue may induce a distracting effect that generalizes beyond those particular trials to even cause the rectangle cues to become more distracting than they naturally would be. An effective way to test this theory would be to have participants also perform a task that consisted only of rectangle cues, and to then compare the pattern of results.

Aside from providing support for the theoretical position that the most influential factor for attentional capture is the 'attention set'-or the current items in focus-our findings also lend support to the notion that attention focuses on objects and features in addition to spatial location (e.g., Duncan, 1984; Egly, Driver, \& Rafal, 1994; for a review, see Scholl, 2001). In refining our understanding of the attention set, it becomes imperative to more precisely define the attention set itself, for the reason that when one is engaged in a task, there are usually multiple objects or different classes of events to attend to. For example, in this experiment, we defined the attention set as being the digit detection task, due to the fact this occurred the majority ( \(67 \%\) ) of the time. The most important object in the central stream was the number, and accordingly the identity of peripheral cues was manipulated to be numbers on half of the trials. \({ }^{1}\) The question remains however, as to what role the letters in the letter stream do play in the attention set.

Despite the fact that the letters within the RSVP stream are of a different category than the number targets, they are nevertheless processed by virtue of proximity to the number targets (both temporally and spatially) and the fact that the participants must monitor the stream in order to accurately detect the number amongst letters. We speculate that the letters should also be in the attention set, but is this assumption warranted? It is possible that the letters themselves may undergo some form on inhibition, and therefore a cue that is a letter might not capture attention. Even if this assumption were to be warranted, what would

\footnotetext{
\({ }^{1}\) Note that on each trial the number cues were different than the numbers presented in the central RSVP task, thereby avoiding any potential confounds.
}
be the precise role of letters in the attention set? Would the letters be afforded equal roles to the numbers, or would their roles be lesser, perhaps even of an inhibitory nature?

Thus it is clear that although Most and colleagues' (2005) framework provides a constructive foundation to build upon, further theoretical refinement and specification through experimentation is needed. Given that many aspects of attention appear to operate in context dependent manners, exploring these contexts within the unifying framework of the attention set may prove to be an informative approach for understanding the mechanisms of attention.

\begin{abstract}
As a ubiquitous trend in the cognitive development of children, the 'relational shift' accounts for a change in preference for absolute percepts towards a preference for relational percepts, and is observed across a wide variety of domains. Extensive evidence indicates that this prepotency for relational processing is also observed in how children process melodies. When recalling melodies, younger children typically recall more absolute pitch properties than older children, while the exact opposite occurs in older children. Using DORA (Discovery Of Relations by Analogy; Doumas et al., 2008), a domain-general symbolic-connectionist model of relation learning, we simulated the relational shift in melodic perception of children age 3-6 years based on an experiment by Sergeant and Roche (1973). DORA's performance matched the children's well, suggesting common developmental and perceptual mechanisms between the relational shift in melodic processing and the shift seen across other domains.
\end{abstract}

Keywords: Melodic perception; relation learning; development; relational shift; absolute pitch; computational modeling; DORA.

\section*{Introduction}

One of the fundamental cross-domain trends in human development is characterized by a qualitative transformation, or shift, in how children process information. Evidence from developmental psychology overwhelmingly indicates that while children initially attend to, recall, and reason about absolute perceptual properties, around the age of 4-6 they begin to rely on structured relational properties (Allport, 1924; Gentner \& Rattermann, 1991; Halford, 2005; Pollack, 1969; Vernon, 1940). This shift has been observed in areas such as language (Gentner, 1988), spatial tasks (Case \& Khanna, 1981; DeLoache, Sugarman, \& Brown, 1985), number comprehension (Gelman \& Gallistel, 1978; Michie, 1985), and visual shape perception (Abecassis, Sera, Yonas, \& Schwade, 2001), to name but a few. This phenomenon has been termed the 'relational shift,' as the characteristic trend is towards greater reliance on relational attributes as children mature.

Consistent with the developmental trajectory for the relational shift in other domains, in the domain of music
children also develop from initially processing more absolute aspects of melodies to processing more relational aspects as they grow older. In an especially revealing study, Sergeant and Roche (1973) trained three groups of children from the age of three to six to reproduce melodies from invariant recordings. When the children were required to recall the melodies one week later, the younger group reproduced the absolute pitches more accurately than the older group, while the older group reproduced the relational aspects (melodic shape, interval sizes, and tonality) more accurately than the younger group. This perceptual shift and exchange in proficiency levels between the recall of absolute and relational musical aspects in younger and older children has been replicated in many other studies as well (Saffran, 2003; Saffran \& Griepentrog, 2001; Sergeant, 1969; Sergeant \& Roche, 1973; Stalinski \& Schellenberg, 2010; Takeuchi \& Hulse, 1993).

Given the prevalence of the relational shift across multiple domains, it is reasonable to assert that any comprehensive theory or model of cognitive development must necessarily account for this phenomenon. One of the models of higher cognition that has successfully been used to account for the relational shift in development is DORA (Discovery Of Relations by Analogy; Doumas, Hummel, \& Sandhofer, 2008). DORA has been used to simulate the relational shift in visual shape perception (Doumas \& Hummel, 2010), analogical problems (Doumas, Morrison, \& Richland, 2009; Morrison, Doumas, \& Richland, 2011), categorical reasoning, spatial reasoning, general relational reasoning, and progressive alignment (Doumas et al., 2008).

In this study, we aim to understand how the relational shift in melodic processing occurs in children. We hypothesize that the same processes that cause the relational shift in other domains are also responsible for the shift in the domain of melodic processing. Specifically, we propose that as children learn about the world, they increasing rely on relational invariants in the environment. This reliance is itself a direct result of the cognitive processes that allow for relational invariants to be detected in the first place. That is, equipped with a cognitive architecture that allows for intersection discovery of shared properties, the natural trend over time (i.e., repeated exposure) is to preferentially
perceive the world in terms of these regularly occurring relational invariants (Doumas \& Hummel, 2010; Doumas et al., 2008).

This raises the question as to how relational invariants are discovered in the first place. Our proposal for this mechanism of discovery is instantiated in DORA's symbolic-connectionist architecture, and has been used to account for how melodic perception occurs in infants (Lim, Doumas, \& Sinnett, 2012). Consequently, providing an account for the relational shift in melodic processing may also help to shed light on other issues. For instance, the argument could be made against the existence of a musical relational shift by citing evidence of infants' ability to detect relational properties from melodies (Plantinga \& Trainor, 2005; Stalinski \& Schellenberg, 2012; Trehub, Bull, \& Thorpe, 1984). That is, given that the relational shift indicates that younger children preferentially process melodies based on absolute percepts (i.e., absolute pitch), would evidence of infants ability to process melodies based on relative percepts (i.e., relative pitch) not be contradictory? Since DORA has been used to simulate the latter phenomenon (Lim et al., 2012), by using DORA to simulate the former phenomenon (i.e., the relational shift in musical processing), we hope to provide an answer to this question as well. \({ }^{1}\)

\section*{The LISA/DORA models}

LISA (Learning and Inference with Schemas and Analogies; Hummel \& Holyoak, 1997, 2003) is a symbolicconnectionist model of analogy and relational reasoning. DORA is an extension of LISA that learns structured (i.e., symbolic) representations of relations from unstructured inputs. That is, DORA provides an account of how the structured relational representations LISA uses to perform relational reasoning can be learned from examples. At present, DORA accounts for over 30 phenomena from the literature on relational learning, and cognitive development, and as it learns representations of relations it develops into LISA and can simulate the additional \(40+\) phenomena in relational thinking for which LISA accounts for (e.g., Doumas et al., 2008). In the following, we provide a very brief description of the LISA/DORA models (for full details, see Hummel \& Holyoak, 1997, 2003; Doumas et al., 2008)

LISAese Representations In LISA (and DORA after it has gone through learning), relational structures are represented by a hierarchy of distributed and localist codes (see Figure 1). At the bottom, "semantic" units (small circles in Figure 1) represent the features of objects and roles in a distributed fashion. At the next level, these distributed representations are connected to localist units (POs) representing individual

\footnotetext{
1 Due to spatial constraints, we provide only summary information on melodic and relational processing here, for more background on melodic processing, including details about absolute and relative pitch and the other features used within these simulations, see Lim et al. (2012).
}
predicates (or roles) and objects (triangles and larger circles in Figure 1). Localist role-binding units (RBs; rectangles in Figure 1) link object and role units into specific role-filler bindings. At the top of the hierarchy, localist P units (ovals in Figure 1) link RBs into whole relational propositions.

Figure 1: LISA/DORA representation of the proposition, chase (dog, cat).

Relational structures (or propositions) are divided into two mutually exclusive sets: a driver and recipient(s). In LISA/DORA, the sequence of firing events is controlled by the driver. Specifically, one (or at most three) proposition(s) in the driver become(s) active (i.e., enter working memory). When a proposition enters working memory, role-filler bindings must be represented dynamically on the units that maintain role-filler independence (i.e., POs and semantic units) to allow for reusability of units and preservation of similarity across different bindings (Hummel \& Holyoak, 1997). In LISA, binding information is carried by synchrony of firing (with roles firing simultaneously with their fillers). In DORA, binding information is carried by systematic asynchrony of firing, with bound role-filler pairs firing in direct sequence (for details, see Doumas et al., 2008). \({ }^{2}\)
Relational Learning In broadest strokes, DORA learns structured representations by comparing objects to isolate their shared properties and to represent these shared properties as explicit structures. More specifically, DORA starts with simple feature-vector representations of objects (i.e., a node connected to set of features describing that object; large and small circles from Figure 1). When DORA compares one object to another, corresponding elements (i.e., shared features) of the two representations fire simultaneously (Figure 2a). Any semantic features common to both objects receive twice as much input and thus become roughly twice as active as features connected to one but not the other (Figure 2b). By recruiting a new PO unit and learning connections between that unit and active semantics via Hebbian learning (wherein the strength of connections is a function of the units' activation), DORA learns stronger connections between the new PO unit and more active

\footnotetext{
\({ }^{2}\) Asynchrony-based binding allows role and filler to be coded by the same pool of semantic units, which allows DORA to learn representations of relations from representations of objects (Doumas et al., 2008).
}
semantic units (Figure 2c). The new PO thus becomes an explicit representation of the featural overlap of the compared objects and can act as a single place predicate, taking other object representations as arguments to form role-filler pairs (Figure 2d; see also Doumas et al., 2008). Applied iteratively, this process allows DORA to learn structured explicit single-place predicate representations of any properties that compared objects may share. Comparison also allows DORA to learn representations of multi-place relations by linking sets of constituent role-filler pairs into relational structures (i.e., to learn the chases relation by linking together representations of the roles chaser and chased; see Doumas et al., 2008 for details). Moreover, when DORA has learned representations of whole relational structures, this intersection discovery algorithm allows it to learn schemas by comparing sets of structural relations to one another. For example, if after DORA has learned about a dog chasing a cat (chase (dog, cat)) and a boy chasing a girl (chase (boy, girl)), it can compare these and learn a representation coding for the intersection of the two chase relations and their arguments, or chase (generic-object1, generic-object2).

Figure 2: The process through which DORA learns a singleplace predicate representation of "higher" from two musical notes.

Mapping For the purpose of analogical mapping, LISA/DORA learns mapping connections between units coactive of the same type in the driver and recipient (e.g., between PO units in the driver and PO units in the recipient). These connections grow whenever corresponding units in the driver and recipient are active simultaneously. They permit LISA to learn the correspondences between matching structures in separate analogs. They also permit correspondences learned early in mapping to influence the correspondences learned later.

\section*{Methods}

In this section we describe the Sergeant and Roche (1973) study, followed by the details and outcomes of DORA's simulations.

\section*{Task Description}

In Sergeant and Roche's (1973) cross-sectional study, children were divided into three groups: one group with children between 3 to 4 years, one with children of 5 years, and one with children of 6 years. All groups received the same training and testing procedures. They were trained to vocally reproduce three melodies from an invariant recording in six training sessions spread out over three weeks. All children were given the exact same melodies at each training session. Each melody lasted for 8 or 16 bars.

One week after training, the children were then asked to vocally recall the melodies, which were tape recorded and scored by two independent judges on perceptual dimension (pitch accuracy), and conceptual dimensions (melodic shape, intervals, and tonality).

\section*{Simulations}

In the first simulation, we simulated the development of representations of individual relations that could define auditory sequence from experience with the world. In the second simulation, we used the representations DORA learned during the first simulation to simulate the behavior of Sergeant and Roche's (1973) subjects. Crucially, these two simulations were interleaved, which allowed us to test
Simulation Part 1 In the first simulation we tested DORA's ability to learn relational concepts from examples. This simulation proceeded like several simulations of relation learning from our previous work (e.g., Doumas \& Hummel, 2005, 2010; Doumas et al., 2008; Doumas et al., 2009). We started DORA with representations of 100 objects (represented as PO units) attached to random sets of features (chosen from a pool of 100). We then defined 4 relations (those that could be used to describe a melodic sequence, e.g., contour (higher/lower), and interval (long-interval, short-interval, medium-interval)).

Each relation transformation consisted of two roles each with three semantic features (e.g., for the higher relation, both the roles above and below were each defined by three specific semantic units). Each of the 100 objects was attached to the features of between 2 and 4 relational roles chosen at random such that if an object was part of a relation, it was attached to the features of one of the roles, chosen at random. For example, objectl might be attached to the features for above (one role of the relation higher) and start-long-interval (the agent role of the relation longinterval). We presented DORA with sets of objects selected at random, and allowed it to compare the objects and learn from the results (as per DORA's relation learning algorithm). As DORA learned new representations it would also use these representations to make subsequent comparisons. For instance, if DORA learned an explicit
representation of the property above by comparing two objects both attached to the features of above, it could use this new representation for future comparisons. On each trial we selected between 2 and 6 representations and let DORA compare them and learn from the results (i.e., perform predication, and relation learning routines). We assume that this act of inspection and comparison is similar to what happens when children encounter objects in the worldwhere objects are part of several relations-and learns from these experiences.

We ran 600 learning trials and measured the quality of the representations DORA had learned after each 100 trials. Quality was calculated as the mean of connection weights to relevant features (i.e., those defining a specific transformation or role of a transformation) divided by the mean of all other connection weights +1 ( 1 was added to the mean of all other connection weights to normalize the quality measure to between 0 and 1). A higher quality denoted stronger connections to the semantics defining a specific transformation relative to all other connections (i.e., a more pristine representation of the transformation). Figure 3 indicates the quality of the representations DORA learned at each level of iteration. Early in learning, DORA's representations are 'dirty' in that it's representations of relations and their roles are also highly connected to extraneous features specific to the instances from which the representations are learned. These representations are consequently very context dependent. As learning progresses however, DORA's representations become progressively more refined. By the end of learning, DORA has learned representations of relations and their roles that are context-independent, connected strongly to only the features specific to the particular relational roles defining the relation and very weakly connected to context features. Thus, in time DORA can use these representations to reason about instances regardless of context, like older children and adults (see, e.g., Doumas et al., 2008).

For the analysis herein, the 'quality' of DORA's representations (how relationally clean or context dependent they are) is considered an analogous measurement to the vocal reproductions of the children in Sergeant and Roche's (1973) study. That is, more pristine representations in DORA would be analogous to children reproducing melodies with more conceptual (relational) dimensions, whereas dirty presentations in DORA would be analogous to children reproducing melodies with more perceptual (absolute) dimensions.

Simulation Part 2 During the second simulation we simulated Sergeant and Roche's (1973) training and test conditions. We created a 20 note melody represented as 20 PO units attached to features indicating absolute frequency (between f 1 and f 24 ), the note's place in the sequence (120), two semantics describing whether the note is higher (above) or lower (below) the previous note in the sequence, two semantics describing the relative interval from the previous note (high-, medium-, low-interval), a semantic
describing the absolute interval from the previous note, and four random features (from a pool of 100). The features represent the properties that infants, children, and adults are capable of representing about melody (Thorpe \& Trehub, 1989; Trehub et al., 1984). Importantly, all of the frequency direction (higher/lower) and frequency interval, both absolute and relative, can be generated from raw frequency values (i.e. sensory input) using a simple comparator circuit described in Doumas et al. (2008) and Hummel and Biederman (1992).

Figure 3: The quality of DORA's representations as a function of learning iterations.

During training, we presented DORA with the note sequence and allowed it to fire each two note sequence in the melody (e.g., notes 1 and 2, then notes 2 and 3). During each two note firing sequence DORA attempted to retrieve relations from LTM describing the sequence (these representations were the same as those DORA had learned during part one of the simulation; see below for details). If DORA successfully retrieved a relation from LTM, DORA predicated the respective roles of the relation about the notes in the sequence. For example, if a two note sequence caused DORA to recall the higher \((x, y)\) relation from LTM (consisting of the roles above \((x)\) and below \((y)\) ), DORA would link the above PO to the note that was higher with an RB unit, and the below PO to the note that was lower. This process reflects our assumption that children and adults attempt to understand melodies using representations at their disposal. After DORA has attempted to classify the 2 note sequences in the melody, DORA stores the resulting representation in LTM.

Importantly, to simulate 4,5, and 6-year olds, we used representations that DORA had learned during the first part of the simulation in DORA's LTM. Specifically, to simulate the representations of 4 year olds, we used the representations that DORA had learned after 200 training iterations, to simulate 5 year olds we used the representations DORA had learned after 400 iterations, and to simulate 6 year-olds we used the representations DORA had learned after 600 iterations. At each age we also included distractor predicates describing extraneous properties (e.g., loudness, timbre, etc.) in LTM. For every relevant relation in DORA's LTM (i.e., relations describing
higher and relative interval) we also included 2 irrelevant relations. Our addition of distractor relations in LTM instantiates our assumption that children learn about multiple relations at the same time during development.

We trained DORA in this manner six times (reflecting the six training sessions from the Sergeant \& Roche (1973) study). After the second training session, and after each subsequent training session, DORA compared the representation it had learned during training to the representation it had learned during the previous training session and learned a new representation (or a schema) using it's learning algorithm.

To simulate the testing phase from Sergeant and Roche's (1973) study, we examined the representation of the melody DORA has learned after the six training sessions. Four-yearold DORA's relational representations were quite dirty and tied to the semantics of the objects from which they had been learned. DORA, consequently, had difficulty retrieving these representations from memory given the melody as a context cue. As a result, the representation of the melody that DORA stores is essentially the melody itself, without much (if any) explicit relational information predicated about it. As DORA get's older (i.e., has its LTM populated with representations produces by more extensive learning during simulation part 1 ), it becomes more likely to retrieve and thus predicate relations about the two note sequences in the melody during training. More precisely, 4 -year old DORA retrieved predicates about only \(18 \%\) of the 2 note sequences it thought about, 5 year-old DORA retrieved predicates about \(63 \%\) of the two note sequences it thought about, and 6 year-old DORA about \(91 \%\) of the instances it though about. Importantly, the predicates in DORA's LTM that it could retrieve varied in their refinement across ages (as described above). We used the representations that DORA had learned after the six training session as a proxy for what it would recall as melody production during the test session of the Sergeant and Roche study. We evaluated these final representations for the presence of relational properties with the assumption that increases in relational properties indicate increased reliance and accuracy on the conceptual dimensions of melodic shape and relative interval. Just as the children in Sergeant and Roche (1973), early in development DORA's ratio of relational/categorical features to absolute features was low, but as DORA learned the ratio increased strongly. At age 4, the ratio value was 0.85 . This value increased to 1.1 at age 5 and 1.6 at age 6 . This progression very closely mirrors the change in reliance on absolute to relational properties observed in children.

\section*{Discussion}

The purpose of this study was to 1 ) test our hypothesis that a common mechanism could potentially underly both the relational shift in melodic perception and the relational shift observed in other domains, and to 2) instantiate this mechanism within a computational model. To this end, our hypotheses were supported by DORA's simulations, which matched the behavioral data from children in Sergeant and

Roche's (1973) study. To our awareness this is the first time the relational shift in melodic processing has been modeled using 1) a neurally plausible architecture, 2) a domaingeneral model of cognition, and 3) the first run of simulations without any parameter fittings.

Consequently, DORA's success in simulating both the relational shift in children's melodic processing in this study, and in simulating infants' ability to detect relational properties of melodies (Lim et al., 2012), provides insights into a misunderstood (what we view as nonexistent) contradiction. Specifically, the argument has been made (e.g., Stalinski \& Schellenberg, 2012) that the evidence for a relational shift in melodic processing may be contradicted by findings that infants can process relational properties of melodies (for a review, see Trehub, 2001). We argue that these two findings are not contradictory, as evidence of a relational shift does not indicate that younger children cannot process relations, only that they show a preference for absolute pitch percepts. As they grow older this preference shifts towards relational melodic features (Takeuchi \& Hulse, 1993). Our theory posits that detection of relational features in melodies by infants (and humans of all ages for that matter) is facilitated by the temporal nature of melodies (each note in the melody sequentially occurs over time), and the corresponding temporality through which our brain encodes and recalls each note (i.e., binding through asynchrony). \({ }^{3}\)

We propose that cognitive systems (e.g., DORA) that use temporality as a binding mechanism between the individual units (notes) of a perceptual group (melodies), is inherently equipped to detect relational invariants within the group (Lim et al., 2012). Through development, learning (i.e., repeated exposure to the environment) occurs and the system inevitably detects more relational invariants, develops cleaner representations that are closer to these invariants (Simulation 1), and learns that this type of information is valuable and predictive. As a result, the system comes to prefer these types of percepts, as observed in the relational shift and predicted by DORA.

It has been proposed that the ability to detect relational properties in melodies may have a common ontogenetic origin as the ability to process vocal speech patterns, where our ability to detect relational melodic features may be a by product of our ability to detect invariants in speech (Terhardt, 1974). Additionally, our model lends support to the notion that absolute (i.e., perfect) pitch-the ability to recount specific note names or frequencies of auditory stimuli-may be a common ability in all humans that is robust in early childhood and subsequently diminishes through development, specifically as the relational shift occurs (Sergeant, 1969; for a review on aboslute pitch, see Takeuchi \& Hulse, 1993). We speculate that the high correlation of musical training during childhood with

\footnotetext{
\({ }^{3}\) Although we propose for time as a binding mechanism, we agnostically acknowledge that other mechanisms could serve a similar function. For a detailed algorithmic level account of DORA's mechanisms, see Doumas et al., 2008.
}
absolute pitch abilities (that subsequently endures into adulthood) may be due to increased exposure to pitch relevant stimuli as young children, and hope to examine such questions in future research.

\title{
Effects of Response and Presentation Format on Measures of Approximate Number System Acuity
}

\begin{abstract}
Human adults, infants, and non-human animals are believed to be equipped with an Approximate Number System (ANS) supporting non-symbolic representations of numerical magnitudes. Recent research has questioned both the validity and reliability of tasks intended to measure acuity in the ANS. Issues with validity and reliability might be due to differences in methodology. In the present study, we compare four tasks designed to measure ANS acuity, using a within-subjects design. The tasks are compared with respect to response and presentation format effects previously studied in the psychophysics literature, but largely ignored in the ANS literature. We find a presentation format effect and show that when non-symbolic numerical stimuli are presented sequentially the magnitude of the second stimulus is overestimated. Further, the results indicate that people's sensitivity to differentiate between non-symbolic numerosities is dependent on response format. The implications of the results to measures of ANS acuity are discussed.

\section*{Introduction}

Imagine walking in the countryside. As you approach a large field you spot two flocks of sheep, one with only white sheep and one with only black sheep, and amuse yourself by making a snapshot judgment of whether there are more white than black sheep. Later in your walk, you encounter another two flocks of sheep. This time the two flocks emerge from a tunnel, one flock after the other, separated by some short time interval. Once again, you test your judgment skills by deciding which of the two flocks that is the more numerous.

Human adults, infants and non-human animals have a common ability to represent numerical magnitudes, such as the number of sheep, without using symbols (Feigenson, Dehaene, \& Spelke, 2004). The core cognitive system supporting this ability, the Approximate Number System (ANS), represents magnitudes in an approximate fashion with representations becoming increasingly imprecise as numerosity increases (Dehaene, 2009; but see, Brannon, Wusthoff, Gallistel, \& Gibbon, 2001).

The accuracy with which the ANS can represent numerical magnitudes, often referred to as the acuity of the ANS, is conceptualized as the smallest change in numerosity that can be reliably detected and is often quantified by a Weber fraction (w). Acuity in the ANS progresses (i.e., \(w\) decreases) developmentally from
childhood to adolescence (Halberda \& Feigenson, 2008; Halberda, Ly, Wilmer, Naiman, \& Germine, 2012) but even among adults there is considerable individual variability (e.g., Halberda \& Feigenson, 2008; Halberda et al., 2012; Tokita \& Ishiguchi, 2010).

Studies using brain imaging have identified a neurological basis for the ANS in the intraparietal sulcus (IPS) on the lateral surface of the parietal lobe (Castelli, Glaser, \& Butterworth, 2006). Within the IPS, specialized neurons (numerons) sensitive to numerosity have been identified in macaque monkeys (Nieder, Freedman, \& Miller, 2002). The IPS, however, is not only activated by non-numerical stimuli. In humans, it is also activated when they observe numbers in different modalities and when they perform simple arithmetic tasks (Piazza, Izard, Pinel, Le Bihan, \& Dehaene, 2004). That the IPS is activated for a wide variety of numerical stimuli suggests a relationship between ANS acuity and achievement in formal mathematics. Such a relationship has been documented with children, even when controlling for a large number of cognitive abilities, (Halberda, Mazzocco, \& Feigenson, 2008; Inglis, Attridge, Batchelor, \& Gilmore, 2011) but results from studies on adults are mixed (Gebuis \& van der Smagt, 2011; Inglis et al., 2011; Price, Palmer, Battista, \& Ansari, 2012).

At least part of the mixed results might be attributed to differences in methodology. Recently the reliability and validity of some of the most commonly used measures of ANS acuity have been challenged (Gebuis \& Van der Smagt, 2011; Gilmore, Attridge, \& Inglis, 2011; Lindskog, Winman, Juslin, \& Poom, 2013; Price et al., 2012) and studies indicate that while some formats show reasonable reliability and validity others are neither reliable nor valid (Lindskog et al., 2013). The differences in reliability and validity between different tasks that measure ANS acuity highlight the question of whether task features influences performance. Put differently, will you be better at deciding which of the two flocks of sheep that is the more numerous when you see them coming out of the tunnel, one flock at a time, or when you see both flocks at the same time on the field? The question of what factors that influence the reliability of ANS acuity measures is important also because reliability sets an upper limit on correlations between ANS acuity and other cognitive abilities. The present study addresses this question by comparing four ANS acuity tasks, in a within-subjects design, that use different presentation and response formats.

\section*{Response and Presentation Formats}

While ANS acuity tasks use response and presentation formats that have been studied within the psychophysics literature (e.g. Macmillan \& Creelman, 2005) little or no attention has been given to how the choice of format influences the measures of ANS acuity per se. The typical ANS acuity tasks present participants with two arrays of non-symbolic stimuli. Most often the stimuli are dots (e.g., Halberda et al., 2008) but other types of stimuli, for example arrays of squares, have also been used (e.g., Maloney, Risko, Preston, Ansari, \& Fugelsang, 2010). After being presented with the two arrays participants' ability to differentiate between the numerosities of the two arrays is tested using one of two response formats. With a comparison format, similar to the two-alternative forced choice (2AFC) procedure used in psychophysics (Macmillan \& Creelman, 2005), participants indicate which of the two arrays that is the more numerous. For example, Halberda et al. (2008) presented participants with two arrays of dots, one array of yellow dots and one of blue dots, and asked participants to indicate whether blue or yellow was the more numerous color. In contrast, with a discrimination format, similar to a same-different procedure used in classification tasks in psychophysics (Macmillan \& Creelman, 2005), participants are to respond whether the two arrays have the same amount of dots or if the amounts of dots in the two arrays differ. The distinction between the two formats is relevant because even though psychophysicists have long known that the discrimination format is notoriously more difficult than the comparison format (Macmillan \& Creelman, 2005) this difference has not been acknowledged and investigated within the ANSliterature. Therefore, the present study compares the two response formats directly in a within-subjects design.

In addition to the discrimination-comparison distinction, tasks that measure ANS acuity can be classified with respect to how the stimulus is presented temporally. With a simultaneous presentation format, both arrays of stimuli are presented at the same time. For example, in the study by Halberda et al. (2008) the arrays of blue and yellow dots were spatially intermixed and presented on a monitor at the same time. In contrast to the simultaneous presentation format, several studies have employed a sequential presentation format (e.g., Gilmore et al., 2011) where the two arrays are presented one at a time, separated temporally by a short interstimulus interval (ISI). Two reasons make the presentation format distinction important. First, previous research has indicated that while tasks using a simultaneous presentation format exhibit a reasonably good validity, tasks with a sequential presentation format do not (Lindskog et al., 2013). Second, the introduction of an ISI in 2AFC tasks has been shown to introduce a bias, the time-order-error (TOE), where the second stimulus is commonly judged larger more often than the first (Hellström, 1985; Macmillan \& Creelman, 2005). Consequently, a sequence presenting
the two arrays as; Less numerous \(\rightarrow\) More numerous, would be correctly reported more often than the opposite sequence; More numerous \(\rightarrow\) Less numerous. Whether a TOE exists or not in ANS acuity tasks is an empirical and potentially important question. In the present study, we compare the two presentation formats and investigate if a TOE is present in ANS acuity tasks when using the sequential presentation format together with the comparison response format.

\section*{The Present Study}

Experiment 1 was designed to investigate the effects of presentation format and response format on performance in non-symbolic number differentiation tasks (i.e., ANS acuity tasks). To foreshadow the results; the experiment documented a TOE with a sequential presentation format and a comparison response format. Experiment 2 was designed to investigate the origin of the TOE by the use of direct estimates of non-symbolic numerosities. Experiment 1 also documented an effect of response format with better performance in the comparison than the discrimination format. We designed Experiment 3 to investigate if this effect was due to features of the ANS or due to a difference in sensitivity related to task features.

\section*{Experiment 1}

In Experiment 1, participants performed four tasks designed to measure ANS acuity. The tasks were modeled from those used in previous research on ANS acuity. The experiment was designed to compare response formats and presentation formats in general and more specifically to investigate if two classical phenomena documented in the psychophysics literature, the time-order-error and the comparison/discrimination difference, were present in tasks measuring ANS acuity.

\section*{Method}

Participants. Participants (10 Male, 20 Female) were undergraduate students from Uppsala University with a mean age of 26.1 years ( \(S D=6.6\) years). They received a movie ticket or course credits for their participation.

Materials and procedure. Participants carried out a set of four tasks, described in detail below and illustrated in Figure 1. The order of tasks was counterbalanced using a Latin square. In none of the tasks did participants receive feedback on their performance.

Parallel comparison. The parallel comparison task was based on Halberda et al. (2008). On each of the 200 trials, participants saw spatially intermixed blue and yellow dots on a monitor. Exposure time ( 200 ms ) was too short for the dots to be serially counted. We used five ratios between the numerosity of the two arrays of dots (1:2, 3:4, 5:6, 7:8, \(9: 10\) ) with the total number of dots varying between 11 and 30. One fifth of the trials consisted of each ratio. Half of the

Figure 1: Illustration of the parallel (Panel A) and sequential (Panel B) presentation formats together with the comparison (Panel A) and discrimination (Panel B) response format.
trials had blue and half had yellow as the more numerous set. The dots varied randomly in size. To counteract the use of perceptual cues dot arrays were matched for total area on half of the trials and for average dot-size on the other half of the trials. The participants judged which set was more numerous by pressing a color-coded keyboard button.

Sequential comparison. The sequential comparison task used the same stimuli as the parallel comparison task. Here, however, the stimuli were presented sequentially and separated by a 300 ms interstimulus interval. The order of color, and whether the first or second array was the more numerous, was counterbalanced over trials.

Parallel discrimination. The parallel discrimination task presented the stimuli in the same way as the parallel comparison task. Stimuli for half of the trials were created as in the comparison tasks with the same ratios between the numerosity of the two sets of dots and the same total number of dots. For the second half of the trials, both sets of dots (i.e. the blue and yellow set) had the same number of dots. Using the same numerosities as when the two sets differed in the number of dots resulted in the total number of dots varying between 10 and 32. In addition, while the comparison tasks required participants to determine whether the blue or the yellow set of dots was the more numerate, the parallel discrimination task asked participants to determine if the two sets of dots had the same or different amount of dots.

Sequential discrimination. The sequential discrimination task used the same presentation format as the sequential comparison task and the same response format and stimuli as the parallel discrimination task.

\section*{Results and Discussion}

Because the discrimination tasks do not easily allow for the modeling of an individual weber fraction, and because previous research (Lindskog et al., 2013) indicates that proportion correct is just as reliable and valid as \(w\), we used proportion correct as a measure of performance in all of the four tasks.

We compared performance in the four tasks by entering proportion correct as dependent variable into a 2 x 2 repeated measures ANOVA with presentation format
(parallel/sequential) and response format (comparison/discrimination) as within-subjects independent variables. This analysis showed a significant main effect of presentation format \((F(1,29)=55.6, p<.001)\) with better performance with the sequential format ( \(M=.73, S E M=\) \(.009)\) than with the parallel format ( \(M=.67, S E M=.008\) ). There was also a significant main effect of response format \((F(1,29)=546.1, p<.001)\) with higher proportion correct with the comparison ( \(M=.81, S E M=.01\) ) than with the discrimination ( \(M=.59\), SEM \(=.008\) ) format. The two-way presentation format by response format interaction did not reach significance ( \(F<1\) ).There were no effects of the order of the ANS tasks \((F<1)\).

In the two tasks using a sequential presentation format, the dot arrays are presented in one of two orders, either the larger or the smaller array came first. To investigate if this ordering influenced performance we entered proportion correct as dependent variable into a \(2 x 2\) repeated measures ANOVA with response format (comparison/discrimination) and array-size order (larger-smaller/smaller-larger) as within-subjects independent variables. The significant interaction \((F(1,29)=19.2, p<.001)\), illustrated in Figure 2, show that while the array-size order does not influence performance with the discrimination format there is a significant and substantial difference between the two orders with the comparison format.

Figure 2: Proportion correct as a function of response format and array order. Vertical bars denote 95 \% - confidence intervals.

In the comparison format the order which presents the smaller array first leads to significantly higher proportion correct ( \(M=.92, S E M=.012\) ) than the order which presents the larger array first ( \(M=.75, S E M=.022\) ). The analysis thus suggested that there might be a TOE present.

A TOE may occur either because the first stimulus is underestimated, because the second stimulus is overestimated or because it is psychologically easier to detect an increase in numerosity rather than a decrease. We designed Experiment 2 to distinguish between these three possibilities and to investigate the origin of the TOE when using non-symbolic numerosities as stimuli.

The response format effect might emerge for at least two different and independent reasons. First, it might be a feature of the ANS that it is adapted to detect the direction of a difference. For example, the ANS might have developed to determine that bush A contains more berries than bush \(B\), rather than to just determine that there is a difference in the amount of berries on the two bushes. Second, it might be that participants' sensitivity is higher with the comparison format than with the discrimination format as suggested by signal detection theory (Macmillan \& Creelman, 2005). We designed Experiment 3 to distinguish between these two possibilities.

\section*{Experiment 2}

Experiment 2 investigated the origin of the TOE observed in Experiment 1. Participants made direct estimates of the number of displayed dots in a task closely matching the sequential tasks from Experiment 1.

\section*{Method}

Participants. Twenty undergraduate students took part in the study, 12 females and 8 males. Average age was 24.8 ( \(S D=5.49\) ). Participants received a cinema voucher or course credits for their participation.

Stimulus and procedure. Stimuli were three numbers of dots ( 8,11 , and 14) that were presented in temporal sequence in stimulus pairs (e.g. \(8-11,14-8\) etc.) in a randomized order in a fully crossed design (two presentation positions (first/second) by three numerosities (8/11/14)). The dots were either blue or yellow. The sequence of colors was always the same for each participant, but randomized between subjects. Each stimulus pair was presented 9 times. Intermixed with these stimulus pairs each numerosity also occurred in isolation as a control. Together this made up 96 trials per participant. The numerosities were presented for 200 ms , with a blank interstimulus interval of 300 ms . Half of the trials were controlled for average dot-size, half for cumulative area. The task consisted of directly estimating the number of dots. This was done by entering a single number (for control stimuli) or two numbers with the keyboard. The input box was color coded, and always occurred in a left/right fashion corresponding to first/second
position. Participants were told that if they altogether had missed a presentation of stimuli, they could indicate this by entering an error code.

\section*{Results and Discussion}

Stimuli for which participants indicated that they had missed the presentation, as well as outlier responses ( \(|z|>3\) ) were excluded from the analysis. These data made up \(2.3 \%\) of the responses. There were no effects of color sequence order or stimulus type (size/area controlled).

Figure 3 shows judgments for control stimuli that appeared in isolated presentations. As can be seen in the figure, ratings were quite sensitive to the number of dots \((F(2,38)=38.0, p<.001\), one-way repeated measures ANOVA), but with a slight overestimation (the actual number is depicted in the dotted line in the figure).

Figure 4 shows the data of the two presentation positions and different numerosities. As can be seen in the figure, ratings are higher in the second presentation position.

Figure 3: Mean judgments of the three numerosities when presented separately (dotted line shows actual numerosity). Vertical bars denote 95 \% - confidence intervals.

Figure 4: Mean judgments of the three numerosities for each presentation position (first /second). Vertical bars denote 95 \% - confidence intervals.

A two-way ANOVA with numerosity (8/11/14) and stimulus presentation position (first/second) as independent within-subjects variables and judged numerosity as dependent variable shows that this presentation position effect is statistically significant \((F(1,19)=34.5, p<.001)\). The interaction was not significant \((F(2,38)=1.8, p=.17)\)

A one-way ANOVA with condition (control/1st presentation/2nd presentation) as independent variable shows a significant effect on absolute error \((F(2,38)=11.4\), \(p<.001\) ). Error was lowest in the control condition ( \(M=\) \(1.93, S E M=.26\) ), higher in the first presentation position ( \(M\) \(=2.16, S E M=.27\) ) and highest in the second presentation position ( \(M=2.55\), \(S E M=.34\) ). A Scheffé's post hoc test revealed that the error in the second presentation position was statistically significant from the two other conditions, which did not differ significantly from each other. The means of the absolute difference between participants' estimates and the three numerosities 8,11 , and 14 (i.e. the absolute error) were \(1.42,2.16\), and 2.28 respectively. This increase in absolute error was statistically significant \((F(2,38)=6.8, p=.00292)\).

The results of Experiment 2 show that when two numerosities occur in a brief temporal sequence, separated by a short interval, the second numerosity is rated as more numerous than the first, and with a larger error. There is no clear indication of interference in the reversed temporal direction, presenting a second numerosity does apparently not have a deteriorating effect on the judgment of the first numerosity. The results support the one of the proposed explanations for the TOE found in Experiment 1; Participants' better performance with the smaller \(\rightarrow\) larger presentation order than with the larger \(\rightarrow\) smaller order is due to the inflation in experienced numerosity of the second stimulus. This effect leads to participants correctly identifying this order, but will hinder performance on the larger \(\rightarrow\) smaller sequence.

\section*{Experiment 3}

In Experiment 3, we added an extra response alternative to the comparison format. In addition to answering whether the blue or yellow array was the more numerous, participants could also respond that they had the same numerosity. If a feature of the ANS is that it is adapted to detect direction (i.e. to detect that \(A>B\) rather than just that \(A \neq B\) ) we expected better performance with this new response format than with a discrimination format as a result of increased performance on trials with different amount of dots. However, if the effect from Experiment 1 could be attributed to a change in sensitivity, the opposite was expected because adding the extra response alternative would make the task harder.

\section*{Method}

Participants. The participants from Experiment 2 participated in Experiment 3.

Materials and procedure. Half of the participants carried out the two comparison tasks described in Experiment 1. The other half carried out the same tasks but with an alteration to the response format. The alteration combines the response formats of the comparison and discrimination tasks in Experiment 1. In the original discrimination tasks, participants could respond same or different while the comparison format had blue and yellow as response alternatives. In the modified task, participants had three response options: blue, yellow, and same. All other features of the task were identical to the comparison tasks of Experiment 1. The order of tasks was counterbalanced.

\section*{Results and Discussion}

We compared performance in the four tasks by entering proportion correct as dependent variable into a \(2 \times 2\) split-plot ANOVA with presentation format (parallel/sequential) as within-subjects independent variable and response format (same-different/yellow-same-blue) as between-subjects independent variable. Both the main effect of presentation format \((F(1,18)=36.3, p<.001)\) and the main effect of response format \((F(1,18)=20.4, p<.001)\) were significant while the interaction was not \((F<1)\). Participants in the same-different condition performed better ( \(M=.61\), SEM \(=\) .012) than did those in the yellow-same-blue condition ( \(M=\) \(.51, S E M=.012\) ). Further, and replicating the results from Experiment 1, performance was better in the sequential ( \(M\) \(=.60, S E M=.013\) ) than in the parallel presentation format ( \(M=.52, S E M=.011\) ).

These results show that the response format difference from Experiment 1 was eliminated, and even reversed, when an extra response alternative was added to the comparison format. This indicates that the discrimination format is more difficult than the comparison format and that the difference seen in Experiment 1 could be accounted for by a difference in sensitivity. However, even though the results lend support for a sensitivity explanation it does not exclude the possibility that the ANS is adapted not only to detect differences but also to detect the direction of a difference. This should be a question for future research to examine in more detail.

\section*{General Discussion}

Recently, a large body of research has investigated the ANS and its relationship to mathematical achievement. This research has used several different tasks to measure ANS acuity. The present study extends previous research by investigating response and presentation format effects on performance in ANS acuity tasks and shows that comparisons between tasks might not always be straightforward.

In Experiment 1, we found three effects with potentially important implications. First, the sequential presentation format yielded approximately \(8 \%\) (. 72 vs. .67) better performance than the parallel format. In ANS experiments
were w, which is modeled on proportion correct (e.g., Halberda et al., 2008), rather than proportion correct is used as a performance measure this corresponds to a \(30-45 \%\) difference in \(w\) for a typical participant ( \(w=[.15-.20]\) ). Thus, changing the presentation format can give rise to a substantial difference in estimated \(w\).

Second, in the sequential comparison task the order of stimulus was found to affect performance, similar to a TOE. Experiment 2 showed that the effect was due to an overestimation of the second stimulus compared to the control stimulus while no such bias could be found for the first stimulus. While it remains for future research to determine why the second stimulus is overestimated, one possibility could be residual activation in the IPS from the first stimulus. The effect has implications for measurements of ANS acuity. First, it will be necessary for future research using a sequential presentation format to counterbalance the order of stimulus for each ratio. Second, counterbalancing the order of stimulus might not be sufficient if numerosities are used that give rise to asymmetric differences in proportion correct. That is if the gain in one presentation order is larger/smaller than the loss in the opposite order. It remains for future research to investigate such asymmetries.

Finally, performance with a comparison format was significantly better than with a discrimination format. We proposed two possible explanations for this effect, that the ANS is adapted to detect direction or a difference in sensitivity, and showed in Experiment 3 that the latter was supported. This suggests that research on ANS acuity might benefit from, in addition to \(w\) and proportion correct, introducing a measure of sensitivity as a performance measure. The pattern of results, however, does not exclude the possibility of the ANS being a system adapted to detect the direction of a difference. This possibility should be an intriguing question for future research.

\begin{abstract}
Successful learning from text takes place when the cognitive demands of the learning task - i.e. the comprehension and retention of text material - and the metacognitive demands of the learning task - i.e. the accurate assessment of one's own learning process-are met. The present study was designed to investigate text titles - a factor known to affect cognitive learning processes- as well as the timing of keywording tasks - a factor known to affect metacognitive processes - and their effects on metacognitive monitoring and learning outcomes. The results of the study showed that both factors affected learning on the cognitive as well as the metacognitive level.
\end{abstract}

Keywords: Text-based learning; metacognition.

\section*{Effects of Titles on Learning and Metacognitive Monitoring}

Text titles, a common feature of written text, affect cognitive learning processes and outcomes by: (a) providing a context for an upcoming text (Ausubel, 1968), (b) activating relevant prior knowledge (Ausubel, 1968), and (c) guiding a reader's attention towards certain information in the text (Lorch \& Lorch, 1996). Titles also serve as retrieval cues for previously learned text information (Sadoski, Goetz \& Rodriguez, 2000) and foster the recall of text information that is related to the title (Ritchey, Schuster \& Allen, 2008). While the cognitive effects of titles are well-investigated, it is interesting to consider their potential influence on metacognitive monitoring, as well.

Metacognitive monitoring takes place when learners evaluate their own learning process with respect to a learning goal (Butler \& Winne, 1995; Dinsmore, Alexander \& Loughlin, 2008). In other words, learners engage in metacognitive monitoring whenever they judge their current state of learning relative to a desired state of learning (Thiede \& Dunlosky, 1999). The quality of metacognitive
judgments is influenced by the cues that learners use to make their judgments. According to the Cue-UtilizationFramework (Koriat, 1997), metacognitive judgments are inferential in nature. '[Learners] do not monitor directly the strength of the memory trace of the [to-be-judged information], but use a variety of cues that are generally predictive of subsequent test performance’ (Koriat, 1997, p.2).

The authors believe that titles may function as such cues whenever they are used to prompt learners' metacognitive judgments. Considering that a title related to a text provides a stronger link to relevant information from the text than an unrelated title, related titles should serve as more valid cues for metacognitive monitoring than unrelated titles.

\section*{Effects of Immediate vs. Delayed Keywording on Metacognitive Monitoring}

Aside from cues that arise from the text material, such as titles, learning tasks provide further cues for metacognitive monitoring (Thiede, Anderson \& Therriault, 2003). Keywording tasks are a type of learning task in which learners summarize a previously studied text using a set of keywords. The timing of when learners generate their keywords affects the quality of their metacognitive judgments with respect to recall test performance at a later point in time. Learners who generate keywords immediately after reading a text are less accurate in their metacognitive monitoring than learners who generate keywords after a delay (Thiede, Anderson \& Therriault, 2003; Thiede, Dunlosky, Griffin \&Wiley, 2005).

Current research relates these findings to Activation Theories of Text Understanding (Britton \& Guelgoez, 1991)-theories that describe a spreading activation during reading. More text information is available shortly after reading a text than after a delay, when text information has
decayed in memory. That means learners who generate keywords immediately after reading a text experience a high ease of recall in every keywording task. The high ease of recall in each keywording task makes it hard for learners to distinguish between well and less-well learned texts. It is hard for learners to make that distinction because the performance on an immediate keywording task is not a valid indicator of performance on tests that occur at a later point in time when text information has decayed in memory.

Learners who generate keywords after a delay do not experience the same ease of recall in every keywording task, because the learners need to access text information that has been subject to memory decay to a much larger extent at the time of the keywording task. Hence, the learners may be able to generate only a few keywords for a text that they do not recall well, while they may generate more keywords for a text they recall better. Since delayed keywording requires learners to access text information that has been subject to memory decay to a larger extent than immediate keywording, delayed keywording is a more valid indicator of recall test performance with regard to tests taken at a later point in time. Hence, learners who generate keywords after a delay provide more accurate metacognitive judgments than learners who generate keywords immediately.

While most of the current research has focused on the effects of the timing of keywording tasks on relative monitoring accuracy - i.e. the ability of learners to distinguish between well-learned and less well-learned text, the present study aims to investigate the effects of the timing of keywording tasks on monitoring bias - i.e. the extent to which learners over- or underestimate how much they have learned from a text.

\section*{Purpose of the Present Study and Hypotheses}

In order to develop learning materials that foster successful learning from text, learning materials should be constructed so that they foster learning on the cognitive, as well as on the metacognitive level. Thus, the present study was designed to investigate how related vs. unrelated text titles, and immediate vs. delayed keywording, affect metacognitive monitoring and learning outcomes.

The dependent measures of the study were comprised of a set of cognitive and metacognitive measures, namely a) performance on a keywording task as measured by the number of keywords correct, b) metacognitive judgments of learning for each text as measured by ratings on a 6-point Likert scale, and c) recall test performance as measured by the number of idea units recalled correctly in a free-recall essay task. Monitoring bias (d) was calculated by relating learners' metacognitive judgments to their recall test performance using the Self-Criterion-Residual-Strategy (Paulhus \& John, 1998).

With regard to the objectives of the present study, the authors aimed to investigate the following hypotheses:

\section*{Hypotheses: Effects of Titles}
1. Titles affect learning outcomes - titles related to a text serve as more valid retrieval cues than unrelated titles. Thus, the authors expect higher recall test performance for texts with related titles in both, the keywording task (Hypothesis 1.1) and an essay task (Hypothesis 1.2).
2. Titles affect metacognitive monitoring - titles related to a text serve as more valid cues for metacognitive monitoring than unrelated titles. Thus, the authors expect unrelated titles to evoke a stronger monitoring bias than titles related to the text.

\section*{Hypotheses: Effects of Immediate vs. Delayed Keywording}
3. The timing of keywording tasks affects learning outcomes in the keywording task (Hypothesis 3.1), but not in the essay task (Hypothesis 3.2). Learners who generate keywords immediately after reading a text have access to text information that is presumed to still be rather active in their memory. They experience a high ease of recall in every keywording task and are able to generate many correct keywords. Learners who generate keywords after a delay need to access information in their memory that has been subject to decay to a much larger extent. They do not experience the same ease of recall as learners in the immediate keywording group and, thus, are expected to generate a smaller number of correct keywords. The authors do not expect to find the same effect in the essay task, because, in the essay task, learners in both keywording conditions have to rely on text information that has been subject to memory decay to the same extent (i.e. about the same amount of time has passed in between reading and essay writing).
4. The timing of the keywording task affects metacognitive monitoring - learners who generate keywords immediately after reading a text experience a high ease of recall in every keywording task, which may cue them to overestimate their ability to retrieve the same text information at a later point in time, when memory activation for text information has decayed. Thus, the authors expect learners in the immediate keywording group to show a stronger overestimation bias than learners in the delayed keywording group.

\section*{Hypotheses: Interactive Effects of Titles and Immediate vs. Delayed Keywording}
5. Titles and the timing of keywording tasks interact with the learning outcomes in the keywording task (Hypothesis 5.1.), but not with the essay task (Hypothesis 5.2). While learners who generate keywords after a delay rely on titles as retrieval cues, learners in the immediate keywording group do not, because the text they just read is presumed to still be rather active within memory. Thus, the authors expect learners in the immediate keywording group to generate
more correct keywords for texts with unrelated titles than learners in the delayed keywording group. The authors do not expect to find the same effect in the essay task, in which learners in both keywording groups have to access text information that has been subject to memory decay to the same extent.
6. Titles and the timing of keywording tasks interact with metacognitive monitoring - learners who generate keywords immediately are expected to overestimate how much they learned from texts with unrelated titles. Learners who generate keywords after a delay are expected to show less of an overestimation bias with regard to texts with unrelated titles.

\section*{Methods}

Participants. 213 undergraduate students of an American university - 56 males and 157 females - participated in the study. Participant's ages ranged from \(18-57\) years ( \(\mathrm{M}=\) 22.2).

Design. The study follows a 2-Keywording (Immediate vs. Delayed) x 3-Title (Related/Close vs. Related/Distant vs. Unrelated) - design with repeated measures on the factor 'Titles'. The order of topic and title appearance was balanced within a Latin Square.
Materials. The study was conducted online. Materials were comprised of 6 expository texts derived from online databases and modified to suit the purpose of the study. Each expository text consisted of 2 distinct subtopics of an overall related theme. Themes varied for each text and were chosen from topics which are neither part of the standard US high school curriculum, nor part of the standard undergraduate curriculum at the university from which participants were recruited. The text concerning the overall theme of 'Art', for example, was comprised of the subtopics 'Expressionist Painting' and 'Dualism in Art'. To control for confounding effects between a topic and its position in the text, the order of topic appearance was counterbalanced within a Latin Square, so that every participant experienced every title condition twice throughout the study. In order to control for confounding effects of text position, the order of text appearance was also balanced within the Latin Square. Each subtopic in a text consisted of 30 idea units. Idea Units were defined as "single, meaningful piece[s] of information conveyed by the passage, whether [they] consisted of a word, a definition, or a phrase in the passage" (Meyer, 1975). The subtopics were balanced for word count (range: 190-284 words) and readability (Flesh-Kincaid readability score; range: 11-13). The readability range was chosen to match the target participant group of undergraduate university students. Each text was accompanied by one of three titles - a title that was related to the first subtopic in the text (Related/Close), a title that was related to the second subtopic in the text (Related/Distant), or a title that was unrelated to either of the subtopics in the text (Unrelated). While the authors had explicit hypotheses on the effects of related versus unrelated titles on metacognitive monitoring and learning outcomes, the distinction between

Related/Close and Related/Distant titles was made in order to detect whether the position of the related information in the text would have distinct effects on metacognitive monitoring and learning outcomes.

Study procedure. Participants were randomly assigned to the immediate or delayed keywording condition. Each participant read 6 texts and was instructed to learn as much from them as possible. Each text was presented for 2.5 minutes. Participants were asked to generate a maximum of 6 keywords prompted by the title, in order to capture the main gist of each text. The immediate-keywording group generated keywords immediately after reading each text. The delayed-keywording group generated keywords only after reading all 6 texts. After reading and keywording, participants provided a metacognitive judgment of learning on a 6 -point Likert scale \((1=\) learned very little to \(6=\) learned very much). Then, the text titles were presented one at a time, and participants were asked to write essays about what they remembered from the text. The time limit for each essay was 3 minutes. Reading and writing times were controlled in order to encourage participants to engage in each task thoroughly. Reading and writing times were allocated according to data derived from a pilot study conducted prior to the actual investigation.

\section*{Results}

Keywording task. Keywords were scored using a 4-category scoring rubric. Keywords could be correct, incorrect, missing, or they could be derived from prior knowledge, rather than from the text. Only correct keywords were included in the keyword analyses. The results of the keywording task were analyzed using a 2-keyword (Immediate vs. Delayed) x 3-title (Related/Close vs. Related/Distant vs. Unrelated) Analysis of Variance (ANOVA) with repeated measures on the factor 'titles' and Bonferroni correction for multiple testing.

The ANOVA revealed a significant main effect for the timing of keywording tasks \([\mathrm{F}(1,211)=132.64\); MSerror \(=\) 2.71; \(\mathrm{p}<0.01\); partial \(\eta 2=0.39\) (large effect)]. Learners who generated keywords immediately after reading a text were able to generate more correct keywords ( \(\mathrm{M}=3.97\); SD \(=0.09)\) than learners who generated keywords after a delay ( \(\mathrm{M}=2.47\); \(\mathrm{SD}=0.09\) ).

The ANOVA also revealed a significant main effect for titles \([\mathrm{F}(2,422)=20.86\); MSerror \(=1.19 ; \mathrm{p}<0.01\); partial \(\eta 2=0.09\) (moderate effect)]. Learners generated more correct keywords when the title was related to the text ( M ~ 3.41; \(\mathrm{SD}=0.09\) ), than when the title was unrelated ( \(\mathrm{M}=\) 2.82; \(\mathrm{SD}=0.09\) ). The number of correctly generated keywords did not differ significantly depending on whether the title-related information was stated first in the text \(\left(\mathrm{M}_{\mathrm{RC}}\right.\) \(\left.=3.41 ; \mathrm{SD}_{\mathrm{RC}}=0.09\right)\), or second \(\left(\mathrm{M}_{\mathrm{RD}}=3.42 ; \mathrm{SD}_{\mathrm{RD}}=0.09\right)\). In other words, learners generated more correct keywords as long as the title was related to the text, no matter in which position the related information appeared.

The main effects of keywording and title conditions were further qualified by a significant two-way interaction
between the timing of keywording tasks and titles [ F (2, 422) \(=11.95\); MSerror \(=1.19 ; p<0.01\); partial \(\eta^{2}=0.05\) (small effect)]. Learners who generated keywords immediately after reading a text had no problem generating keywords for texts with unrelated titles ( \(\mathrm{M}=3.87\); \(\mathrm{SD}=\) 0.13 ). Learners who generated keywords after a delay, on the other hand, generated a smaller number of correct keywords for texts with unrelated titles ( \(M=1.78\); \(\mathrm{SD}=\) \(0.13)\).

Metacognitive judgments of learning. Metacognitive judgments of learning were analyzed using a 2 -keyword (Immediate vs. Delayed) x 3-title (Related/Close vs. Related/Distant vs. Unrelated) ANOVA with repeated measures on the factor 'titles' and Bonferroni correction for multiple testing. The results of the ANOVA revealed a significant main effect for keywording conditions [F (1, 211) \(=7.47\); MSerror \(=1.66 ; \mathrm{p}<0.01\); partial \(\eta^{2}=0.03\) (small effect)]. Learners who generated keywords immediately after reading a text provided higher judgments of learning ( \(\mathrm{M}=3.14\); \(\mathrm{SD}=0.07\) ) than learners who generated keywords after a delay ( \(M=2.86\); \(S D=0.07\) ).
The ANOVA also revealed a significant main effect for titles [F \((2,422)=39.62\); MSerror \(=0.68 ;\) p \(<0.01\); partial \(\eta 2=0.16\) (moderate effect)]. Learners provided higher judgments of learning for texts with related titles ( \(\mathrm{M} \sim 3.2\); SD \(=0.07\) ) than for texts with unrelated titles ( \(M=2.60\); SD \(=0.07\) ). The judgment magnitude did not vary significantly depending on whether the related information was stated close to the title \(\left(\mathrm{M}_{\mathrm{RC}}=3.25\right.\); \(\left.\mathrm{SD}_{\mathrm{RD}}=0.07\right)\), or distant from it \(\left(\mathrm{M}_{\mathrm{RD}}=3.16 ; \mathrm{SD}_{\mathrm{RD}}=0.07\right)\).

Essay task performance. Essays were scored for idea units using a 5 -category scoring rubric. Recalled idea units could be correct, incorrect, partially correct to \(50 \%\) or \(25 \%\), or correct, but derived from prior knowledge rather than from the text. Only partially or fully recalled idea units derived from the texts were included in the essay analysis. The results of the essay task were analyzed with a 2 -keyword (Immediate vs. Delayed) x 3-title (Related/Close vs. Related/Distant vs. Unrelated) ANOVA with repeated measures on the factor 'titles' and Bonferroni correction for multiple testing.

The ANOVA revealed a significant main effect for titles \(\left[\mathrm{F}(2,422)=21.14 ;\right.\) MSerror \(=3.54 ; \mathrm{p}<0.01\); partial \(\eta^{2}=\) 0.09 (moderate effect)]. Learners recalled more idea units from text with related titles ( \(\mathrm{M} \sim 4.9\); \(\mathrm{SD} \sim 0.21\) ) than from texts with unrelated titles ( \(\mathrm{M}=3.89\); \(\mathrm{SD}=0.21\) ). The number of idea units recalled did not vary significantly depending on whether title-related information was stated first in the text \(\left(\mathrm{M}_{\mathrm{RC}}=4.98 ; \mathrm{SD}_{\mathrm{RC}}=0.22\right)\), or second \(\left(\mathrm{M}_{\mathrm{RD}}\right.\) \(=4.84 ; \mathrm{SD}_{\mathrm{RD}}=0.21\) ).

Metacognitive monitoring bias. Metacognitive monitoring bias was computed using the Self-Criterion-ResidualStrategy (SCR-Strategy: Paulhus \& John, 1998). For SCRAnalyses, self-reports (i.e. metacognitive judgments of learning) are regressed on an external criterion (i.e. essay task performance). The standardized residuals are used as indices for monitoring bias (i.e. the extent to which an
individual's monitoring accuracy differs from the average monitoring accuracy observed in the participant sample). The closer the standardized residual is to 0 , the more accurate the learner. Standardized residuals with negative values indicate underestimation, while standardized residuals above 0 indicate overestimation.
In a first step, the metacognitive judgment of learning for each text was regressed on the learner's essay task performance on that text and the standardized residuals from these simple regressions were saved. In a second step, the mean standardized residual for each title condition was computed for each participant. In a third step, a 2-keyword (Immediate vs. Delayed) x 3-title (Related/Close vs. Related/Distant vs. Unrelated) ANOVA with repeated measures on the factor 'titles' and Bonferroni correction for multiple testing was computed on the mean standardized residuals for each title condition.
The ANOVA revealed a significant main effect for keywording conditions \([F(1,211)=5.72\); MSerror \(=0.95\); \(p=0.02\); partial \(\eta^{2}=0.03\) (small effect); see figure 1]. In general, learners showed virtually the same monitoring bias ( \(\mathrm{M}=|0.09|\); SD \(\sim 0.05\) ) in both keywording groups - except that learners who generated keywords immediately tended to overestimate how much they had learned ( \(\mathrm{M}=0.09\); SD \(=0.05\) ), while learners who generated keywords after a delay tended to underestimate how much they had learned ( \(\mathrm{M}=-0.09 ; \mathrm{SD}=0.06\) ).
The ANOVA also revealed a significant main effect for titles [F \((2,422)=29.12\); MSerror \(=0.39 ; \mathrm{p}<0.01\); partial \(\eta^{2}=0.12\) (moderate effect); see figure 1]. Learners tended to overestimate how much they had learned when texts were related to the title, while it did not matter whether the titlerelated information appeared first in the text \(\left(\mathrm{M}_{\mathrm{RC}}=0.16\right.\); \(\left.\mathrm{SD}_{\mathrm{RC}}=0.05\right)\), or second \(\left(\mathrm{M}_{\mathrm{RD}}=0.11 ; \mathrm{SD}_{\mathrm{RD}}=0.05\right)\). When texts were unrelated to the title, learners tended to underestimate themselves instead \(\left(\mathrm{M}_{\mathrm{UR}}=-0.26 ; \mathrm{SD}_{\mathrm{UR}}=\right.\) \(0.05)\).

Figure 1: Metacognitive monitoring bias at timing of keywording task (Immediate vs. Delayed) x titles (Related/Close vs. Related/Distant vs. Unrelated).

\section*{Discussion}

\section*{Effects of Titles and Qualifying Interactions}

Hypothesis 1: The authors expected titles to influence learning outcomes in both - the keywording task (Hypothesis 1.1) and the essay task (Hypothesis 1.2). The results of the study are in line with the hypotheses - learners generated more correct keywords for texts with related titles, than for texts with unrelated titles. Learners also recalled more idea units from texts with related titles, than from texts with unrelated titles. These findings support the idea that related titles provide a stronger link to relevant text information than unrelated titles, and, thus, serve as more valid retrieval cues for recalling text information than unrelated titles.

It is important to note that the timing of the keywording task influenced how strongly learners relied on titles when generating keywords (Hypotheses 5.1). While learners in the immediate keywording group were able to generate almost as many correct keywords for texts with unrelated titles (M \(=3.87\); \(\mathrm{SD}=0.13\) ) as for texts with related titles \((\mathrm{M}=4.01\); \(\mathrm{SD}=0.13\) ), learners in the delayed keywording group generated less correct keywords for texts with unrelated titles \((M=1.77 ; S D=0.13)\) than for texts with related titles ( \(\mathrm{M}=2.81 ; \mathrm{SD}=0.12\) ). This finding is in line with the assumptions of Activation Theories of Text Understanding (Britton \& Guelgoez, 1991) suggesting a spread of activation during reading. Learners who generated keywords immediately after reading a text were able to access text information that was presumably still active within memory. That is, the learners did not have to rely on the title as a retrieval cue to the same extent as learners in the delayed keywording group. The delayed keywording learners needed to access text information from memory that had decayed to a much larger extent at the time of their keywording task. This interaction was not observable in the essay task (Hypothesis 5.2), because for the essay task, learners in both keywording groups had to access text information in their memory that had been subject to decay. About the same amount of time had passed in between reading and essay writing in both keywording groups. Thus, learners in the immediate keywording group could not rely on information that was presumably active within memory for the essay task, but needed to access information that had decayed.

Hypothesis 2: The authors expected titles to affect metacognitive monitoring. The authors specifically hypothesized that related titles would serve as more valid cues for making metacognitive judgments than unrelated titles, resulting in a smaller monitoring bias for texts with related, than for texts with unrelated titles. The results of the study showed that monitoring bias was indeed influenced by the title conditions. Learners tended to overestimate how much they had learned from texts with related titles, while they tended to underestimate how much they had learned from texts with unrelated titles. The strength of the monitoring bias differed between title conditions in the way
the authors hypothesized - while learners just slightly overestimated how much they had learned from texts with related titles (Mean standardized residual \(=0.14\) ), they underestimated how much they had learned from texts with unrelated titles to a much larger extent (Mean standardized residual \(=-0.26\) ). This finding supports the idea that related titles serve as more valid cues for making metacognitive judgments than unrelated titles.

\section*{Effects of Immediate vs. Delayed Keywording}

Hypothesis 3: The authors expected the timing of the keywording task to influence the number of correctly generated keywords (Hypothesis 3.1), but not the number of correctly recalled idea units in the essay task (Hypothesis 3.2.) The results of the study provided evidence for these hypotheses. Learners in the immediate keywording group generated more correct keywords ( \(\mathrm{M}=3.97\); \(\mathrm{SD}=0.09\) ) than learners in the delayed keywording group ( \(\mathrm{M}=2.47\); \(\mathrm{SD}=0.09\) ). This finding again supports the assumptions of Activation Theories of Text Understanding (Britton \& Guelgoez, 1991). Learners can easily access text information shortly after reading, while it is harder to access text information after a delay when memory activation has decayed. This effect was not observable in the essay task anymore, because for the essay task, learners in both keywording groups had to access text information in their memory that had been subject to decay to the same extent, i.e. about the same amount of time had passed in between reading and essay writing in both keywording groups.
Hypothesis 4: The authors expected the timing of the keywording task to influence metacognitive monitoring. The authors specifically hypothesized that learners in the immediate keywording group would show a stronger overestimation bias than learners in the delayed keywording group. The results of this study support this hypothesis. While learners in the immediate keywording group showed a slight overestimation bias ( \(M=0.09\); \(\mathrm{SD}=0.05\) ), learners in the delayed keywording group showed a slight underestimation bias ( \(M=-0.09\); \(S D=0.06\) ). It is important to note that this result was influenced by the effects of the unrelated title condition, although the authors could not detect the hypothesized interaction (Hypothesis 6). That is, the general underestimation bias evoked by unrelated titles decreased the mean monitoring bias in both keywording conditions.
In order to detect whether the direction of monitoring bias was overall affected by the unrelated title condition, the authors removed the effects of the unrelated title condition from the analysis by conducting a separate analysis for texts with related titles only. That is, the authors compared the mean standardized residual for texts with related titles in the immediate keywording condition \((\mathrm{M}=0.2 ; \mathrm{SD}=0.08)\) to the mean standardized residual for texts with related titles in the delayed condition ( \(\mathrm{M}=0.07\); \(\mathrm{SD}=0.08\) ). The t -test revealed a significant difference between the keywording groups ( \(\mathrm{t}(211\) ) \(=-11.86 ; \mathrm{p}<0.01\) ). While learners in both keywording groups tended to generally overestimate how
much they learned from texts with related titles, as indicated by mean standardized residuals above 0 , learners who generated keywords immediately showed a significantly stronger overestimation bias than learners who generated keywords after a delay. This finding is in line with former research investigating the delayed keywording effect (Thiede, Anderson \& Therriault, 2003). The authors believe that this effect is due to the high ease of recall that learners experience in the immediate keywording task, as indicated by the large amount of keywords generated correctly. The ability to generate a large number of keywords may cue learners to believe that they have learned the text information well and that they will be able to recall it at a later point in time, as indicated by higher judgments of learning in the immediate keywording group. Yet, a learner's performance on an immediate keywording task is not a valid indicator of performance in the essay task, which takes place at a later point in time when text information has been subject to memory decay. Thus, learners who generate keywords immediately tend to show a strong overestimation bias due to the ease of recall they experience in their keywording task. Learners who generate keywords after a delay, on the other hand, need to access text information that has already been subject to memory decay to a larger extent and that is a much better indicator of performance in the essay task, which takes place after an even larger delay. That means that learners in the delayed keywording group do not experience an ease of recall that could cue them to overestimate themselves to the same extent as learners in the immediate keywording group, resulting in more accurate metacognitive monitoring in the delayed keywording group, as compared to the immediate keywording group.

\section*{Conclusions and Outlook}

The present study contributes to the current literature in three ways. First, the authors could show that titles do not only affect cognitive learning processes and learning outcomes, but also metacognitive monitoring, with related titles functioning as more valid cues for making metacognitive judgments than unrelated titles. Second, the results of the study showed that delayed keywording does not only foster relative monitoring accuracy (i.e. the ability to distinguish between well and less-well learned texts), but also prevents overestimation bias (i.e. the tendency to overestimate oneself) to a larger extent than immediate keywording. Third, the results of the study showed that titles and the timing of keywording tasks interact with regard to certain learning tasks. This finding raises the question of how closely cognitive and metacognitive processes are related - a question that may be very interesting to investigate in further studies.

\begin{abstract}
The blocking effect in causal learning, once taken as a hallmark of associative learning, has recently been explained in terms of an explicit deductive reasoning process. Yet when the conditions necessary for deduction are removed, a small blocking effect is often still present. We examined the relationship between blocking and participants' performance on analytical thinking and probabilistic reasoning measures. Inferential processes predict blocking or an absence of blocking in this situation, depending on the observer's consideration of conditional probabilities. Although Bayesian inference predicts blocking, most individuals are not inclined to use this form of probabilistic reasoning explicitly, an observation we confirmed using a logical problem with similar properties to the relationships present in the blocking effect. Furthermore, participants who showed the greatest capacity for analytical reflection were less likely to show a blocking effect, suggesting that blocking in causal learning is the product of an intuitive and unreflective thought process.
\end{abstract}

Keywords: Blocking; causal learning; inferential reasoning; associative learning; Bayesian inference.

\section*{Introduction}

Many theories of causal learning assume that when individuals make judgments about the relationship between putative causes and their effects, some form of inferential reasoning is involved. However, theories differ substantially in how they place inferential reasoning amongst other contributing mechanisms. Some authors have argued that all causal judgments are necessarily the product of explicit inferential processes based on consciously mediated propositions about the relationships between events (Mitchell, De Houwer and Lovibond, 2009). Others assume that in making causal judgments about a cue, relatively automatic memory retrieval mechanisms based on associative learning play a much greater role, bringing to mind the events that were previously paired with that cue. According to this account, inferential thoughts of an analytical nature - for instance based on formal logic and reasoning - play a smaller role, in some cases perhaps only when strongly encouraged.

\section*{Blocking in causal learning}

The blocking effect has become an important test bed for these arguments. In a typical blocking experiment, one cue (A) is presented and is reliably followed by a particular outcome. In a second stage, \(A\) is presented with another cue (B) and this compound of two cues is followed by the
outcome. B is never presented by itself and its relationship with the outcome is thus ambiguous. When asked to give a rating of the extent to which each of a number of cues causes the outcome, participants often given a lower rating for B than for control cues ( C and D ) that were also presented in compound and followed by the outcome but were never presented on their own.

The cues and outcomes are often presented within a hypothetical scenario. For instance, in the allergist task, the participant assumes the role of a doctor trying to determine the cause of a patient's allergic reactions. The participant might observe that when the patient eats Fish they suffer from a reaction \((\mathrm{A}+)\), and later when the patient eats Fish and Rice \((\mathrm{AB}+)\), they suffer from the same allergic reaction. The patient might also suffer from an allergic reaction after eating Mushrooms and Pasta (CD+), but does not suffer a reaction after eating various other foods (e.g. E-). After learning to predict what will happen after certain meals, through a process of trial and error, the participant must then make an explicit judgment about the extent to which a food or foods cause the allergic reaction, or the likelihood that a reaction will occur given that certain foods have been consumed.

The blocking effect is well documented in causal learning experiments using the allergist task and other similar scenarios. Its presence was originally taken as evidence that a similar associative learning process was responsible for causal learning and conditioning in humans and other animals because blocking in classical conditioning is widely replicated and well explained by associative learning theories (Dickinson, Shanks, and Evenden, 1984). Several other prominent theoretical approaches to causal reasoning also provide explanations of blocking (e.g. Cheng, 1997; Griffiths, Sobel, Tenenbaum, Gopnik, 2011; Waldmann, 2000). Whether based on associations or statistical computation, many theories of causal learning share an assumption that causal judgments partly reflect an implicit sensitivity to the contingencies between observed events. This sensitivity allows the observer to make judgments about causation with little deliberate mental effort, even when the causal relationships between cues and outcomes are ambiguous and must be inferred indirectly, as in the case of blocking (e.g. see Sternberg and McClelland, 2011).

\section*{Blocking and inferential reasoning}

Recently, several authors have argued for an explanation of blocking that relies only on inferential reasoning based
upon a relatively simple set of propositions (De Houwer, Beckers, \& Glautier, 2002; Lovibond, Been, Mitchell, Bouton, \& Frohardt, 2003). Proponents of this account point out that there are circumstances under which the observer can logically deduce that the blocked cue (B) is not a cause of the outcome. For instance, this position is reached if one assumes that the effects of the patient's allergies are additive and that a more severe reaction could be observed if it were present. Holding these assumptions, if one does not observe an increase in the severity of the outcome when B is eaten at the same time as the allergenic food A , then one can deduce that B does not contribute to the allergic reaction. For example, if eating Fish causes an allergic reaction of severity 5 (on a fictitious allergy scale with a maximum of 10) and eating Fish and Rice also causes an allergic reaction of severity 5 , then Rice has not made the reaction worse and thus probably isn't a cause of the reaction itself. Consistent with this inferential reasoning hypothesis, Lovibond et al. (2003; see also De Houwer et al., 2002; Livesey \& Boakes, 2004) observed that pretraining and explicit instructions that encourage this outcome additivity assumption enhance the blocking effect.

Lovibond et al. (2003) also argued that if the observer assumes that the effects of the causal cues do not add to create a larger effect then this deduction is no longer valid and therefore there should be no blocking observed. This "nonadditive" assumption is encouraged by explicitly showing that the addition of two causes does not result in a stronger outcome than one cause on its own. According to this argument, participants with an assumption that the outcome is nonadditive should identify that they cannot be certain of the causal status of B, any more than the control cues \(C\) and \(D\), and thus give each of these cues an equivalent causal rating that reflects that uncertainty.

In practice, a statistically robust blocking effect is often observed even after explicit nonadditive pretraining, albeit one that is numerically smaller than after additive pretraining (e.g. Lovibond et al., 2003; Mitchell, Lovibond, Minard, \& Lavis, 2006). The presence of this persistent blocking effect has been viewed by some as a problem for the inferential reasoning account of causal learning because blocking after nonadditive pretraining is not the result that a participant would generate when applying inferential reasoning in a rational way (Lovibond et al., 2003).

Yet it is worth noting that, at least from the perspective of classical probability theory, this blocking effect is entirely rational. For both the blocking and control cases, the problem involves determining the probability of the hypothesis that a certain cue, \(X\), is a reliable cause of the outcome, \(\mathrm{p}(\mathrm{X}+)\). Relevant information is gained from observing that X in compound with another cue does cause the outcome \((\mathrm{XY}+\) ). Thus the problem becomes one of calculating the conditional probability that X is a cause of the outcome given the observation that the compound XY causes the outcome, \(\mathrm{p}\left(\mathrm{X}^{+} \mid \mathrm{XY}+\right)\). We can use Bayes' theorem to calculate this conditional probability as follows:
\[
p(X+\mid X Y+)=\frac{p(X Y+\mid X+) \times p(X+)}{p(X Y+)}
\]
where
\[
p(X Y+)=p(X+)+p(Y+)-p(X+) p(Y+)
\]

In the case of the blocked cue, \(B\), we can assume that participants are already certain that \(A\) causes the outcome the first time they experience \(\mathrm{AB}+\) trials, i.e. \(\mathrm{p}(\mathrm{A}+)=1\). In the case of the control cue, D , there is equal uncertainty about it and cue \(C\), and thus \(p(C+)=p(D+)\). In the absence of any further information, these unconditional probabilities, as well as \(p(B+)\), are assumed to be equal to the base rate (the probability that the outcome will occur on any given trial or for any given cue). If we assume that, when a nonadditive outcome follows a compound of two cues, the outcome is independently caused by at least one of the cues, then \(\mathrm{p}(\mathrm{XY}+\mid \mathrm{X}+)=1\). This is a reasonable assumption unless it is explicitly shown to be false, as in the case of patterning discriminations (Harris \& Livesey, 2008; Livesey, Thorwart, \& Harris, 2011). The predicted blocking effect derived from these assumptions is a function of the base rate probability, as shown in Figure 1. As the base rate approaches zero, \(p(B+)\) approaches zero and \(p(D+)\) approaches 0.5 . As the base rate approaches \(1, \mathrm{p}(\mathrm{B}+)\) and \(\mathrm{p}(\mathrm{D}+)\) both approach 1 . Importantly, for every base rate between 0 and \(1, \mathrm{p}(\mathrm{B}+)\) is less than \(\mathrm{p}(\mathrm{D}+)\). Most causal learning experiments (including this study) present equal numbers of outcome and no outcome trial types, meaning that the base rate is around 0.5 . This means that a modest blocking effect is predicted, is can be seen in Figure 1.

Figure 1. Probability that a test cue (B or D) causes the outcome as a function of the baseline probability that any given cue causes the outcome. Values were calculated by applying Bayes' theorem to the propositions that can be derived from a typical blocking design involving the "blocked" cue B and the control cue D (see parentheses).

The solution can also be derived without the previous equations using a series of simple inferential steps. For ease
of illustration, let us also assume that the probability of any cue shown in the experiment causing the outcome is 0.5 . Given these assumptions, for any given compound of two cues A and B, there are four equally likely possibilities; i) A and \(B\) are both causal, ii) A only is causal, iii) B only is causal, or iv) neither A nor B is causal. In the case of the blocking cue, we know that A leads to the outcome, which allows us to rule out two of these possibilities (iii and iv), leaving possibility (i) in which B is causal, and possibility (ii) in which \(B\) is not causal. Thus the probability the \(B\) causes the outcome is 0.5 . In the case of the control cues, we observe only that the compound causes the outcome, which allows us to rule out only possibilities (iv) that neither cue causes the outcome. The remaining three possibilities are still equally likely, and D causes the outcome in two of these three possibilities. Thus the probability that D causes the outcome is 0.67 (likewise for C ).

\section*{Inferences and probabilistic reasoning}

Although it may seem surprising to some that blocking under these circumstances is completely logical, the temptation to conclude that blocking is the result of an explicit rational inference based on classical probability theory needs to be tempered by an equally striking observation. In a host of similar situations, most participants are very unlikely to apply this form of reasoning. The rationale applied above to blocking shares formal qualities with other problems involving conditional probabilities, which most normal adults find extremely difficult (e.g. BarHillel \& Falk, 1982). A prominent example is the MontyHall dilemma (see Burns \& Wieth, 2004), in which participants are so resistant to the solution derived from conditional probabilities that the problem is often referred to as a cognitive illusion. Thus, even though the blocking effect under nonadditive assumptions could be described as being rational, one should question whether participants are capable and inclined to explicitly use the inferential process that is necessary to arrive at the judgment in a rational and logical fashion.

If participants do use explicit reasoning processes akin to Bayesian inference, and the nonadditive blocking effect is a consequence of this reasoning, then the participants who show the greatest inclination to engage critically in inferential reasoning will be the most likely to give ratings in line with the blocking effect. Alternatively, Lovibond et al. (2003) assume that the most prevalent rational inference will be one in which the blocked and control cues are treated as being equally ambiguous, and thus no difference in their causal ratings should be observed. If this assumption is correct then those participants who are most likely to engage in that rational inference will be the least likely to produce a blocking effect in their judgments of causality. This hypothesis also implies that the blocking effect that has previously been observed after nonadditive pretraining is the result of a non-rational process such as a failure to retrieve the outcome associated with the blocked cue (Mitchell et al., 2006).

The current study sought to assess exactly what types of reasoned inference participants were inclined to use in this situation and how the inferential skills of individual participants were related to the blocking effect.

\section*{Blocking and critical thinking}

To test the relationship between inferential thinking and blocking, we coupled a typical blocking task with a test of cognitive reflection developed by Frederick (2005). The test presents three mathematical problems, each of which can be solved with minimal calculation. The problems were specifically designed to provoke an intuitive answer that is incorrect. Deriving the correct answer requires a modest amount of self-reflection and analytical thought in order to reject the first number that comes to mind and to then apply the inferences that are appropriate for the logic of the question at hand. Frederick's (2005) analysis of this cognitive reflection test (CRT) over multiple samples of young American adults revealed that a substantial proportion scored 0 out of 3 on the test, revealing a strong tendency to accept and report the intuitive foil answer for each question. CRT performance is associated with general cognitive ability (Frederick, 2005). However, some studies have shown that performance on the test is influenced by the conditions under which the information is presented; for instance when the questions are more difficult to read they are more likely to be answered correctly (Alter, Oppenheimer, Epley, \& Eyre, 2007). This suggests that participants' propensity to engage in critical reflection of the questions fluctuates and can be manipulated. For this study, the CRT was administered immediately after participants had finished making the causal judgments and thus, we assumed would assess their engagement in critical reflection around the time when the key measures of blocking were taken.

Participants were also given an additional problem designed to have similar logical properties to the contingencies in the blocking effect, in particular the presence of relevant conditional probabilities. Participants were instructed to "Imagine you are playing a game where, on every turn, a player tosses two normal everyday coins - a 50 -cent coin and a \(\$ 1\) coin - in the air. The coins are not biased: they are equally likely to show heads or tails. If either of the coins lands heads up, the player wins the round." They were then given two scenarios and asked to provide a probability for each:
1) "It is your turn next and you toss the coins. The \(\$ 1\) coin shows heads but the 50 -cent coin falls out of sight. What is the probability that the 50 -cent coin is showing heads?"
2) "Your turn to toss the coins comes around again. This time, when you toss the coins, both coins fall out of sight. The other players in the game say (honestly) that you have won but you cannot see the coins. What is the probability that the 50 -cent coin is showing heads?"

The answer to the first of these questions is relatively straightforward. Because the \(\$ 1\) coin lands heads, the fact that the participant has won has no bearing on the
probability that the 50 -cent coin is showing heads. Thus the correct answer is 0.5 . The answer to the second question is more difficult because the information indicating that the participant has won is important for the probability that either one of the coins has landed heads. The correct answer is 0.67 because two of the three equally probable circumstances that could lead to the participant winning involve the 50 -cent coin landing heads. We anticipated that most participants would say that the probability in this instance was also 0.5 . This result would be consistent with the logical inference that Lovibond et al. (2003) assume is most likely to occur in a blocking experiment with nonadditive outcomes.

Of most importance in this experiment was the relationship between CRT performance and blocking, and specifically whether blocking was found to be larger or smaller in those individuals that showed greater capacity for cognitive reflection. The coin-toss problem was added to further assess how participants engaged in inferences about similar uncertain events. If, as expected, many participants conclude that the uncertain events in each part of the cointoss problem are equally likely, then it shows a tendency to use the inferential reasoning described by Lovibond et al. (2003). On the other hand, if participants tend to give the correct answer then it suggests they are very capable of using conditional probabilities in this context and may do so to make explicit inferences in causal learning that would produce a blocking effect.

Table 1: Design of the current Experiment.
\begin{tabular}{|c|c|c|c|}
\hline Pretrain & Train 1 & Train 2 & Test \\
\hline & A+ & AB+ & B \\
\hline W- & & CD+ & C, D \\
\hline X+ & E+ & & \\
\hline Y+ & G- & F+ & E, F, EF \\
\hline Z- & GH- & GH- & EM, FM \\
\hline WZ- & IJ+ & KL- & H \\
\hline XY+ & L- & L- & L \\
\hline
\end{tabular}

Note: Letters A-M and W-Z denote randomly allocated foods used as predictive cues. These cues were followed by either no allergic reaction (-) or an allergic reaction (+). Trials above the dotted line in Train 1, Train 2 and Test comprise the blocking contingencies.

\section*{Method}

Participants. Forty-four introductory psychology students at the University of Sydney participated in the experiment in partial fulfillment of course requirements ( 32 female, mean age \(=18.9\) years).
Apparatus and Stimuli. Participants were tested in individual cubicles in a quiet laboratory. The causal learning experiment was programmed using the Psychophysics toolbox for Matlab and was presented using Apple Mac Mini computers attached to 17 inch displays. Experimental stimuli included images of a banana, apple, fish, lemon, cheese, milk, coffee, eggs, garlic, bread, pasta, peanuts,
avocado, meat, mushrooms, olive oil, strawberries, peas, and rice accompanied by written labels. The allocation of foods to cue (A, B, etc.) was randomized for each participant. The CRT and coin-toss problems were administered in paper and pencil format, with each test presented on a single side of A4 paper, printed clearly in 14 point Times New Roman font.
Procedure. Participants were asked to assume the role of a doctor whose task was to ascertain which foods were causing the allergic reactions of a fictitious patient, Mr X. Participants were given general instructions about the scenario and the procedure, as well as explicit instructions about the nonadditive nature of the outcome. The latter was reinforced by presenting a pretraining phase in which two cues ( X and Y ) had demonstrably nonadditive effects. Here trials with \(\mathrm{X}, \mathrm{Y}\) and the compound XY were presented, each with followed by an identical allergic reaction. The presentation of the reaction outcome was the same throughout the experiment and was always accompanied by a fictitious severity index showing the same level of severity for all allergic reactions.

For each of the Pretrain, Train 1 and Train 2 phases shown in Table 1, each of the trial types was presented 8 times in a randomized order. On each trial, either one or two foods were presented and participants predicted what outcome ("no allergic reaction" or "ALLERGIC REACTION") occurred by clicking either option. When an outcome was selected the options disappeared and were replaced with feedback about the actual outcome.

In the Test phase, participants were presented with a cue (or cues) and asked to make several judgments. First they were asked to judge "What is the probability that this food (these foods) will cause Mr X to have an allergic reaction?" and were required to make a rating on a linear analogue scale ranging from 0 to 1 with 0.1 increments marked along the scale. They were also asked to rate "How confident are you that your first rating is correct?" and "How severe will the reaction most likely be?" on additional linear analogue scales. The order of presentation of trials within the test phase was randomized, with each trial type presented only once. The critical cues in this phase for assessing blocking were cues B, C and D.

On completion of the allergist task, participants were given the CRT and conditional probability coin-toss problem in paper and pencil form. Participants were told to take as much time as they needed to finish these questions. Two versions of the coin-toss problem were used (counterbalanced between participants), one with the "neither coin visible" question first, the other with the " \(\$ 1\) coin visible" question first. Above the response line for each question, participants were reminded that "A. If EITHER of the coins shows heads, you win the round" and "B. You know that you have won this round."

\section*{Results}

Learning during the pretraining and training phases of the causal judgment task was generally very rapid. In the final
block of pretraining, phase 1 and phase 2 training, mean accuracy exceeded 0.95 for every cue-outcome contingency. All participants performed well above chance. Statistical analyses focused on the critical test data only. All analyses were performed with an alpha level of 0.05 .

Test Ratings. Of greatest importance was the probability rating for cue \(\mathrm{B}(\mathrm{M}=0.52)\) compared to the mean probability rating for C and \(\mathrm{D}(\mathrm{M}=0.65)\). The difference between these ratings was statistically significant, \(\mathrm{t}(43)=\) \(2.83, \mathrm{p}=.007\) ), indicating a reliable blocking effect overall.

CRT scores. Performance on the CRT was generally poor. Participants made on average just 0.70 correct responses out of a maximum of 3 . The vast majority ( \(84.1 \%\) ) of errors resulted from reporting of the intuitive foil answers to each item (for further details, see Frederick, 2005). Table 2 shows the number of participants who scored \(0-3\) on the CRT test, and the mean blocking score for participants with each score.

Table 2: Frequency of CRT scores and blocking score.
\begin{tabular}{|c|c|c|c|}
\hline CRT score & N & \multicolumn{2}{|c|}{Blocking} \\
\hline /3 & Participants & Mean & SEM \\
\hline 0 & 26 & . 207 & . 059 \\
\hline 1 & 7 & . 019 & . 115 \\
\hline 2 & 9 & . 005 & . 086 \\
\hline 3 & 2 & -. 001 & 0 \\
\hline total & 44 & . 13 & . 047 \\
\hline
\end{tabular}

Note: "Blocking" refers to the difference in probability rating given for the control cues \(\mathrm{C} / \mathrm{D}\) and the target cue B .

Of greatest interest was whether the number correct was related to blocking (as indicated by the difference in probability ratings for \(B\) and \(C / D\) ). The correlation between CRT score and blocking was negative and significant, \(\mathrm{r}=-\) \(0.304, \mathrm{p}=.045\). As can be seen in Table 2, this was mainly due to a large blocking effect in those that scored 0 on the CRT, with little variance in blocking scores amongst participants with CRT scores of 1 to 3 . Participants who scored 0 on the CRT showed significantly more blocking than those who scored more than \(0, \mathrm{t}(42)=2.27, \mathrm{p}=.028\). This is illustrated in Figure 2.

Coin-toss problem. Of the 44 participants, 29 responded 0.5 for the answer to both questions. Just two participants gave the correct responses, answering 0.67 for the scenario where neither coin is visible and 0.5 for the scenario where one coin is visibly showing heads (both scored 2 out of 3 on the CRT task and both exhibited a blocking effect). The remaining 13 participants did not systematically assign a higher probability to the "neither coin visible" scenario (M \(=.52)\) than to the "one coin visible" scenario \((\mathrm{M}=.54)\). As can be seen in Figure 3, participants who gave the same response to both questions (i.e. \(0.5 / 0.5\) ) produced equivalent blocking scores to those that produced different answers to the coin-toss problem, \(\mathrm{t}(42)=0.15, \mathrm{p}=.88\).

Figure 2. Mean causal probability judgments for the blocked cue B and control cues (mean of C and D), as a function of CRT performance. Left: Mean ratings for participants who failed to correctly answer a single question on the Cognitive Reflection Test. Right: Mean ratings for participants who scored at least 1 on the CRT. Error bars show SEM of the difference between B and \(\mathrm{C} / \mathrm{D}\) ratings.

Figure 3. Mean causal probability judgments for the blocked cue B and control cues C and D, as a function of answers to the coin-toss problem. Left: Mean ratings for participants who answered 0.5 for both items. Right: Mean ratings for participants who gave other answers (including two who gave the correct answers). Error bars show SEM of the difference between \(B\) and \(C / D\) ratings.

\section*{Discussion}

Overall, participants showed a modest but statistically reliable blocking effect. This observation is typical of many studies in causal learning, including several that involve non-additive pretraining to discourage participants from deducing that cue B is not causal (e.g. Lovibond et al., 2003; Mitchell et al., 2006).

More importantly, the size of the blocking effect was significantly related to participants' CRT performance. In particular, participants who scored zero on this test showed a substantial blocking effect whereas those that answered at least one of the three questions correctly gave comparable judgments for cue B and the control cues. The participants that scored zero on the CRT demonstrated the weakest ability to reflect critically on the questions in order to reject the most obvious answer and derive the correct one. These results are consistent with Lovibond et al.'s (2003) assertion that participants who reason carefully about the cues in a
blocking task involving nonadditive outcomes will judge the blocked and control cues to be equally likely to cause the outcome rather than adopting a Bayesian inference that appropriately accounts for conditional probabilities and is actually best aligned with the blocking effect itself.

Thinking about cause and effect under uncertainty is a difficult task and people do not readily adopt the approach typified by classical probability theory. The final probability question we used in this study is an example - with formal qualities similar to the blocking contingencies - where only two participants out of 44 gave the correct answer. Most (29 out of 44) gave the same answer, \(\mathrm{p}=0.5\), to both problems, suggesting that they assumed the status of the unseen coin was unaffected by information about the outcome (i.e. winning the round) in both of the examples. This logic is very similar to Lovibond et al.'s (2003) argument about reduced blocking with a nonadditive outcome. They argued that participants will conclude that no information is known about cue B and, likewise, no information is known about either of the cues C or D and, therefore, all three should be given the same rating. However, unlike the coin toss scenario, the conservative logic expressed in this inference was not as prevalent in the causal ratings for the cues \(B, C\) and D. Furthermore, participants who gave the \(0.5 / 0.5\) response to the coin-toss problem, and thus should not show blocking based on Lovibond et al.'s inference, were just as likely to show a blocking effect in their causal ratings as those who gave different answers to the coin-toss problem. These results suggest that, although the logic described by Lovibond et al. is prevalent in decisions involving uncertain causal relationships, the application of the inference is not necessarily consistent across different scenarios.

This result is correlational and should be interpreted cautiously. Blocking may arise from other forms of explicit inference, such as deductive reasoning, which is encouraged by additive outcome assumptions (Lovibond et al., 2003). Thus the key relationship observed in this study should only arise if the assumptions that participants bring into the experiment are tightly constrained to prevent deduction.

Conclusion. Although the blocking effect is arguably rational, even when assuming that the outcome is nonadditive, it is nonetheless associated with an uncritical mode of causal judgment. Only the minority of participants displaying some critical analytical ability on the CRT gave equivalent ratings to the blocked and control cues, consistent with the type of inferential reasoning outlined by Lovibond et al. (2003). The results are consistent with an account of causal learning that assumes that judgments are based on both explicit inferences and some form of associative learning or other automatic psychological operation that approximates Bayesian inference.

\begin{abstract}
Visual working memory (VWM) is a crucial part of our cognitive system. Currently there is an active debate how the apparent limitations of VWM should be described. Limited-slot and flexible-resource theories are discussed, but so far the temporal dynamics of representations stored in VWM are not fully understood. In this paper we present data that supports the notion of dynamic VWM contents with changing precision. To account for these observations in a qualitative way, we propose a neural network that is able to account for emerging capacity limits as well as for changes in the precision of stored information.
\end{abstract}

Keywords: VWM; Visual Attention; Neural Network

\section*{Introduction}

Successful interaction with our environment requires the storage and maintenance of task-relevant information. Planning of behavior as well as evaluation of the outcome would not be possible without this ability. The fact that we are able to perform these tasks indicates that there is some kind of interface between our environment and cognition. This interface is provided by the working memory system. Due to its importance in linking cognition to the external world, working memory has been studied extensively for decades.

An apparent limitation of working memory and especially visual working memory (VWM) with respect to the amount of preserved information has been observed throughout the years (see Miller, 1956 for an early review). Until today it is still in discussion how these limitations might be characterized. While limited-slot theories (Zhang \& Luck, 2008) state that the maximum number of stored representations is limited and cannot be increased by decreasing the precision of individual representations, flexible-resource theories (Bays \& Hussain, 2008) assume a mnemonic resource that can be used to either store a large number of low-precision representations or a small number of high-precision representations. The differentiation between both theories is fundamental as the alternatives suggest rather different bases of cognition.

There is empirical evidence for both alternatives (see Fukuda, Awh, \& Vogel, 2010 for a recent review), even if resource models seem more plausible from a modeling perspective (Berg, Shin, Chou, George, \& Ma, 2012). Recent studies investigated the neural basis for capacity limits, but again the results are mixed. While Anderson, Vogel, and Awh (2011) found behavioral as well as electrophysiological evidence for a limited number of slots in humans, Buschman, Siegel, Roy, and Miller (2011) reported mixed evidence in rhesus monkeys. The results imply the existence of discrete slots, containing some kind of resource that determines the precision of the stored representations.

To sum up, it remains unclear if capacity limits of VWM can be described in terms of slots or resources, but the empirical evidence indicates that it is unlikely that a strict resource or slot model will be the consensus - some kind of mixed model seems most probable. Interestingly, in contrast to the limitations with respect to the number of stored items, the temporal dynamics of VWM contents are far less investigated. Also in this respect the results are inconclusive. Zhang and Luck (2009) reported clear evidence for abrupt loss of information, whereas Salmela, Lahde, and Saarinen (2012) found evidence for the gradual loss of information. The results of Zhang and Luck (2009) are more in line with a slot model. The gradual decay observed by Salmela et al. (2012) is more in line with a resource model, in which the precision of the representations degrades over time. To investigate the temporal dynamics of information maintained in VWM we applied the same experimental paradigm as Zhang and Luck (2009). Furthermore, we developed a neural network model that can qualitatively account for the observations.

In the next section we describe the experimental setup. Next we report the obtained results. After this we give an outline of the neural model. A short discussion concludes the paper.

\section*{Experimental Setup}

Since the influential study of Luck and Vogel (1997), change detection paradigms have become the standard approach in VWM research. As it was highlighted by Brady, Konkle, and Alvarez (2011), however, change detection paradigms do not allow to assess the precision of the representation that underlies the response of the participants. Zhang and Luck (2009) proposed a paradigm that allows to obtain a measure for the precision of the stored representations.

Participants had to remember Fourier descriptors which varied continuously in their phase (see Fig. 1 for the trial sequence and the stimuli). After the presentation of the stimuli a response screen appeared after a variable interstimulus interval (ISI). The position of one of the presented shapes was highlighted and participants had to indicate the presented stimuli on a "shape-wheel" containing the whole shape dimension. If the critical shape was in working memory, participants should report a shape close to the original shape, the response distribution should be bell-shaped and its deviation would be a measure of the precision of the representation. Without a representation participants should guess. Guessing should follow a uniform distribution. Together these processes result in a mixed distribution, consisting of a bellshaped distribution reflecting the precision (referred to as \(\sigma\)

Figure 1: Sequence of a single trial. After the initial presentation of the fixation cross, three, four, or five Fourier descriptors were displayed on a invisible circle for 200 ms . After this a variable interstimulus interval (ISI) of 500, 2500, or 5000 ms followed. At the end of the trial a "shape-wheel" appeared. One of the stimuli positions was highlighted and participants had to indicate the identity of the descriptor on the wheel.

Figure 2: Normalized histogram of exemplary artificially generated data and fitted von Mises distribution.
in the following) and a vertical offset, indicating the probability that participants had no representation of the critical shape (referred to as \(\mathrm{p}_{\mathrm{F}}\) in the following).

We were interested in the effects of different ISIs on the precision and the amount of stored information, i.e. the variation of \(\sigma\) and \(\mathrm{p}_{\mathrm{F}}\). A slot-model would predict a constant \(\sigma\) over time and furthermore that \(\sigma\) would not be affected by the number of stimuli. Once the available slots are filled \(\mathrm{p}_{\mathrm{F}}\) should strongly increase. A resource model would predict an increasing \(\sigma\) with increasing numbers of items, while \(\mathrm{p}_{\mathrm{F}}\) should not change.

\section*{Participants}

16 healthy students ( 11 males) of the cognitive sciences participated in our experiment, their age ranged between 22 and 33 years (mean age 23.125). All participants reported normal or corrected-to-normal vision and received course credit in exchange for their participation. All participants provided informed consent.

\section*{Apparatus}

Stimulus presentation and collection of responses were performed by an IBM-compatible computer with a \(22-\mathrm{in}\). dis-
play. The stimuli were displayed at a resolution of 1680 by 1050 pixels. The experiment was implemented in C++.

\section*{Stimuli}

The stimulus set consisted of three, four, or five Fourier descriptors. The phases were chosen pseudo-randomly. The minimal phase difference was \(30^{\circ}\). Each descriptor subtended \(1.6^{\circ} \times 1.6^{\circ}\) degrees of visual angle (viewing distance \(\approx 70\) \(\mathrm{cm})\). The descriptors were randomly arranged on an invisible circle with a radius of \(4.7^{\circ}\) of visual angle. This arrangement was restricted to six possible locations, each spaced by \(60^{\circ}\). To obtain the responses a wheel containing 30 shapes evenly distributed over the phase space was presented as well as a cue indicating the critical descriptor (see Fig. 1). The shape wheel was centered on the screen with a radius of \(10.2^{\circ}\) of visual angle.

\section*{Procedure}

Each trial started with a fixation cross which lasted for 2000 ms . After this three to five Fourier descriptors were presented for 1000 ms . This was followed by a blank screen which lasted for 1000,2500 , or 5000 ms . Then the response screen was presented and one of the locations was highlighted. The participants responded by clicking on the "shape-wheel". We collected the absolute angle as well as the angular distance to the cued descriptor. Trials lasted until the participants confirmed their response by pressing a key. All \(3 \times 3\) combinations of number of stimuli and ISI were repeated 30 times, totaling 270 trials. The whole procedure took about 60 min utes.

\section*{Results}

We applied a quantitative model (Zhang \& Luck, 2008) to the data to estimate the probability that a cued descriptor was present in memory \(\left(1-\mathrm{p}_{\mathrm{F}}\right)\) as well as the precision \((\sigma)\) of the representation. We first describe this model, then we report the obtained results.

\section*{Data Analysis}

According to the model participants have a noisy representation of the crucial descriptor in some trials, in the remaining trials participants are assumed to guess. The noisy representation can be described in terms of a von Mises distribution \({ }^{1}\), whereas guessing is modeled as a uniform random process. The resulting mixed distribution is displayed in Fig. 2 and can be described as
\[
\begin{equation*}
p\left(x \mid \mu, \kappa, \mathrm{p}_{\mathrm{F}}\right)=\left(1-\mathrm{p}_{\mathrm{F}}\right) \frac{e^{\kappa \cos (x-\mu)}}{2 \pi I_{0}(\kappa)}+\frac{1}{2 \pi} \mathrm{p}_{\mathrm{F}}, \tag{1}
\end{equation*}
\]
where \(\mu\) is the mean of the von Mises distribution, \(\kappa\) denotes the density of the distribution (this can be considered as the inverse of the deviation), \(I_{0}\) is the modified Bessel function of 0 th order, and \(\mathrm{p}_{\mathrm{F}}\) is the guessing probability.

\footnotetext{
\({ }^{1}\) Due to the circular nature of the response dimension a Gaussian distribution is not feasible.
}

Later on we will report the deviation of the distribution instead of \(\kappa\), which can be obtained by
\[
\begin{equation*}
\sigma=\sqrt{1-\frac{I_{1}(\kappa)}{I_{0}(\kappa)}} \tag{2}
\end{equation*}
\]
where \(I_{1}\) is the modified Bessel function of 1 st order.
Since the phase of the relevant descriptor varied from trial to trial, the data analysis was based on the angular distance between the response and the phase of the descriptor. Hence the mean of the von Mises distributions should equal 0 . As noted above, \(\sigma\) reflects the precision of the representation, larger values of \(\sigma\) indicate a lower quality of the representation. The probability \(\mathrm{p}_{\mathrm{F}}\) is an indicator for the amount of preserved information. Higher values of \(\mathrm{p}_{\mathrm{F}}\) indicate less information to be preserved.

The parameters cannot be directly inferred from the observed data. Therefore we fitted the mixed distribution via maximum likelihood estimation.

\section*{Estimated Parameters}

We concentrated on the estimated values of \(\mathrm{p}_{\mathrm{F}}\) and \(\sigma\) of the mixed model. We estimated \(\mu, \kappa\), and \(\mathrm{p}_{\mathrm{F}}\) separately for each participant and each level of the varied factors. The results have to be treated with caution, since the data basis for these fits was quite small, consisting of only 90 samples per fit. For three participants the likelihood values remained comparatively small, indicating that the applied model was not well suited for their data. Hence, the respective data sets were not entered in the analysis.

Fig. 3 shows the obtained results. The estimates with respect to the number of stimuli are plotted on the left panel, whereas the estimates for the different ISIs are plotted on the right panel. Error bars indicate the standard error of the mean.

For a quantitative analysis of the differences of the estimates we performed paired t-Tests. Significant differences on a \(5 \%\) level are indicated by an asterisk. With respect to the number of stimuli, \(\sigma\) increased significantly. For \(\mathrm{p}_{\mathrm{F}}\) the estimate was significantly higher in case of four items compared to three items. With respect to the ISI, significant differences were only observed for \(\sigma\). None of the six \(\mu\) parameters differed significantly from zero.

The precision of preserved information decreases with the number of items. The amount of preserved information seems less effected, since there was no significant difference between the \(\mathrm{p}_{\mathrm{F}}\) estimates for three and five items. The precision also seems to change over time, whereas the amount of stored information remains constant. Compared to the effect of the number of stimuli the effect of the ISI is much weaker. The fact that we observed significant changes in the precision of stored information is in conflict with the results reported by Zhang and Luck (2009), but fits the observations of Salmela et al. (2012).

Figure 4: Overview of the model architecture. Input units accumulate spikes from sensory neurons. Memory units receive activation from the input units. Lateral inhibition as well as self-recurrent excitation determine the overall activations of the memory units, which is proportional to the precision of the respective representation. See text for details about the parameters.

\section*{Neural Model}

So far there are only few models that can account for the temporal dynamics of VWM contents. One of these models is the time-based resource-sharing (TBRS) model (Barrouillet, Bernardin, \& Camos, 2004, see Oberauer \& Lewandowsky, 2011 for an implementation). TBRS assumes an interplay between temporal decay and a refreshment process to account for dynamic changes in the quality of VWM representations. The encoding stage is neglected however. Another, more neural model is the dynamic field theory (DFT, Johnson, Spencer, \& Schöner, 2009), where the dynamic interactions between excitatory and inhibitory layers of neurons are applied to model dynamic changes in VWM content. On the one hand, DFT has a lot of desirable features, for instance capacity limits emerge naturally from the model properties. On the other hand, DFT has a lot of degrees of freedom, rendering direct fitting to observed data rather difficult. Furthermore, the encoding stage is not specified.

We propose a model that can account for encoding of stimuli, as well as for the maintenance of stored representations. We want to achieve this with less degrees of freedom than DFT but still with a neural model. The proposed model is a combination of the theory of visual attention (TVA, Bundesen, 1990) and the short term memory network proposed by Usher and Cohen (1999). Since this network models discrete states, we extended it with the single trace fragility theory (Wickelgren, 1974) to model continuous changes in

Figure 3: Parameter estimates with respect to the number of stimuli (left panel) and ISI (right panel). Significant differences in the estimates are indicated with an asterisk. Deviation \((\sigma)\) increases with number of stimuli as well as with ISI. For the failure probability \(\mathrm{p}_{\mathrm{F}}\) effects were observed for the number of stimuli only.
the precision of stored representations. The input layer of the model accumulates spikes from sensory neurons. The spiking rate of the sensory neurons is based on TVA. Activation from the input layer is forwarded to memory units. The overall activations of the memory units depend on lateral inhibtion and self-recurrent excitation. The activity of the memory units varies continuously and is proportional to the precision of the respective representation. Temporal decay is modeled via the leakage of input activation in the absence of sensory input. Initially, the binding between memory units and the input layer is fragile. The longer a representation resides in VWM, the stronger the binding and the weaker the leakage. Fig. 4 gives an overview of the model architecture. The different components of the model are described in the next paragraphs. After this we give a short example of the performance of the model.

\section*{Encoding of Stimuli}

The encoding stage is modeled via TVA. TVA is a quantitative model of visual encoding that is well suited to account for the selection and categorization of visual stimuli. TVA models visual attention by integrating bottom-up as well as top-down processes.

TVA assumes a competition between different categorizations for incorporation in VWM. This competition can be quantified via a race model, where the rate parameter \(\mathrm{v}(x, i)\) determines the time needed for a categorization of the type "item \(x\) belongs to category \(i\) " to be finished. The rate parameter depends on the task as well as sensory parameters (see Bundesen, 1990 for details).

We assume a fixed number of sensory neurons that spike during the presentation of stimuli with a rate equal to \(v(x, i)\) (cf. Bundesen, Habekost, \& Kyllingsbæk, 2005). Spikes are accumulated in a separate input layer, which forwards activation to the memory layer that is described in the next paragraph.

\section*{Maintenance of Representations}

We model VWM in terms of a dynamic neural network (Usher \& Cohen, 1999). The activation of each unit is affected by three processes. First, activation is stabilized by self-recurrent excitatory feedback. Second, each unit is inhibited by its neighbors. Third, a unit might receive sensory input that increases its activation (see Fig. 4). We modeled this input in terms of accumulated spikes emitted from the sensory neurons described in the previous paragraph. The dynamics of a single unit in the memory layer can be described via the following differential equation:
\[
\begin{equation*}
\frac{d \kappa_{i}}{d t}=-\kappa_{i}+\alpha F\left(\kappa_{i}\right)-\beta \sum_{j \neq i}^{N} F\left(\kappa_{j}\right)+I_{i}+\text { noise } \tag{3}
\end{equation*}
\]
where \(\kappa_{i}\) indicates the activation of unit \(i, \alpha\) is the selfrecurrent excitatory weight, \(\beta\) is the weight of the lateral inhibition, \(I_{i}\) denotes the current sensory input supporting unit \(i\), noise indicates a uniform noise term, and \(F(\kappa)\) is the activation-function (in this case a linear one).

Without sensory input Eq. 3 can be used to model decay of activations to a baseline, given the noise is small enough to prevent random fluctuations. The system has a lot of interesting emergent properties despite its simple structure. It is possible to model serial position effects, capacity limits (with proper choices for \(\alpha\) and \(\beta\) ), and the development of stable states.

We assume the activation of the memory units to be proportional to the precision of the according representations, which is quantified by the \(\kappa\) parameter of the von Mises distribution in the mixed model. We assume one memory unit per stimulus. If there are more stimuli, lateral inhibition is increased, resulting in an overall reduced activity. The reduced precision observed for higher numbers of stimuli (see Fig. 3, lower panel) emerges naturally. In its original formulation the described network can be used to model discrete states of mem-
ory units, either the activation is above the baseline or not, the transitions are non-linear. Since our data indicates continuous decay of the precision over time, we extended the original model with the single trace fragility theory (Wickelgren, 1974). This extension is described in the next paragraph.

\section*{Temporal Decay}

As it can be inferred from Eq. 3, the activation of a memory unit depends on the sensory input. Since Buschman et al. (2011) found that neural activation first decays in early areas, we modeled continuous changes in the precision by a decay of the accumulated sensory input \({ }^{2}\). Since older memory traces are more resistant than younger ones (Jost's second law), we assumed this decay to slow down over time.

The single trace fragility theory provides a formal framework for these assumptions, by introducing the concept of fragility, which quantifies the susceptibility of stored information for temporal decay. In our model, fragility refers to the binding between input and memory units (see Fig. 4), which modulates the leakage of the input units. Applied to the input term in Eq. 3, decay after display offset can be described by:
\[
\begin{equation*}
\frac{d I_{i}}{d t}=-\xi f I_{i} \tag{4}
\end{equation*}
\]
where \(\xi\) is the decay rate and \(f\) denotes the fragility, which is reduced over time:
\[
\begin{equation*}
\frac{d f}{d t}=-\psi f^{2} \tag{5}
\end{equation*}
\]
here \(\psi\) denotes the decay rate of the fragility. We assume that fragility starts to decline when a categorization is encoded, hence early categorizations are less prone to temporal decay. Furthermore, we assume that the temporal decay starts after display offset, when sensory information is no longer available to maintain the activity of the memory units. This mechanism concludes the model specification.

\section*{Modeling Continuous Representations}

To illustrate the functionality of the system, let us assume a simple display containing three stimuli, lets further assume that only one feature dimension of these stimuli is task relevant (e.g. shape) and that the stimuli do not differ with respect to visibility (see Fig. 4, center). In this case the spiking rate of all sensory neurons is equal during the presentation of the stimuli. This process is displayed in the upper panel of Fig. 5. Encoding is a random process, hence the encoding times \(\left(t_{0}\right)\) differ. After the offset of the display \((t>D)\) the decay mechanism described in Eq. 4 begins to operate. Over time the decay attenuates, since the fragility is reduced (see Eq. 5).

Lateral inhibition between stored representations is visible around time-step 30; the encoding of an additional representation reduces the activation of the previously stored ones.

\footnotetext{
\({ }^{2}\) Please note that Buschman et al. (2011) interpreted this finding in terms of an encoding failure instead of a temporal decay.
}

Figure 5: Example of the dynamics produced by the proposed model. Dynamics of the input units are displayed in the upper panel, the overall activation of the memory units is displayed in the lower panel. Parameter D in the upper panel refers to the presentation duration, while \(t_{0}\) denotes the encoding time of the according representation. Activation of the memory units is assumed to be proportional to the precision of the representation, the decreasing activation reflects the increasing deviation in Fig. 3 (right panel).

After the offset of the stimuli (at time-step 50, vertical dashed line), decay starts. For highly active representations a nearly exponential decay occurs, which attenuates over time, whereas the decay of less active, or older representations can be better described by a power function. As can be concluded from the Fig. 5, it is possible that representations are completely lost (i.e. the according activation falls below zero). The resting level of the system varies, depending on the strength of the lateral inhibition, that is the number of simultaneously active units.

The model so far specifies activations over time; to fit the model to the data in the experiments, we need to convert these activations into probability distributions for memory recollection. We assume the activation of a memory unit to be proportional to the precision of the according representation. Hence, the activations are a measure of the \(\kappa\) parameter of the von Mises distribution. The overall response distribution can be modeled as a mixed distribution, with \(\kappa\) 's equal to the activations multiplied with a constant scaling factor (values below zero are considered to be zero). Since a von Mises distribution with \(\kappa=0\) becomes a uniform distribution, \(\mathrm{p}_{\mathrm{F}}\) can be modeled as well.

Our model is able to account for the encoding of visual stimuli, as well as for changes in the precision of the stored representations. The observed reduction in precision (see

Fig. 3, left panel) due to more stimuli can be accounted for by TVA and lateral inhibition. The change in precision over time is captured by the network dynamics described in Eq. 3 and the temporal decay described in Eq. 4. The apparently high number of parameters is greatly reduced since the TVA parameter \(v\) can be set to one (like in the example). This leaves \(\alpha, \beta, \xi, \psi\), and the number of sensory neurons per input unit as free parameters. The different components of the model are modular, for instance it is quite simple to model the memory dynamics without Eq. 4. To evaluate the relevance of the different components, we will perform Bayesian model comparisons, once a broader data basis has been acquired.

\section*{Conclusions}

In this paper we presented data on the temporal changes in the precision of VWM contents. The results indicate that the precision of the representations is strongly affected by the number of stimuli. Precision decreased over time, whereas the amount of preserved information was rather stable (no significant increase of \(\mathrm{p}_{\mathrm{F}}\) ). We proposed a neural network model, which models the encoding as well as the maintenance of information. So far the key findings can be replicated qualitatively, since the overall precision decreases with increasing memory loads as well as over time.

The different approaches to account for VWM properties reflect different paradigms of understanding cognition. While limited-slot models with static precision adhere to the computer metaphor of cognition, resource models are more in line with the dynamic system approach to cognition. The fact that VWM capacity is limited is not questioned, however. Given the findings of Buschman et al. (2011), who observed discrete slots with flexible resources per hemisphere and a possible gating mechanism in the lateral intraparietal cortex, our model offers an implementation of this neural mechanism. As it was noted above, capacity limits emerge naturally in the network due to the interplay of excitation and lateral inhibition, while the individual activations implement a continuous process, modeling the precision of individual representations over time. Thus, the approach integrates slot and resource model perspectives. Further evaluation is necessary to assess the quantitative fit of the model. This requires a broader data basis, involving larger numbers of stimuli to assess the ability of our model to account for higher memory loads, which is usually better accounted for by slot models (Rouder, Morey, Morey, \& Cowan, 2011).

\begin{abstract}
Communication depends on the production and interpretation of representations, but the study of representational processes underlying communication finds little discussion in computational experiments. Here we present an experiment on the emergence of both interpretation and production of multiple representations, with multiple referents, where referential processes can be tracked. Results show the dynamics of semiotic processes during the evolution of artificial creatures and the emergence of a variety of semiotic processes, such as sign production, sign interpretation, and sign-object-interpretant relations.
\end{abstract}

Keywords: Sign; Communication; Semiotics; Artificial Intelligence; Computer Simulation.

\section*{Introduction}

Computational modeling and simulation of the emergence of semiotic processes, such as language and communication, ,has been consolidating as an important methodology and has a growing community of researchers involves in scientific and technological issues related with such phenomena (Wagner et al., 2003; Nolfi \& Mirolli, 2010; Noble et al., 2010). This computational approach have been dedicated to building environments and creatures through which it is possible to simulate the minimum conditions to observe the evolution and emergence of semiotic behaviors. As the main form of interaction between agents, in most of these synthetic experiments, communication has, particularly, been a significant research subject. Primarily, it depends on the production of representations (by an utterer) and the interpretation of them (by an interpreter). Despite the fact that representation processes are in the foundations of communication, little discussion about such processes can be found, such as, the emergence of fundamental types of representations and their referential relations.

We have previously simulated the emergence of interpretation of two different types of representations (symbols and indexes) in communicative interactions (Loula et al., 2010), and have also studied further the cognitive conditions to the emergence of such interpretation processes (Loula et al, 2011). However, the experiments previously done focused only on the emergence of interpretation, with fixed production of a single representation with only one referent. Here we propose to evaluate representation
processes in the emergence of both interpretation and production of multiple representations, with multiple referents. To do so, we use a similar scenario of resource collecting, but apply a neural network model as the cognitive architecture for creatures, that can become utterers and interpreters. The experiment involves empirical constraints from studies of animal communication and also theoretical constraints from Peircean pragmatic theory of signs.

In the next section, we review related work on simulation of the emergence of communication. Next, we briefly describe the theoretical principles and biological motivations. We then describe our experiment on the emergence of production and interpretational processes in communication events. Finally, we outline our results and conclusions and point out perspectives on the study of the emergence of sign processes types.

\section*{Related work}

The emergence of communication in computer simulations is the topic of many works, but discussions on the underlying representational processes find little space in such literature. We review two important ones to reveal this.

Floreano et al (2007) studied the evolutionary conditions that could allow the emergence of a reliable communication system, following biological motivations of animal communication. Groups of robots controlled by neural networks were evolved to adapt to a foraging task. Robots could use a ring of blue light as a signal, as the authors call, to each other. Even though the ring of light was used to cooperate, nothing was discussed on what it represented to the robots or what type of representation could be involved.

In an experiment with artificial creatures in a grid world, Cangelosi (2001) simulated the emergence of communication systems to name edible and poisonous mushrooms. He proposed the emergence of different modalities of representations in this experiment on the evolution of communication. In typifying communication systems, Cangelosi (2001) distinguished between signals, which have direct relation with world entities, and symbols, which in addition are related to other symbols. The simulated creatures were controlled by a neural network which were both evolved and trained in various tasks, and,
at the end, a shared communication system emerged, involving signals and symbols, according to Cangelosi. But he did not described how these signals and symbols were interpreted by the creatures, i.e. if a heard signal was first mapped to a mushroom as its referent, and then to an action, or if it was mapped to an action, with a referent being associated with it.

Other works have also studied the emergence of communication in artificial agents (see Nolfi and Mirolli, 2010, Wagner et al. 2003). Nevertheless, we have not found works that have studied the emergence of different types of interpretations processes and referential processes.

\section*{Theoretical and Empirical Constraints}

Synthetic experiments are heavily influenced by theoretical principles and biological motivations, and such background should be an essential part of any synthetic experiment (Parisi, 2001). To model the emergence of communication processes based on different types of representation, it is certainly important to look at theoretical models and principles, and also look for biological motivations, and avoid arbitrary or naïve assumptions about the underlying processes.

In computational simulation works dealing with the emergence of communication, there is always something that is communicated from an agent to another one, and that is given various names: signal, symbol, sound, word, expression, or utterance. In most of these works, that which is communicated also seems to have representation capabilities. We have used the term representation in the first section, to emphasize this and also to apply a more familiar word for the artificial intelligence community. Nevertheless, we will now use the expression 'sign', as a technical term in a theoretical background.

A sign is defined, following Peirce (1958), as something that refers to something else, an object (which the sign represents in some aspect) and produces an effect (interpretant) in the interpreter. A sign is also defined by Peirce in relation to communication, as something that mediates between an utterer and an interpreter (Peirce, 1967, MS318), with the sign originating in the first and determining its interpretant in the last (Peirce, 1967, MS11). It is important to notice that a sign is only regarded as a sign if and when it is interpreted, so a sign communicated by an utterer is only a sign to the interpreter, but not to the utterer himself, unless it interprets the produced sign himself.

Sign processes show a remarkable variety. A basic typology (and the most fundamental one), proposed by Peirce (1958), differentiates between iconic, indexical, and symbolic processes. Icons are signs that stand for their objects by a similarity or resemblance, no matter if they show any spatio-temporal physical correlation with an existent object. In this case, a sign refers to an object in virtue of a certain quality which is shared between them. Indexes are signs which refer to their objects due to a direct physical connection between them. Since (in this case) the sign should be determined by the object (e.g. by means of a
causal relationship) both must exist as actual events. Spatiotemporal co-variation is the most characteristic property of indexical processes. Symbols are signs that are related to their object through a determinative relation of law, rule or convention. A symbol becomes a sign of some object merely or mainly by the fact that it is used and understood as such by the interpreter, who establishes this connection.

Communication is a process that occurs among natural systems and therefore we followed biological motivations on building our synthetic experiment. Animals communicate in various situations, from courtship and dominance to predator warning and food calls. Following Peirce's definition of sign classes, many animals can actually be capable of communicating by means of diverse types of signs (Ribeiro et al., 2007).

To further explore the mechanisms behind communication, a minimum brain model can be useful to understand what cognitive resources might be available and process underlining certain behaviors. Queiroz and Ribeiro (2002) described a minimum vertebrate brain for vervet monkeys' predator warning vocalization behavior. It was modeled as being composed by three major representational domains: the sensory, the associative and the motor domains. Different first-order sensory representational domains (RD1s) receive unimodal stimuli, which are then associated in a second-order multi-modal representation domain (RD2) so as to elicit symbolic responses to alarmcalls by a first-order motor representation domain (RD1m).

In order to model the emergence of indexical and symbolic interpretation competences, we must specify the requirements for each and how to recognize them. Indexical interpretation is a direct interpretation of signs, such that the interpreter is guided by the sign to recognize its object as something spatio-temporally connected to it. In the minimum brain model, this corresponds to an individual capable of connecting RD1s to RD1m without the need for RD2. But a symbolic interpretation undergoes the mediation of the RD2 to connect the sign to its object, in such a way that a habit (either inborn or acquired) must be present to establish this association. Thus, in symbolic interpretation,

Figure 1: Cognitive architectures for representations interpretations. Left: Type 1 architecture - RD1s are connected directly to RD1m. Right: Type 2 architecture data from visual RD1s and auditory RD1s can be associated in RD2 before connecting to RD1m.

RD2 is needed once it is the only domain able to establish connections between different representation domains. To evaluate what conditions might elicit each response type indexical or symbolic -, we implemented these two possible cognitive processing paths as mutually exclusive paths: either the creature responds to auditory events indexically, with direct motor actions (Type 1 architecture), or the creatures responds to auditory events symbolically, associating them with a visual stimulus and responding as if that was seen (Type 2 architecture) (see figure 1). For an external observer, who only watches the information available to the creature and its motor responses, it may not be possible to see changes in the interpretation process. But the underlying mechanisms behind each sign process are qualitatively different.

\section*{The experiment}

The scenario to test the conditions for the emergence of semiotic processes is inspired by food foraging behavior of animals. Two types of resources can be found in the environment, with positive and negative values. Resources are differentiated by perceptual features and creatures can produce the two types of signs, which are also perceptually different. Here all creatures are potential utterers and interpreters. An evolutionary process is applied to allow creatures' adaptation to the task of collecting resources, which involves action selection, sensorial categorization, and sign production and interpretation.

The environment is a 50 by 10 grid and the resource (alternating positive and negative in each trial) is placed in one position. Five creatures are placed randomly at each trial, and they are capable of seeing resources within 2 positions distance and hear signs within 25 positions. Each perception of a resource or a sign corresponds to a sequence of bits. A resource is a 4 bit sequence, with positive ones starting with 01 bits and negative ones, with 10 bits. Signs produced by creatures have 3 bits, and can start with bits 01 (called sign 1) or with bits 10 (called sign 2). The other bits are randomly generated.

Creatures can execute a limited set of motor actions: move forward, turn left, turn right, stand still, positive visual taxis, negative visual taxis, positive auditory taxis, negative auditory taxis, protect; and vocal actions: produce sign 1, produce sign 2. Taxis actions are directional motor responses to sensorial input, with positive taxis guiding to the sensorial input position and negative taxis guiding away from it. When a sign is produced by a creature it can be heard by other creatures in the next instant.

Creatures are controlled by a feed-forward neural network with three layers (figure 2), with weights between -2.0 and +2.0 with 0.1 intervals. In type 1 cognitive architecture, auditory middle layer is connected to the output layer, but in type 2 architecture auditory middle layer is connected to the visual middle layer, defining an associative memory between auditory activations and visual activations.

To allow better analysis of neural network activation patterns and to augment the descriptive power of assessing

Figure 2: Neural networks used by creatures. Top: Type 1 architecture with direct connection between auditory middle layer and output layers. Bottom: Type 2
architecture with auditory middle layer connected to visual middle layer.
neurons activations, we applied a winner-takes-all (WTA) mechanism to the each middle layer and each output layer. In WTA, only the neuron with the highest positive activation (calculated as the sum of products of inputs and weights) is going to have an output of 1.0 . The other neurons within the layer will have a null activation. If no neuron has a positive activation, then all will have null output. Applying WTA activation, both visual middle layer and auditory middle layer perform a localist categorization, with each neuron responding for a given pattern from sensorial input. In the motor output layer and in the vocal output layer, the use of WTA allows only one motor action and one vocal action, at most, to be executed.

The neural networks of all creatures have initially a type 1 architecture with random weights. Evolution allows the creatures to adapt to the task of collecting positive resources and avoiding negative resources. Creatures that stand on the same position as the positive resource gain 10 resource units per instant. When a negative resource is placed on the environment, any creature standing in the same position loses 100 units. Besides, each creature, in any position, not executing a protection action when a negative resource is present, loses 10 units. However, execution of the protection action costs 5 units per instant.

Since this experiment involves the co-evolution of sign production and interpretation, to allow a stable communication system to emerge, selection is done at group level of identical individuals, following conclusions from Floreano et al (2007). The performance of each individual in the proposed task corresponds to the number of resource units collect by their group, composed of cloned individuals (same weights and architecture type).
The population of 500 individuals is divided in 100 groups of 5 clones. Each group is evaluated for 4 to 8 trials, half with positive resource and half with negative one. After groups are evaluated, one individual from the 20 best groups are selected for the next generation. These individuals will be included in the next generation along with 80 new individuals, and each of these 100 individuals will be cloned to form 100 groups of 5 clones again. To generate the 80 new individuals, the 20 best ones go through recombination and mutation. During recombination, if architecture types from parents are not the same, type 1 prevails. Mutation can change each weight to a new value also change architecture type, with \(1 \%\) chance of going from a type 2 to a type 1 and \(0.05 \%\) of changing from a type 1 to a type 2 .

During the evolutionary process, we observed groups performance in resource collecting task, the auditory middle layer connection (cognitive architecture type), and sign production, along with sign-object relations, sensorial categorization and motor responses.

\section*{Results}

To evaluate the emergence of sign interpretation and sign production, we simulated the experiment in an initial configuration. There are two cycles. In the first one, 300 generations, creatures did not have the auditory sensor and could not vocalize, and creatures were evaluated for 4 trials, in which they were near the resource. In cycle 2, after 300 generations, creatures were evaluated in 8 trials, 4 without communication, just as before, and 4 with communication, when one creature was placed 1 position away from the resource, but the other 4 were placed far away.

First simulation. During cycle 1, in a few generations, creatures adapted to the task of resource collecting, with the best groups obtaining around 2000 resource units. Creatures quickly acquired a response of protection action for a negative resource seen and a visual taxis response to a positive resource. Visual input categorization was also gradually adjusted, and ended up with creatures categorizing positive resources in neuron number 3 (see neuron numbers in figure 2), negative resources in neuron number 2 and null visual inputs in neuron number 1 .

At the start of the second cycle, resource collection performance dropped with the extra trials when most creatures are placed far away from the resource. Observing vocal responses to resources in the start, groups were split between those which vocalized sign 1 , sign 2 or no sign. Motor responses to signs, however, were not appropriate yet. The first adaptive use of communication appeared later on, with creatures vocalizing sign 1 to positive resources
and responding to it with auditory taxis, with sign 1 categorized in neuron 1 from auditory middle layer. In a further generation, this sign production behavior was expanded; a group vocalized sign 1 to both types of resources. This helped all creatures see the type of resource present in the environment, since they went after the sign utterer, saw the resource, and chose the correct motor response, but with a certain delay because of the distance they had to move. This response was a typical indexical interpretation of the sign that drew interpreters' attention to the utterer, searching for referents spatial-temporally related to the sign.

Later on, one group started a distinguished vocalization for each type of resource, with sign 1 being used for negative resource and sign 2 for positive one. Sign 1 was categorized in neuron 2 in auditory middle layer and had a protection action response. Sign 2 was categorized in neuron 1 with an auditory taxis response. This response dominated all groups after some generations and was the final behavior of all best groups. We could notice that type 1 architecture was dominant during all cycle 2 , and therefore indexical interpretation was the only interpretation processes during this simulation.

Second Simulation. A type 2 architecture, with symbolic interpretation, allows the establishment of multi-modal associations and could make auditory signs connect to visual signs. We have previously proposed that symbolic interpretation can act as a cognitive shortcut to an earlier acquired competence, when a cognitive trait is hard to be acquired (Loula et al., 2010). If the interpreter already had appropriate motor responses to visual inputs and this sensormotor coordination had a high acquisition cost, symbolic interpretation could connect auditory signs to visual signs and reuse the previous acquired competence.

In this second experiment, we modified the scenario of the first simulation by making it harder to learn motor coordination. The WTA activation in the output layer is changed so that the highest active neuron only stays active if its activation (sum of products of neuron inputs and weights) is 1.0 higher than the second highest active neuron. Since weights are between -2.0 and 2.0 , this severely limits possible connection weights.

We executed the simulation with this new configuration. Results are shown in figure 5, with the number of collected units and the auditory middle layer connection.
The initial resource collecting performance was much worse than in the first simulation, because most groups remained non-functional with the modified activation of output layer. It took much longer for creatures to respond appropriately to visual inputs. At the end of cycle 1 , the number of collected resources by the best groups was similar to the first simulation. At this point, creatures categorized positive resources in neuron number 1 of the visual middle layer, negative resources in neuron number 3, and null visual inputs in neuron 2 .

When cycle 2 started and creatures gained auditory sensor and vocal actions, all of them had the auditory middle layer

Figure 4: Evaluation of foraging task and auditory middle layer connection along the generations for the second simulation.

Figure 5: Activation of auditory and visual middle layers for each sign for the second simulation.
connected to the output layer. Different from the last simulation, almost none of the groups vocalized a sign. In the first generations of this second cycle, some groups already had the auditory middle layer changed to connect to the visual layer, but still without vocalizing. After some generations, the first group, to actually produce and interpret signs, vocalized sign 1 when a negative resource was seen, and when this sign was heard, it was categorized by neuron 1 in the auditory middle layer, which in turn activated neuron 3 in the visual middle layer, since creatures in this group had a type 2 architecture. Neuron 3 in visual layer is used to categorize seen negative resources, so an associative
memory is established. From then, other groups appear with different strategies, therefore, around generation 400, there was an intense competition between alternative strategies, with different architecture types and different categorizations, as can be seen in figures 4 and 5 .

During this dispute, a new strategy appeared with a group of creatures using distinct signs for each resource type: sign 2 for positive resources and sign 1 for negative ones. However, when either signs were heard, they were categorized in the same neuron (number 1) in the auditory middle layer and then connected to neuron number 1 in the visual middle layer, used to categorize seen positive
resources. Even though, diverse signs were produced, sign categorization was indistinct and the same motor response of visual taxis was produced. This was still an adaptive response, since even if a negative resource was present, it guided creatures close to the resource which, when seen, made creatures have a protection action. Note that this is different from what occurred in the first simulation, because in this case there was an interpretation (misleading, however) where any sign always refers to a positive resource, before the creature actually saw the resource.

This undistinguished categorization of signs, however, was not the best adaptive behavior still, since there was a delay in the protection action choice. In a later generation, starting from this strategy, a group categorized signs differently, with sign 2 being categorized in neuron 1 of the auditory middle layer, but sign 1 categorized in neuron 2 which is then associated with neuron 3 in the visual middle layer, used for seen negative resources, ending with an immediate protection action. This becomes the dominant communication strategy, with specific signs being produced by an utterer for each resource type and when an interpreter hears each signs. It internally associates signs with a referent and responds with an adaptive action, without the need of seeing the referent in the environment, so symbolbased communication emerged.

\section*{Discussion and Conclusion}

In previous works, we have simulated the emergence of interpretation processes based on symbolic and indexical signs. Here, besides interpretation processes, we were able to observe the emergence of sign production, sign-object and sign-object-interpretant relations, involving multiple signs, objects and interpretants.

In the first simulation, motor actions could be easily coordinated with sensorial input, and therefore an adaptive behavior evolved into a direct response to the communicated signs. This response defined an indexical interpretation and had two distinct moments for actual interpretation: first, interpreter's attention is directed to the utterer, then, when interpreter gets close to the utterer, it can visualize the object and thus the sign is spatiotemporally associated with the object. At the end of first simulation, this indexical interpretation occurs for sign 2, which is associated with a positive resource, as the interpreter creature performs auditory taxis and finds the utterer creature and the positive resource. In case of sign 1, we cannot say that the creatures interpret it as referring to a negative resource, because upon hearing sign 2 , the creatures perform a protection action and stop moving without seeing the negative resource.

Increasing cost of cognitive traits acquisition, we imposed a restriction on neural network's output layer activation in the second simulation. In this case, symbolic interpretation of signs was the adaptive response, confirming our hypothesis that symbolic processes can act as a cognitive shortcut mapping auditory signs to visual categories and reusing visual module mapping to motor actions.

In the second simulation, interpretation of each sign became distinguished with creatures associating each type of sign with a different visual category. Symbolic interpretation of signs emerged as a cognitive shortcut to already established visual-motor connections.

An important step for our experiment was to apply a neural network with a localist activation as the cognitive architecture for artificial creatures. This way, we were able to analyze middle layer categorization of sensorial inputs and what each category activates in the subsequent layer. For type 2 architecture, it was possible to determine the referent of each sign evaluating neural network activation. This model, therefore, allows an objective verification of what signs represent for interpreters in an experiment on the emergence of communication.

Additional investigations on semiotic processes and cognitive processes must be done to complement studies on the emergence of communication and language. We expect that a careful analysis of underlying semiotic processes will bring forth novel findings and stimulate new discussions.

\begin{abstract}
Recent works indicated that performing a joint spatial compatibility task with an incompatible stimulus-response mapping affects subsequent joint Simon task performance, eliminating the social Simon effect (social transfer of learning effect or SToL effect). Crucially, the SToL effect was not tuned to the specific identity of the co-actor, and depended on the overlap between the spatial relations of the practice and transfer tasks. Starting from these findings, this study aimed at investigating which spatial relations between stimulus ( S ), response (R) or participant \((\mathrm{P})\) positions are relevant for the SToL effect to occur. Two experiments were run in which the participant-response associations were incompatible (participants were required to respond with crossed arms), whereas the stimulus-response and stimulus-participant associations were manipulated. We found that learning derived from the practice task did not transfer to the subsequent task when stimulus-response associations were spatially incompatible and stimulus-participant associations were compatible (Experiment 1). However, a SToL effect was evident when stimulus-participant associations were spatially incompatible and stimulus-response associations were compatible (Experiment 2), hence suggesting that the spatial relation between stimulus and participant positions is crucial for the SToL effect to occur.
\end{abstract}

Keywords: social cognition; joint performance; spatial compatibility; social transfer-of-learning

\section*{Introduction}

Learning involves the acquisition and modification of new or existing knowledge through the application of which humans may be able to perform new tasks. This knowledge is shaped by the experience humans could acquire alone or in a social context (e.g., Vygotsky, 1978).

As regards individual performance, there is evidence that knowledge acquired in a task (i.e., practice task) can be transferred to and affects the way a subsequent task (i.e., transfer task) is performed. In the transfer-of-learning (ToL) paradigm, developed by Proctor e Lu (1999, see also Iani, Rubichi, Gherri, \& Nicoletti, 2009) participants are required to perform a spatial compatibility task with an incompatible stimulus-response (S-R) mapping (i.e., they are instructed to press a right key when a left stimulus is presented and a left key when a right stimulus is presented), followed by a Simon task in which stimulus location is irrelevant and responses have to be emitted on the basis of a non spatial stimulus feature (e.g., color). When the Simon task is performed alone, performance is more efficient when stimuli and responses spatially correspond (corresponding trials) than when they do not correspond (non-corresponding trials). Thus, if participants are instructed to press a right key to a red stimulus and a left key to a green stimulus, their reaction times (RTs) will be shorter and accuracy higher if a red stimulus appears on the left compared to when it appears on the right. The influence of the irrelevant spatial stimulus feature on performance is known as the Simon effect (Simon \& Rudell, 1967; Rubichi \& Nicoletti, 2006; Rubichi, et al., 1997; Rubichi, et al., 2004; for reviews, see Proctor \& Vu, 2006; Rubichi, et al., 2006).
It has been demonstrated that performance on the Simon task could be modulated, that is the Simon effect is reduced, eliminated or reversed, after practicing with a spatially incompatible mapping (e.g., Iani et al., 2009; Proctor \& Lu, 1999; Tagliabue, et al., 2000). This is thought to occur because the non-corresponding stimulus-response associations acquired during the transfer task remain active and influence performance in the subsequent Simon task. Hence, the fact that after an incompatible practice the Simon
effect is modulated indicates that performance depends not only on the goals of the task that is currently being performed, but also on immediate prior experience.
Sebanz and colleagues (Sebanz, Bekkering, \& Knoblich, 2006; Sebanz, Knoblich, \& Prinz, 2003) have shown that the Simon effect occurs even when the Simon task is shared between two agents with each one responding only to one stimulus color (from now on, social Simon effect). In the social variant of the Simon task, one participant has to press the left key in response to green stimuli and the other participant has to press the right key in response to red stimuli, so that each participant is performing a go/no-go task. The observation of a social Simon effect provides evidence that, although each participant is responsible for only half of the task and hence for only one response alternative, they tend to represent the co-actor's task and to integrate self and other's task into a common representation (see also Ferraro et al., 2012). Starting from these evidences, two studies (Milanese, Iani, \& Rubichi, 2010; Milanese, Iani, Sebanz, \& Rubichi, 2011) investigated, by means of the social transfer of learning (SToL) paradigm, whether and to what extend specific contextual determinants influence the way knowledge acquired in a given task could be transferred to a subsequent one. Milanese et al. (2010) modified the transfer of learning paradigm used in individual context. In their modified paradigm (from now on, the SToL paradigm), two participants performed together the spatial compatibility task (practice task) and the Simon task (transfer task) one after the other. They found that individually and jointly acquired stimulus-response associations acquired in the practice task remained active and transferred to the joint Simon task leading to an elimination of the joint Simon effect, whereas jointly acquired stimulus-response associations did not transfer to individual task performance. In other words, transfer-oflearning effects were maximal only when both practice and transfer tasks took place in a social setting, suggesting that what was transferred was not only what was specifically practiced, but also aspects of the interactive context in which learning took place.
Milanese et al. (2011) further investigated the elements of the contexts that needed to remain constant for transfer between a jointly performed practice task and a subsequent joint transfer task to occur, that is the identity of the co-actor and the spatial relation between the two co-actors. Results showed that a spatially incompatible practice performed jointly with another person influenced performance on a subsequent joint Simon task even if the co-actor's identity changed (Experiment 1), whereas when participant's position changed from the practice to the transfer task (that is, participant sitting on the left in the practice session sat on the right in the transfer session, the opposite was true for the other participant), the social-transfer-of-learning effect did not occur (Experiment 2). To sum up: the SToL effect was not tuned to the specific identity of the co-actor, and depended on the overlap between the spatial relations of the practice and transfer tasks.

Starting from these results, one might wonder which specific spatial relations are really necessary in order to obtain the modulation of performance on the subsequent joint Simon task. We know that in the solo condition, the non-corresponding link between stimulus and response positions is crucial. What does it happen when the joint task requires a further spatial determinant that is the participant's position? In other words, what does it happen if participants are required to take into consideration both the position of the response-key and the position of their body? To this aim, we performed two experiments, using the SToL paradigm, in which we manipulated the spatial relation between the stimulus, the response and the participant. For sake of clarity, the position of the response-key referred to the right/left button location on the keyboard, and the participant's position referred to the left/right displacement of the participant's body with respect to the center of the table. In both experiments the participant-response associations were incompatible (participants were required to respond with crossed arms), whereas the stimulusresponse and stimulus-participant associations were manipulated. In the practice session of Experiment 1, stimulus-response associations were spatially incompatible, while stimulus-participant ones were spatially compatible. We achieved this by requiring participants to respond with their arms crossed to the stimulus which was contralateral with respect to the position of the response-key (i.e., for instance, participants sitting on the left responded by pressing the right key to the left stimulus). In the practice session of Experiment 2, stimulus-participant associations were spatially incompatible, while stimulus-response ones were spatially compatible. In this experiment, participants were required to respond with their arms crossed to the stimulus that was contralateral with respect to their sitting position (i.e., for instance, participants sitting on the left responded by pressing the right key in response to the right stimulus). These manipulations will allow us to define which incompatible association is crucial for the SToL effect to occur.

\section*{Experiment 1}

\section*{Method}

Participants Sixteen students (1 male; 4 left-handed; age range: 19-26 years) of the University of Modena and Reggio Emilia took part in Experiment 1 for partial fulfillment of course credit. They reported normal or corrected-to-normal vision and were naïve as to purpose of the study. Once selected, they were randomly paired.
Apparatus and stimuli As in Milanese et al. (2010, 2011), stimuli in the spatial compatibility task were white solid squares ( 4.5 X 4.5 cm ), whereas stimuli in the Simon task were red or green solid squares ( \(4.5 \times 4.5 \mathrm{~cm}\) ). All stimuli were presented on a black screen, 9.5 cm to the left or to the right of a central fixation cross ( 1 X 1 cm ). Stimulus presentation was controlled by an IBM computer. In both tasks, responses were executed by pressing the "z" or "-" keys of a standard Italian keyboard with the left or right
index finger, respectively. In the spatial compatibility task participants' hands were crossed (the participant sitting on the left pressed the right key with his/her left hand; the participant sitting on the right pressed the left key with his/her right hand).Viewing distance was about 60 cm .
Procedure The experiment consisted of two consecutive sessions: a practice session and a transfer session. Participants first performed a joint spatial compatibility task (practice session) with an incompatible mapping (stimulus positions were mapped incompatibly to response-key positions, that is participants were required to respond to the controlateral stimulus with respect to the response-key position). Each participant was instructed to respond to only one of the two stimulus locations by pressing the contralateral key (by crossing their arms) and refraining from responding when a stimulus appeared in the alternative position. Hence, half of the participants responded to left stimuli by pressing a right key, whereas the other half responded to right stimuli by pressing a left key (see Fig. 1). After a 5 -min rest, participants were administered a joint Simon task (transfer session), in which the red and green stimuli were always location-irrelevant trials. Participants were instructed to respond to only one stimulus color by pressing the key at their disposal. For half of the participants, instructions required to press the right key in response to red stimuli and the left key in response to green stimuli, whereas for the other half instructions required to respond with the opposite stimulus-response mapping. Each participant kept the same position in both practice and transfer tasks, but changed the response position from the practice to the transfer task. That is, for instance, the participant sitting on the left and responding with the right key in the practice session sat on the left and responded with the left key in the transfer session (see Fig. 1).
In both tasks, a trial began with the presentation of the fixation cross at the center of a black background. After 1000 ms the stimulus appeared to the left or to the right of the fixation. In the spatial compatibility task, the stimulus remained visible for 600 ms , and the maximum time allowed for a response was 1200 ms . In the Simon task, the stimulus remained visible for 800 ms and the maximum time allowed for a response was 1000 ms . The inter-trialinterval was 1 s , and it was initiated immediately after the response was made.
The spatial compatibility task was composed of 12 training trials and 300 experimental trials divided into 3 blocks. The Simon task consisted of 12 training trials and 160 experimental trials divided into two blocks of 80 trials each. For both tasks, instructions stressed both speed and accuracy of performance.

Figure 1: Schematic representation of the experimental conditions used in the two experiments. In the practice session the participant sitting on the left (A) was required to press the right key in response to the left stimulus (participant-response and stimulus-response associations were spatially incompatible and the stimulus-participant association was compatible, Experiment 1) or to the right stimulus (participant-response and stimulus-participant associations were spatially incompatible and the stimulusresponse association was compatible, Experiment 2). In both experiments, each participant kept the same sitting position in both practice and transfer tasks, while the position of the response-key changed.

\section*{Results and discussions}

Since our predictions concern performance in the joint Simon task, for the current and the following experiment we report only the data for the Simon task (transfer session). Correct reaction times (RTs) were submitted to a repeatedmeasures Analysis of Variance (ANOVA) with Correspondence (corresponding vs. non-corresponding) as within-subject factor.

Responses in corresponding trials ( 328 ms ) were faster than responses in non-corresponding trials ( 350 ms ), \(F(1,15)=48.18, p<.001\), see Fig. 2. The significant 22 -ms Simon effect indicates that the joint Simon task was not influenced by prior joint performance on the spatial compatibility task \({ }^{1}\). Thus, practice on a spatial compatibility

\footnotetext{
\({ }^{1}\) In order to understand whether the \(22-\mathrm{ms}\) social Simon effect found in Experiment 1 was influenced by prior practice, we compared the data of this experiment with the data of the baseline condition of Milanese et al. (2010)'s Experiment 1 in which a 14ms social Simon effect was evident. Correct RTs for the two conditions were submitted to an ANOVA with Correspondence (corresponding vs. non-corresponding trials) as within-subject factor and Condition (baseline vs. Experiment 1) as between-
}
task with an incompatible association between the participant and the location of the response-key is not sufficient to produce SToL. These results suggested that stimulus-participant associations may play a crucial role in the occurrence of the STol effect.

Figure 2: Means reaction times (ms) for the transfer session of Experiments 1 and 2 as a function of stimulus-response correspondence.
subjects factor. The Correspondence x Condition interaction did not reach significance, \(F(1,30)=2.91, p=.10\), indicating that the effects found in the two experiments did not differ. Based on this result, we can safely conclude that in our Experiment 1 there was no evidence of SToL.

\section*{Experiment 2}

\section*{Method}

Participants Sixteen new right-handed students of the University of Modena and Reggio Emilia (all female; age range 19-20 years), selected as in the previous experiment, took part in Experiment 2.
Apparatus and stimuli and procedure Apparatus and stimuli were the same as in Experiment 1, whereas the procedure varied as follows. Participants performed the joint spatial compatibility task with a different incompatible mapping: stimulus positions were mapped incompatibly to participants seating position, that is participants were required to respond to controlateral stimuli with respect to their seating position. Each participant was instructed to respond to only one of the two stimulus locations by pressing the contralateral key (by crossing their arms) and refraining from responding when a stimulus appeared in the alternative position. Each participants kept the same position in both practice and transfer tasks, while the position of the response-key changed. That is, for instance, the participant sitting on the left and responding with the right key in the practice session sat on the left and responded with the left key in the transfer session (see Fig. \(1)\).

\section*{Results and discussion}

Correct RTs were submitted to an ANOVA with Correspondence as within-subject factor. RTs did not differ between corresponding ( 316 ms ) and non-corresponding trials ( 319 ms ), \(F<1\) (see Fig. 2). The lack of a significant Simon effect is indicative of SToL. This result can be taken as an indication that it is the spatial association between the stimulus and the participant acquired during the practice task that is crucial for the occurrence of the SToL effect, while stimulus-response associations are irrelevant.

\section*{Additional analysis}

In order to compare the Simon effect found in the two experiments, we ran an ANOVA with Correspondence (corresponding vs. non-corresponding trials) as withinsubject factor and Experiment (Experiment 1 vs. Experiment 2) as between-subjects factor. Responses in corresponding trials ( 322 ms ) were faster than responses in non-corresponding trials \((334 \mathrm{~ms}), F(1,30)=25.64, p<.001\). The main effect of Experiment was nearly significant, \(F(1,30)=3.64, p=.07\), showing that responses were slower in Experiment \(1(339 \mathrm{~ms})\) than in Experiment \(2(317 \mathrm{~ms})\). The Correspondence x Experiment interaction was significant, \(F(1,30)=15.23, p<.001\), indicating that the \(22-\mathrm{ms}\) found in Experiment 1 differed from the \(3-\mathrm{ms}\) (non-significant) effect found in Experiment 2.

\section*{Discussion}

It is well known that in the ToL paradigm, when the practice task is performed in a solo condition, what is acquired and transferred to the subsequent Simon task is an association between stimulus and response-key positions (Proctor \& Lu, 1999; see also see also Iani, et al., 2009).
The results of previous studies (e.g., Milanese et al., 2010, 2011) seem to suggest that in social settings a crucial factor for the occurrence of transfer-of-leaning effects may be the type of relation between the participant and the stimulus positions acquired during practice rather than the relation between stimulus and response-key positions. The present study was aimed at assessing the relative contribution of the spatial relations between stimulus and response-key, between stimulus and participant or rather between participant and response-key positions in the occurrence of the SToL effect. More specifically, the participant-response associations were always incompatible (participants were required to respond with crossed arms), whereas stimulusresponse and stimulus-participant associations were manipulated. In this way we were able to investigate independently whether crucial for the SToL effect to occur is the incompatible association between stimulus-response positions (Experiment 1) or between stimulus-participant positions (Experiment 2).
We found a SToL effect when participant-response and stimulus-participant associations were spatially incompatible and stimulus-response associations were compatible (Experiment 2). No evidence of SToL was found when participant-response and stimulus-response associations were spatially incompatible and stimulusparticipant association were compatible (Experiment 1).
The present findings suggest that the incompatible association between the positions of the stimulus and of the participant may be crucial for the emergence of the SToL effect. It would seem, thus, that in a joint setting, where participants are (implicitly) required to take into account the presence of another person, the participant's position acquires greater relevance than in a solo setting. These results point to an intriguing and debated issue remained open so far: do correspondence effects emerging in joint setting depend on the relationship not only between stimuli and responses but also between stimuli and responding agents?
Recently, Philipp and Prinz (2010; see also Liepelt, et al., 2010) proposed that the joint compatibility effect may rely not only on the stimulus-response spatial correspondence (as is known to be crucial for the standard Simon effect to occur), but also on social correspondence, that is the one between stimulus and responding agents. According to these authors, when the Simon task is shared between two acting individuals, space may be used as an indication of whose turn it is. This would mean that a stimulus appearing on the left does not bring to the automatic activation of the left response, but rather is perceived as a stimulus signaling that the person sitting on the left is in charge of responding.

Starting from this account, our study investigated whether social correspondence may play a crucial role also in the SToL effect. It should, however, be noted that in Philipp and Prinz's study, the positions of the participant and of the response-key always corresponded and hence the correspondence between stimulus and response-key position could not be distinguished from the correspondence between the stimulus and the responding agent. In the current study, we separated the positions of the response-key and of the participant, as in the practice task participants were required to respond with crossed arms. In this way we were able to investigate independently whether crucial for the SToL effect to occur is the incompatible association between stimulus and response-key positions (Experiment 1) or between stimulus and participant positions (Experiment 2). Based on the findings of the current study, the observation of a null joint Simon effect in the transfer task could be the result of the acquisition and subsequent transfer of the incompatible link between the stimulus and participant positions. In other words, as the present results suggest, the SToL effect in these studies may rely not only on the spatial association correspondence between stimulus and response, differently from the individual condition (ToL effect), but also, and crucially, on the incompatible link between the stimulus and participant positions. These results underline the importance of both spatial and social features. Indeed, it seems that acting in a social context increases the importance of the participants' position with respect to the stimulus.
To conclude, in this study, we used the social transfer of learning paradigm to identify which elements of the context need to remain constant for social transfer-of-learning effects to occur. This issue is not trivial, because sometimes the practice context (i.e., the context in which we implicitly acquire new knowledge) and the transfer context (i.e., the subsequent context in which we utilize the acquired knowledge) are not identical and may differ in several aspects. The results of this study are particularly relevant since they provide insights on the way we represent another's task (and how we integrate the other agent information about action with our information, see Knoblich \& Jordan, 2003) in particular joint action situations.

\begin{abstract}
Aim of the present study is to investigate whether and to what extent movements performed with the whole body can influence calculation processes. Participants were asked to perform additions or subtractions while executing an ascending or descending movement in a passive (i.e., by taking the elevator) or active (i.e., by taking the stairs) mode. Results revealed a congruency effect between the type of calculation made and the direction of the movement performed, but only when participants experienced it through a passive mode. Our data are in line with studies providing evidence of a strict link between numerical and spatial representations, and between motor actions and number magnitude processing (motor-to-semantic effect). Implications of the results for the embodied and grounded nature of numerical cognition will be considered and discussed.
\end{abstract}

Keywords: numerical cognition; body movement; embodied cognition

\section*{Introduction}

One of the main challenges of embodied and grounded cognition views (e.g., Barsalou, 2008) is to account for the representation of abstract concepts, such as numbers. The present study focuses on numerical cognition, an important area in which this challenge can be addressed. The mental representation of quantity (i.e., number magnitude) is the main focus of an increasing number of researches. In a well known study, Deahene and colleagues (Dehaene, Bossini, \& Giraux, 1993) demonstrated that numbers ranging from 0 to 4 and from 6 to 9 facilitate left and right responses, respectively, even if number magnitude was a taskirrelevant feature. These results led the authors to claim that number magnitude is visuo-spatially represented along an horizontal mental number line (MNL) with small numbers on the left and large numbers on the right of a continuum (for a review, see Hubbard, Pinel, Piazza, \& Dehaene, 2005). In a recent study, Holmes and Lourenco (2012) investigated the strength of this Spatial Numerical Association of Response Codes (SNARC effect), on both the horizontal (i.e., small left; large - right) and vertical (i.e., small - bottom; large - up) MNL and found that the horizontal organization is rather dominant. Their data also showed, though, that the vertical organization depends on how number are conceptualized. In other words, the vertical organization emerged only when numbers are conceptualized as magnitudes that elicit an orientation (e.g., \(1^{\text {st }}\) floor from surface, \(2^{\text {nd }}\) floor from surface, etc.).

To our knowledge, all the studies so far were aimed at investigating whether and how the numerical magnitude, that is the representation of the number as a small or large quantity, impacts two processes. First, recent studies analyzed the influence of the numerical magnitude on the spatial representation of the horizontal/vertical axis, that is left/low and right/high spatial position (Fisher, Castel, Dodd, \& Pratt, 2003; Nicholls, Loftus, \& Gevers, 2008; Pecher \& Boot,
2011). Second, several researches focused on the impact of the magnitude on the action related processes investigating the bi-directional interaction between the magnitude code and the action plans of grasping objects with precision or power grip (Andres, Ostry, Nicol, \& Paus, 2008; Badets, Andres, Di Luca, \& Pesenti, 2007; Badets, Bouquet, Ric, \& Pesenti, 2012; Badets \& Pesenti, 2010, 2011; Chiou, Chang, Tzeng, \& Wu, 2009; Ranzini et al., 2012).

Starting from this evidence, the current study aims at investigating whether and to what extent processes leading to numerical magnitudes, such as arithmetical calculations of addition and subtraction, can be influenced by real upward and downward movements experienced with the whole body. In a study by Knops, Viarouge, and Dehaene (2009) participants tended to select the numerosity displayed in the upper right location for additions, and in the upper left location for subtractions (Space-Operation Association of Responses: SOAR). Differently from Knops and colleagues, our task required participants to: (a) keep adding or subtracting the same quantity from a starting number in a given period of time; (b) repeat the result of each calculation aloud, so that participants had to focus on the on-line and progressive calculation process; (c) experience an ascending or descending movement with the whole body in a passive (i.e., taking the elevator) or active (i.e., taking the stairs) mode.

In a recent research, Hartmann, Grabherr, and Mast (2011) demonstrated that the passive displacement of the body was sufficient to influence the magnitude of self-generated numbers. In their Experiment 1, participants were positioned on a motion platform and were asked to generate numbers at random while the platform was moving (leftward, rightward, downward, upward, forward, and backward) or when it was stationary. Results indicated a bias for small numbers, which were generated more easily during leftward and downward motions as compared to rightward and upward motions, respectively. Differently from Hartman et al. (2011), we asked participants to experience the movements through an active and a passive mode, and to make additions and subtractions rather than generating random numbers.

To summarize, our experimental procedure is new with respect to current literature in two aspects: first, we focused on the processes leading to a numerical magnitude, rather than focusing on the number magnitude per se. Second, we asked participants to experience real movements engaging their whole body through passive and active modes. We hypothesized a congruency effect between the direction of the experienced ascending or descending movement and the spatial orientation inferred by the type of calculation made, that is additions-upward orientation vs. subtractions-downward orientation. More precisely, we predicted that participants would be facilitated when asked to make additions while experiencing an upward movement and subtractions while experiencing
a downward movement (congruent conditions) as compared to the opposite instructions (incongruent conditions). Finally, we also assessed whether this congruency effect was modulated by the passive or active mode through which the movements were experienced. It is crucial to say that the type of movements and the sense of their direction were different in these two modes. In fact, when taking the elevator participants passively perceived themselves moving in a given direction. Conversely, when the stairs were taken, participants performed an overt and real motor action with a full physical body involvement. Moreover, the sense of the movement was fast and clearly vertical when using the elevator, while it was more progressive and less vertical when using the stairs, since that the awareness of going up or down changed progressively step by step. Hence, these two modes can modulate results differently: if the congruency effect requires an active motor process, we hypothesize to find the effect only in the stairs mode. Conversely, if the fast and vertical passive displacement of the body is sufficient to obtain the congruency effect, we expect the effect even when participants take the elevator.

\section*{Method}

Participants Twenty-eight undergraduate students from the University of Bologna ( 15 females, age range 19-24 years) took part in the experiment in exchange of 5 Euros. The majority of them had a background in humanities. All were naïve as to the purpose of the experiment and gave informed consent.

Apparatus and Stimuli Participants were asked to add or subtract 3 to a starting number (e.g., 342) for 22 seconds and to say the result of each calculation aloud (e.g., \(345,348,351\) or \(339,336,333\) and so on, for additions and subtractions, respectively, until 22 seconds were elapsed). In order not to make the calculation process too easy, the starting numbers: a) were composed by three digits; b) started with two different digits (i.e., 3 or 5 , such as 378 or 516).

Procedure The task required participants to make the additions or subtractions while taking the elevator or taking the stairs. In order not to mix these modes, the task was divided in two blocks, whose order was balanced between subjects. In one block, participants performed the calculations while taking the elevator, whereas in the other block calculations were performed while taking the stairs. Within each block, four trials were performed, resulting from the combination of the two types of calculation, additions and subtractions, and movement, ascending and descending. We designed each block in order to make additions and subtractions always alternate: an addition was always followed by a subtraction and vice versa. At the beginning of each trial, the experimenter explicitly informed the participant about the type of calculation that had to be performed and about the type of movement that was going to be experienced. For each trial, the experimenter spoke the starting number aloud
and then a go signal followed. Immediately after the go signal, the passive or active movement began and, at the same time, participants were required to repeat the starting number and then to keep saying the result of each calculation aloud for 22 seconds consecutively, until the experimenter gave the stop signal. If a calculation error was made, the trial was stopped and a new trial began with a different starting number. No feedback was given during the task and the importance of accuracy over speed was stressed at the beginning of each trial. The experimenter was present during the whole experiment. For the passive mode, she went up/down using the elevator together with the participant. For the active mode, she walked close to the participant while going up/down the stairs and asked the participant to keep her pace throughout the whole movement. In other words, each participant and the experimenter went up/down the stairs together so that the number of steps taken was held constant across participants. Overall, the experiment lasted about 15/20 minutes.

\section*{Results}

We considered the correct number of calculations made within the 22 seconds time window as our dependent variable. Since we predicted a congruency effect between the direction of the movement and the type of calculation, we divided the trials in congruent (ascending movements - additions; descending movements - subtractions) and incongruent (ascending movements - subtractions; descending movements additions), and then we averaged the number of calculations separately for each group of pairings.

The correct calculations were entered into a repeatedmeasures ANOVA with Congruency (congruent vs. incongruent) and Mode (elevator-passive movement mode vs. stairs-active movement mode) as withinsubjects factors. The Congruency \([F(1,27)=10.20\), \(\left.\operatorname{MSE}=7.51, n^{2}{ }_{p}=0.27, p<.01\right]\) and Mode \([F(1,27)=\) \(\left.32.50, \mathrm{MSE}=3.96, n_{p}^{2}=0.55, p<.001\right]\) factors were significant. We found a higher number of calculations: a) for congruent pairings ( \(\mathrm{M}=11.2\) ) with respect to incongruent ones ( \(\mathrm{M}=10.7\) ); b) when the movement was experienced with a passive \((\mathrm{M}=12)\) with respect to an active ( \(\mathrm{M}=9.8\) ) mode. Crucially, the Congruency x Mode interaction was significant \([F(1,27)=5.16\), MSE \(\left.=1.36, n_{p}^{2}=0.16, p=.03\right]\). Fisher's LSD posthoc test showed that, in the passive mode, participants performed a higher number of calculations for congruent pairings than for incongruent ones ( \(\mathrm{Ms}=\) 12.5 vs. 11.5 , respectively, \(p<.01\) ). Conversely, this pattern failed to emerge for the active mode ( \(\mathrm{Ms}=9.9\) vs. 9.8, for congruent and incongruent pairings, \(p=\) 0.95 , see Figure 1).

Figure 1: Number of calculations for congruent and incongruent pairings performed through a passive (i.e., elevator, leftmost panel) or active (i.e., stairs, rightmost panel) mode. Bars are standard error of the mean.

\section*{Discussion}

We investigated whether calculation processes, such as additions and subtractions, are influenced by real movements experienced with the whole body. Our findings showed a facilitation, in terms of correct number of calculations made, for the congruent condition, that is when additions and subtractions were performed while experiencing an ascending and descending movement, respectively, with respect to the opposite mapping. This result is in line with recent behavioral findings showing the influence of the motor process over the semantic one (i.e., motor-to-semantic effect, see Badets et al., 2012; Badets \& Pesenti, 2010, 2011; Ranzini et al., 2012).

The fact that we did not find the congruency effect for the active mode could be due to different factors. First, climbing the stairs required an overt movement and a full physical body involvement. Second, the sense of the movement direction was more progressive and less vertical, with respect to when the elevator was used, since the awareness of going up or down changed step by step. Hence, the lack of a congruency effect could be due to the higher amount of resources required by the dual-task of climbing the stairs and counting at the same time, as also suggested by the lower amount of calculations yielded for this mode compared to the passive one. In addition, the fact that the movement was probably perceived as faster and more vertical when taking the elevator, could have yielded a significant effect for this mode only.

In a recent study Hartmann and colleagues (2011, Experiment 1; see also Hartmann, Farkas, \& Mast, 2012) found that the number generation process was influenced by experiencing a passive whole body movement. Our results are in line with these findings, but we also obtained a congruency effect between the body movements and the calculation processes, instead of a given set of numbers. Moreover, participants in our study also experienced real movements with their whole body instead of passive movements while seated in a chair. We claim, indeed, that experiencing
ascending and descending movements with the whole body can influence the processes responsible for numbers representations as magnitude with an upward and downward orientation, that is addition and subtraction calculations.

Our results can have intriguing implications for the embodied and grounded cognition view, which claims a close link between perception and action, due to the influence of both our sensory-motor system and previous experiences on the cognitive processes (e.g., Barsalou, 2008). Of particular relevance to our work is the debate concerning the claim that both concrete and abstract concepts, such as numbers, are grounded in perception-action systems (e.g., Borghi \& Pecher, 2011; Fischer, 2012; Gianelli, Ranzini, Marzocchi, Rettore Micheli, \& Borghi, 2012; Pecher \& Boot, 2011). So far few studies demonstrated the grounding of abstract concepts on sensory-motor experiences (for reviews, see Borghi \& Cimatti, 2012; Pecher, Boot, \& van Dantzig, 2011) and thus our study, by focusing on an interesting example of abstract concepts such as numbers, can be relevant for this issue. In fact, the influence of whole body movements on numbers representation can be interpreted as a proof that also number processing can be embodied. Interestingly, our findings are in line with a recent proposal, advanced by Fischer and Brugger (2011) on the origin of the Spatial-numerical associations (SNAs), that recognizes the grounded and embodied nature of numerical cognition, which would origin from finger counting.

To summarize, our study contributes to highlight the close link and interaction between our everyday activities, as movements in real-life situations, and higher-order cognitive processes, as spatial representation and number processing.

\begin{abstract}
Individuals are frequently asked to make sacrifices in an attempt to produce benefits for future generations. Such decisions are referred to as intergenerational dilemmas. Previous research on intergenerational dilemmas has shown that situational manipulation of factors such as the delay between sacrifice and benefits and the perceived similarity with future others modulate intergenerational preferences. However, it is unclear whether there are traits that predict intergenerational preferences across a variety of dilemmas. Individual differences were quantified using econometric measures of delay discounting and social discounting. Results indicated that individual differences on these measures accounted for a significant portion of the variance observed in a broad measure of intergenerational preferences.
\end{abstract}

Keywords: intergenerational choice, delay discounting, social discounting

It is increasingly clear that many of our everyday actions not only have immediate consequences, but also have consequences for those in future generations. Decisions about such actions are somewhat peculiar in that a thorough evaluation requires considering the interests of individuals that do not yet exist. These decisions become even more complicated when they require short-term sacrifices on the part of the present generation in order to achieve benefits for (or to avoid harming) future generations. Decisions about such tradeoffs have been referred to as intergenerational dilemmas (e.g., Gardiner, 2006).

Intergenerational dilemmas are frequently encountered in the context of policy-making and involve everything from global warming and overfishing to more mundane decisions about infrastructure investments. Occasionally, policy makers place will act on behalf of future generations. For example, Norway's gasoline prices are among the world's highest at \(\$ 10.12\) per gallon, resulting from taxes on fossil fuels designed to reduce global warming (Randall, 2012; Romero, 2005). However, due to a lack of political will, intergenerational dilemmas are often resolved in ways that favor the current generation.

Intergenerational dilemmas are an example of a larger class of social dilemmas in which the interests of the decision maker are at odds with the interests of others. Despite the pervasive assumption of self-interested motives by economists (see Frederick, Loewenstein, \& O’Donoghue,

2002 for a review of this literature), altruistic behavior has been observed in a range of contexts and across a variety of species (Piliavin \& Charng, 1990). The dominant models suggest that altruism is highly dependent on reciprocity. That is, decision makers may act in order to achieve benefits for others, even at personal cost, if the beneficiaries may later return the favor. In the context of intergenerational dilemmas, however, reciprocity plays no obvious role. That is, decision makers in the present generation have no reason to behave altruistically towards future generations because future generations have neither an opportunity to reciprocate beneficial actions nor the means to retaliate for detrimental actions. In fact, according to traditional models of altruism, it is in the present generation's best interest to make decisions that ignore the welfare of future generations.

\section*{An Economic Perspective}

When contemplating intergenerational dilemmas at the policy level, economists are typically employed to produce cost-benefit analyses that are used to guide policy-making. When a policy's consequences (either costs or benefits) extend over long time periods, these analyses are forced to specify exactly how current and future welfare are balanced. The strategy typically taken is to take the interests of future generations into consideration, but to a lesser extent than the interests of the current generation. The degree to which future consequences impact intergenerational choices is controlled by what is known as the social discount rate (Moore, Boardman, Vining, Weimer, \& Greenberg, 2004). Assuming a social discount rate of ten percent, immediate consequences are considered to be twice as important as identical consequences that will occur in seven years and ten times greater than consequences that will occur in 14 years. For example, imagine a proposal to fix aging sewer systems. If the proposed legislation would cost \(\$ 100\) million dollars immediately, but would avert a potentially costly failure estimated to occur in 30 years, then the ultimate cost of the failure would have to exceed \(\$ 2\) billion in order to justify the immediate expenditure.

These social discount rates can lead to potentially undesirable conclusions. For example, the ten percent discount rate suggests that the welfare of the current generation's grandchildren (two generations or 50 years from now) will be valued at less than one percent of the
welfare of the current generation. Thus, these standard discount rates suggest that we ought to essentially disregard the welfare of future generations and instead act to maximize welfare over a short temporal horizon.

However, policymakers and even economists themselves often disagree about what social discount rates are appropriate. For example, the Stern Review (2007), a comprehensive report assessing the costs of climate change, was criticized by some economists for employing a social discount rate that was too low (e.g., Beckerman \& Hepburn, 2007), whereas others have argued for a lower discount rate (e.g., a discount rate of zero, Cline, 2008).

In contrast, Dasgupta (2007) noted that one could be similarly dissatisfied with the selection of another parameter in Stern's model, what Stern calls eta ( \(\eta\) ). Eta is an ethical parameter that reflects people's attitude about disparities in welfare both between individuals within the current population and disparities in welfare between current and future populations. Dasgupta (2007) argues that society ought to have more egalitarian attitudes than implied by the value of eta Stern selected.

\section*{A Psychological Perspective}

Psychologists have also investigated factors related to intergenerational preferences (though to a far more limited degree). Wade-Benzoni (2008), for example, has compiled a set of factors that appear to modulate intergenerational preferences. These factors include the delay and uncertainty associated with future consequences, affinity towards future generations, and the behavior of past generations. Both individually and taken together, these factors appear to predict, to varying degrees, one's intergenerational choices.

One intuitive influence on intergenerational preferences is the delay between the current generation's behavior and the associated consequences. This mirrors the economic idea of a social discount rate reviewed above. That is, consequences expected to occur only after long delays are discounted more (i.e., exert less of an influence on intergenerational choices) than those expected to occur after shorter delays. For example, Wade-Benzoni (2008) found that participants who were told that future generations would begin to reap the benefits of a proposed gas tax in the relatively near future were willing to bear significantly higher gas taxes than those who believed the benefits were more temporally delayed.

Preferences in intergenerational dilemmas have also been found to depend on the affinity between decision-makers and the recipients of future benefits. For example, WadeBenzoni (2008) asked office staffers to distribute a sum of money between themselves and a future subject in the study. Results indicated that participants left significantly larger sums of money if they believed they were leaving money for a fellow staff member (high affinity) than when they believed they were leaving money for a stranger (low affinity). This is in line with past findings (e.g., Hoffman,

McCabe, \& Smith, 1996) that social distance acts to attenuate generosity toward others.

Lastly, intergenerational preferences appear to be influenced by the behavior of past generations. As described above, intergenerational generosity (or greed) cannot generally be reciprocated. However, there is recent evidence that individuals unable to reciprocate may "pay forward" past acts on unrelated third parties (Gray, Ward, \& Norton, in press). In the case of intergenerational dilemmas, this would suggest that individuals might attempt to "reciprocate" the actions of previous generations, but to do so with future generations. That is, if previous generations have sacrificed on our behalf, then perhaps we may be more willing to do so on behalf of future generations. Consistent with this suggestion, Wade-Benzoni (2002) found that intergenerational precedents can exert a strong influence on intergenerational choices, but only when individuals believed that previous generations were willing to make sacrifices. Apparently, previous generations' generosity serves as a model for the current generation in a way that previous generations' selfishness does not.
This previous work has pointed to several major factors that influence intergenerational preferences. However, these previous studies have focused on the manipulation of situational factors. For example, beliefs about the consequences of overfishing predicted were related to willingness to accept fishing quotas (Wade-Benzoni, 2008). Furthermore, because factors such as delay, uncertainty, and precedent should vary from one intergeneration dilemma to another, one would also expect people's intergenerational preferences to vary from one dilemma to another as well.
The goal of the current study is to explore how intergenerational preferences may be predicted by decisionrelated traits that are relatively stable across decision making contexts. That is, the current study concerns our ability to predict individual differences in intergenerational preferences. Because of our focus on individual differences, we evaluate decision-relevant traits using measures that are both quantitatively rigorous and that generalize across a variety of contexts.
Specifically, we evaluate decision makers' preferences regarding delay and social distance because past work has found situational manipulation of these factors to modulate intergenerational preferences. To evaluate preferences about delay, we use a standard delay discounting task (Kirby \& Marakovic, 1996). Delay discounting refers to the tendency for immediate rewards to be preferred over delayed rewards and for the value of rewards to decline with increasing delay. To evaluate social preferences, we employ a recently developed measure of social discounting (Rachlin, 2002). Similar to delay discounting, work on social discounting has found that rewards to the self are preferred over rewards given to others and that the subjective value of others' rewards declines as social distance increases.

\section*{Method}

\section*{Participants}

Sixty-three Stony Brook University undergraduate students participated for partial course credit.

\section*{Dependent Measures}

The intergenerational decision-making task consisted of four scenarios. Specifically, we adapted items involving the topics of overharvesting fisheries and a gasoline tax (based on materials from Wade-Benzoni, 2008). Two additional scenarios were developed specifically for the current study, one involving an increase in tuition and one involving an increase in rent. These items were included to increase the relevance of the intergenerational dilemmas to our undergraduate participants. Each scenario embodied the same basic set of features characteristic of a standard intergenerational dilemma. That is, the scenarios each described an immediate, costly sacrifice and stated that the benefits of this sacrifice would only be enjoyed by other individuals (but not by the participant) and that the benefits would only arrive at some point in the future. As in WadeBenzoni's (2008) study, each scenario involved reading a brief passage that provided factual information about the issue, including short-term costs and future benefits, and included a graphical visualization of the relationship between the magnitude of the short-term sacrifice and the corresponding benefits to future generations. The graph did not include numbers of any sort and was not intended to be thoroughly informative. Instead, it was intended to simply illustrate the idea that greater present sacrifice would yield greater future benefit. Participants were then asked to indicate whether they would agree with a series of proposed sacrifices. For example, participants were asked if they would agree to pay an additional \(\$ 0.20\) tax, raising the price of a gallon of gasoline to \(\$ 3.20\).

The delay discounting task was adapted from a previous study by Kirby and Marakovic (1996). On each trial of this task, participants chose between a smaller reward, which was available immediately (i.e., "tonight"), and a larger reward, which was only available after some delay. For example, one item asked participants to select between \$30 dollars tonight and \(\$ 85\) to be delivered in 70 days. Each of these items is associated with a discount rate that represents how patient a decision maker would need to be in order to be indifferent between the immediate and delayed rewards. For example, in the preceding example, indifference would be associated with a discount rate of exactly .008571 . The task consisted of 27 items. Twenty-one of these items were identical to those used by Kirby and Marakovic (1996), capable of detecting discount rates from 0.0007 to 0.25 . In our experience, we have found that undergraduates' preferences fall toward the impatient end of this range. To ensure that we did not artificially exclude particularly impatient participants, we amended the original 21 items with 6 additional items that extended the range of measurable discounting rates from 0.0007 to 1.0 , a change
we have adopted in previous investigations (Luhmann, in press).

The social discounting task was adapted from Jones and Rachlin (2006). Participants were first asked to imagine 100 people, ranging from one's closest friend or relative (i.e., person \#1) to a mere acquaintance (person \#100). On each trial, participants were asked to choose between a reward for themselves and a reward for someone on their list of 100 people. For example, one item asked participant to choose either \(\$ 30\) dollars for themselves and \(\$ 85\) for Person \#70. The specific quantities were identical to those used in the delay discounting task. That is, the reward magnitudes were identical and the delays (e.g., 70 days) were converted into social distances (e.g., person \#70).

\section*{Procedure}

Before the experiment began, instructions were read to participants. Participants were told that they would complete a number of measures on their preferences on a variety of topics. The instructions further emphasized that there were no "correct answers". The order for both the scenarios within the intergenerational decision task and the three measures themselves were counterbalanced across participants. The entire procedure took approximately 30 minutes.

\section*{Results}

Each participant's delay discount rate was estimated as the discount rate most consistent with her choices. For example, if a participant chose the larger reward for all items representing discount rates equal to and smaller than .01 but chose the smaller reward for all items equal to and larger than .02 , her discount rate would be estimated as the geometric mean of the discount rates associated with the items on each side of this "switch point" (.014 in this case). If more than one discount rate was found to be equally consistent with a set of choices, the geometric mean of the consistent estimates was taken to be the participants' discount rate (for further details, see Kirby \& Marakovic, 1996). The procedure for estimating of social discount rates was identical. Because discount rates are highly skewed, they were transformed by taking their natural log before being submitted to the statistical analyses described below.

To quantify participants' intergenerational preferences, we first estimated the maximum sacrifice that each participant would accept in each scenario. This maximum was estimated using a procedure similar to that used to estimate the discount rates. For example, if a participant agreed to all the sacrifices equal to and smaller than \$300 but rejected all sacrifices equal to and larger than \(\$ 400\), her maximum willingness was estimated as the mean of these two "cross-over" quantities (e.g. \$350). If more than one estimate was found to be equally consistent with a set of choices, the mean of the most consistent estimates was taken. These estimates were then normalized by computing z-scores. This yielded a total of six z-scores for each participant, one for each scenario. Finally, each

participant's six z-scores were averaged. These averages represent participants' intergenerational preferences: their average, relative willingness to sacrifice on behalf of future generations.

We constructed a multiple regression model with the social and delay discount rates acting as predictor variables and the intergenerational preference measure acting as the outcome variable (Table 1). Results demonstrated that this model accounted for a significant proportion of the variance in intergenerational choices. Turning to the individual factors (see Figure 1), results indicate that participants' delay discount rates significantly predicted their intergenerational choices, with lower delay discount rates (i.e., greater patience) predicting greater willingness to sacrifice on behalf of future generations. Social discount rates were also a significant predictor of intergenerational preferences, with lower social discount rates (i.e., greater generosity) predicting greater willingness to sacrifice on behalf of future generations. Finally, results indicate that the interaction between social discounting and delay discounting was also a significant predictor of intergenerational preferences. Specifically, the direction of this relationship suggests that delay and social discounting combined super-additively to predict intergenerational choices. That is, a decision maker who was both patient and generous was even more willing to sacrifice on behalf of future generations than would have been expected by her individual delay and social discount rates.

\section*{Discussion}

The goal of the current study was to investigate intergenerational preferences; the willingness to make sacrifices on behalf of future generations. Whereas prior studies have focused on situational factors that influence intergenerational decision making, we have instead investigated how individuals' decision-related traits might predict their intergenerational preferences. Our results suggest that both delay discount rates (i.e., patience) and
social discount rates (i.e., generosity) were significant predictors of intergenerational preferences. Individuals displaying greater patience when choosing between personal rewards were also significantly more willing to make sacrifices for the benefit of future generations. Similarly, individuals who made more generous choices, more frequently preferring rewards to others at personal cost, were also more inclined to make intergenerational sacrifices. Finally, we also found that individuals who displayed both greater generosity and greater patience were even more willing to sacrifice on behalf of future generations than would be expected given these individual traits.

The finding that individuals' generosity predicts their intergenerational preferences is consistent with previous research. For example, Jones and Rachlin (2009) have demonstrated that social discount rates (but not delay discount rates) predict altruistic behavior in public goods games, which is a multi-player version of the classic Prisoner's Dilemma game (Axelrod, 1984). Those with low social discount rates (i.e., high generosity) have been found to be more cooperative than those with high social discounting rates. Jones and Rachlin (2009) suggest that when assessing the tradeoff between personal rewards and rewards to others, the latter is necessarily discounted according to the social distance between the decision maker themselves and the others. Wade-Benzoni (2008) has also reported that individuals are more willing to make intergenerational sacrifices on behalf of similar others than dissimilar others. Wade-Benzoni (2008) refers to this dimension as affinity, but it is roughly equivalent to social distance, particularly as it has been conceived by Trope and colleagues (Trope \& Liberman, 2011).

The finding that individuals’ patience predicts their intergenerational preferences is somewhat more curious. Of course, individuals' distaste for delayed payoffs is a robust finding (Soman et al., 2005). Indeed, delay has been found to systematically devalue rewards. Wade-Benzoni (2008) has reported a related finding in which intergenerational

Figure 1 - Partial residual plots illustrating the relationship between intergenerational preferences and delay discounting (A), social discounting (B), and the interaction between delay and social discounting (C). Discount rates have been log-transformed.
preferences were found to be more generous when the benefit to future generations was described as occurring sooner rather than later. Given that intergenerational benefits only arrive in the distant future, it may seem reasonable that patience should be associated with greater intergenerational discounting. However, delay discount rates are typically assumed to describe attitudes toward the delay associated with personal rewards, not the rewards of others. Given that intergenerational tradeoffs are between the current self and future others, it is not immediately obvious why one's evaluation of one's own future rewards is particularly relevant. However, if one is attempting to assess the magnitude of the intergenerational benefits, it may not be possible to perform this evaluation without one's own intertemporal attitudes influencing the valuation. Alternatively, some researchers have suggested that intertemporal attitudes may reflect one's beliefs about the uncertainty present in the environment (Bixter \& Luhmann, 2012). That is, it is permissible, and even advisable, to be impatient if it is believed that future rewards are unlikely to be delivered as promised. Under this view, patience is not about one's unique attitudes toward personal rewards, but about the risk associated with waiting; risk that everyone faces. Consistent with this account, Wade-Benzoni (2008) reported that intergenerational preferences were more selfish when the future benefits were associated with greater uncertainty.

The interaction between patience and generosity is interesting and may be a natural extension of the reasoning outlined above. Because intergenerational sacrifices are made so as to bring about benefits that are both temporally and socially distant, it makes sense that these two factors might jointly influence intergenerational preferences. Indeed, the way in which discounting is typically formulated suggests that rewards are reduced by a discount factor that combines both the magnitude of the dimension (e.g., delay) and the decision maker's attitude toward that dimension (e.g., patience). When rewards are discounted along more than one dimension, these discount factors are combined multiplicatively (e.g., Ho, Mobini, Chiang, Bradshaw, \& Szabadi, 1999), which naturally predicts an interaction and more specifically suggests that patience and generosity should combine super-additively.

It is also interesting to note that our results found patience and generosity to be independent because prior work (Jones \& Rachlin, 2009) has found these traits to be significantly correlated. The correlations reported by Jones and Rachlin were not overwhelming ( \(r=.25-.28\) ), so it is possible that we did not have sufficient power to detect this relationship. However, the predictive power each factor provided in our multiple regression analysis suggests that this may not be a plausible explanation. It is perhaps even more surprising that we failed to find any overlap between patience and generosity because our study assessed these dimensions using nearly identical tasks (e.g., identical rewards and distances). If participants were not paying close attention to the materials and simply making choices based on the
numbers presented on each trial, their choices should have been identical. This suggests that the independence of delay and social discounting is even stronger evidence for separable traits.

The current results suggest implications for policymaking. Specifically, the current study suggests that social discount rates should reflect a variety of decision-related psychological attitudes. For example, one cannot simply assume that the delay between immediate costs and future benefits captures the entirety of the current generation's attitudes toward future generations. Echoing the concerns of Dasgupta (2007), more general attitudes about equality, fairness, and generosity appear to be just as powerful in determining individuals' intergenerational preferences. Though this may complicate the calculation of social discount rates, attitudes about social equality are arguably easier to contemplate because they can be evaluated intragenerationally.

The notion that intergenerational preferences are a unique blend of intertemporal and social preferences also has implications for those seeking to encourage intergenerational sacrifice. For example, policymakers can make efforts to deemphasize the delay until intergenerational benefits will be achieved (thereby mollifying impatience) and deemphasize the social differences between current and future generations (encouraging greater generosity). Indeed, because of the interactivity between these factors, policymakers accomplishing both of these goals simultaneously would be expected to get an extra "boost" of selflessness toward future generations.

\begin{abstract}
Linguistic features can predict several aspects of human behavior. Little is known, however, about whether syntactic, semantic and structural language features can also predict psychological disorders such as posttraumatic stress disorder (PTSD). The current study investigated whether the linguistic properties in trauma narratives written by survivors of a Motor Vehicle Accident (MVA), change as function of the intensity of PTSD symptoms. A short form diagnostic tool known as the Posttraumatic Stress Disorder Checklist (PCL) was used to determine the severity of participant PTSD symptomatology. Using a text capture paradigm participants were then asked to write a neutral narrative or a narrative that described their traumatic event. PCL scores were compared to linguistic variables from eight different computational linguistic algorithms. Results from this study suggested that the relative intensity of PTSD symptomatology affects syntactic, semantic, and structural aspects of the narrative.
\end{abstract}

Keywords: Posttraumatic Stress Disorder; PTSD; Trauma Narrative; Linguistic Features.

\section*{Introduction}

Language patterns can be good predictors of relations in the world. For instance, language statistics can predict the modality of a word (Louwerse \& Connell, 2011), the iconic relationship of words (Louwerse, 2008), social networks (Hutchinson, Datla, \& Louwerse, 2011), and even geographical locations of cities (Louwerse \& Benesh, 2012; Louwerse \& Zwaan, 2009). Language patterns have also shown to be predictors of aspects of human behavior. For instance, linguistic features predict fraudulent events (Louwerse, Lin, \& Semin, 2010), predict an individual's personality type (Gill, Nowson, \& Oberlander, 2009), whether they are lying (Hancock, 2004), and even to what extent they visit their doctor's office (Campbell \& Pennebaker, 2003).

Despite the predictive utility of language, there is very little computational linguistic research that investigates whether language features predict psychological symptoms such as those associated with Posttraumatic Stress Disorder
(PTSD). Considering the ability of linguistic patterns to demonstrate mental processes and behaviors, and the concise delineations of PTSD symptomatology, the question can be raised whether linguistic patterns in written narratives from trauma survivors can be related to the severity of the trauma. More specifically, can language use reflect PTSD symptoms and their relative intensity? This research question was investigated in the current study.

PTSD is an anxiety disorder diagnosed to persons having "experienced, witnessed, or having been confronted with events that involve potential death, serious injury, or a threat to the physical integrity of oneself or others" (DSM-IV, 2000, p. 467). PTSD patients will persistently re-experience the event, while simultaneously avoiding thoughts, and/or environmental reminders of the event, with some or all of these symptoms lasting for longer than one month. Specific symptoms include re-experiencing the traumatic event, avoiding thoughts of the event, mental/emotional numbing, as well as hyper-arousal. These symptoms are further delineated to include flashbacks, nightmares, sleep difficulties, and irritability. These symptoms are clustered into three overarching categories, "Re-experiencing Symptoms", "Avoidance Symptoms", and "Hyperarousal Symptoms (DSM-IV, 2000), even though not all symptoms are necessary for a PTSD diagnosis.

In recent years the prevalence of PTSD has increased. Studies indicate that \(20 \%\) of women and \(9 \%\) of men will develop PTSD, while \(6.8 \%\) of those diagnosed will live with the disorder indefinitely (Kessler et al., 1995). This increase is due not only to an awareness of the disorder in the clinical community, but also to the development of diagnostic tools such as the PTSD Checklist (PCL). The PCL is a 17 -item self-report measure that monitors trauma symptomatology much like the 30 -item structured interview, Clinician Administered PTSD Scale (CAPS). Despite the CAPS being the longstanding method to PTSD diagnosis, current research validates that the PCL correlates highly with the CAPS measure as well as with its diagnostic efficiency (Blanchard, Jones-Alexander, Buckley, \& Fomeris, 1996).

For instance, one study demonstrated the reliability of the PCL even within highly specific civilian populations (e.g. college students, Motor Vehicle Accident survivors) (Elhai, Gray, Docherty, Kashdan, \& Kose, 2007). These direct questions administered in both the CAPS and PCL have proven to be a valid way of determining PTSD (Blanchard et al., 1996). However, it would be desirable to have an alternative, perhaps less direct, measure that reveals PTSD symptoms identified by the CAPS and PCL. This would allow for patients to be prescreened. Given the evidence from computational linguistic measures predicting human behavior, it might be the case that the language used by PTSD patients predicts the severity of the disorder.

There are indications that language use in PTSD patients might be indicative of the disorder. For instance, one main issue impeding recovery from the disorder is that sufferers have difficulty mentally integrating the event into their current cognitive schemas (Dalgleish, 2004). Traumatic experience is mentally represented by two constructs, situationally accessible memories (SAMs), and verbally accessible memories (VAMs), but only VAMs can be deliberately retrieved; SAMs are activated by situation dependent reminders of the event (Brewin et al., 1996). Ironically, even though VAMs are memory representations that are readily accessible, PTSD patients will still report confusion of the details, as well as difficulty in forming coherent accounts of the traumatic event (Ehlers, Ehring, \& Kleim, 2012). The language of a PTSD patient might reflect this confusion, or reflect their lack of clarity in recalling the details of the traumatic event.

Language use of trauma survivors has been studied before (i.e. therapeutic measures and interventions) (Sloan et al., 2012). One such example comes from work conducted by Tausczik and Pennebaker (2010). In their study writing samples collected in temporal units (e.g. over an extended time period). Some of these samples were related to a participant's traumatic experience, while others were nonemotional in nature. Tausczik and Pennebaker not only demonstrated the health benefits of narrative production by noticing a decrease in doctor visits for those writing about the traumatic experiences, but they were also able to identify word categories related to depression (e.g. pronouns), seeing similar patterns in health improvements as a function of increases or decreases in the usage of these categories.

Similarly, Smyth, Stone, Hurewitz, and Kaell (1999) investigated the effectiveness of PTSD treatment as a result of narrative production rather than fragmented discourse (i.e., discourse without narrative structure) In their study narrative production showed to alter a trauma survivor's tendency to avoid thoughts, as well as aid their recovery. The implication here is that the mental integration of traumatic events can be facilitated by means of narrative production. Smyth et al. (1999) also showed that writing leads to a reduction in symptoms of patients with chronic illness. The Smyth et al. \((1999 ; 2001)\) findings support those of Tausczik and Pennebaker (2010) by isolating the type of
writing task that produces the greatest benefit; specifically, narrative production vs. fragmented and/or controlled discourse.

Often, the analyses of trauma language include global characteristics. For instance, Mansfield et al. (2010) described the foci of their analysis with terms such as complexity, personal growth, and resolution, which indicate positive change in thinking when reflecting on a difficult event, the ability to see different perspectives and outcomes, or the reconciliation with difficult life experiences. Similarly, Tuval-Mashiach et al. (2004) used terms such as coherence, self-evaluation, and meaning. Clearly, these concepts are not problematic in themselves - interrater reliability avoids that the abstract terms might lead to ambiguity - yet a computational operationalization of such concepts is difficult.

Rather than focusing on the global characteristics of trauma language, our analyses of trauma narratives utilized word-level linguistic models that not only offer a large spectrum of linguistic dimensions, but also provide theoretical grounding in the organization of their categories. Based on the theoretical frameworks these models provide, it is possible to isolate constructs similar to those of the aforementioned studies, while simultaneously revealing constructs previously unconsidered?

Because little computational linguistic work has been done on the analysis of trauma narratives, computational linguistic algorithms to analyze the data covered a wide range of dimensions, including syntactic and semantic algorithms. These algorithms can generally be classified into general structural (e.g., word count), syntactic (e.g., connectives) and semantic (e.g., word choice) dimensions of language, whereby some used a bag-of-word approach (e.g. LIWC), whereas others used a probability approach (MRC), whereas yet others relied on the computation of different factors (e.g., type-token ratio). Eight different algorithms were used, categorized in Figure 1.

Within the syntactic dimension, two algorithms were used, one focusing on general linguistic features, the other on interclausal relationships. For general linguistic features, we used 67 features from the Biber model (1988). These features primarily operate at the word level (e.g., parts-ofspeech) and can be categorized as tense and aspect markers, place and time adverbials, pronouns and pro-verbs, questions, nominal forms, passives, stative forms, subordination features, prepositional phrases, adjectives and adverbs, lexical specificity, lexical classes, modals, specialized verb classes, reduced forms, dispreferred structures, and co-ordinations and negations.

Specific interclausal relationships were captured using Louwerse's (2002) parameterization, including positive additive, (e.g. also, moreover), negative additive (e.g. however, but), positive temporal (e.g. after, before), negative temporal (e.g. until), and causal (e.g. because, so) connectives.

The semantic dimension can be broken down in three subdivisions: psycholinguistic ratings, conceptual

Figure 1. Linguistic Category Distinctions
relations, and comprehensive classifications. Psycholinguistic ratings are computed using the MRC Psycholinguistic Database (Coltheart, 1981), to get ratings on the familiarity, concreteness, imagability and meaningfulness of words.

The conceptual dimension covers three categories: interpersonal, social and emotional language. Interpersonal language use is captured by the linguistic category model (LCM) (Semin \& Fiedler, 1991). The model consists of a classification of interpersonal (transitive) verbs that are used to describe actions or psychological states and adjectives that are employed to characterize persons. This classification gives insight into the meanings of verbs and adjectives that people use when they communicate about actors and their social events. The model makes a distinction between five different categories of interpersonal terms

Social language features were captured by Pennebaker et al.'s (2007) Linguistic Inquiry and Word Count (LIWC). LIWC consists of 63 syntactic (e.g., pronouns) and semantic word categories (e.g., death, family) that focus on semantic aspects of discourse, namely aspects of discourse related to social phenomenon.

Emotional words are captured by the classification proposed by Johnson-Laird and Oatley (1989). These words are classified into two classes, broadly basic emotions (anger, fear, disgust, happiness etc.) and complex emotions (guilt, pity, tenderness etc.). The basic emotions indicate no cognitive load hence they are also called raw emotions, whereas the complex emotions indicate cognitive load.

For the comprehensive category WordNet (Miller \& Fellbaum, 1998) was used, consisting of 150,000 words in 44 base types, including 25 primitive groups for nouns (e.g. time, location, person, etc.), 15 for verbs (e.g. communication, cognition, etc.), 3 groups of adjectives, and 1 group of adverbs. For the structural dimension, discourse features such as type/token ratio and word count were used.

The current study aims to utilize these linguistic categories to analyze written narratives produced by participants who experienced an MVA. The intent is to complement the aforementioned studies on the basis of trauma narrative language, but to include measures that have yet to be utilized in these studies; namely the categories featured here, but also participant scores on the PCL. The PCL scores obtained in our sample population will act as a dependent variable from which the associated linguistic features will be compared. Due to PCL scores resting on a continuum, it is possible that the usage of certain linguistic categories will increase and/or decrease as a function of these scores.

Following the analyses of texts captured in this study, the linguistic patterns found will be used as predictor variables to analyze texts collected in studies conducted by Shipherd and Beck \((1999,2005)\). Two data sets from their studies will be analyzed; texts collected from MVA survivors, as well as texts collected from survivors of sexual trauma. In both data sets, there are samples from trauma survivors suffering from PTSD, as well as individuals exposed to trauma though not suffering from PTSD. All of the subjects included in their studies were evaluated using the CAPS or PCL criteria. This allows for a parallel analysis of all of their texts as well as those collected here. The intent is to not only support the reliability of the predictor variables, but also to confirm or deny the possibility that these variables will dependently fluctuate within the range of PCL scores obtained, as we have demonstrated here.

\section*{Experiment}

The current pilot study utilized linguistic category frequencies to analyze written narratives produced by participants who experienced an MVA. These frequencies were then compared with different levels of participant PTSD symptomatology as measured by the PCL.

Table 1: Six featured linguistic categories.
\begin{tabular}{ll}
\hline \multicolumn{1}{c}{ Category } & \multicolumn{1}{c}{ Examples } \\
\hline Determiners (Biber Model) & these, those, few, many, every, any, much, a, an, the, some, all \\
Death (LIWC Model) & died, dead, dying, fatal, alive, grief, mortal, demise, decease(d) \\
Function (LIWC Model) & definitely, ahead, might, nearly, across, enough, among, been \\
Causal Negation (Connectives Model) & although, nevertheless, unless, provided that \\
Punctuation (Biber Model) & \(. ‘, " / ?!()-\) \\
Word Count & (count of words per document) \\
\hline
\end{tabular}

\section*{Methods}

\section*{Participants}

Forty-three undergraduate students from the University of Memphis ( 31 females) participated in the study for course credit. Participants were prescreened to assess PCL scores and to determine whether they had experienced an MVA. All participants in this study had at some time experienced an MVA, though not all participants suffered from PTSD.

\section*{Procedure}

A \(2 \times 2\) design was employed, both counterbalanced and randomized, where half of the participants first wrote about their MVA, while the others completed the neutral text first. Each condition included both tasks. Both text capture tasks were ten minutes in length. Each task, regardless of order, was partitioned by a ten minute cognitive distractor task to minimize carryover effects. The cognitive distractor task utilized in this experiment was a number-based Sudoku puzzle.

\section*{Results and Discussion}

PCL scores ranged from 17-65 \((M=25.07, S D=9.38)\). Five participants from the study \((10 \%\) of the sample population) had PCL scores high enough to suggest a PTSD diagnosis (composite score of 35 of higher), falling within the range of earlier reported estimates of PTSD prevalence (Kessler et al., 1995).

Mixed effects regression analyses were conducted on the normalized frequencies of the linguistic variables with PCL scores and text type (trauma or neutral) as fixed factors, and condition (neutral and trauma narrative) as a random factor (Baayen, Davidson, \& Bates, 2008). The model was fitted using the restricted maximum likelihood estimation (REML) for the continuous variable (PCL scores). F-test denominator degrees of freedom were estimated using the Kenward-Roger's degrees of freedom adjustment to reduce the chances of Type I error (Littell, Stroup, \& Freund, 2002).

Results suggested a significant relationship between PCL scores and six linguistic variables, four categories from the syntactic dimension, and one from both the semantic and structural dimensions. (See Table 1).

PCL scores were related to the use of punctuation, \(F(1\), 81.09) \(=13.474, p<.001\), such that when PCL scores increased the more punctuations were found. Word Count and PCL score were related, \(F(1,81.029)=4.467, p<.05\), with high PCL scores yielding longer texts. The relevance of these categories might be explained by the fact that the patient is unable to lock in the event's specifics, instead using more words in an attempt to accurately describe the event. The presence of these linguistic units could be a byproduct of suppression, in that they are avoiding the acknowledgement of the traumatic event's specifics.

Another variable related to PCL scores were the frequency of determiners (Biber), \(F(1,82.004)=8.597, p<\) . 01 , with higher PCL scores yielding fewer determiners. Determiners, in written and spoken discourse, are used to add discrete specification to the information being conveyed (Argamon et al., 2003; Biber et al 1998; Mulac \& Lundell 1994). It makes sense that determiners in texts written by a PTSD sufferer would find less use, as the disorder affects an individual's ability to concretize specifics from the event.

Negative causal connectives (e.g., although, nevertheless) showed a positive relation with PCL scores, \(F(1,81.136)=\) \(4.74, p<.05\). The increase of negative causal connectives as a function of higher PCL scores might be explained both by suppression and avoidance. Negative causal connectives imply a causal relation that is negated, perhaps to create a distance to the events described, or reflecting an uncertainty in the claims made in the preceding clause.

In addition, the LIWC semantic category "death" was related to PCL scores, \(F(1,81.127)=7.113, p<.01\), likely explained by the inherent nature of traumatic events regardless of whether the trauma experienced was psychological or physical in nature. Also from LIWC, the category "function" yielded a positive relation with PCL scores, \(F(1,82)=6.911, p=.01\) (e.g. as PCL scores increased, the use of "function" words increased).

Interestingly, emotions categories from the LIWC and Johnson-Laird and Oatley Emotions models did not reach significance in relationship to PCL scores. However, "Negative Emotions" from the LIWC model reached significance in comparison of text types, \(F(1,81.151)=\) 4.955, \(p<.05\), as well as "Basic Emotions" from the Johnson-Laird and Oatley Emotion model, \(F(1,81)=9.742\), \(p=.002\). The findings here imply an emotional foundation
in texts written about the PTSD sufferer's recall of the traumatic event.

\section*{General Discussion}

Previous research has shown that linguistic features can predict a multitude of aspects of human behavior. Whether linguistic features might also be indicative of psychological disorders is however less clear. We investigated whether the linguistic properties in trauma narratives written by survivors of a Motor Vehicle Accident (MVA), change as a function of the intensity of posttraumatic stress disorder (PTSD) symptoms. The severity of participant PTSD symptomatology was compared to linguistic variables from eight different computational algorithms.

It may not be surprising from the quantity of variables used in our analysis that some would demonstrate the hypothesized relationship between PCL scores and language use. However, the results featured here can be grounded in theoretical constructs that are in line with what would be expected from the clinical psychological literature. Just as well, since not all of the associated PTSD symptoms are required for a PTSD diagnosis, it is possible that not all of the symptom clusters would emerge in the texts collected. Of the three main PTSD symptom clusters, the variables revealed in our analyses align most with that of the "Avoidance" distinction. The Avoidance cluster of the PTSD symptom inventory identifies a PTSD sufferer's propensity to avoid thoughts and reminders of the event. This cluster includes the thought suppression behavioral phenomenon often associated with PTSD as well (DSM-IV, 2000).

For example, Chung and Pennebaker (2007) have highlighted the ability of function words to reveal psychological states. Function words are subjectively personal, and have a multifaceted utility in the personalization of discourse. Due to the personal nature of traumatic experience it is notable that function word usage would fluctuate as a result of the severity of the traumatic event. The difficulty in mentally integrating the traumatic experience could be one reason why higher PCL scores would reflect a decreased usage of this category. The PTSD patient is unable to work the experience into their current cognitive schemas. The lack of personalization in the narrative reflects the individual's inability to map the experience into long-term memory.

The deficiency of the determiners category can be explained through "Avoidance" symptoms. Determiners, in written and spoken discourse, are used to add discrete specification to the information being conveyed (Argamon et al., 2003, Mulac \& Lundell 1994; Biber et al 1998). It makes sense that determiners in texts written by a PTSD sufferer would find less use, as the disorder affects an individual's ability to concretize specifics from the event.

An increase in negative causal connectives aligns with the "Avoidance" distinction as well, as though an individual suffering from PTSD second-guesses their statements, demonstrating uncertainty as a product of cognitive
distancing. The word count and punctuation could be explained here as well, as the participant is unable to lock in the specifics, and instead uses more words in an attempt to accurately describe the event. The presence of these linguistic units could be a byproduct of suppression, in that they are avoiding the acknowledgement of the traumatic event's specifics. Or just as well, as suggested earlier, PTSD survivors are unable to recall these specifics. From these relationships there is evidence that a person suffering from PTSD trauma can cognitively distance themselves from the details of the event. And while it does not map well in the "Avoidance" cluster, the revealed presence of words from the semantic category "Death" can be explained by the inherent nature of traumatic events regardless of whether the trauma experienced was psychological or physical in nature.

The emotion categories that were shown to differ across text types can be reasoned to explain a PTSD patient's propensity for emotional numbing. Despite the existence of emotional numbing, emotions are still attached to the experience. In writing about the traumatic experience these emotions are faced and thus resurface. This might explain the relative intensity of emotion word usage when describing the traumatic event and the lack of presence in narratives irrelevant to this experience.

Even though the computational linguistic variables show a relationship with PTSD measures, it is clearly not the case that a direct relationship can be assumed, nor should the findings here be seen as an attempt to replace existing clinical psychology measures of diagnosis. At the same time, the current study is encouraging enough to pursue further analysis that might provide a first filter to identify those at risk of PTSD. The categories revealed here are promising, as they align with crucial aspects of the fragmented nature of a PTSD sufferer's recall of their traumatic experience. As well, from the categories discovered here, it is reasonable to presume these same categories and patterns will appear in the analysis of texts collected during the Shipherd and Beck (1999, 2005) studies.

\title{
Language Dominance Modulates Cross-language Lexical Interaction in Late Immersed Bilinguals
}

\begin{abstract}
Languages differ in the way they package elements of the world into words, which poses a challenge for bilinguals. We examined word use patterns for common household objects for late-immersed Chinese-English bilinguals to investigate how the bilingual lexical network develops when the first language is fully mature at the time of second-language immersion. We found changes to both first- and secondlanguage word use with increased English dominance, indicating continued plasticity and mutual influence.
\end{abstract}

Keywords: bilingualism; word learning; word use; lexicon; categorization.

\section*{Introduction}

Second-language learning research traditionally examined transfer from the first language (L1) to the second (L2) assuming a stable L1. Separately, language attrition research examined changes to L1 in the face of L2 dominance. Only recently has it been appreciated that L1 and L2 may exert mutual influences, and that performance in each may best be understood by studying their interplay across conditions of learning and use (Schmid \& Köpke, 2007).

Most inquiry from this new perspective has focused on phonology and morpho-syntax. These domains are considered to engage procedural memory and potentially be affected by phenomena such as critical periods for learning. In contrast, the lexicon is considered to be stored in declarative memory, with performance subject to standard memory parameters such as frequency of retrieval (e.g., Ullman, 2004). But appropriate use of words depends on much more than retrieval of word forms. Languages differ in the way they package elements of the world into words. For instance, in English, upholstered seats for one person receive the same name as hard wooden seats for one person (chair), whereas in Mandarin they receive the same name as upholstered seats for several (safa). Even cognates show
differing patterns. In Spanish, a Coke bottle is botella but a baby bottle is mamadera, and a tennis ball is not a bola but a pelota.

These subtle differences can be thought of in terms of a lexical network in which the conceptual level of representation includes features, instances, and associations rather than unitary concept nodes. Associated word forms of the two languages can have different patterns of connection to elements of the conceptual layer (Ameel, Storms, Malt, \& Sloman, 2005; Pavlenko, 2009; Van Hell \& de Groot, 1998). Given this model, influences of one language on the other can be conceived as changes to the weights on connections between word forms and elements of the conceptual layer. When a new L2 word form is taught as, or implicitly assumed to be, a translation equivalent of an L1 word, the network will set initial weights to match those of the L1 word. With experience, the connection weights might be adjusted to more closely match those of native L2 speakers. However, cross-connections between words might cause adjustments to the L1 connection weights as well, shifting them away from those of native L1 speakers.

The theoretical issues raised about bi-directional influence in phonology and morpho-syntax (e.g., Schmid, 2011; Köpke, Schmid, Keijzer, \& Dostert, 2007) are closely echoed for lexical knowledge when framed in these terms. A potential key variable on the degree of mutual influence is age of acquisition. The network's weight configurations may stabilize after mastery of L1 and become resistant to change. If L2 is introduced after the network has stabilized, and if the L2 connection patterns initially reflect those of L1, two consequences may result. First is difficulty adjusting the L2 weights toward the L1 standard. Second is that the L1 will be protected from an influence of L2 -because weights for the L1 words are resistant to change, and also because the L2 weights will diverge little from L1 weights and so have little potential to influence L1 weights. This situation resembles a critical period effect with regard
to acquisition of the L2. Because it also entails protection of the L1 from change, though, it may better be framed in terms of entrenchment of the network. The effects of L1 lexical entrenchment have begun to been tested in connectionist models. Zhao and Li (2010) simulated early versus late bilingual learners and found significant differences between them with regard to the organization of word classes.

A different possibility is that the network may not exhibit stabilization that is resistant to change after the initial L1 learning. In that case, with sufficient input at any time of exposure, the L2 connection weights may be gradually shaped to a close approximation of those of native speakers. This requires that the network be never fully committed to the weight configurations even later in learning. The degree to which a network should be flexible versus committed poses a classic 'stability-plasticity' dilemma in computational modeling (see Li, Farkas, \& MacWhinney, 2004). Under this scenario, because of cross-connections between the L1 and L2 lexicons, the more the L2 weights diverge from initial L1 settings, the greater the impact on L1 usage may be. Conversely, predominant use of the L1 may leave L1 patterns largely intact. This possibility is compatible with suggestions that continued use of L1 protects it against attrition. However, because the more one language is used, the less the other must be, it also implies the trade-off that greater preservation of the L1 patterns will entail lesser progression in the L2.

Yet a third possibility is that if the acquired L1 pattern does not resist change, the network will, under the influence of L2 input, arrive at a configuration for both languages that is a compromise between L1 and L2 patterns. In this case, patterns of usage may not fully match those of monolingual speakers of either language. Ameel et al. (2005) found a convergence of this sort for Belgian early bilinguals who grew up with both French and Dutch. It may be less likely to be found for late bilinguals, having one well-established language before substantial exposure to the second. Conversely, the patterns of the two languages may be functionally separable for late bilinguals, allowing mastery of native -like patterns for both given sufficient exposure to each. This outcome may be most likely under conditions where the languages are dissimilar overall and/or in terms of naming patterns within a domain, yielding weaker crossconnections as L2 learning takes place.

We focus here on late L2 learners to examine plasticity of the network after L1 is well-established. In related work, Malt \& Sloman (2003) found that, for immersed L2 users of English, elements of non-native usage patterns for concrete nouns in the L2 persisted for many years despite evolution toward more native-like usage. On the other hand, Pavlenko and Malt (2011) found evidence for some L2 impact on L1 word use in Russian immigrants to the U.S. who continued to speak Russian at home. These bilinguals treated several L1 Russian terms for drinking vessels as if they were more equivalent to English terms than did largely monolingual speakers in Russia. The L2 influence on L1 was greatest for
those who came to the U.S. in early childhood, but some influence was seen even for those who arrived after age 18. These results point toward limited but continued plasticity of the network. Malt and Sloman's study did not isolate late learners, however, and neither study looked at performance in L1 and L2 in relation to each other, or at outcomes as a function of language dominance or attainment. Malt and Sloman's participants came from many L1 backgrounds, creating variable L1-L2 similarity, whereas Pavlenko and Malt's Russian-English language pairing can be considered to involve languages of intermediate similarity.

The current study investigated naming patterns for common household objects by native speakers of Chinese attending school in the U.S. They named the objects in both English and Chinese, in separate sessions. Participants had arrived no earlier than age 15, thus having a mature L1 at the time of immersion. They varied in the extent to which they had become more English-dominant. Their two languages are dissimilar on many dimensions from syntax to writing systems, and the naming patterns in this domain are dissimilar. We asked three questions that will shed light on fundamental aspects of how bilingual patterns of word use develop for dissimilar languages under conditions of late L2 immersion. These are:
(1) What constrains learning of subtle aspects of \(\mathbf{L} \mathbf{2}\) word use patterns given mature L1 knowledge at time of immersion? Can L2 usage evolve toward native-like patterns as a function of experience, even in light of a mature L1, or will entrenched L1 knowledge defeat reshaping of L2 word usage patterns?
(2) How stable are \(\mathbf{L} 1\) usage patterns when L 2 immersion occurs after L1 is mature? In particular, are highly entrenched L1 patterns immune to an L2 influence, or does the impact vary depending on L2 experience?
(3) If progress in L2 mastery is observed and linked to the extent of L2 dominance, does it have a negative relation to the preservation of the native L1 patterns, or do they vary independently?

\section*{Method}

Sixty-two Lehigh University students, native speakers of Mandarin, participated. All used English on a daily basis. Average age of immersion in English was 21, with a minimum of 15 . Mean self-rated proficiency for English was 4.94 on a 7 -point scale; for Chinese, 6.92. Twenty-five largely monolingual speakers of Mandarin resident in China and 28 largely monolingual speakers of English resident in the U.S. served as comparison groups.

Stimuli for assessing naming patterns consisted of 67 pictures of objects for preparing and serving foods and 73 pictures of objects for holding and dispensing products such as health and beauty aids, cleaners, and foods (see Ameel et al., 2005). For brevity we call the first the dishes set and the second the bottles set, but each contained many objects with other names, as reported below.

Figure 1. Sample pictures from the dishes set.

Figure 2. Sample pictures from the bottles set.

Each set of pictures was presented on a web page. Instructions indicated (in English or Mandarin, depending on test session) that for each picture, they should give whatever name seemed best or most natural, and that their response could be one word or more than one. The photos followed, with each accompanied by a response box into which participants typed their choice of name.

Monolingual speakers of English and of Mandarin each participated in only one experimental session in which they viewed the web pages (with order balanced across participants) and typed in their responses to the pictures.

Bilinguals participated in three sessions. In the first, conducted in English, they filled out an extensive language history questionnaire (in English) that asked for information such as age of exposure to English, years of formal instruction, age of immersion, years of immersion, and other aspects of language experience and usage. They then completed an English word/non-word discrimination task as one measure of English proficiency. The second session was also conducted in English, always by a native speaker, and participants' responses were in English. Participants first completed the naming task for the two stimulus sets (with order balanced across participants). Additional measures of proficiency and current language accessibility were then taken including a speeded picture-naming task and a verbal fluency task in which they were asked to list all the exemplars they could to each of three prompts (Clothing, Transportation, and Food) in 60 seconds each. Last, they told the story depicted in a wordless picture book to the experimenter. The final session was conducted in Mandarin by a native speaker of Mandarin and took place at least one week after the second. The same tasks were completed in the same order, with responses in Mandarin.

\section*{Results}

Monolingual naming patterns. We first tabulated the names produced by monolingual speakers of each language to determine the most common ("dominant") name for each picture. Those names, along with how many objects of the set had each listed name as dominant, are presented in Tables 1 and 2. The tables show that the lexical categories of the two languages do not have a simple relation for either stimulus set. For both, each language has one broad term that covers \(1 / 3\) or more of the objects, but these terms do not correspond closely to one another: Objects labeled by a single term in one language are distributed across several in the other. This is also true for most of the other terms that cover multiple objects of the set. These complex relations pose a challenge for the L2 learner. The neatest mapping across languages is the close correspondence of Mandarin bei to the combined English cup, mug, and glass. However, in this case, an L1 speaker of Mandarin must still learn to segment a broader category into several narrower ones.

For the dishes stimulus set, the number of terms that are dominant for at least one object is similar between the two languages, with 9 for English and 8 for Mandarin. For the bottles set, however, English has 13 compared to Mandarin's 5. The greater number of discriminations, along with absence of a clean mapping between any major terms, may make acquiring English naming patterns for the bottles set more challenging for Mandarin-English bilinguals. At the same time, if dissimilarity decreases cross-connections to the L1, it may exert less influence on the L1.

Table 1a: Distribution of names across the 67 pictures of the dishes set, grouped by English.
\begin{tabular}{ll}
\hline English & Mandarin \\

\hline
\end{tabular}

What constrains L2 learning given mature L1 knowledge at time of immersion? Can L2 usage evolve toward native-like patterns as a function of \(L 2\) language experience, or will entrenched L1 knowledge defeat reshaping of word usage patterns? Naming performance of each participant for each stimulus set was assessed using a measure of individual agreement with monolingual name choice across all pictures of the set. For each object, the bilingual was credited for the name produced for it proportional to the number of monolingual English speakers who produced that name. For instance, if a given object was called bottle by \(80 \%\) of monolingual speakers, jar by \(10 \%\), container by \(5 \%\), and \(j u g\) by \(5 \%\), then a bilingual who called it bottle received a score of .8 , one who called it jar received a score of .1 and so on. A 0 was assigned for responses not produced by any monolingual speaker. An individual's scores for the 67 dish pictures and 73 bottles pictures were each averaged to produce a summary value for each person for each set. As a baseline for comparison, we also calculated the mean level of agreement for individual monolingual speakers of English with their own monolingual group for each stimulus set.

\footnotetext{
\({ }^{1}\) Because responses were typed in pinyin, we cannot distinguish guan with tone 3 from guan with tone 4 , but for our stimuli, most or all are likely to be guan4.
}

To evaluate whether language experience - in particular, the dominance of one language over the other in current usage - influences match to the monolingual pattern, bilinguals were divided into two groups according to the extent to which English had become dominant for them. To do so, all the individual language performance measures other than naming responses were correlated with one another and with responses to the various language history questions. The relative number of items produced to the category prompt Clothing in English vs. Mandarin correlated significantly with more other measures (20 out of 36) than any other performance measure and was selected as the basis for grouping. To the extent that the bilinguals can retrieve more English than Mandarin words for items of clothing in 60 seconds, their English can be assumed to be more highly activated than their Mandarin.

The distribution of number of English minus Mandarin clothing items produced by each participant was examined for a break point. Participants assigned to the Higher English Dominance group ( \(\mathrm{n}=27\) ) had a mean value of 0.15 (s.d. 3.22), indicating that on average they produced about equal numbers in Chinese and English. Those assigned to the Lower English Dominance group ( \(\mathrm{n}=35\) ) had a mean value of -9.0 (s.d. 3.26), indicating that on average they produced 9 more in Chinese than English. Correspondingly, mean self-rated English proficiency for the Higher English Dominance group was 5.14 and for the Lower, 4.76. For Chinese self-ratings, it was 6.87 and 6.95 respectively. Table 3 presents the mean individual agreement scores of each speaker group to the monolingual English group for each stimulus set.

Table 3: Mean agreement scores of monolinguals and bilinguals to the monolingual English group.
\begin{tabular}{llll}
\hline & & Monolingual \\
English
\end{tabular} \begin{tabular}{l} 
Higher \\
English \\
Dom. \\
Bilinguals
\end{tabular}\(\quad\)\begin{tabular}{l} 
Lower \\
English \\
Dom. \\
Bilinguals
\end{tabular}

An ANOVA with speaker group as a between-subjects factor showed a significant main effect of speaker group for both stimulus sets: F \((2,87)=46.16, p<.0001\) for dishes; \(\mathrm{F}(2,86)=8.14, p<.001\) for bottles. Post hoc comparisons (LSD) showed that bilinguals differed significantly from monolinguals for both stimulus sets ( \(p<.001\) ). The effect of extent of English dominance differed by stimulus set, though. For dishes, the bilingual groups differed from each other ( \(p<.001\) ), but for bottles, they did not. Thus, the ability to progress toward an L2 native-like naming pattern differs by semantic domain.

For dishes, both bilingual groups differed from the monolinguals by greatly over-using cup and plate and under-using mug and dish. Higher English dominance bilinguals added to the dominant term list one word
dominant in monolingual usage for only one object (pot) and one dominant for two (glass), as well as a more important term, mug, dominant for 12 objects for the monolinguals. However, the bulk of their progress does not appear to be due to addition of these vocabulary words. Removing from the data the three stimuli that had monolingual dominant names of pot or glass leaves the scores virtually unchanged (. 50 vs. .45). Furthermore, about 40\% of lower English dominant bilinguals did produce mug, even though it was not dominant for any object for them. Looking only at the scores of those who did produce mug in each group, the mean score for lower English dominance was . 47 and for higher English dominance was .52, maintaining the difference between groups. It appears that progress in matching monolingual patterns is largely due to more appropriate use of terms known to both groups.

For bottles, both bilingual groups differed from the monolinguals by greatly over-using bottle and, to a lesser extent, box, and by under-using container, jar, and several minor terms (dominant for monolinguals for only one to three objects of the set). As already noted, though, there was no sign of greater shaping of the word-object connections toward native-like with higher English dominance.

In short, these late bilinguals speaking two dissimilar languages do show movement toward overcoming entrenched L1 patterns as a function of language experience. However, they do so only for one of the domains, a point to which we will return.

How stable are L1 usage patterns when L2 immersion occurs after L1 is mature? In particular, are highly entrenched L1 patterns immune to an L2 influence, or does the impact vary depending on \(L 2\) experience? Performance on Mandarin naming was scored in the same way as for English naming. Table 4 presents the mean individual agreement scores of each speaker group to the monolingual Mandarin group for each stimulus set.

Table 4. Mean agreement scores of monolinguals and bilinguals to the monolingual Mandarin group.
\begin{tabular}{llll}
\hline & & Higher & Lower \\
& Monolingual \\
Mandarin & \begin{tabular}{l} 
English \\
Dom. \\
Bilinguals
\end{tabular} & \begin{tabular}{l} 
English \\
Dom. \\
Bilinguals
\end{tabular} \\
\hline Dishes & \(.85(.07)\) & \(.69(.03)\) & \(.68(.04)\) \\
Bottles & \(.86(.06)\) & \(.63(.09)\) & \(.68(.06)\) \\
\hline
\end{tabular}

An ANOVA with speaker group as a between-subjects factor showed a significant main effect of speaker group for both stimulus sets: \(\mathrm{F}(2,84)=100.94, p<.0001\) for dishes; \(\mathrm{F}(2,82)=73.44, p<.001\) for bottles. Post hoc comparisons (LSD) showed that bilinguals differed significantly from monolinguals for both stimulus sets ( \(p s<.0001\) ). This indicates that entrenched L1 patterns are not immune from an L2 influence, even under late immersion for bilinguals speaking dissimilar languages. Changes appear to be largely
due to over-extension of ping and guan and under-extension of he and tong. The latter two may have particularly unclear relations to any English words (see Tables 2a and b).The effect of extent of English dominance again differed by stimulus set, though. For bottles, the bilingual groups differed from each other ( \(p<.01\) ); those with higher English dominance were further from the monolingual standard. For dishes, the groups did not differ. Whereas progression toward the \(\mathbf{L} 2\) standard with greater English dominance was shown for dishes, greater loss of agreement with the L1 standard appears here for bottles.

If progress in \(L 2\) mastery is observed and linked to the extent of \(L 2\) dominance, does it have a negative relation to the preservation of the native \(L 1\) patterns, or do they vary independently? The data already presented suggest that they must vary independently, since bilinguals showed differential progress toward the L2 standard only for dishes and differential movement away from the L1 standard only for bottles. To further address this question, we correlated individual bilinguals' mean scores for English and Mandarin performance. For dishes, there was no relation between the two ( \(r=.10\), n.s.). For bottles, there was a small and marginally significant positive relation rather than a negative one ( \(r=.21, p=.06\) ). Overall, then, it appears that progress in one language does not mandate a declining performance in the other across the board with respect to naming patterns.

\section*{Discussion}

We initially outlined several possibilities for how the bilingual lexical network might develop under conditions of late L2 learning. The data argue against the idea that the network stabilizes at an L1 configuration that both protects it against L1 change and prevents progress in L2 acquisition. The data also argue against a reciprocal relation where shifts toward the naming pattern of one language inevitably result in shifts away from the other. At the same time, there was no evidence for the full separation of the two language learning experiences (whereby there could be preservation of the L1 while also progressing toward L2). The current data are most compatible with the situation found in Ameel et al. (2005)'s data for simultaneous French-Dutch bilinguals in Belgium: The network adjusts weights for both languages such that convergence results, and the word usage patterns for each language are more similar for bilinguals than they are for two monolinguals of the corresponding languages.

This outcome is more surprising in the current context, given that the two languages were acquired asynchronously and are dissimilar on many dimensions, as well as having divergent naming patterns with no cognates that might promote incorrect assumptions of word-to-word equivalences. In light of the naming strategies adopted by the bilinguals in each language, though, it may be less surprising. For both L1 and L2, the trend was to over-extend the words that are prominent in the domain (covering a large
numbers of objects for monolinguals) and under-extend words used for smaller subsets of objects. We cannot ensure that our stimulus sets exactly match the distribution of objects in the real world, but we sampled widely and it is likely that, if anything, we somewhat over-represented less common object types. It is probably inevitable that bilinguals receive less of the input needed to maintain (for L1) or establish (for L2) appropriate connection weights to object types for the infrequent words, and will use these less. Some mutual influence may then be exerted across the word-object inputs more commonly encountered, such that the major categories come to resemble each other more.

The remaining critical question is why the two domains showed different outcomes for the effect of increased English dominance. The observed outcomes most likely do derive from the different L1-L2 relations in the two domains, as alluded to earlier. The agreement scores of the monolinguals show that Mandarin speakers use their dominant terms for both domains with a high degree of consistency. English speakers used theirs with much lower consistency, and the full sets of response shows many more uncommon terms (e.g., cylinder, dispenser, vial, tub, tin; platter, saucer, trough, Tupperware) used sporadically. The lower English consistency is especially pronounced for the bottles set. In addition, as noted earlier, this set lacks any terms having a neat mapping to the Chinese terms, whereas the dishes set at least has a fairly clean correspondence of cup, mug, and glass jointly to Chinese bei. For dishes, bilinguals may be able to make progress in the distinctions among cup, mug, and glass without reshaping their use of bei. For bottles, bilinguals are more likely to struggle to acquire the native-like distinctions without success because the input is so highly variable. Nevertheless, the more they tilt toward becoming English dominant, the less they are reinforcing their Chinese usage patterns, and those weaker word-object connection weights may further diminish.

The current discussion has been framed in terms compatible with connectionist modeling. The network perspective provides a framing that links theoretical issues for the lexicon with those for phonology and morpho-syntax and highlights questions about bi-directional influence on patterns of word usage. Implementation is an important next step toward understanding the dynamics of lexical crosslanguage influence. Modeling stands to yield significant insights into the competition and representation of multiple languages in the bilingual mind (see Li, 2013 for a recent discussion). In naturalistic or experimental settings it is often difficult to bring learning variables under tight control, but these variables can be parametrically manipulated in a computational model. For instance, characteristics of the naming patterns, amounts of input in each language, proficiency or dominance in L1 or L2, and temporal characteristics of the input (blocked by language, as in a complete switch to L2, or intermixed as for immersed bilinguals who maintain contact with an L1 community) can be manipulated to make further predictions about what effects might emerge under what circumstances.

Conversely, the behavioral data as reported here help inform the nature of the models to be developed.

\title{
Do Language Structure or Language Proficiency Affect Critical Evaluation?
}

\begin{abstract}
This study examined whether language structure or language proficiency might influence students' use of evaluative language in written reports, and whether instruction might improve students' use of evaluative language. Reports in Japanese and in English written by second year Japanese university students, who had received instruction in academic discourse pertaining to critical evaluation, were analyzed for use of evaluative statements. This revealed no disadvantage for use of the Japanese language, which is considered as having a more indirect structure that may make critical evaluation more difficult. English proficiency test scores, however, were found to correlate with production of evaluative statements in English, but not in Japanese, suggesting that inadequate second language proficiency could limit critical evaluation use. The second year students' use of evaluative statements was also found higher than their first year counterparts' (who had not yet received instruction), suggesting that such instruction is beneficial for skills development in both languages.
\end{abstract}

Keywords: critical evaluation; critical thinking; language structure; second language proficiency; cognitive cost

\section*{Introduction}

The cultivation of students' abilities to critically evaluate the soundness of knowledge claims and arguments is considered as one of the most important objectives of education (e.g., Glassner, Weinstock, \& Neuman, 2005) and, with the proliferation of unvetted available information through the Internet and other forms of media in modern societies, the ability to determine credibility has become crucial (e.g., Thomm \& Bromme, 2011). Developing students' critical thinking skills (the broader set of skills to which critical evaluation belongs) is, however, not without its challenges (e.g., Halpern, 1998). There are various factors that have been claimed to affect people's use of critical thinking, including some culture-related factors. Asian students, in particular, have often been portrayed as lacking in critical thinking skills compared to Western students (e.g., Atkinson, 1997; Fox, 1994), and many tertiary instructors have been found to subscribe to such a view (e.g., Lee \& Carrasquillo, 2006; Robertson, Line, Jones, \& Thomas, 2000).

One explanation that has been put forward for the apparent differences in critical thinking skills manifested by students from different cultural groups concerns the structure of their native language. This explanation posits that, due to their structure, some languages may present constraints in the ease with which certain thinking skills can
be carried out or expressed. This explanation is sometimes referred to as the "Sapir-Whorf hypothesis" (see Au, 1983; Hockett, 1954), which suggests that languages differ in the relative ease with which they can be used to convey certain ideas. An example of a claim of this kind is Bloom's (1981) proposal that counterfactual thinking (i.e., thinking about what might have been, contrary to facts) may be more difficult in Chinese compared to English.

More recent observations of linguistic differences, such as "indirectness" being a feature more prevalent in some languages, particularly Asian languages (e.g., Kong, 2005), would appear to support the notion that language structure could affect the ease with which certain modes of thinking could be undertaken or expressed. In a study by Itakura and Tsui (2011), for example, evidence was found that book reviewers use different strategies to convey critical evaluation when writing in Japanese compared to English. For example, in Japanese, criticism is usually indirectly conveyed and is frequently preceded by an apology.

\section*{Language Structure or Language Proficiency?}

Previous studies, however, had not clarified whether language structures could actually impose constraints in what users of the language can do. Although the earliermentioned study by Bloom (1981) claimed to have found evidence for this where counterfactual thinking in the Chinese language is concerned, subsequent investigations failed to replicate or support Bloom's results (Au, 1983). Thus it remains unclear whether, for example, the structure of a language like Japanese would make it relatively more difficult to undertake tasks like critical evaluation (cf. Itakura and Tsui's, 2011, findings), and hence make a person appear less competent in his or her critical thinking skills.

Concerning international students who have been reported as appearing less competent in critical thinking skills (cf. Lee \& Carrasquillo, 2006; Robertson et al., 2000), there is another possible explanation that other authors have previously suggested (e.g., Floyd, 2011; Lun, Fischer, \& Ward, 2010; Paton, 2005) but which had not been adequately tested. This explanation hinges on the fact that many international students have to use a second language (L2), like English, in their host environment. It suggests that, if a person is not so proficient in a language, he or she would generally manifest lower competence in carrying out tasks when using that language. Tasks that are likely to get affected include cognitive tasks like critical thinking.

This possible influence of language proficiency on critical thinking skills application can be explained in terms of cognitive cost (i.e., the mental resources cost associated with executing tasks). Language processing entails the use of cognitive resources in working memory (Baddeley, 1986, 1998), and lower proficiency in a language would require the use of more resources (i.e., the cognitive cost would be higher). The application of critical thinking skills would likewise require the use of working memory resources. The resources available in working memory, however, are limited (Baddeley, 1986, 1998) and, if a considerable amount of those resources has already been expended on utilizing a language in which proficiency is low, there may not be adequate resources remaining for the satisfactory execution of critical thinking.

The negative impact of the higher cognitive cost entailed in using a language in which proficiency is low, on the execution of other cognitive tasks, has been demonstrated in previous research. Takano and Noda \((1993,1995)\) showed that the use of a foreign language detrimentally affects performance in concurrently undertaken non-linguistic tasks like arithmetic calculation and mental imagery, and Manalo and Uesaka (2012) reported evidence indicating that students' lower proficiency in an L2 limits their ability to use diagrams when explaining information in that L2. Where critical thinking is concerned, both Lun et al. (2010) and Floyd (2011) reported indications that lower proficiency levels in English could detrimentally affect Asian students' performance in critical thinking tests administered in English. However, neither of those studies used appropriate, objective measures of L2 proficiency to reliably confirm the connection between L2 proficiency and critical thinking skills performance.

\section*{Overview of the Present Study}

The main purpose of the present study was to examine the possible influences of language structure, and proficiency in L2, on students' manifestation of critical thinking in their writing. The study was not intended to be a comprehensive test of the language structure hypothesis: it examined only whether, in the written work of Japanese university students, there might be observable differences in the presence of critical thinking qualities, depending on the language being used, Japanese or English. Critical thinking was operationalized as students' use of evaluative statements. Such use was chosen for investigation because it comprises a salient expression of critical evaluation, which in turn is central to the notion of critical thinking application (cf. Fisher \& Scriven's, 1997, p. 21, definition of critical thinking as "skilled and active interpretation and evaluation of observations and communications, information and argumentation" - italics added).

In the present study, Japanese was deemed an appropriate language to examine because, like a number of other Asian languages, it employs patterns of expression that make it more indirect and inductive compared to English (e.g., Itakura \& Tsui, 2011; Scollon \& Wong-Scollon, 1991).

Evaluation, however, requires precision and directness in conveying judgments about the quality or value of the subject being referred to. Thus, structural features of the Japanese language could make the production of evaluative language relatively more difficult. If so, it should be possible to detect lower rates of evaluative language use in the students' written work in Japanese compared to English.

As this study was focusing on students' written work in both L1 and L2, it was equally important to consider whether using an L2 may detrimentally affect students' critical evaluation performance. Thus, possible relationships between students' TOEIC test scores (Test of English for International Communication, a norm-referenced test of English listening comprehension and reading skills, widely used as a measure of students' English language proficiency levels in Japan; http://www.ets.org/toeic) and their production of evaluative statements were investigated. The question here was whether L2 proficiency would manifest as a limiting factor because lower proficiency entails higher cognitive cost when using the L2, leaving insufficient resources in working memory for critical evaluation. If this explanation is supported, a relationship should be found between the students' TOEIC scores and their evaluative statements production in the L2, but not in the L1. A relationship in the L1 would suggest that general language or intellectual abilities - rather than L2 proficiency - affect critical evaluation performance. The reason is that language abilities, and intellectual abilities and performance, are generally considered as being related (e.g., Ackerman, 1986; Neisser et al., 1996). Thus, a student with higher language and intellectual abilities could be expected to score higher in the TOEIC test, and evidence better performance in tasks like critical evaluation - in both their L1 and L2.

The research conducted comprised two related studies. In Study 1, evaluative statements that second year Japanese university students produced in Japanese (their L1) and in English (their L2) were examined. These students had received instruction on academic discourse. Thus, they were not naïve as to the requirements of expressing evaluative language, and any differences in the writing they produced in L1 and L2 could be attributed to either the inherent structure of the language they were using or their proficiency in using that language (particularly the L2).

In Study 2, the same writing task was given to first year students who had received little instruction on academic discourse, and nothing explicit on the production of evaluative language. The purpose of this second study was to find out if the characteristics of L1 and L2 written work produced by the first year students, compared to their second year counterparts, differed - and hence, whether the additional instruction that had been received by the more advanced second year students might have made a difference.

\section*{Study 1}

The first study was carried out to test the hypothesis that students' production of evaluative statements in Japanese
and in English would differ. A second hypothesis was also tested: that, if L2 proficiency is a limiting factor in students' critical evaluation performance, their TOEIC scores would be related to their evaluative statements production in L2, but not in L1. Lower use of evaluative statements in the students' L2 work should also be observable if this L2 proficiency hypothesis applies.

\section*{Method}

Participants The participants were 111 Japanese university students in their second year of study in science and engineering disciplines. For these students, Japanese is L1 and English is L2. These students were taking a compulsory English communication skills development course that covers oral and written academic discourse in task-based discussion and research development. The students came from four different classes in that course.

The students were required to sit the TOEIC test at regular intervals during their period of enrolment, and their scores on that test were available to their course teachers.

Materials and Procedure As part of the communication skills course, the students were provided class instruction, textbook explanations and examples (Anthony, Rose, \& Sheppard, 2010), and practice in the use of language appropriate for critical evaluation, including ranking and debating different reasons and other forms of alternatives (e.g., clearly stating the premises, and then drawing conclusions). These were all provided in English.

For the purposes of the present investigation, the students were additionally provided with a single page Japanese translation of the part of the textbook dealing with how to make valid arguments. They were also supplied brief (one page) written examples (one in English and one in Japanese) of how alternative reasons could be ranked according to judgments about their relative importance. The example texts conveyed someone's opinion about the most important reason for learning the English language, among four possible reasons. The texts provided examples of evaluative statements and provision of support for claims, although those were not labeled or overtly identified in any way in the texts. The equivalence and appropriate use of language in the English and Japanese versions were checked by several bilingual teachers of the course. Although all materials provided in the course are usually in English, the Japanese versions were supplied in this case to avoid possible disadvantage to the students' production of evaluative language in Japanese (i.e., without the Japanese versions, it could be argued that the students might have simply been unfamiliar with the equivalent Japanese expressions for critical evaluation).

During two 90 -minute class sessions of the communication skills course, the students were introduced to the Titanic and Space Shuttle Challenger disasters, including four basic causes that have been proposed for the occurrence of each of those disasters. During the class sessions, the students participated in guided exercises to
explore and discuss the disasters and their corresponding possible causes.

For homework, the students were asked to write two brief reports to explain what they considered to be the most important cause of each of the disasters. To avoid any possible misunderstandings about the requirements of the homework task, written instructions were provided in Japanese. The students were randomly assigned to write one report in English and the other in Japanese (i.e., if they were asked to write the Titanic report in English, they had to write the Challenger report in Japanese, and vice versa).

Analyses The following were counted and scored in the analysis of the students written work:
a) Number of sentences [Total];
b) Number of evaluative sentences (i.e., sentences where some evaluation of the relative value of the topic is made) [Evaluative];
c) Number of evaluative sentences specifically about the causes of the disaster (i.e., sentences where some evaluation is made about the relative importance of the causes given for the occurrence of the disaster) [Causes];
d) Number of evaluative sentences that are supported by reason or evidence of some kind [Supported].
Operational criteria were drawn up for determining what data counted under each of these categories. For example, where "evaluative sentences" were concerned, the following were required: the sentence must explicitly say something about the worth or value of the subject, and that worth or value must be in comparison to something else. Conditional statements that explicitly convey a relative evaluation of the subject were counted. The following examples, in contrast, did not count: the use of simple adjectives or adverbs to describe something, prescriptive statements not explicitly expressing a relative evaluation or judgment, and conditional statements in general.

Inter-rater reliability was checked by asking an independent coder to score a randomly selected sample of \(25 \%\) of the data. Reliability coefficients obtained (Cronbach's alphas) were deemed to be satisfactory (e.g., .922 and .940 in English and .960 and .963 in Japanese for the "Evaluative" and "Causes" scores, respectively).

Analyses of variance were conducted to compare the students' scores in each of the categories noted above in English and in Japanese. Correlational analyses were carried out to examine possible relationships with the students' most recent TOEIC test scores.

\section*{Results}

Table 1 shows the means, and standard deviations (in brackets), obtained under each category for the students' written work in English and in Japanese.

No significant effects were found due to the task (i.e., the Titanic compared to the Challenger reports). The analysis however revealed significant effects due to language in the total number of sentences written [Total], \(F(1,110)=11.51\),
\(p=.001, \eta_{\mathrm{p}}{ }^{2}=.095\); the number of evaluative sentences [Evaluative], \(F(1,110)=4.85, p=.030, \eta_{\mathrm{p}}{ }^{2}=.042\); the number of evaluative sentences about causes [Causes], \(F(1\), \(110)=5.00, p=.027, \eta_{\mathrm{p}}^{2}=.044\); and the number of evaluative sentences with support [Supported], \(F(1,110)=\) \(9.61, p=.002, \eta_{\mathrm{p}}^{2}=.080\). These results indicate that the students wrote more sentences in English compared to Japanese, but they wrote more evaluative sentences, evaluative sentences about causes, and evaluative sentences with support in Japanese compared to English.

Table 1: Mean report scores according to language used
\begin{tabular}{lcccc}
\hline & Total & Evaluat. & Causes & Support. \\
\hline English & 20.35 & 3.48 & 3.38 & 2.08 \\
& \((5.58)\) & \((1.77)\) & \((1.77)\) & \((1.42)\) \\
\hline Japanese & 18.72 & 3.76 & 3.67 & 2.49 \\
& \((5.91)\) & \((1.80)\) & \((1.80)\) & \((1.38)\) \\
\hline
\end{tabular}

Because the total number of sentences that the students wrote in English and in Japanese differed, the proportions (i.e., Evaluative, Causes, and Supported sentences as proportions of Total) were also calculated and compared according to the language used. The comparisons revealed significant differences in each case: for Evaluative, \(F(1\), \(110)=20.17, p<.001, \eta_{\mathrm{p}}^{2}=.155\); for Causes, \(F(1,110)=\) 20.29, \(p<.001, \eta_{\mathrm{p}}^{2}=.156\); and for Supported, \(F(1,110)=\) 24.90, \(p<.001, \eta_{\mathrm{p}}^{2}=.185\). These results, depicted in Figure 1, indicate that the proportions of Evaluative, Causes, and Supported sentences were higher in the reports that the students wrote in Japanese compared to those they wrote in English.

The results of the correlational analysis are shown in Table 2. In the students' written work in English, TOEIC scores correlated significantly with all categories of scores obtained. However, in Japanese, TOEIC scores significantly correlated only with Total and Supported sentences.

\section*{Discussion}

Differences were found in both actual numbers and proportions of evaluative sentences that the students produced in English and in Japanese. The direction of the differences, however, was opposite to the language structure-based prediction: higher proportions of evaluative sentences were found in Japanese instead of English. This result suggests that the students were better at producing evaluative language in their L1. The significant correlation found between students' TOEIC scores and their English writing scores, and the lack of significant correlations in Japanese where the Evaluative and Causes sentences were concerned, suggest that the students' English/L2 proficiency accounts for at least part of that difference.

The significant correlations between TOEIC scores and the numbers of Total and Supported sentences that were also present in Japanese suggest that general language skills (which is also correlated with TOEIC scores) may affect
students' productivity and use of evidence in writing, irrespective of the language being used.

As noted earlier, the student participants in this first study had already received instruction in academic discourse that includes the use of evaluative language. Therefore, an important next question to address was, "To what extent had that instruction affected the relative production of evaluative language in English and in Japanese?" - which was pursued in the second study.

Figure 1: Evaluative, evaluative about causes, and evaluative supported sentences, as proportions of the total number of sentences written, in English and in Japanese.

Table 2: Correlation coefficients between students' TOEIC scores and categories of their report scores, according to the language used (effect sizes shown in brackets)
\begin{tabular}{lcccc}
\hline & Total & Evaluat. & Causes & Support. \\
\hline English & \(.22^{*}\) & \(.22^{*}\) & \(.22^{*}\) & \(.23^{*}\) \\
& \((.047)\) & \((.049)\) & \((.048)\) & \((.051)\) \\
\hline Japanese & \(.27^{* *}\) & .18 & .15 & \(.25^{* *}\) \\
& \((.075)\) & \((.032)\) & \((.023)\) & \((.062)\) \\
\hline\(* p<.05{ }^{* *}\) &
\end{tabular}
* \(p<.05\). ** \(p<.01\).

\section*{Study 2}

The purpose of the second study was to examine whether first year students manifest lower use of the target evaluative language compared to the second year students, and whether any such differences might be consistent across English and Japanese.

\section*{Method}

Participants The participants were 44 Japanese university students who were in their first year of studies in the same science and engineering faculty as the students in Study 1. The students came from two classes of a compulsory first year English communication skills course which deals with various aspects of oral and written academic discourse, but nothing explicit about evaluative language (which is not covered until the second year course).

Materials, Procedure, and Analysis For one of their homework assignments, the students were given brief
reading materials (in English and in Japanese) about the Titanic and Space Shuttle Challenger disasters, including the proposed causes of those disasters. These materials were drawn from the textbook used in the second year course. The Japanese translations were provided to these first year participants to ensure that their subsequent writing performance would not have been compromised by possible difficulties in understanding the English versions. The content of those materials were not covered in class.

The homework task that the students had to do was the same as that given to the second year students: to produce two brief reports to explain what they considered to be the most important cause of each of the disasters, after reading the materials provided. Like the second year students, they were randomly assigned to write one report in English and the other in Japanese. Also, like the second year students, they were provided with the one-page examples (one in English and one in Japanese) of how alternative reasons (for learning the English language) could be ranked according to judgments about their relative importance. The crucial difference was that the first year students were not provided class instruction and exercises on the use of academic discourse specifically pertaining to evaluative language.

The written reports that the students produced were analyzed and scored in the same manner described in the first study. The first and second year students' data were then compared.

\section*{Results}

Analyses of variance revealed significant effects due to year of enrolment (first year compared to second year) in the students' scores for: Total, \(F(1,153)=23.37, p<.001, \eta_{\mathrm{p}}{ }^{2}\) \(=.133\); Evaluative, \(F(1,153)=27.79, p<.001, \eta_{\mathrm{p}}^{2}=.154\); for Causes, \(F(1,153)=27.15, p<.001, \eta_{\mathrm{p}}^{2}=.151\); and for Supported, \(F(1,153)=6.99, p=.009, \eta_{\mathrm{p}}{ }^{2}=.044\). Significant language effects were also found for Total, \(F(1\), \(153)=26.84, p<.001, \eta_{\mathrm{p}}^{2}=.149\); Causes, \(F(1,153)=4.31\), \(p=.04, \eta_{\mathrm{p}}^{2}=.027\); and Supported, \(F(1,153)=14.03, p<\) \(.001, \eta_{\mathrm{p}}{ }^{2}=.084\). No significant interaction effects between language and year were found; nor were any significant effects found due to the task (Titanic versus Challenger).

These results indicate that, compared to the second year students, the first year students wrote fewer sentences in total for their reports. They also produced fewer evaluative statements (evaluative sentences, evaluative sentences about causes, evaluative sentences that are supported). These differences in the students' production of evaluative language are depicted in Figure 2. Significant language differences were found in the total number of sentences, number of evaluative sentences about causes, and number of evaluative sentences with support that the students wrote: in each case, the students produced more in Japanese compared to English.

\section*{Discussion}

The results of Study 2 showed that the second year students wrote more sentences in their reports, and produced more of
the target evaluative language, compared to the first year students. This finding suggests that instruction on appropriate language to use - which had been provided to the second year students - can improve students' abilities in manifesting critical evaluation in their written work. Although as noted the instruction was provided almost entirely in English, the significant language effects found were all in favor of the Japanese language, which suggests that there is transfer across the languages in skills acquisition. In other words, skills taught and learned in English also produce improvements in the production of evaluative language in Japanese.

Figure 2: Mean numbers of evaluative, evaluative about causes, and evaluative supported sentences produced in English and Japanese reports by the first year (English 1, Japanese 1) and second year (English 2, Japanese 2) students.

\section*{General Discussion}

The findings of this study provide clear evidence that, at least for Japanese students, using the Japanese language (their L1) presents no disadvantage compared to English (their L2) in the production of evaluative language (i.e., the Japanese language structure is not a limiting factor). How Japanese students' evaluative language use might compare to that of students whose first language is structured differently (e.g., native English speakers responding to the same tasks), or students who are fully bilingual in Japanese and English, would need to be examined in future research. However, in the present study, there appeared to be no obvious deficits in evaluative language production in Japanese among the second year students who had received instruction in the necessary academic discourse.

There is evidence in the present study, however, that language proficiency can be a limiting factor in the production of evaluative language. The significant correlations between the students' TOEIC scores and their production of evaluative sentences in English (their L2) but not in Japanese (their L1) - indicate that performance varied with L2 proficiency. This provides useful evidence to corroborate previously made claims (e.g., Floyd, 2011; Lun
et al., 2010; Paton, 2005) that some of the shortcomings in critical thinking skills manifested by international students can be attributed to their having to use an L2 in which they may not be as proficient compared to their native speaker counterparts.

The finding about L2 proficiency being a potential limiting factor in students' use of the target critical evaluation language suggests that, to address the perceived deficiencies in Asian and other foreign students' critical thinking skills, educational strategies that would improve their proficiencies in English (or whatever language is used in the host country) would be helpful.

The findings of this study also show that appropriate classroom instruction promotes university students' development of skills in critical evaluation. The second year students evidenced similar writing profiles to those of first year students; however, having received instructions in academic discourse relevant to critical evaluation, they also produced more of the target evaluative language. They did this in both languages, L1 and L2, even though academic discourse instruction was primarily provided in the L2 suggesting some transfer of skills across languages.

\begin{abstract}
A wide literature demonstrates that people prefer harm caused by omissions over equal or lesser harm caused by actions. This omission bias has been explained referring to several principles, such as causality or responsibility. A convincing research view has been suggested by Sunstein (2005): harmful acts are generally worse than harmful omissions when moral intuitions reflect the "Do not play God" principle: inactions interfere less with the "natural order." In two preliminary studies, we examine the influence of the "Do not play God" principle on individuals moral preferences, using the switch version of the trolley problem. Study 1 demonstrates that our participants' justifications for their inaction choice explicitly refer to the intention of not interfering with the "natural order". Study 2 demonstrates that the presence of stimuli influencing a reduction of protagonist's decisional autonomy (e.g. an authority) activates the "Do not play God" principle, leading them to prefer inaction.
\end{abstract}

Keywords: Omission bias; Moral choices; Trolley dilemma; "Do not play God" principle.

\section*{Introduction}

It's quite common the intuition that it is worse for a doctor to kill a patient with a deadly disease then let him die by abstaining from any kind of medical intervention. Consequentialist philosophers argue that these cases should be considered equivalently (Singer, 1979). In a number of well-controlled experiments Baron and colleagues have shown instead that people consider harmful acts worse than harmful omissions with otherwise identical, predictable outcomes (i.e., omission bias). For example, Spranca, Minsk and Baron (1991) showed that people find it worse when somebody who wants to harm a person offers this person a food item with an allergenic ingredient than when she passively watches the person who does not know about the ingredient taking this item himself. Ritov and Baron (1990) used also vaccination to illustrate the bias: many people consider the risk of harm from vaccination as more serious than the risk from omitting vaccination. This bias seems to affect real vaccination decisions (Asch et al., 1994; Meszaros et al., 1996), and it has been replicated in several situations (e.g. Royzman \& Baron, 2002; Baron \& Leshner, 2000).

Wroe and Salkovskis (2000) explain this kind of choices arguing that most people regard themselves as more responsible for what they actively do than what they fail to do, and that this omission bias occurs due to perceived differences in causality and differing degrees of responsibility. In particular, according to these authors participants' judgments about the immorality of commission depend on several factors that ordinarily distinguish omission and commission, such as physical movements in commission.

Sunstein (2005) suggests instead that harmful acts are generally worse than harmful omissions when individuals' moral intuitions reflect an overgeneralization of the "Do not play God" principle: omissions or inactions interfere less with the "natural order." Omission generally carries less negative moral weight than commission, intervening less in individual's destiny.

Let's go back to the doctor who decides to let a patient die by refraining from any kind of medical intervention. According to the common sense, this case is considered less morally negative than the case in which the same doctor gives the patient a medication that quickly kills him. But the former case (to suspend any medical treatment, i.e. the omission) does not imply less responsibility or physical movements than the second decision (to give a deadly medication, i.e. the commission): the doctor could ask to move the patient from the emergency room, or could proceed by removing tubes or catheters, or finally by communicating the nurses his instructions and supervising how they follow them. In other words, contrary to Wroe and Salkovskis (2000), the harmful omission could not necessarily imply less responsibility or physical movements than actions. From this point of view there are no differences between action and omission.

So what does differentiate them? According to Sunstein's hypothesis, the omission choice has less impact on the "natural order" (in the example the patient's destiny), not violating the "do not play God" principle, and this would make the difference. It's like people say: nobody can claim the right to decide over the life and death of someone, even if s/he explicitly asks to die. S/he can only follow and adapt to the events.

Moreover, Haidt and Baron (1999) showed that the differences between harmful actions and omissions disappear (i.e. the omission has the same moral weight of
action) with people that are in roles that make them responsible. They have an equal responsibility to prevent harm through both action and omission, like for example a captain of a ship, who is equally responsible for both the acts and omissions that lead to similar harm for the passengers. That is, the higher is the social role, the higher is the decisional autonomy and the right to intervene on the natural order (i.e. responsibility to protect) and thus the less is the weight of the "do not play God" principle.

So far, no empirical studies have investigated whether the "do not play God" principle influences individuals choices when faced with problems like moral dilemmas.

The present study aimed to examine whether individuals tend to prefer harm caused by omissions over equal or lesser harm caused by acts, on the basis of their moral intuition based on the "Do not play God" principle. To this aim, we used the well-known switch version of the trolley problem. In its original form, the problem asks people to suppose that a runaway trolley is headed for five people, who will be killed if the trolley continues on its course. The question is whether one would throw a switch that would move the trolley onto another set of tracks, killing one person rather than five. This moral dilemma requires participants to choose one of two undesirable courses of action (both involving loss of life). The action option requires subjects to act, thereby causing the death of one person (but indirectly saving the lives of others). According to Sunstein's hypothesis, it allows modification of the "natural order" in the attempt to minimize the number of victims. The omission option involves no action, and the failure to act results in the deaths of five people. But omission does not modify the "natural order" and respects the "Do not play God" principle.

In line to the consequentialist point of view, in this dilemma, people should prefer the action option: it involves a lower number of victims. According to Suntein, people would prefer the omission option, consistent with the "Do not play God" principle.

To test this hypothesis two different studies were carried out. In the first, we wanted to verify whether subjects preferring inaction would actually tend to justify it by referring to the "Do not play God" principle, while those preferring action would tend to justify it by referring to the consequentialist idea of minimizing suffering and victims. According to Cushman and colleagues (Cushman, Young, \& Hauser, 2006), we assume that the principles used in judgments are articulated in justifications. In the second study, we wanted to verify whether the preference for the omissions would enhance with stimuli leading to a reduction of protagonist's decisional autonomy (e.g. an authority).

When faced with the original trolley problem, most subjects (80-90\%) prefer action (see Greene, Sommerville, Nystrom, Darley, \& Cohen, 2001; Greene, Nystrom, Engell, Darley, \& Cohen, 2004; Greene, Cushman, Stewart, Lowenberg, Nystrom, \& Cohen, 2009). In order to avoid this sort of ceiling effect, which could interfere with the results of the second experiment, we used a version of the
problem with a modified proportion of victims, five vs. three instead of the original five vs. one.

In a preliminary study of the first study we tested this modified version with a group of 54 volunteers, undergraduate students from the University of Rome, with a mean age of 20.2 (ranging from 18-32). All participants were given four moral dilemmas (see below) with the new proportion of victims. Each dilemma required participants to indicate which of two courses of action they would take if confronted with such dilemmas in real life (Greene \& Haidt, 2002; Greene et al., 2004). Participants were asked to respond to each dilemma by marking "yes" (action) or "no" (inaction). The total number of inaction choices made by each participant was the dependent variable. With this modified trolley problem, there were about \(50 \%\) action choices in all dilemmas.

\section*{Study 1}

In this study we wanted to verify whether subjects preferring inaction would tend to justify it by referring to the "Do not play God" principle (e.g. "Who am I to decide who lives and who dies?'"), while those preferring action would tend to justify it by referring to the consequentialist attempt to minimize suffering (e.g. "it's better that three people die instead of five"). Four moral dilemmas were shown to a group of participants. For each dilemma participants were asked to justify their choice. Two judges codified all justifications into two categories: deontological and consequentialist.

\section*{Method}

\section*{Participants}

Participants were 69 undergraduate and postgraduate students recruited by advertisements at the University of Rome (Italy) ( 45 females and 24 males). Their ages ranged from 18 to 45 with a mean age of 23.8 . All of the participants were thus volunteers and provided informed consent.

\section*{Materials and Procedure}

After completing a demographic questionnaire, participants received seven brief scenarios comprised of 6-8 sentences each. Four scenarios concerned moral dilemmas, each requiring participants to indicate which of two courses of action they would take if confronted with such dilemmas (Greene \& Haidt, 2002; Greene, et al., 2004). In one (action) alternative, the participant acted, thereby killing three human beings, but saving the lives of five others. In the second (inaction) alternative the participant did not act, and therefore did not kill three human beings. However, in this second alternative, the participant's failure to act resulted in more deaths (five) than in the first alternative. The other three scenarios required participants to choose between action and inaction. These control scenarios did not involve moral dilemmas. They did not present any victims or harm, but were included as filler items. The order of the seven dilemmas was randomized. Following is an example of the two kinds of dilemmas, moral and control, presented in the study (translated from Italian):

Moral Dilemma

You are near a Ferris wheel. It does not work. Just under the wheel, there are five tourists. Suddenly, the wheel starts turning and soon a cabin will kill them. There is no way to warn them and they cannot escape in any way. The only way to save the five tourists is to pull a lever that can change the rotation of the wheel. Unfortunately, there are three people on the other side that would be killed. Should you pull the lever?

\section*{Control dilemma}

You have just sent an e-mail order for three books that you need for your studies (they are by your favorite writer), when a colleague suggests that you buy the same books and two more (five books in total) at a discount. The order cancellation procedure requires too much time. Should you proceed with the cancellation procedure?

The text of all seven scenarios is available on the web at www.apc.it. After having responded to each scenario by marking "yes" (action) or "no" (inaction), participants were asked to justify their choice in their own words. Of 276 justifications, 18 were removed from the analyses because participants provided a nonsensical response or a judgment that made it clear they had misunderstood a scenario. Two colleagues of the authors who were blind to the hypotheses being tested coded a total of 258 justifications. Justifications were coded into two exclusive categories:

Deontological: justification refers to the importance of not substituting God, not interfering with a destiny already determined, or not taking the responsibility of deciding for others.

Consequentialist: justification refers to the importance of saving the greatest number of lives.

\section*{Results}

According to our hypotheses, we found that almost all participants preferring inaction (96\%) justified it by referring to the "Do not play God" principle (e.g. "I cannot decide who lives and who dies") \((\chi 2(1, N=69)=213.6 ; p\) \(<0.001\) ), while most of those preferring action (86\%) justified it by referring to the importance of minimizing suffering (e.g. "it’s better that three people die instead of five") \((\chi 2(1, N=69)=133.9\), see Table 1\()\).

Table 1. Proportions (and frequencies) of justifications given by participants for their action/inaction choices.
\begin{tabular}{ccc}
\hline & \multicolumn{2}{c}{ Choice } \\
\hline Justification & Action & Inaction \\
Deontological & \(14(38)\) & \(96(242)\) \\
Consequentialist & \(86(226)\) & \(4(10)\) \\
\hline
\end{tabular}

Table 2 provides the overall agreement between coders for the two categories of justifications, along with Cohen's kappa, a statistic of interobserver reliability for which values between .60 and .70 are considered fair, from .70 to .75 are considered good, and above .75 are considered excellent (Fleiss, 1981). The overall agreement for the four moral dilemmas, .83 , was quite high.

Table 2. Agreement between coders for each moral dilemma for the two categories of justifications, along with Cohen's kappa.
\begin{tabular}{cc}
\hline & \begin{tabular}{c} 
Inter-Observer \\
Reliability
\end{tabular} \\
\hline Dilemma & kappa \\
1 & .84 \\
2 & .71 \\
3 & .89 \\
4 & .90 \\
\hline
\end{tabular}

Overall, these results show that participants tend to prefer omission in order to respect the moral principle of "Do not play God."

\section*{Study 2}

With the first study we have demonstrated that individual preferences for omissions in moral dilemmas are actually influenced by the moral goal of respecting the "Do not play God" principle. But these results raise the question whether participants' justifications of their moral choice reflect their actual reasons for deciding. It is possible that participants simply report a justification that corresponds to their decision, but it is not clear whether the justification preceded and causally influenced their decision (e.g. Haidt, 2001), although Cushman and colleagues (Cushman, Young, \& Hauser, 2006) state that the principles used in judgments are well articulated and reflected in justifications. For these reasons a second study is carried out.

With this second experiment we wanted to further verify whether the preference for the omissions in problems like the trolley dilemma is influenced by the goal of respecting the "natural order", activated by a restriction of one's decisional autonomy.

To this aim, we compared three versions of the trolley dilemma to isolate the effects of 1.authority presence, and 2.closeness, on moral judgments concerning harmful actions. The original version of the trolley dilemma was used as control condition (neutral problem, cf. study 1). We expected that in the "authority" problem participants would choose the inaction options more than participants in the "closeness" and neutral problems. The presence of an authority would indeed limit the decisional autonomy of the protagonist, leading participants to prefer the omission.

\section*{Method}

Subjects
Participants were 105 undergraduate and postgraduate students recruited by advertisements at the University of Rome (Italy) ( 70 females and 35 males). Their ages ranged from 18 to 51 with a mean age of 24.5. All of the participants were thus volunteers and provided informed consent.

\section*{Materials, and procedure}

Subjects responded to one of three versions of the trolley dilemma, in a between-subject design. In each condition, participants received the seven scenarios used in the earlier
experiment (4 moral dilemmas, 3 control dilemmas), in which information about the presence of the "authority" and the "closeness" of the protagonist to the victims were systematically varied. In the "authority" condition ( \(n=45\) ), the moral scenarios presented an authority close to the protagonist (e.g. a policeman, a judge). In the closeness condition ( \(\mathrm{n}=30\) ), in all the moral scenarios the protagonist was close to the potential victims. In the neutral condition ( \(n=30\) ), participants were given the original version of the trolley dilemmas.

In each condition, the order of the seven dilemmas was randomized. Following is an example of the two kinds of moral dilemmas, "authority" and "closeness", presented in the study (translated from Italian). Each version started with the same stem but ends differently:

Start of the dilemma:
You are near a Ferris wheel. It does not work. Just under the wheel, there are five tourists. Suddenly, the wheel starts turning and soon a cabin will kill them. There is no way to warn them and they cannot escape in any way. The only way to save the five tourists is to pull a lever that can change the rotation of the wheel. Unfortunately, there are three people on the other side that would be killed.

The "authority" script continues as follows:
You are in the cabin and close to the lever. You know that the cabin is under video surveillance and that cameras are connected to the police and the security service. Should you pull the lever?

The "closeness" script continues as follows:
You are in the cabin very next to the five tourists and you can see clearly their faces from there. Should you pull the lever?

The text of all seven scenarios is available on the web at www.apc.it. In all conditions, as in the earlier study, each dilemma required participants to indicate which of two courses of action they would take if confronted with such dilemmas (Greene \& Haidt, 2002; Greene, et al., 2004). The total number of inaction choices made by each participant was the dependent variable.

\section*{Results}

As expected, the proportion of scenarios for which participants chose inaction was significantly greater in the "authority" condition ( \(\mathrm{F}(2,102\) ) \(=9.55, \mathrm{p}<0.001, \mathrm{M}=2.47\), \(\mathrm{SD}=1.15\) ), than in the other two experimental conditions ("closeness": \(\mathrm{M}=1.46, \mathrm{SD}=1.3, \mathrm{t}(73)=3.48, \mathrm{p}<.002\); neutral: \(\mathrm{M}=1.43 ; \mathrm{SD}=1.88, \mathrm{t}(73)=3.9, \mathrm{p}<.001)\). No differences were found between the "closeness" and neutral conditions, \(\mathrm{t}(58)=0.1, n . s\).

This result demonstrates that participants' preferences for the inaction depend on the goal of reducing or limiting one's own decisional autonomy, according to the not play God moral principle.

\section*{General Discussion}

The two studies present evidence that moral judgments of harmful acts and omissions are affected by the degree of their interference with the "natural order". According to Sunstein (2005), harmful acts are worse than harmful
omissions because individuals' moral intuitions reflect an overgeneralization of the "Do not play God" principle. In this perspective, omissions or inactions interfere less with the "natural order." Omission generally carries less negative moral weight than commission, since it interferes less with individual's destiny.

In particular, in two studies we demonstrated that the "Do not play God" principle influences individuals' moral preferences when faced with problems like the trolley dilemma, traditionally used in moral psychology to study how people reason when choosing between two morally unacceptable courses of action. In particular, in the first study we demonstrated that participants preferring omission justified this choice according to the "Do not play God" deontological principle. The second experiment demonstrated that the presence of an "authority" lead people to limit their decisional autonomy, thus preferring the inaction, that is what interferes less with a given order ("do not play God" principle).

Our findings may contribute to the explanation of the omission bias, which is defined as the tendency to judge harmful actions as worse or as less moral than equally harmful omissions (inactions) (e.g. Baron \& Ritov, 2004; Spranca, Minsk, \& Baron, 2003).

Several experiments have found that across a variety of moral dilemmas, subjects' judgments about the permissibility of harming an individual align with some principles, which usually distinguish between action and inaction, such as harm intended as the means to an end is worse than harm foreseen as the side effect of a pursuit, or that harm involving physical contact with the victim is worse than harm involving no physical contact.

Sunstein (2005) suggests that harmful acts are generally worse than harmful omissions because according to the "Do not play God" principle, they interferes less with the "natural order." Overall, results from our two preliminary experiments confirm this hypothesis. In Study 1, our participants' justifications for their inaction explicitly refer to the intention of not interfering with destiny. In Study 2, our participants are affected in their moral choice by the presence of an authority, which induce them to choose the inaction, the option that does not modify "the natural order".

The omission bias may thus be better considered as a part of a deontological theory that people tend to approve (Sinnott-Armstrong, Young \& Cushman, 2010; Waldmann, Nagel, \& Wiegmann, 2012), and actively influences both commonsense morality and law, including constitutional law, by treating harmful omissions as morally unproblematic or categorically different from harmful actions (see for example the current debate on euthanasia).
The current studies are to be considered as preliminary studies on this topic. They also present several limitations that call for further investigation. First, participants of both our studies were predominantly female, young, and influenced by Catholic culture. It is possible that our results may not generalize to a broader population. Thus, they may not work well for others that differ in culture and religion.

Further experiments could test whether our results will be replicated for individuals of different in cultures and religions.

\begin{abstract}
Creating autonomous virtual agents capable of exhibiting human-like behaviour under uncertainty is becoming increasingly relevant, for instance in multi-agent based simulations (MABS), used to validate social theories, and also as intelligent characters in virtual training environments (VTEs). The agents in these systems should not act optimally; instead, they should display intrinsic human limitations and make judgement errors. We propose a Belief-Desire-Intention (BDI) based model which allows for the emergence of uncertainty related biases during the agent's deliberation process. To achieve it, a probability of success is calculated from the agent's beliefs and attributed to each available intention. These probabilities are then combined with the intention's utility using Prospect Theory, a widely validated descriptive model of human decision. We also distinguish risk from ambiguity, and allow for individual variability in attitudes towards these two types of uncertainty through the specification of indices. In a travelling scenario, we demonstrate how distinct, more realistic agent behaviours can be obtained by applying the proposed model.
\end{abstract}

Keywords: Intelligent agents; Decision making; Cognitive biases

\section*{Introduction}

Uncertainty is a natural part of our world. No one can claim to know everything, no one can predict the future. We deal with uncertainty on our everyday lives and our behaviour is constantly influenced by it, even if we do not always realize it. However, in the context of virtual agents, uncertainty has usually been seen as a problem that the agent must overcome (eg. planning Peot \& Smith, 1992), and thus most existing systems are aimed at achieving optimal agent behaviour under these conditions.

Our approach is different, in which we acknowledge the often sub-optimal, even "irrational" behaviour of humans when confronted with uncertain situations. These decision biases and judgement errors have been extensively studied and are supported by a wealth of empirical evidence (eg. Kahneman \& Tversky, 1979; Camerer \& Ho, 1994). We propose an agent model based on the classical Belief-Desire-Intention (BDI) paradigm, which seeks to integrate in the agent's deliberation process these deviations from rational behaviour.

}

Agents with the aforementioned characteristics can be specially useful for Multi-Agent Based Simulations (MABS) (Davidsson, 2001). In these systems, human behaviour is modelled at the individual (agent) level, and the resulting structure is analysed after it emerges from the agent interactions. Typically, MABS have been used to validate social theories (eg. Davidsson, 2002). The inclusion of uncertainty is of special importance in market simulations, as it strongly impacts the decisions of the agent (Arthur, 1991). From socio-cultural research, the Uncertainty Avoidance dimension of human cultures, identified by Hofstede (Hofstede, 2001), is another example where these agents could be used in the context of MABS. Our solution is also relevant for use in serious games, particularly virtual training environments. As these simulation often focus on social and communication aspects (eg. Johnson \& Valente, 2009; Kim et al., 2009), it is increasingly important to embed the virtual characters with human-like behaviour.

This paper is organized as follows. We start by giving a possible definition of uncertainty and describing Prospect Theory, and follow with work related to ours. Then we present the model, and demonstrate it using an example scenario. Finally we discuss future improvements.

\section*{Background}

In tackling the effects of uncertainty, one should first have an accurate definition of the term. However, this is not an easy task because different research fields or problem approaches use it with different meanings.

One important step is distinguishing uncertainty from the closely related concept of risk. In a decision context, the later refers to choices involving known chances (eg. a spin of a roulette wheel). However, uncertainty arises in a decisions involving personal opinions (eg. betting on what football team will win a game). Moreover, uncertainty has distinct facets (Smithson, 2008): epistemic randomness or risk uncertainty is the subjective counterpart of risk, and is usually represented by subjective probabilities; ambiguity, which results from overlapping beliefs (i.e, strong reasons to believe and not believe) or uncertainty about probabilities (second order uncertainty); and vagueness, reflected by fuzzy statements (eg. "John is tall" - what does "tall" mean?).

The topic of how humans choose (or should choose) under
uncertainty has been extensively studied over the last centuries. Decision making theories which seek to predict the optimal choice, such as the classical Expected Utility theory (EU), are called normative. However, people do not generally obey the axioms of normative theories (some examples of violations are described in the following section). Given our goal of achieving human-like behaviour, we focus on theories seeking to describe how humans actually act. Within these, decision behaviour has been observed to differ when the subject is offered a description of available choices (decisions from description paradigm), versus when he can learn by direct experimentation (decisions from experience paradigm), as shown by Hertwig, Barron, Weber, \& Erev, 2004. As we will see, the solution proposed in this paper assumes that the agent learns by asking and not by experimentation, and therefore we restrict ourselves to the former category.

\section*{Prospect theory}

The most validated descriptive theory of human decision is called Prospect Theory (PT) (Kahneman \& Tversky, 1979; Tversky \& Kahneman, 1992). Some of the decision biases it addresses are:

Framing Effects: there is evidence that the framing of options (in terms of gains or losses) significantly impacts the choices people make (Tversky \& Kahneman, 1986);

Nonlinear preferences: the idea that a risky prospect is linear in outcome probabilities has been proved false, most prominently by the Allais paradox (Allais, 1979);

Source dependence: as demonstrated by the Ellsberg paradox, people's decisions depend not only on the degree of uncertainty but also on its source; this phenomena has been explained both from an ambiguity aversion (people dislike ambiguity, Ellsberg, 1961) and from a competence hypothesis perspective (people prefer a bet on their area of competence when compared to equivalent bet based on objective probabilities, Heath \& Tversky, 1991);

Fourfold pattern of risk: empirical studies indicate that people are generally risk averse for high probability gains and low probability losses, and risk seeking for low probability gains and high probability losses (Tversky \& Kahneman, 1992).

These biases are accounted by PT by assuming a framing phase prior to the actual evaluation; a value function ( \(v\) ) which distort utilities; and a weighting function \((\pi)\) which distorts probabilities. Our focus is on the biases created by these functions, and how to integrate them in the BDI model, as the modelling of framing effects has already been explored in a context similar to ours (Ito \& Marsella, 2011). In PT, the valuation attributed to a prospect (i.e, a gamble) \(f\), which has \(n\) possible outcomes \(x_{i}, i=1 \ldots n\), each with utility \(U_{i}\) and probability \(p_{i}\), is given by:
\[
V(f)=\sum_{i} v\left(U_{i}\right) \pi\left(p_{i}\right)
\]

The choice for the specific value and weighting functions is arbitrary, as long as they obey certain properties. The value function should reflect the effects of diminishing sensitivity (variations in utility are less perceived the further they are from the reference point), and thus be concave for gains and convex for losses (S-shape). Furthermore, it should be steeper for losses than for gains, reflecting the phenomena of loss aversion.

The weighting function transforms a probability, and should also reflect the effects of diminishing sensitivity. However, in this case there are two boundaries ( \(p=0\) and \(p=1\) ), and thus the resulting function is inverse \(S\)-shaped. The curvature of these functions reflect the individual propensity to decision biases, which is usually accounted for by assuming parametrized functional forms.

Our integration of PT in the BDI model, as shown later, is restricted to choices involving prospects with at most two outcomes. Therefore, both Prospect Theory and its more recent development, Cumulative Prospect Theory (CPT) (Tversky \& Kahneman, 1992), coincide. We are presenting the original formulation of the theory. It is also important to note that, although PT is originally based on studies where probabilities were objectively stated, and thus related to decisions under risk, its fundamental properties were also verified in decisions under risk uncertainty (Tversky \& Fox, 1995).

\section*{Related Work}

In Pezzulo's et. al. proposal, measures of ignorance (what the agent does not know), contradiction and uncertainty (difference between opposing beliefs) are computed by the agent, and used in the decision process using custom rules (Pezzulo, Lorini, \& Calvi, 2004).

FAtiMA-PSI (Dias \& Paiva, 2005; Mascarenhas, Dias, Prada, \& Paiva, 2010) is an architecture geared towards the creation of believable virtual characters. It has a strong focus on emotional aspects and human motivations. It already represents some forms of uncertainty, as stochastic action outcomes and estimations of goal success based on past observations. This architecture also provides several parameters which allow an author to define agents with different personalities. However, it does not model unreliable perceptions - the environment is considered completely observable, and the decision process is based on EU theory.

The graded BDI model and abstract architecture (g-BDI, Casali, Godo, \& Sierra, 2009) extends the classical BDI model by allowing uncertainty to be represented in the agent's mental attitudes. g-BDI permits not only uncertain (graded) beliefs, but also desires and intentions. Graded desires correspond to degrees of preference (or rejection) over states of the world, and graded intentions represent the preference over specific ways (plans) to achieve desires. The formalization of the g-BDI allow different contexts to operate each in its own logic. Thus, the belief context (BC), for example, can use probability measures to represent uncertainty.

The Contextually-Based Utility (CBU) model (Ito \&

Marsella, 2011) combines principles of cognitive appraisal theories with decision theoretic notions, with the main purpose of capturing framing effects with greater accuracy. For each possible goal outcome, a contextual utility value is calculated using two salient features: pleasantness, the outcome's intrinsic attractiveness or unattractiveness; and congruence, how much achieving the goal contributes to the agent's expectations. A decision weight is also computed using the outcomes' probabilities. These three measures are transformed by an S-shaped function which models the effects of diminishing sensitivity in relation to a variable reference point, and are then linearly combined to obtain a goal's final valuation.

The work presented above share with ours the purpose of achieving human-like agent behaviours in decisions under uncertainty. However, almost none of them apply a validated descriptive decision theory. The exception is CBU, which is not an agent model in itself. Thus, our approach differs in what we consider fundamental requisites of our solution: 1) capturing widely validated findings on human decision behaviour; and 2 ) being a generally applicable agent model.

\section*{Model}

We chose the BDI model because its folk psychology roots are consistent with our goal of modelling human-like behaviours, and also due to its flexibility and wide application. An overview of the proposed model is shown in figure 1. In the present section, each component is explained in detail.

Figure 1: Model overview

\section*{Uncertainty representation}

This component deals on how to represent uncertainty in the agent beliefs. We used bayesian probability, as it is the most developed model of uncertainty representation. We assume a world defined by a set of crisp (true/false) propositions, represented by upper-case letters, for example \(\mathrm{O}=\) "Hotel is open". Exhaustive and mutually exclusive subsets of propositions are called variables. A probability distribution over the values of each variable forms the agent's belief state, i.e, his opinions on the actual value of propositions. Thus, if \(\Theta=\left\{A_{1}, \ldots, A_{n}\right\}\) is a variable, then \(\sum_{i} P\left(A_{i}\right)=1\), where \(P\left(A_{i}\right)\) denotes the subjective probability of \(A_{i}\) being true.

In order to focus on the behavioural consequences of uncertainty, we made two simplifying assumptions: 1) all variables are conditionally independent; and 2) the agent can only be uncertain about static propositions (propositions whose value never change, because no actions exist with such effects). We expect to address these limitations in future work.

Belief revision The agent can change its opinions by making either a direct observation or by asking questions to other agents. In the latter case, the degree at which the agent believes what he is told depends on the evidence's credibility. We represent the credibility of an evidence provided by source \(i\), asserting a proposition \(A\), as \(\operatorname{cr}\left(\varepsilon_{i}^{A}\right) \in[0,1[\). The value \(c r\) is calculated based on the history of previously received answers from the same source. We follow the method proposed in (Pearl, 1988), which allows Bayes Rule to be applied to uncertain evidence. Assuming independent sources, the agent's beliefs are updated using the formula below:
\[
P\left(H \mid \varepsilon_{i}^{A}\right)= \begin{cases}\left(\operatorname{cr}\left(\varepsilon_{i}^{A}\right)+\frac{1-c r\left(\varepsilon_{i}^{A}\right)}{n}\right) \cdot \frac{P(H)}{P\left(\varepsilon_{i}^{A}\right)} & \text { ifH }=A \\ \frac{1-c r\left(\varepsilon_{i}^{A}\right)}{n} \cdot \frac{P(H)}{P\left(\varepsilon_{i}^{A}\right)} & \text { otherwise }\end{cases}
\]
where \(P(H)\) is the prior probability of value \(H\) in a variable. When new evidence comes which asserts \(A\), the above formula increases the belief in \(A\) while decreasing the belief in the other values of the same variable, such that they still sum to one. Note that a direct observation corresponds to \(\operatorname{cr}\left(\varepsilon_{i}^{A}\right)=1\), and thus always leads to absolute certainty on a variable's value.

\section*{Solutions and doubts}

This section serves as a bridge between the preceding (uncertainty representation) and following (decision process) components, by demonstrating how the agent's beliefs are integrated in the decision process. In the BDI model, the general behaviour of an agent is guided by the active intention - a commitment to achieve a goal and a plan to do it. We call each plan generated by the planning process a solution. We assume that each solution only contains indispensable actions (as usual in classical planning), and therefore if a single action fails, the solution also fails.

The execution of an action, in turn, is dependent on its Action Pre Conditions (APC) validity. APCs are world propositions or their negation. Thus, success in achieving a goal is ultimately dependent on the validity of APCs and, if among the APCs some correspond to uncertain propositions, they possibly invalidate the entire solution and make the goal impossible to attain. Uncertain APCs are what we call doubts, and they are the basic components from which uncertainty related biases will arise (see Figure 2). To distance ourselves from the problem of planning in uncertain environments, during planning doubts are considered valid and thus ignored.

\section*{Decision process}

Within the deliberative process of the agent, our model deals with the evaluation of competing solutions, which essentially

Figure 2: An example of a solution containing two doubts.
correspond to the intentions of the agent - possible paths to commit to and pursue. Prospect Theory (PT), the psychology based model described before, is used during this process. This theory has been shown to accurately predict the choice behaviour of humans in many real life situations, and as such it nicely fits our goal - achieving actual, and not optimal behaviour. The prospects (i.e, the solutions) only have two possible outcomes: success and failure.
Value function We assume a utility of 0 for failing, and a utility of success given by the sum of utility of each individual action within in the solution. Using the status quo as the reference point \((v(0)=0)\), the above definition implies that a solution is always a positive prospect. We applied Tversky and Kahneman two branch power function, but because we only have positive outcomes we can restrict to the positive part (with \(\alpha=0.88\) as estimated in Tversky \& Kahneman, 1992):
\[
v=U^{\alpha}, U \geq 0
\]

Weighting function The weighting function \(\pi(p)\) transforms the beliefs the agent holds about states of the world into the decision weights he actually utilises when making a decision. The probability assigned to the successful outcome corresponds to no invalid doubts at all (as a single doubt failure invalidates the whole solution). Thus, variables being independent, \(p\) is obtained by multiplying the probabilities of all solution doubts being valid. The probability \(p\) is then transformed by the weighting function. We use the function proposed by Wu \& Gonzalez, 1999:
\[
\pi=\frac{\delta p^{\gamma}}{\delta p^{\gamma}+(1-p)^{\gamma}}
\]

In the above function, the two parameters reflect two distinct cognitive biases: \(\gamma\) (estimated as \(\gamma=0.44\) ) represents the impact of diminishing sensitivity to probability variations through the function curvature; \(\delta\) (estimated as \(\delta=0.77\) ) represents the attractiveness to gambles through the function elevation.

Individual variability towards risk uncertainty is allowed via the indirect specification of the \(\delta\) parameter. Staying within the parameter values estimated by \(\mathrm{Wu} \&\) Gonzalez, 1999, we propose to substitute \(\delta\) with \(\delta^{R}\), such that:
\[
\delta^{R}=\delta+(0.5-R)
\]
where \(R \in[0,1]\) is a risk aversion index available to the scenario author. A value of \(R\) close to 1 results in a risk seeking attitude, as the agent will generally overweight probability values; on the other hand, a value close to 0 corresponds to a risk averse attitude, as the probabilities are underweighted.

The resulting functions are shown in figure 3.

Figure 3: Weighting function at different levels of risk aversion \((R)\).

\section*{Ambiguity}

Although PT captures risk biases, ambiguity related biases are not considered. Before discussing them, we present how is ambiguity quantified in the proposed model.

Research in psychology and neuroscience proposes information entropy of possible meanings one attributes to a situation (or the world) as a mathematical quantification of ambiguity (Takahashi, Oono, Radford, \& Others, 2007; Hirsh, Mar, \& Peterson, 2012). Information entropy, also known as Shannon Entropy, measures the amount of "disorder", or uncertainty, associated with a random variable. If \(\theta=\) \(\left\{A_{1}, \ldots, A_{n}\right\}\) is a variable, it's entropy is given by (we use \(e\) as the base of the logarithm):
\[
H(\theta)=-\sum_{i}^{n} p\left(A_{i}\right) \log p\left(A_{i}\right)
\]

In our model, the variables correspond the agent's belief state. The ambiguity being experienced by the agent, however, depends only on the goal under pursuit, i.e, the solution under execution. Thus, it arises from solution doubt variables:
\[
\Delta(S)=\sum_{i} H\left(\theta_{i}\right), \theta_{i} \in\{\operatorname{doubts}(S)\}
\]

Where \(\Delta(S)\) represents the ambiguity of solution \(S\). High levels of ambiguity are caused by ignorance about the actual value of doubts - when the probability distributions are "flat", and/or there are many doubts. Lower levels of ambiguity, on the other hand, are characterized by strong beliefs (probabilities close to either 1 or 0 ) and/or a fewer number of doubts. Note that the amount of ambiguity is independent on what variable values are preferred, and thus distinct from risk.

Existing research seem to indicate that people are averse to this type of ambiguity, i.e, they tend to choose lower entropy
over higher entropy options (Takahashi et al., 2007). In order to represent this effect, we first reduce it to the \([0,1[\) interval:
\[
\Delta^{*}=1-e^{-k \Delta}
\]

Where \(k=0.2\) is a normalizing factor. Then, we introduce ambiguity in the \(\delta^{R}\) parameter defined before, such that:
\[
\delta^{\Delta}=\delta^{R}\left(1-A \Delta^{*}\right)
\]

Where \(A \in[0,1]\) is an ambiguity aversion index. Therefore, values of \(A\) close to 1 reinforce the aversion to solutions with high ambiguity.

\section*{Example scenario}

In this section we demonstrate how the proposed model gives origin to different behaviours, by focusing on preference reversals caused by distinct attitudes towards uncertainty. The scenario being presented is deliberately simple, in order to facilitate the presentation.

Consider an author who wishes to create an uncertain travel scenario. In addition to the agents introduced further below, it contains two other entities: the city of Agra (location of the TajMahal) and the region of Ladakh (home to several beautiful Buddhist monasteries), which will be the available travel destinations. When an agent learns about them (eg. at initialization time), the associated properties are stored in the agent's memory as variables. By default, properties are certain, but uncertainty about specific entities or specific properties may be specified through the agent's configuration file.

In the presented test case, all agents will share the exact same knowledge: they are completely ignorant about finding accommodation in Ladakh, but are almost certain to find it in Agra. This is represented by two different probability distributions over the variables originated by the property accAvailable of Agra and Ladakh, as shown in table 1. The

Table 1: Agent's uncertain knowledge
\begin{tabular}{|lcl|}
\hline \multicolumn{3}{|c|}{ Agra(accAvailable) } \\
\hline Values & \multicolumn{2}{c|}{ Belief } \\
True & 0.9 & Entropy \\
False & 0.3 & 0.3251 \\
\hline \hline \multicolumn{3}{|c|}{ Ladakh(accAvailable) } \\
\hline Values & \multicolumn{2}{c|}{ Belief } \\
True & 0.5 & Entropy \\
False & 0.5 & 0.6931 \\
\hline
\end{tabular}
atomic actions available to the agents in order to achieve their Travel() goal are specified in table 2, which in this case differ only in their utility, as the doubts are equivalent (having a place to sleep). The created solutions are shown in table 3.
\begin{tabular}{lll} 
Actions & \begin{tabular}{c} 
Table 2: Actions \\
Utility
\end{tabular} \\
Doubts
\end{tabular}

In the first case, we show the impact of distinct attitudes towards risk. The solutions are evaluated by Peter, an extremely
\begin{tabular}{lllll} 
& \multirow{2}{*}{ Table 3: Solutions } & & \\
Solutions & Util & Prob & Amb \\
\hline \(\boldsymbol{S}_{1}:\) TravelTo(Agra) \(\rightarrow\) Visit(Agra) & 6 & 0.9 & 0.3251 \\
\(\boldsymbol{S}_{2}: \operatorname{TravelTo(Ladakh)~} \rightarrow\) Visit(Ladakh) & 10 & 0.5 & 0.6931
\end{tabular}
risk averse and ambiguity tolerant agent ( \(R=1 ; A=0\) ), and Sara, who is risk seeking and also ambiguity tolerant \((R=0\); \(A=0\) ). We start with Peter's evaluation:
\[
\begin{gathered}
V\left(S_{1}\right)=v(6) * \pi(0.9)=6^{0.88} *\left(\frac{1.27 * 0.9^{0.44}}{1.27 * 0.9^{0.44}+(1-0.9)^{0.44}}\right)=\mathbf{2 . 0 1} \\
V\left(S_{2}\right)=v(10) * \pi(0.5)=10^{0.88} *\left(\frac{1.27 * 0.5^{0.44}}{1.27 * 0.5^{0.44}+(1-0.5)^{0.44}}\right)=1.61
\end{gathered}
\]

And Sara's evaluation is shown below:
\[
\begin{gathered}
V\left(S_{1}\right)=v(6) * \pi(0.9)=6^{0.88} *\left(\frac{0.27 * 0.9^{0.44}}{0.27 * 0.9^{0.44}+(1-0.9)^{0.44}}\right)=3.72 \\
V\left(S_{2}\right)=v(10) * \pi(0.5)=10^{0.88} *\left(\frac{0.27 * 0.9^{0.44}}{0.27 * 0.5^{0.44}+(1-0.5)^{0.44}}\right)=\mathbf{4 . 2 4}
\end{gathered}
\]

As we can see, Peter avoids the higher utility solution due to its greater risk. On the other hand, Sara is not concerned, and visits Ladakh.

In the second test case, we demonstrate the effects of ambiguity. We use two other agents, both average risk averse. However, John is ambiguity tolerant \((R=0.5 ; A=0)\) while Laura is ambiguity averse ( \(R=0.5 ; A=1\) ). John evaluates the solutions similarly as shown before, resulting in the valuations: \(V\left(S_{1}\right)=3.24\) and \(V\left(S_{2}\right)=\mathbf{3 . 3 0}\), and therefore goes to Ladakh. In Laura's decision, the parameter \(\delta^{A}\) includes the effects of ambiguity as shown below:
\[
\begin{gathered}
\Delta_{1}^{*}=1-e^{-0.2 * 0.3251}=0.0630 \\
\Delta_{2}^{*}=1-e^{-0.2 * 0.6931}=0.1294 \\
\delta_{1}^{\Delta}=0.77 *(1-1.0 * 0.0630)=0.7215 \\
\delta_{2}^{\Delta}=0.77 *(1-1.0 * 0.1294)=0.6703 \\
V\left(S_{1}\right)=v(6) * \pi(0.9)=6^{0.88} *\left(\frac{0.7215 * 0.9^{0.44}}{0.7215 * 0.9^{0.44}+(1-0.9)^{0.44}}\right)=3.17 \\
V\left(S_{2}\right)=v(10) * \pi(0.5)=10^{0.88} *\left(\frac{0.6703 * 0.5^{0.44}}{0.6703 * 0.5^{0.44}+(1-0.5)^{0.44}}\right)=3.04
\end{gathered}
\]

For Laura, the ambiguity associated with travelling to Ladakh is too great to overcome the potential reward, and she prefers to go to Agra. As it can be seen, the effects of ambiguity are independent of risk, given that the agent's only differ in their ambiguity attitude. It should be noted that, although we fixed the uncertainty levels and varied the agent parametrizations, an equivalent preference reversal can be achieved by varying the ambiguity levels while maintaining risk and the indices.

\section*{Conclusion}

In this paper, we proposed an agent model which combines the flexibility and generality of the BDI paradigm with a widely validated descriptive decision model, in order to capture decisions biases in the agent's deliberative process. The two test cases presented in the previous section showed how different parametrizations in agent's attitudes towards uncertainty have distinct behavioural consequences. A rational agent using EU, on the other hand, would always select the
same solution. Furthermore, by considering risk and ambiguity as separate constructs, we expect to better capture human decisions under uncertainty.

Although the modelled risk biases are well grounded on empirical evidence, the effects of ambiguity require further validation. In particular, the magnitude at which entropy causes an aversion effect in a decision context should be further studied, so that a more accurate expression can be used in the calculation of \(\delta^{A}\). We also expect to address the present limitations by possibly integrating a Bayesian Belief Network (Pearl, 1988), allowing for conditional dependences between variables, and using a planner capable of dealing with partially observable domains (eg. Peot \& Smith, 1992), in order to drop the static propositions assumption. Finally, we consider accounting for framing effects as an important step in achieving more realistic decision behaviours, and the ideas behind the CBU model (Ito \& Marsella, 2011) are certainty worth exploring.

\title{
A Computational Framework for Attentional 3D Object Detection
}

\author{

}

\begin{abstract}
We present a computational framework for the detection of unknown objects in a 3D environment. It is based on a visual attention system that detects proto-objects which are improved by iterative segmentation steps. At the same time a 3D scene model is built from measurements of a depth camera. The detected proto-objects are projected into the 3D scene, resulting in 3D object models which are incrementally updated. Finally, environment- and object-based inhibition of return enables to withdraw the attention from one object and switch to the next. We show that the system works well in cluttered natural scenes and can find and segment objects without prior knowledge.
\end{abstract}

\section*{INTRODUCTION}

Object detection is one of the tasks which are easy to solve for humans but hard for machines. Especially unsupervised object detection, i.e., finding all objects in a scene without previous learning, is largely unsolved in machine vision. \({ }^{1}\) However, a system that is able to localize unknown objects in unknown environments is tremendously useful for robotics. For example, a future robot that shall assist in a household must be able to operate autonomously in a new house and is permanently faced with new, unknown objects. Since humans are able to solve such tasks easily, a promising approach for technical systems is to mimic the human visual system. \({ }^{2}\)

In humans as in machines, one of the challenges is to deal with the huge amount of perceptual input. Despite the parallelity of the brain, its capacity is not sufficient to deal with all sensory data in detail and a selection has to take place. Neisser (1967) was the first who proposed a twostage processing of perception that solves this task: first, a pre-attentive process selects regions of interest in parallel, and, second, an attentive process investigates these regions sequentially in more detail. This view has since then widely spread and many psychological theories and models build upon this dichotomy (e.g. Treisman \& Gelade, 1980; Wolfe, 1994). Rensink (2000) has further developed this idea with his coherence theory of attention. It states that the pre-attentive processing determines structures, which he calls proto-objects, that describe the local scene structure of a spatially limited region. After that, focused attention selects a small number of proto-objects which form a coherence field representing a specific object.

Here, we present a computational framework that follows Rensink's idea of proto-objects as pre-processing step for object detection. Our approach generates proto-objects with a

\footnotetext{
\({ }^{1}\) The winner of the latest Semantic Robot Vision Challenge (http://www.semantic-robot-vision-challenge.org) was only able to detect 13 out of 20 objects (Meger et al., 2010), although in this challenge, the target objects were known in advance.
\({ }^{2}\) However, note that our intention is to obtain an improved technical system rather than to mimic the HVS as closely as possible.
}
bottom-up visual attention system (Klein \& Frintrop, 2012) and improves their shape by iterative segmentation steps. In contrast to other attention models, we operate on 3D data from a depth camera and are thus able to obtain 3D object models in space, which are incrementally updated by integrating new perceptual data.

In computational systems based on bottom-up visual attention, the focus of attention is directed to the most salient region in the scene. In order to scan the whole scene, this requires a way to withdraw attention from that region and switch to the next. In human vision, this is performed by inhibition of return mechanisms (IOR) that inhibit the currently attended region (Tipper et al., 1994).

In most computational systems, IOR is implemented by zeroing values in the saliency map (Itti et al., 1998). This is sufficient in static images, but when acting in a 3D world, the correspondence between spatial locations and image regions is required. This affects also the IOR mechanism, since when the perspective of the observer changes or objects are moving, inhibition has to move with them, preventing attention to re-visit the objects directly. This motivates the use of a 3D map that grounds the perceptions in space and enables to maintain a coherent IOR representation over space and time. Corresponding to human vision (Tipper et al., 1994), our IOR mechanism is both object- and environment-based.

The contributions of this paper are threefold. First, instead of operating on 2D images, we perform attention-based object detection on 3D data; this enables us to situate the attention system in a 3D environment, resulting in a coherent representation of objects over time. Secondly, it allows for performing not only an environment-based but also an objectbased inhibition of return mechanism that operates in space and time. Finally, the use of salient blobs instead of only fixation points for initializing the segmentation process lets us bound the amount of perceptual data to be processed.

\section*{Related Work}

Many computational attention systems have been built during the last two decades, first for the purpose of mimicking and understanding the human visual system (survey in Heinke \& Humphreys, 2004), and second to improve technical systems in terms of speed and quality (survey in Frintrop et al., 2010). The general structure of attention systems is based on psychological models such as the Feature Integration Theory (Treisman \& Gelade, 1980) and states that features are computed in parallel before they are fused to a saliency map.

One component of attention systems is the inhibition of return mechanism. While IOR is simple on static images, image sequences introduce the challenge of establishing correspon-

Figure 1: System Overview. The RGB-D camera provides color and depth streams that are processed to obtain proto-objects and a 3D representation of the scene. Here, one proto-object is fixated (1), segmented (2), and projected to the 3D scene (3). The inhibition (5) did not yet take place.
dences between objects over time. In this context, Backer et al. (2001) perform object-centered IOR. However, their approach operates on simple artificially rendered scenes instead of real world data and on 2D images instead of 3D data as we do. Additionally, we combine object-centered and environment-centered IOR to enable both types of inhibition.

Walther and Koch (2006) use an attention system to obtain saliency maps and generate proto-objects inside this map by thresholding. Unsupervised object detection was also tackled by Kootstra and Kragic (2011) who produce saliency maps with a symmetry-based attention system. They use the most salient points as hypothetical centers of objects; these are then provided as seeds to the segmentation process. The figural goodness of the segmentations is evaluated by Gestalt principles. In a robotics context, Meger et al. (2010) search for objects with the mobile robot "Curious George". The robot used a peripheral vision system to identify object candidates with help of a visual attention module. Then, close-up views of these candidates were recorded with a foveal vision system and investigated by a recognition module to identify the object.

\section*{General Structure}

A general overview of the system is depicted in Figure 1. We acquire data with a depth camera that provides color as well as depth information, and is moved around the scene to obtain different viewpoints. The color and the depth information are investigated in two separate processing streams. The color stream determines proto-objects with help of a bottom-up visual attention system (Fig. 1, top), while the depth stream generates a 3D map of the scene (Fig. 1, bottom). The two streams are combined by projecting the proto-objects into the 3D scene. This results in 3D object models that are incrementally updated when new camera frames are available.

The system operates in two behaviors: the saccade behav-
ior and the fixate behavior. When the system starts, it first finds the most salient proto-object (1. in Fig. 1), which is then attended for several frames (fixate behavior), allowing other modules to improve the shape of the attended proto-object by segmentation (2.) and project it to the 3D scene (3.). After fixating an object for a while, the saccade behavior takes over to determine the next focus of attention. This is enabled by object-based and environment-based inhibition of return mechanisms (4.), that inhibit the region of the segmented object \(O\) and the surrounding region \(A\). To maintain a coherent inhibition of return representation, even when moving the camera, the inhibition values are stored within the 3D map data. From its 3D representation, the data can be projected to produce a 2D IOR map (5.), that is used for inhibiting protoobjects in the saliency map. When the attended object is inhibited, a saccade to the next salient proto-object is generated.

\section*{Proto-Object Detection}

We perform object detection in two steps: first, we detect proto-objects in each frame with a visual attention system and second, the extend of the proto-objects is improved by a segmentation step.

\section*{Attention System: Generation of Proto-Objects}

The first step of object detection is the generation of protoobjects with a visual attention system that mimics the preattentive processing stage of the human visual system. Such systems usually investigate several feature channels such as color and orientation in parallel and finally fuse the resulting conspicuities in a single saliency map (Frintrop et al., 2010). The peaks in the saliency map can be interpreted as proto-objects (e.g. Walther \& Koch, 2006). While in human attention, top-down factors also play an important role, such information is not always available in robotics. Therefore, we compute here only the bottom-up attention.

Figure 2: Top left to bottom right: original RGB image; its corresponding saliency map \(S M\); saliency map after adaptive thresholding \(S M^{\prime}\); the \(S M^{\prime \prime}\) map after the final thresholding.

In this work, we use the CoDi system to compute saliency maps (Klein \& Frintrop, 2012). The structure follows the standard architecture of Itti et al. (1998), consisting of intensity, color, and orientation feature channels which belong to the most important features in the human visual system (Wolfe \& Horowitz, 2004). In contrast to other saliency systems, the center-surround contrast is computed with respect to feature distributions; these are approximated by Normal distributions and their distance is quickly computed by the \(W_{2}\) distance (Wasserstein metric based on the Euclidean norm).

To allow the detection of arbitrarily sized salient regions, we perform the computations on 8 different scales. The color channel consists of a red-green and a blue-yellow channel, following the opponent-process theory of human color vision (Hurvich \& Jameson, 1957). The orientation channel computes center surround differences of Gabor filters of four different orientations: \(0^{\circ}, 45^{\circ}, 90^{\circ}, 135^{\circ}\). The saliency map \(S M\) is the result of fusing the color and orientation channels.

To generate the image blobs that correspond to protoobjects, two thresholding operations are performed: first an adaptive thresholding using a Gaussian kernel \({ }^{3}\)
\[
S M^{\prime}(x, y)= \begin{cases}S M(x, y) & : S M(x, y)>T(x, y)  \tag{1}\\ 0 & : \text { otherwise }\end{cases}
\]
where \(T(x, y)\) is the weighted mean of the neighborhood of \((x, y)\). Finally, a binary thresholding is performed on \(S M^{\prime}\) at a percentage of the global maximum saliency value MAX:
\[
S M^{\prime \prime}(x, y)= \begin{cases}S M^{\prime}(x, y) & : S M^{\prime}(x, y)>0.3 \times M A X  \tag{2}\\ 0 & : \text { otherwise }\end{cases}
\]

Fig. 2 shows the saliency map \(S M\) and the thresholded maps \(S M^{\prime}\) and \(S M^{\prime \prime}\) for an example image. On \(S M^{\prime \prime}\) we find the connected components (proto-objects) and compute their average saliency \(\overline{\text { sal }}\). This method provides us with salient blobs instead of only fixation points which determines the center of

\footnotetext{
\({ }^{3}\) We use the adaptiveThreshold function of the OpenCV library: http://opencv.org/
}
fixation as well as the size of the region to use for further investigation. Too small or too big blobs are discarded. If information for the inhibition of objects is already available in terms of a 2D IOR map \(I\) (see below), it is used to inhibit already visited regions. This is done by computing the overlap \(o\) between each blob and \(I\). Finally, the proto-object with the highest value \(\overline{s a l} *(1-o)\) is attended.

Thus, the computational attention system fulfills its two main purposes: first, it directs attention to a region of interest and, second, it bounds the amount of perceptual data to be processed afterwards while ignoring the rest.

\section*{Improving Proto-Objects by Segmentation}

After finding proto-objects, we improve their shape by a segmentation step that bundles parts of the image data. This has a similar effect as grouping mechanisms in human perception that facilitate figure-ground segregation (Wagemans et al., 2012). Such segmentation steps are likely to exist at all levels of human visual processing (Scholl, 2001).

Here, we use the approved GrabCut segmentation (Rother et al., 2004) that was originally proposed for segmenting objects in images with help of user interaction. It takes a rectangle as input, as well as an initialization of pixels with their likelihoods of being object or background. Segmentation is based on the color similarity of neighboring pixels, thus regarding two of the most important factors of perceptual grouping (similarity and proximity). GrabCut performs foreground/background segmentation by iteratively minimizing an energy function. The energy function measures how different each pixel is from the foreground/background model to which it is assigned, as well as from its direct neighbors. It penalizes pixels different from the foreground model to be labeled as foreground as well as labeling pixels as foreground when all its neighbors are background.

The rectangle required for initialization is determined automatically with help of the proto-objects and the information about already detected objects. The pixels of the currently attended proto-object are merged with the information of this object from previous frames (if available). This information can be gathered from the 3D scene representation raycasted to a 2D object map that will be explained later on (cf. Fig. 1). Now, the smallest rectangle \(r\) containing all merged pixels is determined (cf. Fig. 4, top), as well as a rectangle \(r^{\prime}\), obtained by expanding \(r\) 's dimensions by \(10 \%\).

For initializing segmentation, GrabCut requires four possible pixel likelihood values: FG (foreground), BG (background), \(P R_{\_} F G\) (probably foreground) and \(P R_{-} B G\) (probably background). These are obtained by defining three intervals between 0 and the saliency maximum \(\max\) in \(R\) :
\[
L(x, y)= \begin{cases}F G & : S M^{\prime \prime}(x, y) \in\left[v_{3}, \max \right],(x, y) \in R  \tag{3}\\ P R_{-} F G & : S M^{\prime \prime}(x, y) \in\left[v_{1}, v_{3}\right],(x, y) \in R \\ P R_{\_} B G & : S M^{\prime \prime}(x, y) \in\left[0, v_{1}\right],(x, y) \in R \\ B G & :(x, y) \in R^{\prime} \backslash R,\end{cases}
\]
where \(R\) and \(R^{\prime}\) are the sets of pixels contained in rectangles \(r\)

Figure 3: Top: a book as example object. Middle: initialization of GrabCut, the grayscale values correspond to the four possible likelihoods \(F G\) (white), \(P R_{-} F G\) (light gray), \(P R_{\perp} B G\) (dark gray), and \(B G\) (black). Bottom: the segmentation result.
and \(r^{\prime}\) respectively, and \(v_{i}=i \cdot \frac{\max }{4}\) defines each of the interval limits. The likelihoods are corrected by incorporating the information about the current and all other objects. This is done by setting the pixels that correspond to the current object in the 2D object map as \(P R \_F G\), and the ones corresponding to other objects as \(B G\). An example of the initialization values is displayed in Fig. 3. Five iterations of GrabCut produce a binary object mask \(O\) for the attended blob.

\section*{Creating a 3D Scene Map}

While the color image was used to detect proto-objects, the depth data is used to build a 3D map of the scene. This is done with the KinectFusion algorithm \({ }^{4}\) (Newcombe et al., 2011), which builds a 3D map of the environment by integrating multiple range scans from a moving depth camera such as Kinect. It performs two processes in parallel, namely, tracking of the pose of the camera, and registration of the depth scans into a complete scene representation. The result is a 3D scene map consisting of voxels (cf. Fig. 5, right).

To represent the scene at time \(k\), a global truncated signed distance function (TSDF) \(S_{k}(p) \rightarrow\left[F_{k}(p), W_{k}(p)\right]\) is computed by integrating the depth measurements, where \(p \in \mathbb{R}^{3}\) is a point in space, \(F_{k}(p)\) the TSDF value and \(W_{k}(p)\) a weight. The function is discretized in a voxel grid; its zero crossings are points that lie on surfaces. Thus, from the voxel grid, a point cloud can be rendered by choosing the voxels containing zero TSDF values.

\section*{Extended 3D Scene Map}

Our system stores all object information in a 3D structure. It is an extended version of the voxel grid defined in the previous section. For convenience, we will refer to the new voxel grid as \(S_{k}[c]\), where voxel \(c=(x, y, z), x, y, z \in[1 . . V o l]\) and Vol is the number of cells into which the grid is discretized. We extend the \(S_{k}\) function to
\[
\begin{equation*}
S_{k}[c] \rightarrow\left\{F_{k}[c], W_{k}[c], L_{k}[c], L W_{k}[c], I_{k}[c], I W_{k}[c]\right\} \tag{4}
\end{equation*}
\]
where \(F_{k}[c]\) and \(W_{k}[c]\) are the values defined before, \(L_{k}[c], L W_{k}[c]\) are variables that contain object label information, and \(I_{k}[c], I W_{k}[c]\) are IOR related and will be explained

\footnotetext{
\({ }^{4}\) We use the open source implementation available in the Point Cloud Library (http://pointclouds.org/)
}
later on. The 3D information from the voxel grid can at any time be projected to produce a 2 D image containing IOR or object label information (details follow). \({ }^{5}\)

\section*{Generating 3D Object Models}

Now, the 3D object models are created and updated using the binary object mask \(O\) from the segmentation stage. Let us denote the function that maps pixels in the image to voxels in the grid as map : \(p \in \mathbb{Z}^{2}, T \in \mathbb{R}^{4}, D \in \mathbb{Z}^{m \times n} \rightarrow c \in \mathbb{Z}^{3}\), where \(p\) is a pixel, \(T\) the camera pose, and \(D\) a depth image with dimensions \(m \times n\). The pixels in the object mask are mapped to their corresponding voxels in the grid:
\[
\begin{equation*}
\operatorname{map}\left(O, T_{g, k}, D_{k}\right) \rightarrow O^{\prime}=\left\{c: c \in \mathbb{Z}^{3}\right\} \tag{5}
\end{equation*}
\]
where \(g\) is the global frame of reference.
Now it has to be decided which label to assign to the voxels in \(O^{\prime}\). There are two mechanisms corresponding to the fixate and saccade behaviors of the system. During the fixate behavior, the label of the currently attended object is used. When the saccade behavior selects a new focus of attention, it performs as follows. On the set of voxels \(O^{\prime}\) corresponding to the new proto-object, we extract the current labels \(>0\) : \(L a b=\left\{L_{k}[c]: L_{k}[c]>0, c \in O^{\prime}\right\}\). We find the most frequently occurring label \(l\) in \(L a b\). If less than \(5 \%\) of the voxels are labeled, we assign \(l\) a new value corresponding to a newly detected object. The value of \(l\) is now used to update the voxels contained in \(O^{\prime}\). This simple scheme lets us integrate the overlapping segmentations of different views of the same objects in the 3D map.

To be flexible against wrong segmentations or overlapping objects, weights are assigned to the labels. Every time the same label is assigned to a voxel, its label weight \(L W_{k}\) is incremented. If a voxel is updated with a different label, the weight is decremented. Eventually it could reach 0, resulting in an unlabeled voxel. This mechanism lets us incrementally build the object representations with a certain tolerance to failure; furthermore, by thresholding the label weight we can specify the degree of confidence in our object representations that we want for rendering the labeled point cloud. In our experiments, we used \(L W_{k}=5\), meaning that a voxel has to be assigned to a specific object at least 5 times to be considered for this object.

\section*{3D IOR Map}

After fixating an object for several frames, the object must be inhibited to enable the next saccade. To allow a coherent IOR over time, we store the inhibition values within the 3D voxel grid: \(I_{k}[c]\) is a binary flag denoting whether that voxel shall be inhibited and \(I W_{k}[c]\) is a weight that determines how long the effect shall take place. Having IOR information in 3D coordinates lets us generate 2D IOR maps \(I_{k}\) from the required camera poses throughout the sequence.

\footnotetext{
\({ }^{5}\) In (Newcombe et al., 2011), the TSDF function is raycasted, given a camera pose, to generate a depth map prediction. Using this method in our extended TSDF function means we can generate 2D IOR or object label maps for every new pose of the camera.
}

Figure 4: Table Top sequence at different points in time (columns). From top to bottom: (i) image of the scene with currently attended object (blue rectangle); (ii) the saliency map and the segmented part from the currently attended object; (iii) inhibition of return maps; white: object-based IOR, gray: environment-based IOR; (iv) the 3D scene map including detected objects

According to human vision, we use two types of IOR mechanisms: environment-based and object-based IOR (Tipper et al., 1994). The latter comes intuitively from the segmented object mask \(O\). The environment-based IOR is initialized by the regions close to the object but not on the object, i.e., from a so called attended mask \(A=R^{\prime} \backslash O\). The two masks are mapped as in the previous section to obtain their respective voxel sets \(O^{\prime}\) and \(A^{\prime}\). For every voxel \(c\) in \(O^{\prime}\) and \(A^{\prime}\), its weight \(I W_{k}[c]\) is incremented. When it reaches a certain threshold, the IOR flag \(I_{k}[c]\) is activated. The weight of all not considered voxels is decremented. If a weight eventually reaches 0 , the IOR flag is reset to 0 as well.

\section*{Evaluation}

To evaluate our system we recorded two video sequences in an office environment with an RGB-D camera that provides depth as well as color information. The first sequence shows a setting of objects on a table top (cf. Fig. 4). The complexity of this setting corresponds to the complexity of scenes in current state of the art benchmarks and papers on unsupervised object detection in machine vision (cf. Meger et al., 2010; Kootstra \& Kragic, 2011). However, the real world can be much more complex. Therefore, we recorded a second sequence, that shows a very cluttered setting (Fig. 5). Both settings were recorded turning the camera so that the scene was observed from different viewpoints (cf. Fig. 1). \({ }^{6}\)

Fig. 4 illustrates several steps of our approach at different time points. First, the book was attended (fixate behavior).

\footnotetext{
\({ }^{6}\) Videos of the complete sequences as well as the resulting 3D representations can be found at http://vimeo.com/cogbonn/
}

After fixating it for several frames, the region is inhibited (3rd row) and the attention switches to the next proto-object (saccade behavior). This proto-object consists of two real objects (cup and tea box) since these objects are overlapping from this point of view and have similar saliency. The procedure continues, until all objects on the table have been detected.

For the second sequence, we present for space reasons only the resulting 3D map with detected objects (Fig. 5, right). Here, the approach finds 19 objects after 438 frames ( \(\sim 13\) sec ). More objects could be found by longer observing the sequence, but some would be missed, e.g., due to high similarity to the background, and no current computer vision system would be able to find all objects without pre-knowledge in such a complex setting. Note that several of the "objects" still have proto-object characteristics, meaning that they show parts of objects (handle of dishwashing brush (6), bottom of coffee machine (18)) or clusters of objects (tea boxes (11)). Such semantic ambiguities could only be resolved by a recognition system that investigates the attended regions in more detail, or by a robot that interacts with objects and decides on objectness depending on the connectivity of object parts.

To evaluate our system quantitatively, we measure how precisely the detected objects were segmented. For this, the points in the 3D map corresponding to objects were manually labeled to serve as ground truth. We generally denote the ground truth of each object as \(G\), and the 3D points of the object detected by our system as \(S\). We measure the precision \(p\) and recall \(r\) of the detected objects with respect to the ground truth as \(p=(S \cap G) / S\), and \(r=(S \cap G) / G\). The values are shown in Tab. 1 and Fig. 5. It can be seen that the

\begin{tabular}{|l||l|l|l|l|l|l|l|l|l|l|}
\hline object & \(\mathbf{1}\) & \(\mathbf{2}\) & \(\mathbf{3}\) & \(\mathbf{4}\) & \(\mathbf{5}\) & \(\mathbf{6}\) & \(\mathbf{7}\) & \(\mathbf{8}\) & \(\mathbf{9}\) & \(\mathbf{1 0}\) \\

\end{tabular}

Table 1: Table Top sequence: precision/recall values in \% (cf. Fig. 4).
precision values are mostly very good (more than \(90 \%\) for 17 out of 25 objects), that means that only few voxels were accidentally assigned to an object. A bad value usually indicates that a cluster of objects was detected and compared with separate objects in the ground truth (e.g. objects 5 and 11). The recall values are lower, meaning that often not all of the voxels that belong to an object were detected. In the future, this can be improved by additional post-processing steps based on grouping mechanisms for figure-ground segregation.

\section*{Conclusion}

We have presented a flexible framework for the detection of unknown objects in a 3D scene. Unlike other approaches, the system uses depth values additionally to a color image of a scene and is thus able to generate 3D object models that are incrementally updated when new information is available. All perceptual data is spatially grounded and thus consistent over different viewpoints. The results show that the algorithm is able to detect many objects in scenes with high clutter, without using any prior knowledge about the type of objects.

Applying attention mechanisms in space and time introduces new challenges, for example the question of how and when to switch attention between salient regions. We introduced an environment- and object-based inhibition of return mechanism that addresses this problem by using the information from the 3D environment and object models for inhibition.

\title{
Effect of Positive and Negative Instances on Rule Discovery: Investigation Using Eye Tracking
}

\begin{abstract}
This study investigates how participants reject an initial rule when they face positive and negative instances of an initial rule. Using eye movement data, we analyzed a perspective that indicated the type of rules that participants consider. The results show that, only in negative instances, participants considered rules from the perspective that they used for finding and confirming the initial rule. We concluded that, when participants face negative instances, they tried to change the initial rule peripherally to explain them. This appeared in the form of a longer consideration from an initial perspective in negative instances.

\section*{Introduction}

Finding regularities is one of the most important activities not only in science but also in many aspects of daily life. People can find regularities in their daily experiences or observed data and use them for predictions and decision making. However, if a rule that they find at first (i.e., an initial rule) is incorrect, they need to reject it on the basis of their observed data and start considering a new one. We focus on such a situation, specifically one in which people face negative evidence to the initial rule. In particular, we investigate the period in which both positive and negative instances appear.

The process of finding and rejecting the initial rule consists of the following three phases. The first phase is the "initial phase" in which participants find and use the initial rule. In this phase, participants always observe positive instances. Our study focuses on the second phase called the "transition phase." In this phase, participants face both positive and negative instances. The third phase, the "post-transition phase," follows the transition phase, and it includes the time in which participants try to find a rule that is valid for all instances. Almost all instances in this phase are negative to the initial rule; hence, the initial rule is absolutely rejected.

\section*{Perspective and Eye Tracking}

Using a relatively easy rule discovery task, such as Wason's 2-4-6 task, many researchers have shown that disconfirmation is effective to reject the initial rule (e.g., Wason, 1960). They obtained these results from analyses based on the best guess regarding the rule collected by verbal or written reports. However, this method does not reveal thoughts before participants reveal their best guess. This period contains many "unexpressed thoughts" that cannot be reflected in the best guess, such as thoughts that are abandoned before they become obvious rules or that do not yet reach obvious rules. Compared with other phases, it is difficult to make one's thoughts into
the form of a rule in the transition phase; therefore, more unexpressed thoughts appear during this phase. Although unexpressed thoughts are crucial information regarding the process in the transition phase, a traditional analysis of verbal reports of the rule has difficulty in interpreting them because they do not take the form of a rule.

We use the following two new approaches to investigate unexpressed thoughts: the analysis of "perspective" and "eye tracking." The perspective constrains the type of rules that people consider. There are an incredible number of available rules; therefore, participants cannot simultaneously consider all rules. By deciding upon the perspective, participants consider only rules matching their perspective, which makes them able to consider an adequate number of rules. The perspective includes the function or role of rules and the factor used for rules. For example, Klahr and Dunbar (1988) represented hypotheses as frames and clustered them on the basis of the role of frames in scientific reasoning. Participants in their experiment considered the hypotheses in a cluster that had an identical role in their mind. The information provided by the analysis of the perspective about the unexpressed thoughts in the transition phase is more useful than that provided by the analysis of the reported best guess.

Lien and Lin (2011) investigated the effects of perspective on rule discovery performance using Wason's 2-4-6 task. They found that participants who could discover the rule changed their perspective more frequently than those who could not. However, they analyzed only the reported rules, which have a problem as mentioned above. Haverty, Koedinger, Klahr, and Alibali (2000) showed that the crucial factor for rule discovery was the ability to judge which type of rules participants should pursue, that is, which perspective they should use. The protocol analysis used in their study has been used in many preceding studies on rule discovery. Although it provides a detailed process of rule discovery, it still has two problems for the purpose of this study.

The first problem is that participants mention only their conscious thoughts. The verbal protocol cannot always capture unexpressed thoughts because participants are not always conscious of them. The second problem is that protocol data is coarse-grained on the time scale. In general, the speed of thinking is faster and more fluent than that of verbalization. In the transition phase, short thoughts that come and go in the mind appear frequently. Such short thoughts are difficult to put into words. For these reasons, we use eye tracking, which continuously gives more fine-grained data. Recently, eye movement data has been utilized in many studies, such as
category learning and insight problem solving, and has produced good results (e.g., Knoblich, Ohlsson, \& Raney, 2001; Rehder \& Hoffman, 2005).

\section*{Hypotheses}

We define a perspective needed to find an initial rule as an "initial perspective." The hypotheses in this study are as follows. First, in the initial phase, participants mainly consider rules from the initial perspective. The preceding studies on category learning showed that once participants learned a rule, they focused only on the relevant features and ignored irrelevant features (e.g., Rehder \& Hoffman, 2005). Similarly, once participants found a valid rule (i.e., an initial rule), they focused only on the relevant perspective (i.e., the initial perspective) and ignored irrelevant perspectives.

The transition phase has the following two hypotheses: the "shift hypothesis" and "retain hypothesis." In the shift hypothesis, we predict that participants will shift their focus from the initial perspective to other perspectives as soon as they face only one negative instance. According to Popper, a hypothesis can be normatively falsified by just one negative instance. Using Wason's 2-4-6 task, many studies have shown that one disconfirmation is enough to reject the initial rule. If the shift hypothesis is supported, participants will consider rules from the initial perspective to be the same as or shorter than those from other perspectives in the transition phase. The second retain hypothesis suggests that focus on the initial perspective will be retained. In this case, participants will continue to consider rules from the initial perspective rather than those from other perspectives in the transition phase.

There are two possible explanations for retaining consideration from the initial perspective. First, participants use the initial perspective for peripheral changes of the initial rule in order to adapt it to negative instances; for example, to add an additional or exceptional rule. Chinn and Brewer (1993) showed that participants were likely to hold onto their theories by reinterpreting data, using the peripheral theory change, and so on. In addition, Dunbar (1995) demonstrated that participants did not often change their hypotheses even if they faced inconsistent evidence. The second explanation is based on attentional learning. The attentional learning model (e.g., EXIT; Kruschke, 2003) explains eye movement data in category learning according to the following process. First, participants learn the relevant features that should be focused on and irrelevant features that should be ignored. Positive feedback to their learned rule reinforces their focus on the learned features. On the other hand, if they face negative feedback, they shift their focus from the learned relevant features to other features. On the basis of this model, the participants in this study would also shift their focus from the learned initial perspective to other perspectives when they face negative instances. In contrast, when they face positive instances, they again focus on the initial perspective; as a result, consideration from the initial perspective is observed.

We can judge which explanation is accepted from how par-
ticipants consider rules in each negative and positive instance. If the "peripheral change" explanation is accepted, participants consider rules from the initial perspective when they face negative rather than positive instances. The initial rule is not valid in negative instances; therefore, participants need to consider modified rules from the initial perspective to improve the initial rule. On the other hand, when participants observe positive instances in which the initial rule is valid, they do not need much consideration from the initial perspective. If the "attentional learning" explanation is accepted, participants consider rules from the initial perspective when they face positive rather than negative instances. Observing positive instances reinforces the focus on the initial perspective because the initial rule is valid in these instances. On the other hand, negative instances shift participant's focus from the initial perspective to other perspectives.

\section*{Task}

We created a new rule discovery task in which a fixation area and perspective correspond. Figure 1 shows an example screenshot of the task display corresponding to one instance. One instance consists of three panels (arrow, compass, and number) and eight letters (a-h) in the center of the display. These eight letters were arranged in a circle with letter \(a\) taking the 12 o'clock position. One of these letters was displayed in each instance (we call it the "target letter"). Participants were asked to find a rule determining which panel related to the target letter and how the objects in the related panel determined it through observations of some instances. We told them in advance that only one of the three panels was related to the target letter and that the other two panels had no relationship.

We gave a different function to each of the three panels. In the number panel, two numbers from 1 to 4 were displayed. Each number indicated the order of each letter, such as 1 was \(a\) and 2 was \(b\). In the arrow panel, two circular arrows from \(45,90,135\), and \(180^{\circ}\) were displayed. The angle of each arrow indicated the degree of a rotation from the starting letter

Figure 1: Example screenshot of the task display used in this study.
to certain letter. For instance, if the participant set \(a\) as a starting point, a \(45^{\circ}\) arrow indicated \(b\) and a \(90^{\circ}\) arrow indicated \(c\). In the compass panel, two directions from north, east, south, and west were displayed in Chinese characters. Each direction of the compass panel indicated the direction on a map, that is, north was the upper one \((a)\) and south was the lower one (e). The objects within each panel were allowed to be combined. Each panel with a different function corresponded to a different perspective; therefore, the observation times of each panel corresponded to the amount of investigation from each perspective.

We prepared two rules that determined the relationship between the target letter and panel. One was the "initial rule" discovered in the initial phase. In this rule, the target letter is the letter moved from \(a\) by a sum of the angles of two arrows on the arrow panel. For example, when the arrows are at 135 and \(180^{\circ}\) (Figure 1), the target letter \(h\) is identified by moving from \(a\) (at 12 O'clock) by the sum of the two arrows' angles \(\left(135+180=315^{\circ}\right)\). The other rule is the "target rule" that is valid throughout the task. In this rule, the target letter is the letter in the opposite (replace north with south) position to the position of the letter indicated by a combination of two directions on the compass panel. For example, with west and south directions (Figure 1), the target letter \(h\) 's position was indicated by combining two directions (west and south \(=\) south-west) and then replacing south with north (north-west). The initial perspective needed to find the initial rule was the arrow perspective, and the target perspective needed to find the target rule was the compass perspective.

The task consisted of eleven blocks. A block consisted of five observations of an instance and four tests. In an observation, participants considered rules by observing such an instance, as exemplified in Figure 1. By clicking on the NEXT button or after a certain number of seconds, the next instance was presented. Participants were not permitted to return to prior instances. After observing five instances, participants announced the rule which they found and then started the test. In the test display, three panels and the buttons of each of the eight letters were presented. Participants predicted the target letter and selected the button of the letter. The next problem was presented by clicking on the button or after 15 sec . Four problems were conducted in total.

We separated eleven blocks into the following three phases: the first four blocks were the initial phase, the next three blocks were the transition phase, and the final four blocks were the post-transition phase. In the initial phase, only positive instances that supported both the initial and target rules were presented. All participants were expected to find the initial rule and focus on the initial perspective. In the transition phase, both the positive and negative instances to the initial rule are presented, whereas the target rule is valid in all these instances. In the post-transition phase, all instances were positive to the target rule and negative to the initial rule. In this phase, we expected that participants would try to find the target rule. All participants completed eleven blocks, even
if they found the target rule.

\section*{Predictions}

On the basis of our hypotheses, we made the following predictions. First, in the initial phase, the observation time of the arrow panel corresponding to the initial perspective would be longer than those of the other panels. In the transition phase, we expected different result for each hypothesis. If the shift hypothesis was approved, the difference of the observation time between the three panels would disappear. If the retain hypothesis was approved, the observation time of the arrow panel would be longer than those of the other panels. Furthermore, when the retain hypothesis was supported, there were two predictions based on the two explanations for observations of the difference. The prediction derived from the peripheral change explanation was that the tendency of the longer observation time of the arrow panel is more significant in negative instances than that in positive instances. On the other hand, if the attentional learning explanation is accepted, the tendency of the longer observation time of the arrow panel is more significant in positive instances than that in negative instances.

\section*{Experiment 1}

Hereafter, when we mentioned the positive and negative instances, they were defined according to the initial rule. The primary purpose of Experiment 1 was to confirm that the initial rule was rejected progressively in the transition phase, as expected. For this purpose, we compared two types of conditions: one "divided" condition in which the transition phase was removed, and two "mixed" conditions in which the transition phase was conducted as explained in the task section. The second purpose was to investigate whether the more negative instances the participants were given, the faster they rejected the initial rule in the transition phase. For this purpose, we manipulated the ratio of negative instances in the transition phase in the two mixed conditions.

In the divided condition, to remove the transition phase, the post-transition phase followed immediately after the initial phase; namely, after the initial phase ended, all presented instances switched into negative. This manipulation was predicted to make participants reject the initial rule drastically after the initial phase because there was no transition phase in which both positive and negative instances were presented. On the other hand, in the two mixed conditions, the initial rule was rejected progressively in the transition phase. The two mixed conditions consisted of a "mixed-increase" condition in which the ratio of negative instances increased in the transition phase and a "mixed-few" condition in which one negative instance appeared in a block. If the ratio of negative instances affects the timing of rejecting the initial rule, the rejection in the mixed-few condition would occur slower than that in the mixed-increase condition.

\section*{Method}

Participants Ninety undergraduates participated in Experiment 1. Each participant was assigned to one of the three conditions.

Task and Procedure We manipulated the amount of negative instances in blocks 5, 6, and 7. In the divided condition, only negative instances were presented after the second trial of block 5. The number of negative instances increased from one to three in the mixed-increase condition and was always one at each block in the mixed-few condition. Before the second trial in block 5, all instances were positive in all conditions. The maximum observation time of each instance was 35 sec .

The rule discovery task was conducted one at a time in a classroom. Each participant engaged in the task individually at his or her own pace using a computer terminal. Before starting the task, participants were instructed about the task and learned the functions of each panel through practice. Participants used a keyboard to describe the rule they found.

\section*{Results}

Seven participants who did not follow the instructions were excluded from analyses. We categorized the reported rules in each block into the following three categories: the initial rule, the target rule, and others or none. In Experiment 1, we focused on the rejection of the initial rule; therefore, we analyzed the discoverer of the initial rule who described only the initial rule in blocks 3 and 4. Twenty-four non-discoverers were excluded from analyses. The data of 24 participants in the divided condition, 12 participants in the mixed-increase condition, and 22 participants in the mixed-few condition were used for analyses.

Figure 2 shows the ratio of participants in each condition whose reported rule was categorized in the initial rule in each block. As expected, in the divided condition, a drastic decline was observed in block 5 . Only two participants ( \(9.09 \%\) ) stated the initial rule in block 5 and none stated it in blocks 6 and 7. The rejection of the initial rule was slower in the two mixed conditions than that in the divided condition. The ratio of participants who stated the initial rule in block 5 was high and nearly the same in the mixed-increase condition ( \(91.66 \%\) ) and mixed-few condition ( \(86.36 \%\) ). In block 6, this ratio was

Figure 2: Ratio of participants in each condition whose reported rule was categorized in the initial rule in each block.
moderately lower in the mixed-increase condition (16.66\%) than that in the mixed-few condition \((31.81 \%)\). More than \(15 \%\) of participants kept the initial rule in block 7 in both conditions.

The same result was observed in the tests. The use of the initial rule to identify the target letter decreased more slowly in the two mixed conditions than that in the divided condition. The ratio of participants who stated the target rule started increasing in block 5 and reached around \(50 \%\) in block 11 . There was no difference in the three conditions.

\section*{Discussion}

In the results of Experiment 1, we observed a drastic decline in the number of participants who identified the initial rule only in the divided condition. This means that, when only negative instances were presented after a certain point, the initial rule was rejected without taking any time to consider it. In contrast, we observed progressive declines in the two mixed conditions. These results support our prediction that, in the transition phase in which both positive and negative instances were presented, participants would reject the initial rule progressively, considering whether they should reject it. Participants in the mixed-few condition tended to reject the initial rule more slowly than those in the mixed-increase condition. This means that the more negative instances participants were given, the faster they rejected the initial rule. The results of Experiment 1 show the validity of our task.

\section*{Experiment 2}

The purpose of Experiment 2 was to investigate how participants considered rules from each perspective in the transition phase using the task used in Experiment 1. Using eye movement data, we tested the two hypotheses: the shift and retain hypotheses.

\section*{Method}

Participants Twenty undergraduates participated in Experiment 2.

Task and Apparatus We conducted the rule discovery task two times, identified as task 1 and task 2. Task 1 consisted of three blocks and had no rule, and the combinations of the objects on each panel and the target letter in the task were randomly created. The purpose of task 1 was to confirm that there was no inherent difference between the observation times of each panel. Task 2 had the same format as the mixed-increase condition in Experiment 1. The maximum observation time of each instance was 40 sec .

Participants' eye movements were recorded using a Tobii T60 eye tracker at 60 Hz . We presented the task display on a 17 -in monitor with a resolution of \(1280 \quad 1024\) pixels. Participants were seated approximately 60 cm away from the monitor. The size of visual angle on the panels was approximately \(7.57^{\circ} \quad 5.05^{\circ}\).

Procedure Experiment 2 was conducted individually. First, participants were instructed about the task and learned the

Figure 3: Ratio of participants who announced each rule.
functions of each panel through practice. Task 1 was conducted before task 2. Participants were asked to find the rule but were not instructed that there was no rule. The procedure for each task in Experiment 2 was the same as that in Experiment 1, except that the best guess of the rule was announced verbally. Before starting each block, a calibration for recording eye movement was performed. All eye movements throughout each task were recorded.

\section*{Results}

Four participants who did not discover the initial rule were excluded from analyses. Two participants whose eye movement data were not recorded more than \(50 \%\) of the time and one participant whose fixations on the lower panel were not recorded correctly were excluded from analyses.
Reported Rules Figure 3 shows the ratio of participants who announced the initial or target rule in each block. As observed in Experiment 1, the ratio of participants who announced the initial rule declined progressively from blocks 5 to 7. The ratio of participants who announced the target rule was also similar to that of Experiment 1: this number started increasing in block 5 before reaching \(46.15 \%\) in block 11 .
Eye Movement We calculated each participant's observation time of each panel. Then, we calculated the mean observation time of each panel in task 1, the initial phase, and the transition phase to investigate two hypotheses. We did not use the data in block 1 in which not all participants announced the initial rule for calculating the mean observation time in the initial phase. First, we conducted a one-way within subject ANOVA (panel: arrow, compass, and number) for the observation time in task 1 to confirm that there was no coherent difference between three panels. A significant main effect of the panel was not observed \((F(2,24)<1)\). This result means that the different contents of each panel or functions of rules did not affect observation time.

To investigate which hypothesis, the shift or retain hypothesis, was supported, we conducted a 2 (phase: initial and transition) 3 (panel: arrow, compass, and number) within subject ANOVA for mean observation times (Figure 4). The main effect of the phase factor \((F(1,12)=\) \(17.351, p=.001\) ) and the panel factor reached significance \((F(2,24)=13.174, p<.001)\). The interaction of the two factors was not significant \((F(2,24)<1)\). To confirm the difference in the observation times in each phase, we conducted a

Figure 4: Mean observation time of each panel in each phase of the task 2 (bars show standard errors).
planed one-way within subject ANOVA (panel: arrow, compass, and number) for the observation times of each phase. In both the initial and transition phases, a significant main effect of the panel factor was observed (initial: \(F(2,24)=\) 23.367, \(p<.001\); transition: \(F(2,24)=5.528, p=.011)\). We observed the same tendency in both phases. The observation time of the arrow panel was significantly longer than those of the compass panel (initial: \(p<.001\); transition: \(p=.059\) ) and the number panel (initial: \(p=.002\); transition: \(p=.045\) ). There was no significant difference between the observation times of the compass and number panels (both phases: \(p s=1.000\) ). These results support the retain hypothesis that participants focused on the initial perspective; therefore, we continued the analyses to examine two explanations for the retain hypothesis.

We calculated the observation times for each positive and negative instance in all instances from the second trial in block 5 to the fifth trial in block 7, i.e., the transition phase (Figure 5). We conducted a 2 (instance: positive and negative) 3 (panel: arrow, compass, and number) within subject ANOVA for the mean observation time. As a result, the interaction between the instance and panel factors reached significance \((F(2,24)=5.489, p=.011)\). The significant simple main effect of the panel factor was not observed in positive instances \((F(2,24)=1.723, p=.200)\). In contrast, in negative instances, the simple main effect of the panel factor was significant \((F(2,24)=7.123, p=.007)\). The observation time of the arrow panel was significantly longer than those of the compass panel marginally ( \(p=.067\) ) and the num-

Figure 5: Mean observation time of each panel for each positive and negative instance in the transition phase (bars show standard errors).
ber panel ( \(p=.016\) ). There was no significant difference between the observation times of the compass and number panels ( \(p=1.000\) ). The main effect of the instance factor \((F(1,12)=57.298, p<.001)\) and the panel factor reached significance \((F(2,24)=6.139, p=.007)\). The result that the participants considered rules from the initial perspective in negative instances rather than positive instances supports the peripheral change explanation.

\section*{Discussion}

In Experiment 2, we tested two hypotheses using eye movement data. In the initial phase, the results were consistent with our prediction: the observation time of the arrow panel was longer than those of the other panels. This means that the investigation from the initial perspective was conducted more often than that from other perspectives. This tendency was retained in the transition phase. This supports the retain hypothesis that focus on the initial perspective is retained if participants face negative instances. The analysis comparing the observation times in each positive and negative instance reveals that, although participants considered the rules to the same extent from all perspectives in positive instances, they considered rules from the initial perspective longer than those from other perspectives in negative instances. These results suggest that retained focus on the initial perspective is because of an attempt to improve the initial rule from the initial perspective when negative instances are given.

\section*{General Discussion}

In this study, we investigated the process of finding and rejecting an initial rule using eye movement data. We analyzed a perspective that indicated what types of rules participants considered. Our experiments yielded the following results: (1) In the initial phase in which only positive instances were given, participants focused on the initial perspective rather than other perspectives. (2) In the transition phase in which both positive and negative instances were given, participants retained a tendency to focus on the initial perspective. (3) The tendency to focus on the initial perspective was observed only when participants faced negative instances. On the basis of these results, we accept the retain hypothesis and the peripheral change explanation.

Participants' consideration of each rule from each perspective is out of the range of our study. We consider some possibilities about what participants were thinking from the initial perspective on the basis of the results of our experiments and the Chinn and Brewer's classifications (1993; Mason, 2001). The first possibility is that participants did not accept negative instances as valid, which corresponds to two of Chinn and Brewer's classifications: ignoring and rejecting. We can deny this possibility because we, as experimenters, guaranteed the validity of the instances. The second possibility is that participants did not try to explain negative instances, which corresponds with the categories of excluding and abeyance. If this possibility is true, the observation times of negative instances would be short; however, they were not. Furthermore, the
participants' task was to explain all instances. The third possibility is that they reinterpreted negative instances, which is Chinn and Brewer's category of reinterpreting. This possibility is rejected because interpretations other than those we provided regarding how to use the objects on each panel were not allowed.

The last two Chinn and Brewer's classifications are peripheral change and theory change, which, in this study, correspond to a peripheral change of the initial rule and a consideration of a whole new rule, respectively. For the following three reasons, it is most likely that participants tried to change the initial rule peripherally. First, in both experiments, many participants announced the initial rule in the transition phase. Second, the observation times of negative instances were longer than those of positive instances. Finally, there is normatively no benefit to focus on the initial perspective if participants consider a whole new rule. When participants kept the initial rule in their minds, they did not require much investigation from the initial perspective in positive instances. Consequently, a difference in the observation times from each perspective was not observed.

\begin{abstract}
The input to a cognitively plausible model of language acquisition must have the same information components and statistical properties as the child-directed speech. There are collections of child-directed utterances (e.g., CHILDES), but a realistic representation of their visual and semantic context is not available. We propose three quantitative measures for analyzing the statistical properties of a manually annotated sample of child-adult interaction videos, and compare these against the scene representations automatically generated from the same child-directed utterances, showing that these two datasets are significantly different. To address this problem, we propose an interaction-based framework for generating utterances and scenes based on the co-occurrence frequencies collected from the annotated videos, and show that the resulting interactionbased dataset is comparable to naturalistic data. We use an existing model of cross-situational word learning as a case study for comparing different datasets, and show that only interaction-based data preserve the learning task complexity.
\end{abstract}

Keywords: Child language acquisition; computational modeling; child-directed speech; cross-situational word learning.

\section*{Introduction}

A usage-based approach to language claims that natural languages in all their complexity can be learned merely from the input (or usage) data that is available to human learners. Computational modeling has been extensively used as a methodology for supporting this view: using a dataset that is statistically similar to child-directed input, a computational model can show that certain linguistic representations are learnable without domain-specific prior knowledge. Therefore, the input to a cognitively plausible model of language acquisition must have the same information components and statistical properties as the natural child-directed speech (CDS). A careful analysis and reconstruction of such data is a prerequisite of developing a model.

Recent decades have seen a significant growth in the variety and quantity of data collections for studying language. One major resource in this domain is CHILDES (MacWhinney, 2000), a collection of corpora containing recorded interactions of adults with children of different age and language groups. The interaction transcriptions have been used in several models of grammar induction from a large text corpus (e.g., Clark, 2001). The problem arises when a learning task demands perceptual and linguistic input. This
might be due to the nature of the process under study (e.g., learning the meaning of words) or the theoretical framework on which the model is based (e.g., construction grammar). In such cases, each utterance must be paired with a representation of its visual context. Many of the databases in CHILDES contain video recordings of the interaction sessions, but these recordings are mostly not annotated and hard to use without preprocessing or manual coding. Some models in fact use a small set of manually annotated videos as input (e.g., Yu \& Ballard, 2007; Frank, Tenenbaum, \& Fernald, 2013), but this approach is limited in quantity and scalability.

A common strategy for dealing with this challenge is to use artificially generated input: each sentence is constructed by randomly sampling from a presumed distribution over a list of words; the visual context is similarly built by sampling from a set of symbols which represent concepts or objects (e.g., Siskind, 1996; Niyogi, 2002). To make the data more naturalistic, some models select sentences from the transcriptions of actual child-adult interactions, and build the accompanying scene artificially by assuming a semantic representation for each word in the sentence and combining them (Fazly, Alishahi, \& Stevenson, 2010).

Generating the visual context automatically based on childdirected utterances (Utterance-Based Data, or UBD) eliminates the quantity concern (since manual annotation of the surrounding scene is not needed). However, the generated context is different from what the child observes in important ways. In a natural interaction scenario between a child and an adult, the surrounding scene is rather consistent or changes minimally (although the attention of the participants might move from one set of perceivable objects or actions to another). In contrast, in the automatic scene generation approach the utterance determines the scene, so the visual context can change drastically from one sentence to the next. A disproportional variation in visual context or scene can affect language learning; for example, context diversity has been shown to facilitate cross-situational word learning (Kachergis, Yu, \& Shiffrin, 2009). Moreover, a UBD approach guarantees that the relevant meanings for all the words in an utterance are included in the constructed scene. Artificial noise can be added by post-processing data and ran-
domly removing some meaning elements from the scene, but the noise ratio can still be unrealistically low.

UBD also differs from actual exchanges between children and their caregivers in that it lacks any interaction-based features. Crucially, utterances and actions directed at the learner at each point in time are independent of the learner's reaction to previous input data. In reality, the content of adult's utterance often depends on what the child just did or said (Kishimoto, Shizawa, Yasuda, Hinobayashi, \& Minami, 2007; Chouinard \& Clark, 2003). Interaction is suggested to be an essential mechanism of language development (e.g., MacWhinney, 2010).
In this paper, we investigate the characteristics of the visual context in a sample of child-adult interaction sessions, and compare them to those in an automatically generated one. We show that in every measure, the two contexts are considerably different, and argue that these differences might have implications for modeling child language learning. We propose a hybrid approach for generating an input corpus of utterance-scene pairs, where co-occurrence frequencies collected from a sample of manually annotated videos are used for generating utterances and visual contexts. Our framework not only takes the usage frequencies of the words and objects into account, but also includes interaction-based features such as dependence of adult's utterance on child's recent behavior. Finally, as a case study, we use an existing model of word learning (Fazly et al., 2010) to compare the complexity of the learning task using UBD vs. Interaction-Based Data (IBD, generated by our proposed framework). Our results show that using UBD for word learning unrealistically simplifies the learning task. Using IBD, in contrast, yields results that are closely comparable to the ones based on manually annotated scenes from videos of child-adult interaction.

\section*{Analyzing Utterance-based Input}

We analyze the cognitive plausibility of UBD by comparing its characteristics to a carefully annotated set of video recordings of child-adult interactions. The details of this data set are described below.

\section*{Data set}

As part of a larger project to study cross-cultural aspects of child-language acquisition (CASA MILA; Vogt and Mastin, 2013a, 2013b), three 13-month-old children from the Netherlands were recorded on video. The videos were recorded at the children's homes and involved interactions with one of the parents. The parents were instructed to continue their daily routines and ignore the recordings.

For each child, we selected an interaction session in a toy playing setting. The video fragments were 8 min 37 sec , 8 min 50 sec and 10 min long. We excluded some short episodes from the analysis, namely those (1) where the child or the adult was not captured properly by the camera, and (2) where the other parent was present, and the child's attention was focused on him/her. From the videos we extracted
adults' and children's gaze directions, actions, objects or participants that the actions were directed at, and utterances. Using this data, we constructed a corpus of child-directed utterances, each paired with a representation of the accompanying scene.

Scene representation There is no easy way to determine which elements a child perceives as potential referents at a certain moment of time. In fact, any object, action or event from the natural environment can be occasionally referred to in speech. However, studies suggest that children use certain mechanisms and constraints such as referential and salience cues to focus on relevant aspects of the scene (e.g., Behrend, 1990; Moore, Angelopoulos, \& Bennett, 1999). In particular, Yu, Smith, Shen, Pereira, and Smith (2009) show that objects in child's and parent's hands dominate the child's visual field.

In coding the interaction context in the video recordings, we consider two different interpretations for a scene:
active: all the objects that either participant (or both of them) is acting on or looking at during an utterance, in addition to the actions that (s)he performs (a similar approach was used by Frank, Goodman, and Tenenbaum (2008)).
all: the full set of visible objects, the action(s) performed during an utterance and the participants.

In addition, a third dataset was automatically generated:
UBD: Fazly et al. (2010) construct a scene by putting together the semantic symbols that correspond to the words in the accompanying utterance. Referential uncertainty is simulated by merging the representations of two consecutive scenes, and pairing them with only one of the utterances. They include noise into the data by removing the semantic symbol of one word from the scene for \(20 \%\) of the input items. Since we wanted to compare our results to those of Fazly et al. (2010), we applied the exact same approach to the child-directed utterances that we extracted from the CASA MILA recordings.

\section*{Measures}

To compare the datasets described above, we use three measures: scene stability, noise, and referential certainty.
Scene stability As mentioned before, the stability of the visual scene is one of the main points of deviation between natural interaction settings and the artificially generated input. We measure scene stability as the overlap between every pair of consecutive scenes. Since in both cases (the produced scenes in UBD and the annotated ones in our data set) a scene is represented as a set of symbols, we define the overlap between each two sets as the cardinality of their intersection divided by the cardinality of their union:
\[
\operatorname{overlap}\left(S_{i}, S_{i+1}\right)=\frac{\left|S_{i} \cap S_{i+1}\right|}{\left|S_{i} \cup S_{i+1}\right|}
\]

Noise We count a word's usage (or token) in an utterance as noisy if its semantic symbol is not included in the scene representation for that utterance. The total number of noisy words in an utterance, then, is calculated as
\[
\operatorname{noise}\left(U_{i}\right)=\frac{\left|U_{i}\right|-\left|U_{i} \cap S_{i}\right|}{\left|U_{i}\right|}
\]
where \(S_{i}\) is the current scene, and \(U_{i}\) is the (correct) meaning representation of the current utterance. To avoid making arbitrary decisions about the meaning of abstract or function words, we limit our analysis of noise to objects and actions.

Referential certainty We define the referential certainty for a scene as
\[
\operatorname{certainty}\left(S_{i}\right)=\frac{\left|U_{i} \cap S_{i}\right|}{\left|S_{i}\right|}
\]

Conceptually referential certainty shows what portion of a scene is referred to in the respective utterance. Note that this measure is the opposite of the more commonly used referential uncertainty, but it avoids the problem of having zero denominators in case the meaning representation of the utterance does not overlap with the scene.

\section*{Results}

We calculated the above measures for three datasets: childdirected utterances extracted from CASA MILA and paired with two interpretations of the accompanying visual scene (i.e. active and all), or with UBD-style automatically generated scene representations. Results are shown in Table 1.

Table 1: Plausibility measures for three datasets
\begin{tabular}{|l|c|c|c|}
\hline & all & active & UBD \\
\hline Scene stability & 0.916 & 0.436 & 0.112 \\
\hline Noise & 0.414 & 0.426 & 0.099 \\
\hline Referential certainty & 0.019 & 0.112 & 0.602 \\
\hline
\end{tabular}

The average values provided in the table inform us that the all condition differs substantially from the other two in terms of scene stability ( \(\mu=0.916\) vs. 0.436 and 0.112 ) and referential certainty ( \(\mu=0.019\) vs. 0.112 and 0.602 ). For this reason, and taking into account the fact that the standard deviation values for the all condition are rather small as compared to the respective means ( \(\sigma_{\text {stability }}=0.065 ; \sigma_{\text {certainty }}=0.032\) ), we eliminate this condition from the analysis. \({ }^{1}\) To compare the other two conditions, we ran the Mann-Whitney \(U\)-test for each of the three measures. We found significant differences between the annotated data (active condition) and the UBD in terms of all three measures: scene stability ( \(M d n=0.400 \mathrm{vs}\). 0.059 ; \(U=5230, n_{\text {active }}=274, n_{U B D}=133, p<.001, r=-.583\) ), noise ( \(M d n=0.400 \mathrm{vs}\). \(0.000 ; U=8927, n_{\text {active }}=278, n_{U B D}=139, p<.001, r=-.466\) ) and referential certainty \(\left(M d n=0.000\right.\) vs. \(0.571 ; U=3910, n_{\text {active }}=278, n_{U B D}=139, p<\) \(.001, r=-.690\) ). This demonstrates that UBD may be an easier input for the learner than the natural data.

\footnotetext{
\({ }^{1}\) The noise values for the active and the all conditions are almost equal, since the way we interpret a scene has little impact on the amount of noise in utterances. Due to this fact, for noise we also use only the active condition in the further analysis.
}

\section*{An interaction-based framework for input generation}

We propose an interaction-based framework for generating input data which resembles the verbal and non-verbal exchanges between a child and a caregiver. Our model is inspired by the language game model used to study the evolution of language (Steels, 1996; Vogt \& Haasdijk, 2010). In this model, agents communicate with each other through verbal and non-verbal behavior. Language game interactions involve a context, and agents communicate about items in this context, potentially learning associations between words and items.

We simulate the input generation process as a series of interactive sessions between two agents, Adult and Child. Each session starts with constructing a visual context (i.e., a collection of objects), followed by a sequence of exchanges between the two agents, until one of them leaves or terminates the session. In each turn, Adult performs an action (AdAct) while producing an utterance (AdUttr), to which Child responds by performing another action (ChAct) and producing an utterance (ChUttr, implemented as presence or absence of a verbal reaction). \({ }^{2}\) The main algorithm can be described as follows:
```

for }s\leftarrow1\mathrm{ to number of interaction sessions do
t\leftarrow0;
Context }\leftarrow\mathrm{ setupContext(s);
repeat
t\leftarrowt+1;
Situation}t\leftarrow < initialize(Context)
Situation}t\leftarrow < updateAdult(AdAct tr1 , AdUttr r-1 );
Situation}t\leftarrow \leftarrow updateChild(\mp@subsup{ChAct }{t-1}{},\mp@subsup{\mathrm{ ChUttr}}{t-1}{})
(AdAct },\mathrm{ AdUttr
Situation}\mp@subsup{}{t}{}\leftarrow\mathrm{ updateAdult(AdAct
(ChAct}t,\mp@subsup{ChUttr}{t}{})\leftarrow\operatorname{childTurn(Situation}\mp@subsup{|}{t}{})
until ChAct = 'leave' or AdAct }=\mathrm{ 'leave';
end

```

Each of the main steps in the algorithm are explained in more detail below.

Visual context From the sample data we extracted all the objects that were directly used by adults or children in their interactions. In each computational simulation, we randomly selected a fixed number of objects from the list and added them to the context. Since the size of the visual context may depend on the interaction domain (e.g., toy playing, book reading, etc.), we added it as a parameter to our framework.
Actions and action types We compiled two lists of actions, one for each agent. Actions might take arguments that can be an object type or the agents themselves (e.g., take toy or touch child). In order to base our computational model on more general behavioral patterns rather than on occasional events, we classified agents' actions into six types, based on

\footnotetext{
\({ }^{2}\) Since children in our sample video recordings were too young to talk, we did not gather enough statistical information about their produced utterances. However, the main concern of our framework is to create realistic child-directed input, and the child-produced data is an outcome of the learning model.
}
the factors that motivate them. These action types are listed in Table 2.

Table 2: Action types and their motivating factors
\begin{tabular}{|c|c|c|}
\hline Action type & Motivating factor & Example \\
\hline Continuation & Same person's previous action & \begin{tabular}{l}
Adult \(_{t}\) : [move bag] \\
Adult \(_{t+1}\) : [move box]
\end{tabular} \\
\hline Reaction & Other person's previous action & \begin{tabular}{l}
Child \(_{t}\) : [put ball] \\
Adult \(_{t+1}\) : [take ball]
\end{tabular} \\
\hline Result & Same person's prev. utterance & \begin{tabular}{l}
Adult \(_{t}\) : Bumba first \\
Adult \(_{t+1}\) : [take Bumba]
\end{tabular} \\
\hline Reaction to utterance & Other person's prev. utterance & Adult \(_{t}\) : The tree Child \(_{t+1}\) : [take toy tree] \\
\hline Initiating & None & Adult \({ }_{t}\) : sit down] \\
\hline
\end{tabular}

Utterances and utterance types We compiled a list of utterances produced by adults. Some of these contain placeholders which, depending on the context, can be filled with the labels for the respective actions and their arguments. Similar to actions, we recognized six utterance types based on their motivating factor, as listed in Table 3.

Table 3: Utterance types and their motivating factors
\begin{tabular}{|c|c|c|}
\hline Utterance type & Motivating factor & Example \\
\hline Accompanying & Same person's current action & Adult \(_{t}\) : [show ball] Adult \(t_{t}\) :This is a ball \\
\hline Continuation & Same person's prev. utterance & Adult \(t_{t}\) : Dad the ball? Adult \(t_{t+1}\) : Can dad the ball? \\
\hline Reaction & Other person's previous action & \begin{tabular}{l}
Child \(_{t}\) : [stand up] \\
Adult \(_{t+1}\) : Gonna walk?
\end{tabular} \\
\hline Answer & Other person's prev. utterance & Child \(_{t}\) : babbling Adult \(t_{t+1}\) : Yeah, Bumba \\
\hline Unknown & None & Child \(_{t}\) : babbling \\
\hline
\end{tabular}

Producing actions and utterances At each step \(t\) during a session, the actions and utterances produced by the agents are sampled from the frequency distributions collected from the annotated videos, each conditioned on the current situation. A situation includes all the relevant parameters, including the current and previous utterances and actions of both agents, the action arguments, and the visual context. Thanks to these parameters, the agents do not produce completely random actions and utterances, and the interaction process appears to be logical. (For more details on the estimated probabilities for each variable, see Matusevych (2012).)

Each turn in a session consists of the following steps:
1. The current situation \(\left(\right.\) Situation \(\left._{t}\right)\) is set to include the visual context (Context), the previous actions (AdAct \(t_{t-1}\) and ChAct \(_{t-1}\) ) and utterances \(\left(\right.\) AdUttr \(_{t-1}\) and ChUttr \(\left._{t-1}\right)\)
2. Adult's next action is generated:
(a) An action type for Adult ( AdActType \(_{t}\) ) is randomly selected, conditioned on Situation \({ }_{t}\)
(b) An action for Adult \(\left(A d A c t_{t}\right)\) is randomly selected, conditioned on AdActType \({ }_{t}\) and Situation \(_{t}\)
(c) Arguments for the action are randomly selected, conditioned on \(A d A c t_{t}\)
(d) Situation \(_{t}\) is updated to include \(A d A c t_{t}\) and its arguments
3. Adult's next utterance is generated:
(a) An utterance type for Adult (AdUttrType \({ }_{t}\) ) is randomly selected, conditioned on Situation \({ }_{t}\)
(b) An utterance for Adult \(\left(A d U t t r_{t}\right)\) is randomly selected, conditioned on AdUttrType \(t_{t}\) and Situation \({ }_{t}\)
(c) Situation \(n_{t}\) is updated to include \(A d U t t r_{t}\)
4. Child's next action and utterance ( \(C h A c t_{t}\) and \({\left.C h U t t r_{t}\right) ~ a r e ~}_{\text {ar }}\) generated in the same way as Adult's.

\section*{A sample interaction session}

We illustrate the interaction process using the following example (see Table 4).

Table 4: A fragment of a generated interaction
\begin{tabular}{|c|c|c|c|}
\hline \multicolumn{4}{|c|}{ Context: puzzle, piece-clown, bin, ball, piece-frog } \\
\hline Turn & Agent & Action & Utterance \\
\hline 1. & Adult & play puzzle & - \\
1. & Child & play piece-clown & babbling \\
2. & Adult & point puzzle & It fits here. \\
2. & Child & touch bin & babbling \\
3. & Adult & play puzzle & Yes? \\
\hline
\end{tabular}

The example can be interpreted as following. Adult starts the interaction by playing with a puzzle toy without saying anything. Child plays with a clown-shaped puzzle piece and babbles. Adult points at the puzzle saying It fits here. However, Child's attention is distracted by the bin, which he touches. He continues babbling. Adult continues playing with the puzzle toy, asking Yes?. His question can be interpreted either as a support for his previous utterance or as an attempt to clarify the child's utterance. The interaction goes on in this manner until one of the agents leaves.

\section*{Comparing IBD and UBD}

We used the interaction-based framework for generating a dataset. While in UBD scenes were constructed from utterances, in IBD each scene included salient elements, namely, the objects that the agents had in their hands, the agents' most recent actions and their arguments-in a manner similar to the active condition in the Analyzing Utterance-based Input section above. Using the same three measures-scene stability, noise, and referential certainty-we compare IBD to UBD and manually annotated CASA MILA data (both conditions).

Figure 1: Plausibility measures for four datasets

As can be seen in the charts (Figure 1), for each of the three measures the input data generated by our framework is much closer to the manually annotated data from the interaction videos than UBD. Again, for the reasons specified in the Analysis section, we did not use the all condition in the further analysis. For the other three conditions, the KruskalWallis \(H\)-test showed the significant difference in terms of stability \((H(2)=213.822, p<.001)\), noise \((H(2)=95.725, p<.001)\) and certainty \((H(2)=289.410, p<.001)\). To examine the pairwise differences between the three groups, we used Mann-Whitney tests, taking into account Bonferroni correction (which resulted in .025 level of significance). The difference between active and IBD was not significant in terms of noise ( \(M d n=0.400\) vs. \(0.333 ; U=37897.5, n_{\text {active }}=278, n_{\text {IBD }}=278, p>.025\) ), and significant with only small effect size in terms of scene stability \(\left(M d n=0.400\right.\) vs. \(\left.0.500 ; U=30012, n_{\text {active }}=274, n_{I B D}=274, p<.001, r=-.174\right)\) and certainty \(\left(M d n=0.000\right.\) vs. \(0.000 ; U=35002.5, n_{\text {active }}=278, n_{I B D}=278, p<\) \(.025, r=-.100\) ). However, the difference between UBD and IBD was significant with a large effect size for each measure: scene stability ( \(M d n=0.059\) vs. \(0.500 ; U=2586, n_{U B D}=133, n_{I B D}=\) \(274, p<.001, r=-.699\) ), noise ( \(M d n=0.000\) vs. \(0.333 ; U=10008.5, n_{U B D}=\) \(139, n_{I B D}=278, p<.001, r=-.426\) ) and certainty ( \(M d n=0.571\) vs. 0.000 ; \(\left.U=2451.5, n_{U B D}=139, n_{\text {IBD }}=278, p<.001, r=-.760\right)\). These results confirm that data generated by the proposed framework is more suitable for training and evaluating cognitive models than UBD. We further investigate this claim by using these different data sets in an existing model of word learning.

\section*{Case study: learning word meaning}

We used the cross-situational word learning model of Fazly et al. (2010) as a case study for our proposed input generation framework. Our goal is to show that the complexity of the learning task depends on the properties of the input data, and less realistically generated input can considerably simplify the task.

\section*{Description of the model}

The model of Fazly et al. (2010) incrementally learns the meaning of each word (e.g., play) as a probability distribution over all the possible meaning components, each represented as a unique symbol (e.g., Play, Ball). At each moment in time, the model receives a new input item, consisting of an utterance and its (ambiguous) semantic representation, which is an unordered set of symbols. The model uses its previous knowledge of word meanings to align each word in the current utterance with the most likely symbols in the current scene representation. It then uses these alignments to update the meaning of each word by accumulating such cross-situational evidence over time.

\section*{Model performance on different types of input}

We compared the performance of the word learning model on four different data sets:
1. the manually annotated portion of CASA MILA (active);
2. UBD generated from the same data set (UBD-CASA MILA);
3. original UBD used by Fazly et al. (2010) and generated from the Manchester corpus in the CHILDES database (UBD-Manchester);
4. IBD generated by our framework as a result of simulations with 19 objects in the environment (which was the average context size in the analyzed CASA MILA dataset). \({ }^{3}\)
For measuring the learning success at each moment, we used effective ratio calculated as the number of words that the learner has acquired at that time, divided by the number of words that she heard so far. The growth of the effective ratio over time is presented in Figure 2. Note that the size of \(U B D\) (CASA MILA) set is two times smaller than that of the original CASA MILA dataset, because only every other natural utterance could be included into UBD. For UBD (Manchester) and \(I B D\) the graphs show values averaged over 10 word learning simulations.

Figure 2: Overall model performance on four different datasets for 300 (left) and 6500 (right) utterances

The graph on the left shows the effective ratio over the course of 300 input items, which is slightly more than the size of the CASA MILA dataset. It is clear from these results that the performance of the word learning model is very similar when it is trained on data collected from CASA MILA and on data generated by our framework (IBD). In contrast, the model performs much better when it is trained on any of the UBD sets. This difference again suggests that UBD is not representative of what young language learners have access to, and a more realistic approach to data generation must be applied. The graph on the right shows the same measure over the course of 6500 utterances (the size of UBD-Manchester). The same pattern can be seen: there is a considerably large gap between the learning curves in UBD and IBD cases. It is also clear that in the latter case, the size of the input to the learner does not have to be constrained by the amount of data available in an existing collection.

\section*{Conclusion and discussion}

We manually annotated a small dataset of video recordings of child-adult interactions and collected various types of co-

\footnotetext{
\({ }^{3}\) Since one of the main parameters of the framework was the context size, we also investigated whether the learning process would vary with the number of objects in the environment, but our manipulations did not result in changing the overall learning pattern in terms of effective ratio.
}
occurrence frequencies of utterances, utterance types, accompanying actions and action types, action arguments and participants, and other objects available in the visual context. Using three quantitative measures, we compared the characteristics of these utterances and their surrounding scenes with the product of the most realistic existing approach to automatic generation of scene representations (Fazly et al., 2010). Our analyses show significant differences between the two datasets, and using an existing model of word learning as a case study further demonstrates that automatically generated utterance-based data simplifies the learning task to an unrealistic scale. However, manual annotation as an alternative approach (e.g., Yu \& Ballard, 2007; Frank et al., 2013) is not scalable due to the limited quantity of the data available. The hybrid approach that we propose eliminates these problems: we present an input generation framework which can produce an infinite stream of child-adult interaction data containing both linguistic and visual information, whose statistical properties are closely comparable to those of manually annotated data.

Any data annotation or generation scheme inevitably incorporates assumptions about important components and information cues in language learning, which can be seen as built-in biases brought to the learning task. However, computational models need data and will benefit from any attempt to make this data more naturalistic.

An extension of the proposed framework can potentially provide certain interaction features such as the participants' focus of visual attention and head movement. Such extra features can allow computational models to systematically investigate the impact of interaction factors in language learning.

The dataset that we analyzed was limited in size and the interaction domain (toy playing). We add a parameter to our framework to account for potential variation in the size of the visual context. But humans' linguistic behavior (e.g., the structural and pragmatic characteristics of utterances) may also depend on the domain to some extent (e.g., Choi, 2000). Therefore, a larger and more diverse collection of interaction videos will provide a more realistic base for estimating the input generation probabilities in our framework. The larger CASA MILA corpus of interaction data that is currently under development (Vogt \& Mastin, 2013a) is one suitable candidate for such expansion.

\begin{abstract}
Few studies have investigated multitasking in joint actions, especially two joint actions performed by two people together and coordinated via multimodal communication. We investigate the case of two people walking and talking together, a common combination of joint actions. In an experiment, pairs talked together in four varying conditions of mobility. A narrator told a story to a partner. They did this while either standing immobile, walking along a straight-line itinerary, or walking along a complex itinerary featuring several turns. They also completed a walking task along a complex itinerary without having to tell a story. One person (the navigator) was also entrusted with a map of the itinerary. We analyzed how participants coordinated turning while telling a story. Narrators relied more on verbal means to signal turning, and were more distracted during the turn, leading to more repetition of story-related content.
\end{abstract}

Keywords: conversation, coordination, walking, multimodal communication, joint action, collaboration, multitasking.

\section*{Multimodal Coordination of Concurrent Joint Actions}

Multitasking, or the concurrent performance of two different tasks, is common in everyday life. An important question concerns the effect of multitasking on task performance. Research on multitasking has revealed much about the basic cognitive processes involved, showing that sharing processing resources (attention, working memory, and executive control) between multiple tasks can impair performance (Salvucci \& Taatgen, 2011). Much of this research, however, has focused on multitasking behavior of individuals engaged in solitary tasks. Some research focuses on situations where people coordinate concurrent joint actions (e.g., either an individual action and a joint action or two joint actions). For example, Fussell, Kiesler, Setlock, Scupelli, and Weisband (2004) investigated how people coordinated two projects, each one with a different partner, face-to-face and via instant messaging. But few studies investigate the role of dialogue in coordinating concurrent joint actions. This is a significant oversight, because dialogue (which involves both verbal and nonverbal acts, i.e., multimodal communication; Stivers \& Sidnell, 2005) is the commonest means of coordinating joint action (Clark, 1996).

Investigations into the role of multimodal dialogue in coordinating multiple joint actions can significantly expand cognitive science research on multitasking. Recognizing
how processing resources are distributed among multiple individuals and coordinated over multiple communicative modalities challenges existing cognitive theories on multitasking. As we will see, investigating such phenomena requires theories about coordinating meaning and identities in interaction.

What coordination problems arise when people perform concurrent joint actions, and how do people use multimodal communication to solve these problems? An initial investigation of this issue was proposed by Chevalley and Bangerter (2010). They used Clark’s (1996) theory of language use to propose a model of how people suspend a joint action they are doing together in response to an interruption, and how they reinstate those actions after the interruption. Participants have to coordinate on at least three aspects in switching from one joint action to another. First, when reinstating a joint action after a suspension, participants have to update their common ground (Clark, 1996) about the state of the action. They do this by talking together about where they were in the action. Second, they have to attend to their partners' face needs. According to politeness theory (Brown \& Levinson, 1987), people have a right to positive consideration by others (positive face) as well as a right to act freely without being unduly imposed on (negative face). Suspending a joint action and making one's partner wait while one does something else constitutes a threat to negative face. To mitigate this threat, participants engage in politeness like warning about an interruption, asking permission to suspend, minimizing its duration (just \(a \mathrm{sec}\) ) or apologizing. Third, coordinating responses to an interruption raises the question of a division of labor among interaction partners. For example, only one participant in a joint action may be the target of an interruption, leaving the other participant free to keep the current state of the action in memory. The non-interrupted participant may then play a crucial role in reconstructing the state of the action once the interruption is over. Indeed, asymmetries in conversational roles or access to privileged knowledge affect the way partners coordinate suspending and reinstating joint actions (Bangerter, Chevalley, \& Derouwaux, 2010).

Here we pursue this line of inquiry but focus on the case where two people accomplish two joint actions concurrently with each other (rather than suspending one joint action for a longer period of time in order to engage in another one possibly involving another person). In such a case, conflicts between resources used for one task but required for another
may arise. Multimodal communication is a potential way of circumventing this "bottleneck", because communicating about one joint action in a different modality (e.g., via gestures) might leave the primary modality (e.g., talk) undisturbed. Another way of circumventing the bottleneck is to distribute task components among different individuals (Hutchins, 1995). In doing so, participants in multiple concurrent joint actions minimize overall collaborative effort (Clark, 1996). More generally, in coordinating multiple concurrent joint actions, participants respond to two fundamental imperatives of conversation (Enfield, 2006). An informational imperative requires participants to coordinate joint understanding of both actions (e.g., where they are in a narrative, when they are going to turn a corner), and an affiliational imperative requires them to manage each other's identities and commitments to the joint action (e.g., not interrupting a speaker at an interesting point in a story). We apply theories of conversation as joint action to explain processes occurring in multimodal coordination of concurrent joint actions.

\section*{Walking While Talking}

We report initial findings from an experimental study investigating how two people coordinate two concurrent joint actions, namely talking together while walking together. We chose walking and talking because it is a commonly occurring combination in everyday life. Many everyday conversations take place in situations of mobility. For example, hospital personnel spend substantial amounts of time engaging in various activities while walking (Bardram \& Bossen, 2005).
Talking together is a common joint action that is coordinated through a variety of channels, including speech, paraverbal information, gaze, gesture, body posture and so on. Depending on the type of conversation, participants may occupy different roles that constrain their relevant contributions. Of course, talking together has been largely studied in various disciplines (Sacks, Schegloff, \& Jefferson, 1974, Clark, 1996), but comparatively little is known about how conversation is coordinated with other, non-linguistic joint actions.

Walking together is also a common joint action where partners must coordinate walking speed and posture in order to position themselves abreast of each other. Synchronizing gait requires coordination via tactile (hand-holding) or visual signals (Zivotofsky \& Hausdorff, 2007). In some cases, when walking constitutes a means of locomotion to a particular place known to only one of the partners, roles may also emerge (i.e., one person using a map). Indeed, even transitory forms of collective mobility like crossing a street as a group when the traffic light for pedestrians is green require coordination (Relieu, 2008).

Walking normally requires few cognitive resources, and people are typically able to walk and do something else at the same time. But there are measurable decrements in task performance in such cases. For example, older adults are less able to memorize while walking (Lindenberger,

Marsiske \& Baltes, 2000). Also, adults who answer questions while walking are less fluent than while stationary (Kemper, Herman, \& Lian, 2003) Another study (Yatani \& Truong, 2009) found that users of handheld devices are more effective when standing than when walking. These studies fall short of studying true joint actions because they do not investigate interactive conversation. However, they are relevant for understanding walking performed in conjunction with other actions, and suggest that the small decrements in performance could be easily increased by making walking more difficult (e.g., by having participants navigate a complex itinerary using a map rather than just walking a predetermined path). Thus, walking constitutes a convenient and malleable candidate task to investigate in conjunction with talking.

\section*{Our Experiment}

In our experiment, pairs of participants were videotaped while talking together in four within-subjects conditions of varying mobility (the Task variable) designed to instantiate different combinations of concurrent demands related to walking and talking (Table 1). The talking task involved one person (the narrator) telling a story to the other (the partner). Participants kept these roles for the duration of the study. In the talk-only condition, pairs were standing immobile while the narrator told the story. In the talk-andwalk condition, they walked together along a straight-line itinerary which was indicated on a map while the narrator told the story. In the talk-and-navigate condition, they walked together along a complex itinerary (i.e., featuring five turns) which was indicated on a map while the narrator told the story. In the navigate-only condition, they walked together along a similarly complex itinerary (i.e., also featuring five turns) which was indicated on a map but could talk about whatever they wanted, thus creating a situation where navigation is clearly prioritized.

Table 1. Demands of talking and walking instantiated in four within-subjects conditions.
\begin{tabular}{|c|c|c|}
\hline & Talking Demands & Walking Demands \\
\hline Talk Only & High & None \\
\hline Talk and Walk & High & Low \\
\hline \begin{tabular}{c} 
Talk and \\
Navigate
\end{tabular} & High & High \\
\hline Navigate Only & Low & High \\
\hline
\end{tabular}

In addition, either the narrator or the partner was entrusted with the responsibility of making sure the pair followed the itinerary correctly. The person responsible (hereafter the navigator) was given the map. This constituted a betweensubjects variable.

Thus, the design of the experiment was a 4 (Task, withinsubjects) X 2 (Navigator, between-subjects) design. In such a setting, it is possible to investigate many interesting questions. For example, the coordination of story-telling involves the narrator regularly seeking a back-channel
response from the partner. This is often done via gaze (Bavelas, Coates, \& Johnson, 2002). If the partner is distracted and thus kept from producing back-channel responses, the quality of the story suffers (Bavelas, Coates, \& Johnson, 2000). However, when walking and talking, gaze may not be as freely available for this purpose as when people are talking without moving. The effect of walking on gaze allocation and therefore on story-telling coordination via back-channels can be investigated by comparing the talk-only condition with the other conditions. Other comparisons are possible, for example comparing the talk-and-navigate condition with the navigate-only condition allows investigating to what extent talking may interfere with a navigational task, with navigational performance being measured by changes in walking speed (e.g., slowing down or stopping) or by errors (e.g., wrong turns).
In this paper, our analysis focuses on how participants coordinate turning to the left or to the right according to the itinerary while talking. Turning while talking is a good example of how an acute coordination demand may emerge from one joint action, thereby jeopardizing coordination of the other joint action. In our experiment, the responsibility for navigating was often implicitly entrusted to the navigator, who was the only participant who had easy visual access to the map. Thus, turning was typically coordinated via some kind of signal from navigators to the other participant. There are several ways to do this. Navigators might tell other participants to turn, for example by uttering we're going to turn to the right. Or they might point in the direction of the turn. They might also swivel their gaze in the direction of the turn, or nudge or push their partner, or use a combination of several signals. Some pairs even managed to turn without any visible or audible coordination signals (albeit quite rarely). How might participants decide to coordinate a turn? When narrators are navigators, they have the floor, because they are responsible for telling the story. Thus, it seems easier for them to signal the turn via verbal means. On the other hand, when partners are navigators, they must interrupt the narrator and gain the floor if they want to signal the turn verbally. This is a potential threat to the narrator's face (Bangerter, Chevalley, \& Derouwaux, 2010). If, as predicted by joint action theories of conversation, participants deal with this problem by distributing collaborative effort across modalities and by a distribution of labor, we would expect partners as navigators to rely relatively less on verbal means to signal turning than narrators as navigators.
To test this possibility, we investigated the effect of the Task and Navigator variables on the coordination of turning. For each of the five turns in the talk-and-navigate condition for each pair, we coded what kind of verbal or nonverbal means they used to coordinate the turn. We compared this data with the verbal and nonverbal means used to coordinate turning in the navigate-only condition. Because there are no narrator and partner roles in the navigate-only condition, it serves as a baseline for comparison with the effect of roles in the talk-and-navigate condition.

We also investigated the effect of the Task and Navigator variables on the coordination of storytelling. When narrators are navigators, they may be more distracted when they have to both communicate about the turn and keep track of the story they are telling. This might make participants more likely to lose track of the story, and thus more likely that some utterance relative to the story will have to be repeated after the turn as a means of reconstructing the story line (Chevalley \& Bangerter, 2010).

\section*{Method}

\section*{Participants}

Eighty people ( 46 women and 34 men) participated in 40 pairs. Pairs were composed irrespective of gender. Participants were native French speakers and did not know each other before the study.

\section*{Procedure}

We video-recorded each pair in one static and three mobile conditions. In all conditions, participants were also equipped with audio recorders and tie-clip microphones. In the talkonly condition, participants were filmed with a hand-held video camera from a distance of several meters. In the three mobile conditions, participants walked abreast. They were filmed frontally with a device consisting of either a GoPro Hero2 camera or a Contour HD camera attached to a perch that was held by the experimenter who walked about 1.5 m behind the pair. The perch extended over the heads of the pair (see Figure1). It was just above and the out of their field of vision when they looked ahead. The experimenter calibrated his walking speed to the participants' in order to maintain the camera at a constant distance from them. The perch also featured a supplementary backup audio recorder attached above the participants' heads. In this way, the setup allowed frontal mobile videotaping of the participants from above their heads to below their knees (Figure 2).

Figure 1: Setup of portable videocamera perch.
Twenty ordered combinations of the four conditions were randomly computed and randomly assigned to pairs in each
between-subjects condition (the same combinations were used in both conditions). Pairs performed the tasks in the order thereby defined.
In the walking conditions, participants followed an itinerary using a map, responsibility for the navigation being randomly assigned to the narrator or partner before the experiment. Participants were asked to navigate from a starting point to a precisely marked end point. Thus, even straight-line itineraries required some monitoring on the part of the navigator to avoid undershooting or overshooting the end point. All itineraries had a total length of approximately 400 meters. Recordings took place outdoors in a quiet urban area.

Figure 2: Still pictures of two pairs (in both cases, the narrator is the navigator and is on the left). Bottom picture:

The narrator is initiating a turn by gesturing.

\section*{Data preparation}

Video was synchronized with the sound of the two audio recorders (on a separate track) and a file was produced per condition for each group. A video clip of each turn was prepared. Clips started approximately 15 seconds before the initiation of the turn and lasted 30 seconds.
Based on a viewing of each clip, a detailed qualitative description of how each pair coordinated each turn was written by the first author. The description featured a sequential list of the circumstances of the turn, as well as any visible or audible behavior dedicated to coordinating the turn, including specifications of which participant was on the inside of the turn, descriptions of gestures (e.g.,
pointing), verbatim transcription of any utterances or the direction of gaze.

A research assistant then coded each description on the following variables:
- Who produced a signal (narrator or partner).
- When it was produced (before, during or after the turn)
- The signal produced (look at map, look at other participant, look in the direction of the turn, look elsewhere, point in the direction of the turn, point on the map, other gesture, give directions verbally, request help, agree)
- Repetitions of previous story content

Interrater agreement was assessed by having two coders independently code 25 turns. Cohen's kappa indicated excellent agreement (all kappas > .90).
The individual turn-coordination signals were grouped together to compute frequencies with which three types of signals were produced: gaze, gesture and utterance. The number of repetitions per turn was also computed.

\section*{Results}

Pairs took the same amount of time to complete the task in all four conditions, Wilks' lambda \(=.930, F(3,37)=.922\), \(p=.44,(M=297.5 \mathrm{~s}, S D=65.7 \mathrm{~s})\).

Because Task is a within-subjects variable, we performed repeated-measures analyses with the frequencies (by turn) of gaze, gesture, utterance and repetition as dependent variables. Because turns are nested within groups and the dependent variables are count data, we ran mixed model Poisson regressions in R 3.0. These analyses take into account the random effects of pairs. The independent variables were Navigator role and Task, which were entered in that order in the models, prior to the interaction term. Independent variables were dummy coded (0 vs 1 ). Categories coded 0 were Partner for the Navigator variable and Talk-and-navigate for the Task variable. The models were fitted by the Laplace approximation. Table 2 shows the means for each dependent variable as a function of Task and Navigator role. In what follows, \(b\) coefficients for each effect represent natural-log-transformed values.

Table 2: Mean frequencies (standard deviations) of gaze, gestures, utterances, and repetitions by Task and Navigator role per turn.
\begin{tabular}{|l|c|r|r|c|}
\hline & \multicolumn{2}{|c|}{ Talk-and-navigate } & \multicolumn{2}{c|}{ Navigate-only } \\
\hline & Narrator & Partner & Narrator & Partner \\
\hline Gaze & \(4.50(2.52)\) & \(4.36(2.74)\) & \(3.92(2.57)\) & \(4.13(2.29)\) \\
\hline Gesture & \(1.34(2.36)\) & \(0.87(1.03)\) & \(0.81(1.30)\) & \(0.69(1.12)\) \\
\hline Utterance & \(1.63(2.92)\) & \(0.58(1.24)\) & \(1.56(2.34)\) & \(1.36(2.26)\) \\
\hline Repetition & \(0.15(0.38)\) & \(0.03(0.17)\) & \(0.10(0.30)\) & \(0.12(0.41)\) \\
\hline
\end{tabular}

Gaze is used frequently in coordinating turning. While gaze shifts might be primarily produced by participants to steer their own individual walking trajectory, they might also attract the attention of the other participant and thus serve as an unintended cue that a turn is imminent. Pairs
gazed marginally less in the navigate-only condition than in the talk-and-navigate condition ( \(b=-.12, S E=0.07, p=\) 0.07 ). Navigator role was not a significant predictor of gaze. It is worth noting that this model does not fit the data significantly better than a null model (deviance \(=4, d f=3\), \(n s\) ). (Differences from the null models are significant for all other dependent variables.)
Gestures were used regularly, albeit less often than gaze. Pairs gestured marginally less when the partner was responsible for the itinerary than when the narrator was ( \(b=\) \(-0.36, S E=0.20, p=0.07\) ). In the navigate-only condition, pairs gestured less than in the talk-and-navigate condition ( \(b\) \(=-0.48, S E=0.14, p=0.0007\) ). As expected, pairs in the navigate-only condition used less utterances to coordinate turning than did pairs in the talk-and-navigate condition ( \(b=\) \(-1.06, S E=0.29, p=0.0003\) ). The interaction of task and navigator was also significant ( \(b=.86, S E=0.19, p<\) 0.0001): In the talk-and-navigate condition, pairs discussed the navigation task more when the narrator was responsible for navigation than when the partner was. On the contrary, in the navigate-only condition, pairs discussed the navigation task equally often, irrespective of navigator role.

Figure 4: Example of a progressive breakdown in the story following a missed turn.

Utterances related to turning included directions but also expressions of uncertainty, like I just need to look or I think
that's it, as well as occasional requests for assistance, which sometimes could completely override the narrative activity. In one exceptional case (depicted in Figure 4), the narrator progressively realizes she is lost, first interrupting her story by saying I don't understand where to go anymore while pointing vaguely in the direction of the turn. She then looks at her partner and laughs, and then asks her can you help \(m e\), while showing the map to her partner. All the while, the pair is walking straight ahead without slowing down. Subsequent to the frames shown in Figure 4, the pair will slow down and come to a complete stop while the partner explains to the narrator where to go. Only once they have corrected their trajectory will the narrator resume her story. This example illustrates the complex interplay of the multimodal signals produced (verbal utterances, gaze, pointing, and showing the map). It also illustrates a momentary but complete breakdown in one task (talking) when coordination requirements of the other task (walking) briefly overwhelm participants' available resources.

Repetitions of story-related content were infrequent. When they did occur, it was mostly the last utterance before the turn that was repeated immediately after the turn was complete. Nonetheless, repetitions of story-related utterances were less frequent when the partner was responsible for navigation than when the narrator was ( \(b=-\) \(1.60, S E=0.71, p=0.02\) ). There was also an interaction ( \(b\) \(=1.76, S E=0.81, p=0.03\) ). In the talk-and- navigate condition, pairs repeated story content more when the narrator was responsible for navigation than when the partner was. This was not the case in the navigate-only condition, possibly because no participant had an assigned role regarding the discussion (usually participants engaged in small talk while navigating in this condition, each contributing to the discussion).

\section*{Discussion}

Talking together while walking together constitutes a complex set of concurrent joint activities. Using the example of turning, we have shown how the division of labor among pairs affects the coordination of the turn. Narrators used more verbal utterances to signal a turn than partners. This finding converges with those of Chevalley and Bangerter (2010) and Bangerter, Chevalley, and Derouwaux (2010), who found that it was more effortful for listeners to suspend a conversation than for speakers. In refraining from interrupting speakers, listeners also deployed more politeness, suggesting they were trying to mitigate the face threat of interrupting the speaker. In the present case, partners may have preferred to accomplish some signals via gesture, in order to avoid interrupting the narrator's story.

We also found that narrators repeated story-related utterances after a turn more often when they were navigators than when they were not, suggested that they were distracted by the double responsibility of narrating and signaling the turn. It may also be the case that this finding is related to the previous finding that narrators use more verbal
means. Given that they have the floor, narrators may find it comparatively easier to interrupt their story to signal the turn. But in doing so, they may potentially interfere more with their own recall of where they were in the story than if they would use gestural means to signal the turn.

Our findings confirm that, in coordinating concurrent joint actions, participants need to manage common ground, pay attention to face wants of their partners, and that they may accomplish these constraints via a division of labor and using multimodal communication. Thus, coordinating concurrent joint actions expands the phenomenon of multitasking into the realm of conversational interaction and requires consideration of social as well as cognitive processes.

\begin{abstract}
The phenomenon of insight is frequently characterized by the experience of a sudden and certain solution. Anecdotal accounts suggest insight frequently occurs after the problem solver has taken some time away from the problem (i.e., incubation). Here we used Compound Remote Associates problems to examine how incubation affects the subjective experience of insight at different levels of problem fixation. We hypothesized that incubation would elicit a mind-set change resulting in improved problem solving performance regardless of the initial level of fixation. Second, we predicted to the extent that insight reflects a person's assessment of mind-set change, the experience of insight would be more likely after incubation. Results were consistent with these predictions. These findings suggest that the role of incubation in producing insight may have more to do with changing mind-set than forgetting information that fixates problem solvers.
\end{abstract}

Keywords: creativity; fixation; incubation; insight; problem solving

\section*{Introduction}

People frequently describe solving problems with either an analytic, step-by-step process, or a comparatively unconscious process resulting in unexpected answers (Boden, 1994; Morrison, in press; van Steenburgh et al., 2012). In the latter situation people show little ability to predict their sudden insight (Metcaffe, 1986), yet have great confidence in the solution that seemingly came from unconscious processing (Simonton, 2012; Smith \& Ward, 2012). This experience often follows a time away from the problem, also known as incubation (van Steenburgh, et al., 2012).

Insight has been studied using a variety of different approaches. Beginning with the Gestalt psychologists, researchers attempted to create problems where the experience of insight was more likely (e.g., Duncker's (1945) Candle Problem; Katona's (1940) Matchstick Arithmetic Problems; Mednick's (1962) Remote Associates Problems). Using these types of problems researchers have examined the experience of insight, for instance by asking participants to monitor their problem solving progress in situ (Melcalfe, 1986) or asking participants to report whether they experienced insight upon problem completion (Bowden \& Jung-Beeman, 2003a). The latter approach allows researchers to make post hoc comparisons between problems solved with and without insight on a problem-by-problem basis for each participant.
Alternatively, some studies have examined how problem-solving context could facilitate insight solutions (e.g., Barid et al., 2012; Kounios et al., 2008; Smith \& Blankenship, 1991; Storm, 2010, 2011; Wallas, 1926). For instance, Smith and Blankenship (1989) argued that incubation allows problem solvers to forget (or perhaps inhibit) mental representations resulting in fixation and thereby achieve an insight solution.

\section*{The role of incubation in promoting insight}

Building on an earlier study by Smith and Blankenship (1989), Kohn and Smith (2009) asked participants to solve remote associates problems (Mednick, 1962) in which participants must discover a single word that is a remote associate of three different words. Prior to attempting to solve each problem participants completed an initial task

Figure 1: (a) Unrelated - Direct and (b) Blocking - Incubate example trials. In Unrelated Compound Remote Associates (CRA) trials the preceding Two Word Phrase Task (TWPT) problem has no words in common with the CRA problem while in Blocking CRA trials the preceding TWPT problem contains two of the CRA problem words which pair with a third word that is not the correct answer for the CRA problem, thereby increasing CRA problem fixation. In Direct CRA trials participants have two contiguous epochs to try to solve the CRA problem, while in Incubate CRA trials the two epochs are separated by a 40 s incubation period in which participants perform the Digit Monitoring Task (DMT).
designed to manipulate the level of fixation experienced while trying to solve the remote associates problems. Participants briefly tried to solve each remote associates problem and then were given either a second continuous solution period or a brief 30s incubation period during which they performed a working-memory distractor task. Kohn and Smith found a trend towards participants showing an improvement in performance for problems on which they were initially more fixated and received an incubation period. Using a different type of insight problem, Baird and colleagues (2012) also found a benefit for incubation; however, the greatest benefit was found not from a difficult distractor task or simple rest during incubation, but rather from a task designed to promote mind-wandering. This latter result suggests that the benefit of incubation may not be to help participants overcome fixation, but rather, to promote the appropriate cognitive processing conducive to insight. Likewise, sleep studies by Cai and colleagues (2009) demonstrated that implicit priming of answers to unsolved Remote Associates Problems helped participants solve the problems after REM sleep compared to non-REM sleep or an equivalent rest period. This result suggests that time alone is insufficient for incubation effects, but rather solutions involving insight require a change in the underlying cognitive processing used for problem solving. However, none of these studies specifically asked participants whether they had experienced insight while solving the problem.
Bowden and Jung-Beeman (2003a) developed a subjective measure of insight for use with Compound Remote Associates problems (CRA; Bowden \& JungBeeman, 2003b) variants of Mednick's (1962) classic Remote Associates Task problems. Specifically Bowden and Jung-Beeman (2003a) asked participants after they had
solved a CRA problem to report via a numeric scale, how much insight they had experienced. Jung-Beeman and colleagues (Bowden \& Jung-Beeman, 2003b; JungBeeman et al., 2004; Kounios et al, 2006, 2008) have used various versions of this methodology to perform post hoc sorting of problems based on the participant's subjective experience. Using this methodology along with various neuroimaging methods they found evidence that right anterior superior temporal gyrus, a brain area associated with semantic integration, was specifically engaged just prior to CRA problems that participants reported solving with insight (Jung-Beeman, et al., 2004). Importantly, they also found evidence for neural activity indicative of visual gating just prior to the right temporal activity suggesting that a part of solving with insight might involve inhibiting the external world in favor of subconscious processing. Likewise, Kounios and colleagues (2008) identified this same neural signature before participants had initially seen problems they subsequently reported solving with insight, suggesting that the visual gating was likely indicative of a different problem solving strategy (Kounios et al., 2008).

\section*{Current Study}

The purpose of this study was twofold. First we wanted to explore whether taking time away from a problem (i.e., incubation) contributes to the subjective experience of insight. Second, to investigate whether incubation specifically helps participants overcome fixation, we adapted Kohn and Smith's (2009) paradigm for use with CRA problems (Bowden and Jung-Beeman, 2003b) and a subjective measure of insight. Specifically, we used Kohn \& Smith's two-word task to manipulate the degree of fixation prior to attempting to solve a CRA problem. We then manipulated incubation by either giving participants a second immediate opportunity to solve the problem, or

Figure 2: In Epoch 1, there was a reliable effect of blocking on CRA resolution rates demonstrating the effectiveness of the TWPT problem fixation manipulation. In Epoch 2, there was a reliable effect of incubation, with no interaction with initial TWPT induced fixation. Error bars represent \(\pm 1\) SEM.
instead gave them a period of incubation where they performed a working-memory distractor task. Whenever participants solved CRA problems, they were asked to report whether they experienced insight or not. This procedure thus allows us to evaluate whether insight is more likely after incubation and whether insight solutions were likely the result of release from problem fixation.

We hypothesized that incubation with a mild workingmemory distractor would elicit a mind-set change resulting in improved CRA problem solving performance regardless of the initial level of fixation. Second, we predicted that if the experience of insight reflects a person's assessment of mind-set change they would report greater insight on successfully solved problems after incubation than if they simply continued working on the problems without an incubation period.

\section*{Method}

\section*{Participants}

Eighty undergraduate students ( 60 female) from Loyola University Chicago participated in the experiment. Participants gave informed consent to take part in the study. The Loyola University Chicago Institutional Review Board approved all recruitment methods and procedures.

\section*{Task Descriptions}

Three tasks implemented in e-Prime 2.0 were used in this experiment. The primary task consisted of Compound Remote Associate problems (CRA; Bowden \& JungBeeman, 2003b). Each CRA problem consists of three unrelated words that can each be paired with a fourth target word that is a remote associate of each of the cue words to
make three compound word pairs (see Figure 1 for an example problem).
After the methods of Kohn and Smith (2009), we manipulated CRA problem fixation through use of a preceding Two-Word Phrase Task (TWPT) problem corresponding to each CRA problem. This task required participants to combine three presented words, two of which were from the corresponding CRA problem, into two two-word phrases (see Figure 1). This was intended to create a strong association for two of the CRA words to a word that was not the correct CRA answer, and thereby induce CRA problem fixation. We used the corresponding TWPT problem before the CRA problem in the Blocking condition (see Figure 1b), while we used an unrelated TWPT problem created for a different CRA problem in the Unrelated condition (see Figure 1a).
Lastly, we used a Digit-Monitoring Task (DMT; Kohn \& Smith, 2009) as the distractor task during incubation. In the DMT participants saw a series of digits from 1 to 9 presented one digit each second for 40 s. Participants were to track the total number of times that two odd digits were presented in a row and report that at the end of the incubation period.

\section*{Testing Procedure}

Forty-four CRA problems were rotated between four counterbalanced conditions (i.e., Unrelated/Direct, Unrelated/Incubate, Blocking/Direct, Blocking/Incubate; see Figure 1 for a schematic of two of the conditions). Each trial began with a TWPT problem for 20s followed by a CRA problem. On Direct trials if the participant did not solve the CRA problem in 20s (Epoch 1) they were given 10 additional seconds to solve the problem (Epoch 2). On Incubate trials that they did not solve in 20 s they performed the DMT for 40 s and then were given an additional 10s to solve the CRA problem. To encourage

Figure 3: In the first epoch, reports of insight were significantly higher in the unrelated condition suggesting that overcoming fixation was not responsible for the experience of insight. In the second epoch reports of insight were greater following incubation suggesting that the incubation task helped participants to elicit a mind-set change resulting in an insight solution. Error bars represent \(\pm 1\) SEM.
participants to form links between the TWPT and the CRA problems we used 6 additional CRA problems in the Helping condition. In these problems the correct answer for the CRA problem was given as the third word in the TWPT problem.

The definition of insight given to subjects was taken from Jung-Beeman et al. (2004). Briefly, the feeling of insight was described as a sudden experience in which a fully formed answer came to mind all at once. Upon solving a CRA, subjects were asked if they experienced insight. The subjects responded verbally with either yes or no.

\section*{Results}

Due to the CRAs being divided into a first 20s epoch and a second 10s epoch, accuracy was calculated using resolution rates (Kohn \& Smith, 2009). For the first epoch the Resolution rate was simply equal to the proportion solved correctly. For the second epoch we corrected for the number of problems solved in the first epoch and used the number of problems attempted during the second epoch as the denominator in the proportion correct calculation.

Resolution rate in the first epoch was impacted by fixation with participants solving more problems when they were preceded by a TWPT that did not result in greater fixation (see Figure 2; \(t(79)=5.6, p<.001\) ). Next we evaluated whether performance in Epoch 2 was impacted by incubation and whether this interacted with our fixation manipulation. A two-way within subjects ANOVA yielded a main effect of incubation (see Figure 2; \(F(1,79)=11.5, p=.001, \square_{\mathrm{p}}^{2}=.13\) ), but no main effect of fixation \(F(1,79)=.48, p=.5, \square_{\mathrm{p}}^{2}=.006\) ) and no interaction \(\left.F(1,79)=.73, p=.4, \square_{\mathrm{p}}^{2}=.009\right)\). Following the analysis of Kohn and Smith (2009) we also performed planned comparisons to look at the effect of incubation on Blocking and Unrelated trials independently. As in Kohn
and Smith's study participants showed a reliable difference in CRA resolution rate with respect to incubation in the Blocking condition \(\left(F(1,79)=12.0, \mathrm{p}=.001, \square_{\mathrm{p}}{ }^{2}=.13\right)\). However, unlike Kohn and Smith we found a trend towards a difference for the unrelated condition as well \(\left(F(1,79)=2.8, \mathrm{p}=.10, \square_{\mathrm{p}}^{2}=.03\right)\), consistent with our failure to find a reliable interaction between incubation and fixation. Thus, overall our results suggest that incubation aided in CRA problem solving regardless of the level of fixation as manipulated by the TWPT.
Overall, \(62 \%\) of all correct answers were answered with insight and \(38 \%\) were answered without insight. In an effort to measure participant's subjective experience of insight within each condition, we calculated an insight score for each participant by subtracting total number of correct non-insight answers from their total number of correct insight answers and dividing by the resolution rate.
Insight score in the first epoch was impacted by fixation with participants reporting greater insight on solution when they had less fixation as manipulated by the Two-Word Task (see Figure 3; \(t(79)=2.6, p=.012\) ). Next we evaluated whether the experience of insight in Epoch 2 was impacted by incubation and whether this interacted with our fixation manipulation. A two-way within subjects ANOVA yielded a main effect of incubation (see Figure 3; \(F(1,79)=9.0, p=.004, \square_{\mathrm{p}}^{2}=.10\) ), but no main effect of fixation \(F(1,79)=2.3, p=.14, \square_{\mathrm{p}}^{2}=.03\) ) and no interaction \(\left.F(1,79)=.78, p=.4, \square_{\mathrm{p}}^{2}=.01\right)\). Our results suggest that incubation increased the experience of insight, just as it aided solution performance. Likewise, the experience of insight does not appear to be majorly impacted by the initial degree of problem fixation.

\section*{Discussion}

Using a similar incubation and fixation paradigm with different remote associates problems, Kohn and Smith
(2009) reported that incubation led to higher resolution rates when participants were subjected to a task intended to cause problem fixation. They suggested that this improvement was due to distraction during incubation helping participants overcome problem fixation by forgetting wrong associations. In our study, we found that in spite of a strong initial fixation effect, incubation helped participants solve problems regardless of the level of fixation. In addition, participants experienced greater insight when they successfully solved problems after incubation regardless of fixation compared to when they successfully solved problems in a continuous period (Direct condition). Our results suggests that incubation does contribute to the experience of insight, and that incubation likely contributes to insight problem solving in ways other than just through forgetting fixation.

Recently Baird and colleagues (2012) presented evidence suggesting that what people do during incubation affects how likely they are to solve insight problems. Importantly, they found that a more demanding task resulted in less improvement than a less demanding task that encouraged mind wandering. Likewise, Cai and colleagues (2009) found that when participants experienced REM sleep during a Remote Associates Task incubation period they were more likely to benefit from an implicit semantic clue prior to incubation than if they had non-REM sleep or simply rested during incubation. Like our results, these findings suggest that something more than just forgetting must occur during incubation to facilitate insight.

One possible role for incubation may be to shift the mood of the participant. In our study when participants solved CRA problems during the first epoch prior to incubation they reported less insight when they had previously solved a TWPT problem intended to create CRA problem fixation than when they solved an unrelated TWPT problem (see Figure 3 Epoch 1). It is possible that the frustration resulting from fixation may encourage a negative mood. Several previous studies have suggested that participants are more likely to solve insight problems when they are in a positive mood (e.g., Isen, Daubman, \& Nowicki, 1987; Subramaniam et al., 2009). Subramaniam and colleagues showed that when people were high in selfreported positive affect prior to testing they were more likely to solve CRA problems and report insight. Van Steenburgh and colleagues (2012) have speculated that this effect of positive affect may be due to the ability of positive affect to encourage a broadening of attention (see also Rowe, Hirsch, \& Anderson, 2007). A broad attentional focus has long been known to be associated with creative behavior (e.g., Ansburg \& Hill, 2003; Mendelsohn \& Griswold, 1966). While it seems unlikely that performing the DMT incubation task in the present study would likely elicit a positive mood it is possible that the shift away from being stuck on a problem may result in at least a less negative mood perhaps resulting in a broader attentional mindset.

While our findings do support the idea that incubation can contribute to a change in mindset that aids in solving problems with insight, much remains to elucidate the precise nature of cognitive change that occurs during incubation.

\title{
Modeling a reaction time variant of the Perruchet effect in humans
}

\begin{abstract}
This paper presents a reaction time (RT) experiment that follows on from the work of Perruchet, Cleeremans, and Destrebeceqz (2006), investigating the extent to which reaction times (RTs) are governed by the conscious expectancy of a particular response. In this experiment, participants were presented with a single stimulus (which we will call the conditioned stimulus; CS) followed by one of two outcomes (which we will call unconditioned stimuli; USs); to which participants had to make an appropriate instrumental response. On every trial we recorded the time taken to make this response and participants were asked to rate their expectancy that one of the USs (US1) was going to occur. We found that the expectancy rating for US1 correlated negatively with RT on US1 trials. Over successive runs of reinforcement, when participants rated US1 as less likely to occur they were slower to respond to US1 (lower ratings, higher RTs). When we calculated the expectancy for US2 as the complement of that for US1 expectancy, expectancy of US2 correlated positively with RTs. Thus, across runs of reinforcement, participants responded more quickly to US2 when considering US2 less likely (low rating, low RT). We argue that the requirement to make a conscious expectancy rating results in participants attending more to US1 occurrences than those of US2. This results in a qualitatively different relationship between conscious expectancy and automatic responses that cannot be reconciled by a single processing system account. A dual processing system explanation of learning is proposed to explain these results. In support of this position, we successfully modeled our US2 RT data using a modified version of the Augmented simple recurrent network (Yeates, Jones, Wills, McLaren, \& McLaren, 2013).
\end{abstract}

\section*{Introduction}

Recently, there has been a lively debate on the extent to which learning is governed by a single processing system or dual processing systems (e.g. McLaren, Green, \& Mackintosh, 1994). A single processing system view advocates one conscious reasoning process (e.g. Lovibond, \& Shanks, 2002). From this viewpoint, conditioned responding (CR) obtained in an instrumental conditioning paradigm is driven by contingency knowledge that develops during the course of conditioning between a conditioned stimulus (CS) and unconditioned stimulus (US). Within a dual processing system framework, associative automatic processes can be responsible for the CR without explicit contingency knowledge. Based on this account, an associative link forms between a representation of the CS and representation of the US. Presentation of the CS activates the link between the CS and US, which activates the US representation, which then produces a CR.

One of the most convincing sources of evidence (Mitchell, De Houwer, \& Lovibond, 2009; Shanks, \& St John, 1994) for dual processing systems is the Perruchet effect (Perruchet, 1985). In the reaction time (RT) version of this experiment employed by Perruchet, Cleeremans, and Destrebeceqz (2006), participants hear an auditory tone (the CS ) on every trial. Half the time the CS is followed by a visual US to which participants have to make a keypress response. On the other half of the trials there is no US and participants are not required to make a response. Participants make an online expectancy rating on every trial regarding the extent to which they think the US is going to appear on that trial.

Across successive CS-US (reinforced) trials, expectancy ratings that the US will occur decrease. However, after experiencing runs of nonreinforced, CS-noUS, trials participants' ratings indicate they think it more likely that the US will occur; and thus, that a response is more likely to be required. This is consistent with the gambler's fallacy phenomenon (Burns, \& Corpus, 2004). In contrast, the CR (the instrumental response to the US measured by RT) gets faster (improves) with successive reinforcement. This means consecutive CS-US trials result in shorter RTs, whereas runs involving an absence of the US result in slower responding. This pattern of responding is hard to reconcile with the gambler's fallacy, as participants become quicker to respond to the US at the same time as their expectancy of the US (and thus their expectancy that they are required to make a response) decreases. An associative account can, however, explain the change in RT with reinforcement history, as over successively reinforced trials the associative link between the CS representation and the US representation becomes stronger, leading to faster RTs. This link is extinguished and weakened by the absence of the US on the CS-noUS trials, leading to slower RTs. Thus, a dual processing systems account is required to explain both the conscious processes underlying expectancy along with the RT pattern that captures our automatic, associative learning about CS-US relationships (McLaren, Green, \& Mackintosh, 1994).

The experiment presented here aims to further investigate the effects observed in a RT version of the Perruchet paradigm, and to provide support for a dual processing systems account of learning. To build on the original experiments, we presented participants with two USs in order to obtain RT data on every trial and to keep the demands of each trial consistent. We were therefore able to take a measure of CR for the two USs separately and compare these to expectancy of each US. If RT and expectancy of the US are found to follow different trends this would imply that a single processing system
explanation of learning would be unable to explain the results and that a dual processing systems account would be more appropriate. If our assumptions regarding the nature of the processes underlying RT performance are correct, we should be able to model these associatively. Therefore, to assess this claim, we used a model of human learning (the revised augmented simple recurrent network: RASRN; Yeates, Jones, Wills, McLaren, \& McLaren, 2013) in an attempt to simulate the instrumental responding of participants in this experiment.

\section*{Method}

\section*{Participants}

64 University of Exeter students ( 13 men and 51 women) were recruited for course credit to participate in this experiment. Their ages ranged from 18 to 49 years, with a mean age of 21 .

\section*{Design and Stimuli}

The CS was visually presented to participants as a brown cylinder ( \(11 \times 7 \mathrm{~cm}\) ) in the centre of a white screen. The words "Peanut Butter" and "Brown Sugar" were the two USs that followed the presentation of the CS. Both USs were presented to and counterbalanced across each participant as US1 and US2. Each of the USs was presented half the time after the CS, forming a partial reinforcement schedule where the occurrence of each US was equally likely.

In a typical Perruchet design, we are interested in runs of reinforced and non-reinforced trials, therefore a repeatedmeasures factor of run length (the number of a given trial type that occur consecutively in a row) was constructed. There were 8 levels of this factor; \(-4,-3,-2,-1,+1,+2,+3\), and +4 . When analyzing the sequence of trials given to each participant in this experiment, we can examine repetitions of the same US (D, different trials) or repetitions of the opposing US (S, same trials) as equivalents of these positive and negative runs of trials, respectively. A CR measurement is taken on the trial after the run itself, thus when considering US1 trials, a +2 trial would have involved two consecutive CS-US1 trials prior to this, whereas a -3 trial would have been preceded by a run of three CS-US2 trials (see Table 1 for an example of how runs are labeled within the sequence).

Table 1. An example of a sequence of CS-US pairings and the corresponding run lengths of these trials. These are labeled both in terms of classic Perruchet positive and negative runs; and in terms of same (S) and different (D) runs. Trial type indicates whether US1 or US2 is paired with the CS (which occurs on each trial).
\begin{tabular}{cccccccc}
\hline \begin{tabular}{c} 
Trial \\
type
\end{tabular} & US1 & US1 & US2 & US2 & US2 & US1 & US2 \\

\cline { 2 - 8 } & & S1 & D2 & S1 & S2 & D3 & D1 \\
\hline
\end{tabular}

We aimed to compile sequences of US1 and US2 trials that involved these same (S/positive) and different (D/negative) runs from 1 to 4 , following a binominal
distribution as shown in Table 2. However, the original Perruchet experiments only comprised of one CS and one US, while the current experiment involves two USs. As each run has to end in the opposite trial type (e.g. a US1 run would have to end in a US2 trial), two 'different' runs of length five are included in each block. These are a requirement for the sequence, are counterbalanced across the US type across blocks and excluded from the analysis; and so are not discussed further.

Table 2. The binomial distribution of run lengths.
\begin{tabular}{ccccccccc}
\hline Run & -4 & -3 & -2 & -1 & +1 & +2 & +3 & +4 \\
\cline { 2 - 9 } \begin{tabular}{c}

\hline \begin{tabular}{c} 
Number \\
of runs
\end{tabular} & 2 & 4 & 8 & 16 & 16 & 8 & 4 & 2 \\
\hline
\end{tabular}

In this experiment, each participant experienced two blocks of 57 trials, which comprised of unique, randomized sequences of run lengths. These sequences were constructed using MatLab. We measured both expectancy and RT as our dependent variables and compared them across run length for both USs separately.

\section*{Procedure}

A cover story was given to participants, who were told they were playing the role of a doctor seeing a number of patients with both diabetes and a nut allergy. Participants were exposed to the CS for 5 seconds on each trial and were told that this brown cylinder could represent either peanut butter or brown sugar. During this time, participants had to make a rating on a scale of 1 to 9 regarding the extent they thought this trial would be a US1 trial. For half of the participants, peanut butter was US1; for the other half, brown sugar was US1. If US1 was peanut butter, they were told that a rating of 1 would indicate: "I definitely do not think the patient will need adrenaline"; up to a rating of 9: "I definitely think the patient will need adrenaline". Adrenaline was replaced by insulin when brown sugar was US1. Participants were told that half the time "peanut butter" would appear after the CS and on the other half of trials "brown sugar" would appear. One of these stimuli (the US) was then presented immediately after the CS. Participants were instructed to respond as quickly as possible to the stimuli to administer adrenaline to "peanut butter" and insulin to "brown sugar" with left Ctrl and left Alt keys (counterbalanced) to avoid anaphylactic shock or hyperglycemia, respectively. The US remained onscreen until a response was made, followed by a variable ITI of 2 to 5 seconds before the next trial commenced. Participants were allowed a short break between the two blocks to allow them to rest.

\section*{Results}

Both RT and expectancy data were collected using MatLab and PsychToolbox (Brainard, 1997). RTs for US1 and US2 were recorded on each trial in milliseconds (ms). Any RTs over 1 second were excluded from the analyses. The mean RT for each run length for US1 and US2 can be seen in Fig. 1 top panel. In terms of expectancy, participants
were required to make ratings based on the extent they thought US1 was going to occur. Therefore, we divided the data into average expectancy for US1 on US1 trials and average expectancy for US1 on US2 trials for each participant on each run length, see Fig. 1 bottom panel.

Reaction times

\section*{Expectancy of US1}

Figure 1. The top panel displays the RT data for US1 and US2 across run length. The bottom panel displays the expectancy for US1 on US1 and US2 trials across run length.

A two-way repeated-measures analysis of variance (ANOVA) was run on the RT data using the factors US (US1 versus US2) and run length ( \(-4,-3,-2,-1,+1,+2,+3\), \(+4)\). A significant interaction between US and run length was found, \(F(7,238)=2.58, M S E=0.025, p=.029\), as well as a significant linear trend interaction, \(F(1,34)=8.84, M S E\) \(=0.085, p=.005\). This indicates that there is a significant difference in US1 and US2 RTs across run length. From Fig. 1 top panel, it can be seen that US1 RTs appear to increase after a run of US1 trials (i.e. RT increases when run length increases), whilst US2 RTs decrease after a run of US2 trials (i.e. RT decreases when run length increases).

One-way repeated-measures ANOVAs were then used to analyze the US1 and US2 RT data separately. There is a highly significant main effect of run length for the US2 RTs, \(F(7,336)=6.21, M S E=0.07, p<.001\). There was also a significant linear trend decreasing from -4 to +4 across run length, \(F(1,48)=16.86, M S E=0.27, p<.001\). With regards to US1 RTs, however, the numerically increasing linear trend from -4 to +4 was not significant.

A two-way repeated-measures ANOVA was also run on the US1 expectancy data, again with the factors US and run length. A significant interaction between US and run length was found, \(F(7,371)=3.39, M S E=22.42, p=.017\), as well
as a significant linear trend interaction, \(F(1,53)=4.43, M S E\) \(=48.92, p=.040\). This indicates expectancy of US1 on US1 differs significantly from expectancy of US1 on US2 trials across run length. From Fig. 1 bottom panel, it appears that expectancy for US1 on US1 trials decreases across run length whilst expectancy of US1 on US2 trials increases across run length.

One-way repeated-measures ANOVAs were then used to analyze expectancy on US1 and US2 trials separately. There is a significant main effect of expectancy of US1 on US2 trials across run length, \(F(7,399)=2.51, M S E=9.78, p=\) .041, and a significant linear trend increasing from -4 to +4 , \(F(1,57)=5.38, M S E=33.78, p=.024\). With regards to expectancy of US1 on US1 trials, a marginally significant main effect of run length was found, \(F(7,392)=2.44, M S E\) \(=11.26, p=.051\). However, the decreasing numerical linear trend was not reliable.

\section*{Discussion}

Regarding the expectancy measure (Fig. 1, bottom panel), we should make it clear from the start that both lines on the graph reflect US1 expectancy, however we have split this by whether the rating was taken on a US1 or US2 trial. Expectancy for US1 on US1 and US2 trials can be explained by the gambler's fallacy phenomenon (Burns \& Corpus, 2004). Expectancy of US1 after a run of US1 trials numerically decreases, while expectancy of US1 after a run of US2 trials increases. Thus, after a run of US1 trials the participant thinks US2 is more likely to occur, so expectancy of US1 declines; but after a run of US2 trials the participant now believes it is US1s turn, so expectancy of US1 increases.

Within the RT data, participants' responses to US1 numerically increased as a function of run length. This indicates participants were faster to respond after successive CS-US2 trials, and therefore were slower after successive CS-US1 trials. We found a negative correlation between US1 expectancy and US1 RTs, \(r=-.871, n=8, p=.005\). Thus, after a run of CS-US1 trials participants made lower ratings that US1 would occur and were slower to make US1 responses. Therefore it would appear that a propositional explanation would be sufficient to explain this result, by simply claiming expectancy directly influenced RT.

Turning to US2, we propose that, logically, if a participant is expecting one US to happen then they are not expecting the other, so if a participant is expecting a US1 trial to occur then that implies they are not expecting a US2 trial. This would suggest expectancy of the two USs is complementary such that, if expectancy of US1 is the highest possible rating (9), then expectancy of US2 should be the lowest possible rating (1). We can assume that these sum \((9+1=10)\) and thus calculate expectancy for US2 as equal to 10 minus US1 expectancy. Based on this assumption, we can predict participants' expectancy of US2 on US2 trials as being the complement of their expectancy of US1 on US2 trials, see Fig. 2. If this supposition is true, then we have shown expectancy of US2 on US2 trials decreases as a function of run length. Therefore, higher ratings of US2 are made if participants have experienced a
run of US1 trials, and vice versa. This pattern of responding can be attributed to the propositional, gambler's fallacy phenomenon discussed previously.

\section*{Expectancy on US2 trials}

Figure 2. This graph displays expectancy of US1 on US2 trials and the hypothetical expectacny of US2 on US2 trials.

In order to verify if our inference regarding expectancy of US2 on US2 trials was correct, 32 of our participants carried out a further two experimental blocks to those described in the earlier method section. In these blocks, two (identical) cylinders were presented (successively) and participants had to make an expectancy rating to each. One cylinder required the participants to make a "peanut butter" rating, the other a "brown sugar" rating. Participants then had to make the appropriate RT response as in the previous blocks. Comparing participants expectancy of US1 on US1 trials and their expectancy of US2 on US1 trials, there was a highly significant negative correlation, \(r=-.969, n=8, p<\) .001. This shows that on US1 trials, if participants were for example, expecting a US1 trial they were not expecting a US2, and vice versa. Additionally, comparing expectancy of US1 on US2 trials and expectancy of US2 on US2 trials, there was also a highly significant negative correlation, \(r=-\) \(.944, n=8, p<.001\). This also shows that on US2 trials, if participants were expecting a US1 they were not expecting a US2. Therefore, our earlier assumption receives considerable empirical support from this check.

Given that expectancy of US2 on US2 trials decreases as a function of run length, interestingly we found that US2 RTs also decreased as a function of run length (see Fig. 1). Participants were faster to respond to US2 on a run of CSUS2 trials, even though their expectancy that US2 would occur had decreased. We have therefore demonstrated a positive correlation between expectancy of US2 on US2 trials and US2 RTs, \(r=.833, n=8, p=.010\). For example, after a run of CS-US2 trials, participants rate that a US1 trial is more likely (and therefore a US2 is less likely), yet are faster to respond to US2. It is consequently hard to reconcile this expectancy with the RT result if we take the position that a single propositional explanation could explain our data. We would argue that associative, link-based processes are required to explain the RTs for US2. One version of this would be that when a person experiences the CS followed by US2, a link is set up between the two representations of these stimuli. After a run of CS-US2 trials this would strengthen the link between these stimuli, resulting in a stronger CR (i.e. a faster key press response) to US2.

However, after a run of CS-US1 trials, the link between CS and US1 strengthens, but the link between the CS and US2 weakens (extinction). Hence, the more consecutive CS-US1 trials there are, the weaker the CR to US2 (i.e. the slower the RT). The results for US2 are in agreement with previous Perruchet RT experiments, in which a single propositional process cannot explain both the expectancy and RT data.

In one experiment we have shown two different results, one where expectancy and RT appear positively correlated, and another where they are negatively correlated. We have, as a consequence, proposed a dual processing systems explanation of the US2 result. We would now like to pursue this further, by speculating how associative and propositional processes could produce both results. We hypothesize that the difference between the two effects (for US1 and US2) lies in where participants' attention is focused. As participants are directed to focus on one US (US1), to which they are making expectancy ratings, this effectively manipulates the expression of both propositional and associative processing systems for that US. We assume that because participants are attending to US1, they spend less time thinking about US2 and this would suggest conscious reasoning processes are more focused on the processing of US1 than US2. If US2 is not being consciously processed (to the same extent) then changes in US2 performance in the experiment might be driven by an alternative processing system. By reducing attention to US2, we believe we have created an environment conducive to associative learning. In contrast, a large amount of cognitive resource is being directed to processing US1, and perhaps this has led conscious processes to play a larger role in RT performance for this outcome, and inhibited the expression of associative processes in this case.

\section*{Modeling}

To explore how associative processes might be driving instrumental responses to US2, we chose to simulate this experiment using an established model of associative learning. We chose the augmented SRN (Cleeremans, \& McClelland, 1991; as revised by Yeates, Jones, Wills, McLaren, \& McLaren, 2013), which is particularly wellsuited to this task as the simple recurrent network (SRN; Elman, 1990) was devised to account for learning that is observed across sequences of trials. Our aim was to ascertain the extent to which learning is driven by the development of associative strength between the CS and US2, or whether the sequential structure of the experiment (runs of US1 and US2) is what drives this result.

The model (see Fig. 3) is a connectionist network that feeds input activation to a hidden layer, which in turn feeds activation forward into an output layer, each employing the logistic activation function (Rumelhart, Hinton, \& Williams, 1985). The activation of the hidden layer is copied back into a set of context units on each trial, which are then fed into the hidden layer as input on the next trial. This recurrent loop provides the model with a memory of the hidden layer's representation of the last trial. Learning occurs through back-propagation of error correction, comparing output activation to expected responses. Connection weight
changes to represent both short- and long-term learning are calculated using fast and slow learning rates, respectively. Fast weights have a higher learning rate but decay more rapidly, and were introduced to the model by Cleeremans and McClelland (1991) to account for the short term priming effects evident in their data. The slow weights reflect more permanent learning that takes a longer time to develop due to the lower learning rate.

\section*{Revised Augmented SRN}

Figure 3. Architecture of the revised version of the Augmented SRN by Yeates et al. (2013)

The model in this simulation involved two output units to represent Ctrl and Alt keypress responses to US1 and US2. As well as the context units (copy of the previous trial hidden unit activation) there were five additional input units. These followed revisions to the SRN by Yeates et al. (2013, see for further discussion) and included both a representation of the previous response made (two units, one for US1 and one for US2) as well as a representation of the on-screen stimuli on the current trial (one CS unit and two US units, one to represent each of US1 and US2). The free parameters of the model were: 20 hidden units with the learning rates set at 0.4 and 0.533 for slow and fast learning rates, respectively (based on Jones, \& McLaren, 2009).

The model was run 64 times with random initial weights of between -0.5 and 0.5 to give the same \(n\) of networks as participants in the experiment. Each of these simulations used binary input activations representing the exact occurrence of the CS and USs taken from the unique sequences that each of the 64 participants were given. Mean square error (MSE) was calculated as an index of responding to the US on each trial from the squared difference between output activations and the expected activations for the two possible responses ( 0.1 and 0.9 for incorrect and correct response, respectively). Trials were analyzed according to run length and US, like the variables of interest used in the behavioral experiment.

We analyzed the MSE for each US using one-way repeated measure ANOVAs and thus examined the modeling data in the same fashion as the behavioral data. There was a main effect of run length in both US1, \(F(7,406)\) \(=1339.80, M S E=0.67, p<.001\), and US2, \(F(7,441)=\) \(1546.46, M S E=0.67, p<.001\). Thus, for both US1 and US2 MSE differed according to run lengths. Furthermore, we found that there was a highly significant linear contrast on run length for both USs, \(F(1,58)=2633.43, M S E=4.44, p\)
\(<.001\), and \(F(1,63)=2908.722, M S E=4.14, p<.001\), for US1 and US2 respectively. This is seen quite clearly in Fig. 4, which shows a decreasing linear trend for both USs (which do not differ significantly) across run length. It can also be seen from the graph the two functions of MSE lie almost entirely on top of one another. Thus, responding to both of these USs is extremely similar, both demonstrating a reduction in error as run length increases.

\section*{Modelling data}

Figure 4. Graph of the mean square error (MSE) of the model

When comparing the modeling data to the human data we are using MSE as an approximation to RTs, as this is what we consider to capture the automatic, associative relationship between CS and US. We can see that human RT responding to US2 has the same, decreasing function across increasing reinforcement as is produced by the AugSRN. This is supported by a significant positive correlation between run length on RT and MSE results for US2, \(r=\) \(.895, n=8, p=.003\). Clearly then, the Augmented SRN is a good model of human performance on US2 in our experiment, but a poor one for US1.

Further investigation, however, reveals that the basis for performance may not be the conventional associative explanation offered for the Perruchet effect. There is no doubt that transient fluctuations in the strength of CS-US associations could explain the results observed for US2. But, the Augmented SRN can also learn about the sequence of events that take place, rather than just in terms of CS-US associations; and with the parameters given in Yeates et al., (2013) it could be that the pattern shown in Fig. 4 is based on this type of learning, rather than CS-US learning. This can be investigated by running the same simulation, but with the CS unit permanently set to zero so that no change in CS-US associations is possible. When we did this, the same function emerged, see Fig. 5. Thus, we would appear to have evidence suggesting that transient changes in CS-US associations might not be the basis of the function shown in Fig. 4. This result is reminiscent of that reported by Mitchell, Wardle, Lovibond, Weidemann and Chang (2010), who were able to get a Perruchet type effect in an RT experiment without any CSs. We have essentially the same result in our simulation, using a model that is well known for its ability to generate sequential effects.

But if sequential effects are the correct explanation of our modeling result, the removal of all the input units from the model (leaving only the hidden and output layers) should
abolish this effect, as there would be nothing left in the model that could produce sequential effects (no input or copy-back from the hidden layer). However, when we did this, we found the same decreasing function in MSE as seen before in our previous simulations (see Fig. 5). This demonstrates that sequential effects are not necessarily driving our result, but rather that the associative fluctuations between the hidden and output units are.

\section*{Further modelling}

Figure 5. Graph of the MSE for the further modelling
At the beginning of these last simulations the hidden units have activation values of 0.5 (corresponding to zero input). Therefore, after a reinforced trial the link between any hidden unit and the output unit will be strengthened. Consequently, if another reinforced trial follows the previous one this link is again strengthened leading the model to produce \(a\) smaller MSE. In contrast, \(a\) nonreinforced trial weakens this link, and the MSE increases. Therefore, there is an associative explanation for the Perruchet effect that emerges from this model, just not the classic explanation as it is usually cited. It is worth emphasizing that it is an associative explanation that applies here, and not one based on conscious, cognitive expectancy of the US. The pattern seen for US1 in our empirical data follows that generated by the expectancy ratings given by our participants and is quite different from both the pattern seen for US2 and the pattern generated by our model simulating an explanation in terms of CS-US associations, sequential effects, or hidden to output layer connections. The correlation between human RTs and modeling data for US1 is negative and non-significant across run length, \(r=-\) \(.562, n=8, p=.148\). Thus, an associative explanation will not fit these data, and a more cognitive model is required.

\section*{General discussion}

This paper presents behavioral and modeling data based on a new RT variant of the classic RT Perruchet paradigm. In our behavioral experiment we produced a Perruchet-type effect whereby expectancy of US2 decreased as a function of run length while RT responses to US2 decreased. We have rejected a single processing system explanation of learning in favor of a dual processing systems argument to explain this result. The propositional, gambler's fallacy heuristic (Burns \& Corpus, 2004) explains why expectancy of US2 decreased as the run of CS-US2 trials increased, as participants are deciding that it is less likely another US2 trial will happen if they have experienced a run of US2
trials. However, within the RT data, after a run of CS-US2 trials participants are faster to respond to US2 despite low expectancy that US2 will occur. This seems paradoxical when considered from a single systems view, but an associative account can explain the RT result, in terms of fluctuating hidden-output unit associations, sequential effects or CS-US associations. Our feeling is that it would be possible to parameterise the Augmented SRN to produce the US2 pattern of results on the basis of any of these potential mechanisms, though it would appear that in our current simulations the effect is mainly carried by fluctuating hidden-output associations. Note, however, that in Fig. 5 the pattern is more pronounced when the input to the model is enabled (suggesting that sequential effects can contribute), and we have run other simulations that show that the presence or absence of a CS representation can also strengthen or weaken this effect indicating that CS-US associations can also be effective in this model. More research will be needed to determine which of these mechanisms is the correct explanation for our data.

In conclusion, the evidence for dissociable propositional and associative processes provided by Perruchet type RT experiments is perhaps stronger than we thought. Explaining these effects with reference to a single propositional system, however, is likely to prove a difficult challenge for theorists of that persuasion.

\begin{abstract}
During experiments employing Perruchet's (1985) paradigm there are runs of reinforced (CS-US) trials and non-reinforced (CS-noUS) trials. Conditioned responding (CR) is measured, for example, using eyeblink responses (Perruchet, 1985), reaction times (Perruchet, Cleeremans, \& Destrebeceqz, 2006), or changes in skin conductance (SCR; McAndrew, Jones, McLaren, \& McLaren, 2012), as well as an online measure of expectancy for the unconditioned stimulus (US). A double dissociation between CR and conscious expectancy of the US is typically found, whereby expectancy of the US decreases while the CR increases across runs of successively reinforced trials. A gambler's fallacy explanation can be offered for the expectancy data, whereas an associative explanation can be used to explain variations in the CR (consistent with the dual processing theory of McLaren, Green, \& Mackintosh, 1994). However, skeptics of this effect have proposed nonassociative explanations of the CR data seen in these experiments. They note that every CS-US pairing is confounded by the presence of the US. Therefore, it is possible that US sensitization, the phenomenon whereby repeated US presentations leads to stronger unconditioned responding to the US, could produce the increasing CR pattern with successive reinforcements (Weidemann, Tangen, Lovibond, \& Mitchell, 2009). Two experiments are presented investigating whether US sensitization can explain the recently published electrodermal version of the Perruchet effect.
\end{abstract}

Keywords: Perruchet effect; US sensitization; Dual processing systems

\section*{Introduction}

The Perruchet effect (Perruchet, 1985, Perruchet, Cleeremans, \& Destrebeceqz, 2006) is often cited as one of the most convincing pieces of evidence of a dissociation between explicit, conscious, propositional processes and implicit, automatic, associative processes (e.g. Mitchell, De Houwer, \& Lovibond, 2009). McAndrew, Jones, McLaren and McLaren (2012) ran an electrodermal variation of the classic Perruchet experiment in which participants saw a visual conditioned stimulus (CS), a brown cylinder, which was partially reinforced by an electric shock (the unconditioned stimulus, US). The participants made online expectancy ratings on every trial as to whether they thought the US was going to occur. Changes in their autonomic skin conductance response (SCR) were also measured as an index of conditioned responding (CR).

We found that the SCR increased over successive reinforcements, while expectancy of the US decreased across the same sequence of trials. This mirrored the original findings of Perruchet and colleagues in both the eyeblink (Perruchet, 1985) and reaction time (RT; Perruchet, Cleeremans, \& Destrebeceqz, 2006) variants of this paradigm. The gambler's fallacy heuristic (Burns \&

Corpus, 2004), an explicit, propositional phenomenon, explained the expectancy data, implying that as participants experienced successive runs of reinforced (CS-US) trials, they were less likely to rate the subsequent trial as being paired with a US. Conversely, when participants experienced runs of successively non-reinforced (CS-noUS) trials they rated it as increasingly likely they would experience a US. However, this explanation did not apply to the SCR data, but an associative account did (e.g. McLaren, Forrest and McLaren, 2012). SCR increased over successive reinforcements, meaning that the CR was strongest when the participants had experienced a run of CS-US trials. In associative terms, during this type of Pavlovian conditioning, the link between the representation of the CS and the representation of the US was strengthened by the successively reinforced trials, producing a larger CR. However, after a run of CS-noUS trials, the link between the representations of the CS and the US was weakened by extinction, causing smaller changes in SCR and therefore a weaker CR. Hence, these results are consistent with a dual processing systems account of learning, with an explicit propositional system generating the expectancy data and an associative system the changes in SCR.

The Perruchet effect is one of the most compelling examples of dual processing systems due to the simultaneous measurement of CR and expectancy. Previous research demonstrating dissociations between these two variables has often involved subliminal presentations of the CS (e.g. Balderston, \& Helmstetter, 2010), but this research is often criticized about whether the presented stimuli are truly subliminal (e.g. Mitchel, De Houwer, \& Lovibond, 2009). Alternatively, researchers have attempted to use postconditioning questionnaires to assess contingency awareness, however it has been argued this type of measure could be subject to interference or forgetting influencing the reliability and validity of the awareness measure (Lovibond, \& Shanks, 2002). The Perruchet paradigm however, overcomes these problems and is a more convincing demonstration of a double dissociation.

However, the dual processing system account of the Perruchet effect depends critically on the assumption that the linear trend in CRs is the result of associative learning. Alternately the pattern of CRs could be accounted for by US sensitization; this effect refers to the increase in unconditioned responding (UR) seen when there is repeated exposure to a US (Weidemann, Tangen, Lovibond, \& Mitchell, 2009). In the Perruchet experiments, every CS-US pairing unavoidably involves presentation of the US. Therefore, it may not be the pairing of the two stimuli (CS and US) strengthening or weakening the associative link between the stimuli that is causing fluctuations in the SCR.

Instead, it could simply be exposure to the US driving this effect. If this were true, this would undermine the Perruchet effect as evidence for dual processing systems.

Research investigating US sensitization as an explanation of CR in the eyeblink and RT variants of the Perruchet effect has produced mixed results; with US sensitization failing to account for data from the eyeblink paradigm (e.g. Weidemann et al., 2009), but Mitchell et al. (2010) finding US sensitization a plausible explanation of the RT data despite Barrett and Livesey (2010) disagreeing. Given the inconsistency on this point, we felt that further investigation was important to determine whether US sensitization could account for the variations in the CR observed in the Perruchet effect. If it were found that US sensitization could adequately account for these results, a single, explicit, nonassociative processing explanation of the results would be sufficient.

In particular, it was important to try and determine whether US sensitization could explain the results reported in our 2012 paper. A lot of past research within the electrodermal domain finds a strong positive correlation between CR and conscious contingency knowledge, for example, if participants fail to develop CS-US contingency knowledge they often fail to show any CR (Lovibond \& Shanks, 2002). The implication is that to see a CR using electrodermal procedures, participants must explicitly expect the shock to happen when they are presented with a CS. This view is in stark contrast to our earlier findings. We hypothesized that we were able to dissociate the CR and expectancy of the US because of the nature of the Perruchet task. In our experiment there was a partial reinforcement schedule, half the trials were followed by a shock and half were not, and the participants were made explicitly aware of this from the beginning of the experiment. The participants were therefore put into a state of uncertainty from the start, as they were unable to accurately predict when the shocks were going to happen. Consequently, given that the participants were unable to use their rational, inferential processes to determine when the shocks were going to happen, this provides a context in which some reliance on alternative processing systems, which could be implicit or associative, might be expected. There is some evidence in the electrodermal domain to support this hypothesis. One example is Knight, Nguyen, and Bandettini (2003), who presented participants with tone stimuli, one continually reinforced by white noise (CS+) and another never paired with white noise (CS-). They varied US predictability by presenting the CSs above and below the perceptual threshold and found that even in the absence of any conscious ability to discriminate between the stimuli, there was still evidence of higher CRs to the CS+ than the CS-. Additionally, evidence of an implicit/explicit learning distinction can be found within the neuroimaging literature. Different brain structures appear to be involved in different aspects of learning to the extent that one can differentiate brain regions involved in conscious and unconscious learning (e.g. Tabbert, Stark, Kirsch, \& Vaitl, 2006).

Our aim here is to establish whether associative processes govern the CR in our experiments, by checking whether US sensitization can account for our findings. If we can rule out this explanation of our results, then we can add our experiment to the others that show that SCR and conscious expectancy can dissociate.

\section*{Experiment 1}

One of the simplest ways to investigate whether US sensitization governs CR in our Perruchet experiment was to simply remove the CSs. In this way participants would only experience noCS-US trials and noCS-noUS trials. If the same increasing patterns in SCR were found as in the original experiment, this would imply that the result was not dependent on CS-US pairings, as there are no CSs presented in the experiment. Under these circumstances we could conclude that US sensitization would be driving responding. However, if SCR fails to increase over successive US presentations, this would tend to suggest that a US sensitization account could not explain the electrodermal variant of the Perruchet effect.

\section*{Method}

\section*{Participants}

24 University of Exeter students participated in this experiment, 16 women and 8 men; ages ranging from 18-35 (average, 21 years). All were paid \(£ 10\).

\section*{Stimuli}

The US was a 500 ms electrical impulse administered with a PowerLab 26T generator using stainless steel electrodes attached to the left proximal and medial phalanges of the index finger. Participants set their own shock level between 5 and 20 mA where they deemed the shock to be "definitely uncomfortable but not painful".

Throughout the experiment there was a black cross (5 x 5 cm onscreen) in the centre of a white screen. The cross was used to fixate participants' attention.

Skin conductance was measured using LabChart software via MLT116F GSR electrodes attached to the medial phalanges on the left third and fourth fingers. Online explicit expectancy of the US was recorded using a Contour Shuttle Xpress device. Roughly every five seconds participants were required to make an expectancy rating about the extent they thought the shock would happen at that moment in time. The device had 5 buttons and fit nicely into participants' hand whereby 1 button corresponded to 1 finger. The different expectancy values were: 1 "There will definitely not be a shock", 2 "There might not be a shock", 3 "Not sure either way", 4 "There may be a shock", and 5 "There will definitely be a shock". A continuously available key explained which buttons represented which expectancy ratings.

\section*{Design}

There were two repeated-measures factors in this experiment. The first was run length, i.e. the number of trials of the same type in a row; there were six different run
lengths: \(-3,-2,-1,+1,+2\), and +3 . The run length measure is taken on the trial after the run itself. For example, \(a+1\) run length SCR is taken on the trial after a participant has previously experienced a US trial that itself was preceded by a noUS trial. A +2 measurement is taken on the trial following two consecutive US trials. Whereas, a -1 run length measurement is taken if the participant has just experienced exactly one noUS trial, and a - 2 measurement is taken when a participant experiences two noUS trials in a row. A switch between a positive and negative run length measurement occurs when the trial type just experienced switches from a US to noUS trial and vice versa. The other factor used in the design and analysis is the presence or absence of the US on the trials in the run, i.e. shock ( + ) or no shock (-).

The trial sequences used in this experiment were matched to the sequences used in the original McAndrew, Jones, McLaren and McLaren (2012) experiment, using the same trial structure and run distributions, see Table 1. In the McAndrew et al. experiment, on shock ( + ) trials, a 500 ms US was administered after 4500 ms of the CS being on screen, whereas on no shock (-) trials no US occurred. SCR recordings were taken on every trial, during the five seconds prior to CS onset (PreCS), five seconds while the CS was on screen and five seconds after the CS (PostCS). The intertrial interval (ITI) was randomly varied between 30 and 40 seconds on each trial in order to stop participants timing the onset of the CS. Long ITIs were required to allow the SCR recording to reach baseline after the previous US. This experiment, in keeping with the procedures used in the original experiment, was split into two blocks to allow recalibration to the shock to reduce habituation. Overall there were 46 trials, 23 per block. An extra trial was added at the end of each block, the \(23^{\text {rd }}\) trial, to take measurements from the last experimental trial. As there were no CSs in this experiment, on each trial, a hypothetical 5 second "CS" period was measured (where the CS would have occurred), and 5 seconds before this as a "PreCS" measure was taken. On shock trials, the shock would occur in the last 500 ms of the "CS" period.

Table 1. Trial types by frequency of occurrence.
\begin{tabular}{lcccccc}
\hline \multicolumn{1}{c}{ Variable } & & noUS (-) & & \multicolumn{2}{c}{ US (+) } \\
\hline Run length & 3 & 2 & 1 & 1 & 2 & 3 \\
Frequency & 2 & 4 & 8 & 8 & 4 & 2 \\
\hline
\end{tabular}

\section*{Procedure}

The participants were told they would receive shocks randomly throughout the experiment without any warning they were going to occur. The participants were asked to rate their expectancy that the shock would occur at that moment in time roughly every 5 seconds throughout the duration of the experiment. Expectancy ratings were made using the Shuttle Xpress device, on the scale 1 (definitely no shock) to 5 (definitely shock). Otherwise they were asked to remain still to avoid motion artifacts in the SCR.

\section*{Results}

The SCR data was recorded in micro-Siemens in LabChart and exported to Excel. For each trial the mean SCR was taken for the hypothetical "PreCS" and "CS" periods. The data was standardised using a log transformation to reduce the variability between participants. The change in SCR prior to US onset (as a consequence of preceding runs), was calculated using the formula "CS-PreCS". Mean CR for each run length was then calculated for each participant and across participants. For the expectancy data, the rating made closest to the hypothetical CS period was used as the participants' expectancy of the US on that trial. A mean expectancy rating for each run length was calculated for each participant and then across participants. Additionally, as in the 2012 experiment, the SCR and expectancy data were collapsed to form levels 1, 2 and 3. Level 1 averages run lengths +1 and -3 , level 2 run length +2 and -2 , level 3 run lengths +3 and 1. This was done to treat the data in a similar fashion to the 2012 experiment to enable direct comparisons to be made.

Two-way repeated measures analyses of variance (ANOVA) were carried out separately on the SCR and expectancy data. With regards to SCR, there was no significant linear trend over level, \(F(2,46)=0.26, M S E=\) \(0.004, p=.774\), see Fig. 1, a Bayesian analysis (Dienes, 2011) confirmed that we have strong evidence for the null hypothesis, rejecting US sensitization as an explanation of our effect, Bayes factor \(=0.32\). There was a significant effect of US presence, with a higher mean SCR after US absent trials \((-0.02)\) than US present trials \((-0.04\), see Fig. 2), \(F(1,23)=5.43, M S E=0.003, p=.029\). The interaction between level and US presence was not significant ( \(p>.05\) ).

There was a significantly increasing linear trend over level in the expectancy data, \(F(2,46)=5.04, M S E=0.257, p\) \(=.014\), see Fig. 1. There was also a significant effect of US presence with a higher mean expectancy rating for US absent trials (3.68) than US present trials (3.17, see Fig. 3), \(F(1,23)=18.41, M S E=0.496, p<.001\). In addition, there was a significant linear interaction between level and US presence, \(F(1,23)=14.77, M S E=0.213, p=.001\), reflecting the fact that measures taken after US present ( + ) trials increase as a function of level whereas those taken after US absent (-) trials slightly decrease.

\section*{Experiment 1 Results}

Figure 1. Graph depicting changes in SCR and expectancy as functions of level.

\section*{Discussion}

This experiment aimed to investigate the extent to which US sensitization is a plausible explanation of the SCR result observed in our original 2012 experiment. In that earlier experiment participants experienced exactly the same sequences of shocks as used here (NB. a different sequence for each participant), but the shocks followed a CS (a picture of a brown cylinder). This CS also occurred on noshock trials, so that it had a \(50 \%\) rate of reinforcement. McAndrew et al. (2012) found that autonomic SCR increased significantly with level, whilst explicit expectancy decreased significantly with level.

In the current experiment participants experienced runs of USs and noUSs in the absence of this CS. Hence, there was no associative structure to drive changes in SCR, and now SCR is essentially flat across level. This indicates that US sensitization is not occurring in this experiment, as successive shocks are not leading to an increase in SCR as would be expected if this were happening. This suggests that US sensitization is not responsible for the SCR pattern seen in the 2012 experiment, making the case that associative processes are responsible somewhat stronger.

Supporting this analysis, a significant effect of US presence was found in the SCR data, with higher SCRs observed on measurements taken after noUS (-) trials. Therefore, there were bigger changes in SCR just after nonreinforced runs (when shocks were not occurring; see Fig. 2). We conjecture that the SCR may be subject to habituation rather than sensitization using our procedures, because exposure to shocks appears to be causing smaller rather than larger SCR fluctuations. Alternatively, it could be that any learning to the temporal cues is being expressed more in the PreCS period than the CS period, explaining the negative difference scores.

\section*{Changes in SCR}

Figure 2. Graph depiciting SCR as a function of run length.
Regarding expectancy, the data is more complicated. A significantly increasing effect of level was found as well as a significant US presence effect such that expectancy of shock was higher after US absent (-) trials. These two findings at first seem paradoxical, with the latter suggesting participants gave higher expectancy ratings if there had not been any shocks, while the former implies the opposite (see Fig. 3). The increase in expectancy with level is entirely driven by the US present \((+)\) trials, and could simply reflect use of another heuristic, the "hot hand" effect (Burns \&

Corpus, 2004). Here we speculate that participants are simply tracking runs of shocks, and once they have had two in a row decide that the run is likely to continue. Regarding the US presence effect, participants gave higher ratings of shock after US absent trials where no USs occurred. This implies participants expected shocks more when there had not been one recently. We speculate that because participants knew that in this experiment, the only thing that would happen was that intermittent shocks would occur, as time elapsed ratings for a shock occurring would tend to increase as they knew that eventually a shock had to happen. We recorded the expectancy ratings participants made over each trial in 5 second bins (we had to exclude one bin as this varied from 5 to 15 seconds due to recording issues caused by a variable ITI). Supporting our speculation, expectancy significantly increases as time elapses between trials, \(F(1,23)=75.41, M S E=11.99, p<.001\), i.e. once a participant is shocked ratings of another shock occurring are lower just after this, but as time elapses the rating increases. In some sense this is a temporal equivalent of the gambler's fallacy heuristic, but this time it is an entirely rational reflection of the sequences experienced in this experiment.

By combining these two effects we can explain the pattern of results shown in Fig. 3. The gradual increase in expectancy with time since the last shock sets the overall trend, and tracking of runs of USs explains the increasing trend for positive runs superimposed on this overall effect.

This pattern of results conflicts with our 2012 expectancy finding that expectancy of shock decreased as a function of level. Comparing both experiments, we have two very distinct patterns of responding, which suggests we have fundamentally changed the paradigm and the demand characteristics from our original experiment, leading participants to approach the task differently. Given that both SCR and expectancy show an overall decline across run length in this experiment we could even claim that our data are consistent with the conscious expectancy-driven account of SCR often found in the literature on electrodermal conditioning. What this pattern of effects cannot do, however, is explain the quite different pattern found by McAndrew et al. (2012).

\section*{Expectancy rating}

Figure 3. Graph depiciting expectancy as a function of run length.

We hypothesise that the crucial factor causing the difference between the results of this experiment and the 2012 experiment is the absence of the CS. In this experiment participants only experience one stimulus (the US) as opposed to two interacting stimuli (the CS and the US). But can we be sure that sensitization is not a factor in our experiment? We see two possible issues that need to be investigated. The first stems from the possibility that any change in SCR consequent on experience of shock is being expressed in the PreCS period because of timing issues. If sensitization were occurring, but manifesting in the PreCS window, then this would have the effect of driving our SCR measure down. In the McAndrew et al. (2012) experiment the CS could be used to eliminate this timing issue, and so the sensitisation would now manifest in the CS period and drive the measure up. Weidemann et al. (2009) have also proposed that the expression of US sensitization is dependent on a weakly conditioned discrete cue being present. Given this, we cannot establish that US sensitization is not driving the SCR in our 2012 experiment as matters stand. This is addressed in Experiment 2.

\section*{Experiment 2}

This experiment uses a discrete cue to provide the correct context for the expression of US sensitization (Weidemann et al., 2009). Therefore, there are CS-US, CS-noUS, noCSUS and noCS-noUS trials in this experiment. The US sequences used were mapped to those in the previous experiments except that we added strategically placed CSs, one per run length per block. These CSs were placed on these specific runs to avoid the build up of associative strength, and alternated in terms of being reinforced or not. SCR was measured on these trials, and, due to the absence of any associative structure during the preceding run, if an increase in SCR across run length (and level) is found, US sensitization would explain this. However, if we fail to find an increasing pattern an alternative explanation for our 2012 results must be sought, perhaps an associative one.

\section*{Method}

\section*{Participants}

24 people participated in this experiment, all University of Exeter undergraduate students, 15 women and 9 men, ages ranging from 18 to 24 years old (average, 19 years). All participants were paid \(£ 10\).

\section*{Stimuli}

The same stimuli were used in this experiment as in the previous one. However, on the trials where a CS was presented, a brown cylinder ( \(19 \times 13 \mathrm{~cm}\) onscreen) appeared for 5 seconds (the same as used in McAndrew et al., 2012). Participants were asked to make explicit expectancy ratings just as they were in the first experiment, every 5 seconds.

\section*{Design}

The sequences were the same as those used in Experiment 1, however, a CS was added to 6 trials per block, one on each of the \(-3,-2,-1,+1,+2\) and +3 runs. There is only one
+3 and -3 run per block so these always had a CS. A CS was then randomly allocated to a \(+2,-2,+1\), and -1 run. Three additional trials were inserted at the start of each block, CSUS, CS-noUS, CS-US, in order to create the weakly conditioned discrete cue. Thus, overall there were 52 trials.

\section*{Procedure}

Participants were told that sometimes they would see a brown cylinder come on the screen. Half the time it would be followed by a shock and half the time not, but sometimes they would receive a shock when the cylinder was not there. Other procedures were as in the previous experiment.

\section*{Results}

The SCR data was treated in much the same way as in Experiment 1, with regards to data collection and log transformation. A measure of the CR was taken for each trial on which the CS was present using the formula, CSPreCS. A mean SCR measure was then recorded for each run length and averaged across participants. With regards to the expectancy data, the expectancy rating made during the actual CS period was taken as participants' expectancy of the US on that trial. Again, a mean rating for each run length was calculated for each participant and then across participants. Both data sets were collapsed to form the variable level (see Fig. 4).

\section*{Experiment 2 Results}

Figure 4. Graph depicting changes in SCR and expectancy as functions of level.

Two-way repeated measures ANOVAs were run on the SCR and expectancy data separately. In the SCR data, there was no significant linear trend over level, \(F(1,23)=1.82\), \(M S E=.023, p=.190\), Bayes factor \(=0.31\), so we have strong evidence for the null hypothesis leading us to reject US sensitization as an account for this result. Nor was there a significant difference between the US present and US absent trials or any interaction ( \(p>.05\) ). With regards to the expectancy data, there was a significantly increasing linear effect across level, \(F(1,23)=5.52, M S E=2.19, p=.028\). Additionally, there was a significant effect of US presence, with a higher mean expectancy rating for US absent (3.69) compared to US present (2.90) trials, \(F(1,23)=39.35, M S E\) \(=22.56\), \(p<.001\), see Fig 5. However there was no interaction between these two variables ( \(p>.05\) ).

\section*{Discussion}

Weidemann et al. (2009) proposed that in order to see the effects of US sensitization, the experimental context had to incorporate a discrete CS. Therefore, Experiment 2 aimed to do this to keep the context of the experiment similar to that of the original 2012 experiment. The CSs were strategically placed on one of each US run length, to measure UR without the build up of associative strength. In some sense our manipulation has been successful, as now the SCR changes recorded are all positive, as was the case in our 2012 experiment.

Analysis of the SCR data shows we have found another case where SCR is flat across run length and level. There is no sign of an increasing trend, which would be expected if presentation of the US is sensitizing participants. This null result strengthens the case against the nonassociative US sensitisation account as an explanation of the SCR result seen in the original Perruchet experiment. In the absence of any evidence to the contrary, we propose that associative processes are driving performance in the original 2012 paradigm, consistent with a dual processing system account of learning (McLaren, Green, \& Mackintosh, 1994).

\section*{Further Results}

Figure 5. Graph depicting changes in SCR and expectancy as functions of run length.

With regards to the expectancy data, despite our changes to the paradigm, we have obtained the same pattern as we found in Experiment 1. There is a significant linear increase in expectancy across level, yet an overall decrease in expectancy from US absent to US present trials. The explanation we proposed for Experiment 1 can also account for this result. Despite CSs being present in this experiment, participants are still instructed that shocks will happen intermittently throughout the experiment regardless of the presence/absence of the CS. Therefore, as time elapses participants give higher ratings for shock, which then decrease once a shock has occurred. Once again we speculate that they track runs of USs, and this effect is superimposed on the overall trend due to elapsed time.

\section*{Conclusion}

In two experiments we investigated whether nonassociative US sensitization could explain the original result found in McAndrew et al.'s (2012) experiment. In
both cases there was no evidence for sensitization to the US, and the pattern of results was different to that obtained in the Perruchet paradigm. We conclude that a dual processing system explanation (e.g. McLaren et al., 1994), appealing to explicit, propositional processes to explain the expectancy data as opposed to associative, autonomic accounts of the SCR data, is still the most convincing account of McAndrew et al.'s (2012) results.

\begin{abstract}
Theory of mind (ToM) is required when reasoning about mental states such as knowledge, beliefs, desires, and intentions. Many complex reasoning tasks require domaingeneral cognitive resources such as planning, resistance to interference, and working memory. In this paper we present a study of the additional cognitive costs of reasoning about mental states. We presented participants with sequential games in which they have to reason about another player. In the so-called player condition, the other player is reasoning about the participant, whereas in the so-called balance condition, the other player is reasoning about a balance scale. Both types of games require the same comparisons, but only differ in the required depth of ToM reasoning. Games in the player condition require one additional switch between perspectives. The results show that participants make different types of mistakes in the player condition as compared to the balance condition. This finding implies a different reasoning process when reasoning about mental states. The results also show faster decreasing reaction times in the balance condition than in the player condition. Based on these findings, we argue that reasoning about mental states requires unique cognitive resources.
\end{abstract}

\section*{Introduction}

In many social interactions we reason about one another. If, for example, our decisions or outcomes depend on someone else's actions, we try to predict what the other will do. Predicting the other's actions requires an understanding of how behaviors are caused by mental states such as beliefs, desires, goals, et cetera. Such an understanding is often referred to as theory of mind (Premack \& Woodruff, 1978).

A theory of mind, or ToM, is starting to develop around the age of three to four years (Wellman, Cross, \& Watson, 2001; Wimmer \& Perner, 1983). However, younger infants already are susceptible to others' mental states (Onishi \& Baillargeon, 2005). One possible explanation is that they are able to read others' behavior, but cannot yet explicitly reason about the underlying mental states. Only after many interactions, reading many distinct behaviors, do children start to develop a theory of how behaviors generally correspond with beliefs, desires, intentions, et cetera.

So far, we have introduced ToM as being a theory (Gopnik \& Wellman, 1992). However, we do not want to exclude another definition of ToM that considers it to be an ability or skill to reason about mental states of oneself and
others (Apperly, 2011; Leslie, Friedman, \& German, 2004; Van Rij, Van Rijn, \& Hendriks, 2010; Wimmer \& Perner, 1983). In fact, a theory alone would not suffice when reasoning about others' mental states. Such reasoning is an entire process of generating many possible mental state interpretations (Baker, Saxe, \& Tenenbaum, 2009), and ToM reasoning might be qualitatively different from other kinds of reasoning.

Some studies have shown similar but uncorrelated developmental trends in ToM tasks and non-mental tasks that require similar representations (Arslan, Hohenberger, \& Verbrugge, 2012; Flobbe, Verbrugge, Hendriks, \& Krämer, 2008). For example, a relative clause in the sentence "The goat that pushes the cat" requires a similar representation as the complement clause in "Alice knows that Bob is writing", but only the complement clause requires a mental state representation. As children become older, they get better at understanding both types of sentences. However, their performance does not correlate when the factor age is controlled for. These findings show that ToM tasks might consume unique cognitive resources. It is important to note, however, that these tasks might have differed with respect to other factors, besides the aspect of mental representations.

Some studies show similar performance in ToM tasks, on the one hand, and equivalent but non-mental control tasks, on the other. In the false-belief or Sally-Anne task, for example, children have to attribute a false belief about an object's current location to Sally (Wellman et al., 2001; Wimmer \& Perner, 1983). Sally stores an object at location A, but the object is moved from location A to location B while Sally is away. Therefore, Sally still thinks that the object is at location A. To pass this task, children should acknowledge that Sally falsely believes that the object is still at location A. The false-sign task is a similar but nonmental counterpart of the false-belief task. An object is first stored at location A, indicated by an arrow. Next, the object is moved from location A to location B, but the arrow still points at location A. The false sign in this task is the arrow pointing at location A, which is similar to Sally's false belief. Children's accuracy in both tasks is similar, and their performance correlates, even after correcting for age (Apperly, 2011; Leekam, Perner, Healey, \& Sewell, 2008; Sabbagh, Xu, Carlson, Moses, \& Kang, 2006). This finding implies that mental state reasoning might not qualitatively differ from other kinds of reasoning.

Figure 1. Examples of two-player Marble Drop games. A white marble is about to drop, and its path can be manipulated by turning the orange and blue trapdoors. In these example games, participants have to obtain as many orange diamonds as possible and they control the orange trapdoors. The other player has to obtain as many blue diamonds as possible and controls the blue trapdoor. In game \(a\), the optimal decision for a participant is to let the white marble drop into the topmost bin, thereby obtaining 3 orange marbles. The 4 orange diamonds in the bottom-left bin are not obtainable, as the other (blue) player's optimal decision is to let the white marble drop into the middle bin: The other player knows that the optimal (orange) decision at the bottom trapdoors is to go left, yielding a suboptimal outcome of 1 blue diamond for Player 2. Games \(a\) and \(c\) are second-order games, because participants (as Player 1) have to reason about the other player (i.e., Player 2) who in turn has to reason about Player 1. The games in \(b\) and \(d\) are first-order counterparts of the games in \(a\) and c, respectively. They require the same comparisons, as the outcome of the balance scale is congruent with Player 1's last correct / rational decision: Both depend only on Player 1's diamonds in the bottom two bins. However, the games with the balance require one fewer switch between Player 1 and Player 2 perspectives.

Similar accuracy of responses in ToM tasks and their nonmental counterparts, however, does not necessarily imply a similar reasoning process. Moreover, differences might manifest themselves elsewhere, for example, in the reaction times. If, for example, both tasks require overlapping cognitive functions but ToM tasks require additional cognitive processing, the response patterns might not differ as much as the associated response times. Moreover, differences in accuracy might not manifest themselves until the tasks become more complex and exhaust cognitive resources.

Given these mixed findings, the question remains whether reasoning about mental states requires additional cognitive resources. Complex reasoning tasks consume cognitive resources, because oftentimes they require integration of information in the overall reasoning process. Integration of information and reasoning require executive functions such as planning, set shifting, resistance to interference, and working memory. It is not yet obvious why these executive functions alone would not suffice to reason about mental states.

In this study we investigate whether reasoning about mental states consumes unique cognitive resources. Participants are presented so-called Marble Drop games (Figure 1) in which they have to reason about another player. Marble Drop games have a recursive structure because the best possible, or optimal, decision at the first trapdoor depends on the other player's decision at the
second trapdoor, which in turn depends on the outcome at the third trapdoor (Meijering, Van Rijn, Taatgen, \& Verbrugge, 2011). The crucial factor in this experiment is whether the outcome at the third trapdoor is determined by Player 1's decision (player condition) or by the physics of a balance scale (balance condition). Both conditions require the same comparisons, but games in the player condition require one additional switch between player perspectives: Player 1 has to reason about what Player 2 thinks that Player 1 will do at the final trapdoor. If reasoning about mental states requires additional cognitive resources, games in the player condition would be more difficult than games in the balance condition.

\section*{Method}

Participants are always assigned to the role of Player 1, and in both conditions they need to take the perspective of Player 2 to predict the outcome at the second trapdoor. This perspective taking requires ToM. As explained previously, the decision at the second trapdoor depends on the outcome at the third trapdoor. If the participants (i.e., Player 1) control that trapdoor, they need to switch perspective again. They need to re-take their own perspective from within Player 2's perspective. This requires second-order ToM. In the balance scale condition, participants do not have to switch perspective again, and thus need first-order ToM at most. They still need to make the same comparisons, as the outcome of the balance scale depends on Player 1's payoffs
and this outcome is congruent with Player 1's goal to maximize his or her payoffs.

If ToM requires unique cognitive resources, we expect that participants respond faster in the balance condition than in the player condition, because the balance condition requires one switch less between Player 1 and Player 2 perspectives than the player condition. We also expect better performance in the balance condition, because Marble Drop games in which Player 1 controls the third trapdoor might appear to be less deterministic. The assumption, here, is that it is easier to attribute knowledge of physics to Player 2 than to attribute to Player 2 epistemic reasoning about Player 1, as epistemic reasoning involves testing of multiple possible Player 2 perspectives.

\section*{Participants}

Forty-two first-year Psychology students (30 female) participated in exchange for course credit. The average age was 21 years, ranging from 18 to 25 . Each participant reported normal or corrected-to-normal visual acuity.

\section*{Stimuli}

Of all possible payoff structures, only those that are diagnostic of second-order ToM reasoning were included in the experiment. A game is diagnostic of second-order ToM reasoning if it requires a participant to reason about each decision point to arrive at the optimal decision. An example of a non-diagnostic payoff structure is one in which Player 1's first payoff, in the topmost bin, is the maximum payoff in that game. In that case, Player 1 would not need to reason about the second and third decision points. The payoff structures are listed in a table, which can be found at http://www.ai.rug.nl/~meijering/marble_drop.html.

\section*{Design}

The experimental design consists of two between-subjects conditions: balance condition versus player condition. In the player condition, participants are presented with the original second-order ToM games (Meijering, Van Rijn, Taatgen, \& Verbrugge, 2012). In the balance condition, participants play the games with the same payoff structures, but the third decision point is replaced by a balance scale. Importantly, the games in both conditions are equivalent, as they require the same comparisons between payoffs. In each game, the outcome of the balance is the same as the last correct / rational decision of Player 1, because both only depend on the number of Player 1 diamonds in the bottom two bins (see Figure 1).

\section*{Procedure}

After giving informed consent, participants were seated in front of a 24 -inch iMac. They were randomly assigned to the balance scale condition or the player condition. The participants were instructed that their goal was to obtain as many diamonds as possible of their target color, either blue or orange, which was counterbalanced between participants. They were also instructed that Player 2's (i.e., the
computer's) goal was to obtain as many marbles as possible of the other color.

The experimental procedure is the same in both ToM conditions. Participants are presented 62 unique games. At the start of each game, participants have to decide whether to stop the game, by letting the white marble drop into the top bin, or to continue the game, by letting the white marble drop onto Player 2's trapdoor. The game stops if Player 2 decides to let the white marble drop into the middle bin. If Player 2 decides to let the white marble drop onto the third trapdoor, participants in the player condition have to decide whether to stop the game in the bottom-left or bottom-right bin. In the balance condition, the physics of the balance scale determine whether the marble drops into the bottomleft bin or the bottom-right bin. Importantly, the balance scale is set in motion as soon as the white marble drops onto it. Otherwise, Player 2 would not have to reason about the balance scale. Each game is fully animated. See Figure 1 for some example games.

After each game, participants receive feedback that mentions Player 1's outcome. If, for example, the marble drops into a bin that contains two diamonds for Player 1, the feedback mentions: "You get 2 ".

To familiarize participants with the rules of Marble Drop games, participants are presented additional feedback during the first 12 games. Feedback explicitly mentions whether the outcome is the highest attainable Player 1 payoff. In case a participant obtains 3 diamonds and could not have obtained more, feedback is: "Correct. You get 3. The highest possible payoff!". In case a participant obtains 3 diamonds, but could have obtained 4, feedback is: "Incorrect. You get 3. You could have obtained 4".

\section*{Results \& Discussion}

The data consist of 62 unique Marble Drop games (i.e., payoff structures) for each participant. In the statistical analyses, the games are blocked to accommodate non-linear and differential learning rates: The first 12 'training' games comprise the first block, and the remaining 50 games are split into 5 subsequent blocks of 10 games each. The graphs show means and standard errors, which are represented by error bars.

The data are analyzed by means of linear mixed-effects models (Baayen, 2008; Baayen, Davidson, \& Bates, 2008) to accommodate random sources of variation due to sampling of participants and items (i.e., payoff structures). Specifically, each model allows for by-participant and byitem adjustments of the intercept. For each analysis that we report below, we first constructed a full factorial model with all main and interaction effects. Based on likelihood ratio comparisons, we removed main and interaction effects for as long as the corresponding parameters were not justified. If a comparison preferred a simplified model, we report the log-likelihood statistics. The correctness of responses is analyzed by means of logistic linear mixed-effects models, as correctness of responses is a binary variable (incorrect vs. correct).

\section*{Mean Proportion Correct}

The proportion of correct responses in each block is averaged across participants and depicted in Figure 2. The figure does not show great differences between performance in the balance scale and player conditions.

A full-factorial model with main effects and an interaction effect of Condition and Block did not fit the data better than an additive model, \(\chi^{2}(5)=6.08, n s\). The parameters of the additive model are discussed below.

There is a significant effect of Block, \(\beta=1.37, z=10.89\), \(p<.001\). As can be seen in Figure 2, performance increases over the course of playing many Marble Drop games.

Figure 2: Mean proportion of correct responses per block; depicted separately for participants in the balance condition (light gray) and the player condition (dark gray).

There is no effect of Condition, as can be seen in Figure 2. In contrast to our hypothesis, the probability of making a correct decision does not differ between the balance scale and player conditions. An analysis of the types of errors (next section: Types of Errors), however, shows differential errors between the balance scale and player conditions.

\section*{Types of Errors}

The errors that participants made were categorized according to game type, as an overall analysis might not be sensitive enough to differentiate between the balance scale and player conditions. Two types of games were distinguished on the basis of Player 2's (programmed) decision, which is either stop the game or continue.

There is no main effect of Player 2 decision, \(\beta=-.08, z=\) \(-.575, n s\), which means that the difficulty of a game does not depend on Player 2's decision. This finding implies that there is no reason to believe that there are particular subsets of hard(er) payoff structures among the selected payoff structures.

There is a significant interaction effect between the factors Condition and Player 2 response (see Figure 3), \(\beta=\) \(.65, z=3.349\), and \(p<0.001\). In the balance scale condition, the probability of making a correct decision does not differ between games in which Player 2's decision is to stop, on the one hand, and games in which Player 2's decision is to continue, on the other hand. In the player condition, in contrast, there is a difference. One possible explanation is that participants in the player condition expect Player 2 to continue in most games, and this expectation pays off in games in which Player 2 actually decides to continue. In each game, Player 2 has a greater payoff in one of the last two end states than in the earlier end state, and participants might assign too great a probability to Player 2 going for that payoff. Participants in the balance condition, in contrast, might estimate those probabilities more accurately (i.e., lower), because games with a balance scale can be considered more deterministic.

Player 2 decision
Figure 3: Mean proportion of correct responses across participants, depicted separately for the balance scale and player conditions, and Player 2's decision.

\section*{Reaction Times}

There are differences in the types of errors between participants in the balance scale and player conditions, but what about the reaction time data? RTs are analyzed to find out whether a switch between perspectives comes with a time-cost. The RTs are log-transformed as reaction times are skewed to the right. Figure 4 shows the average log-RT across participants.
Figure 4 shows differential learning rates between participants in the balance scale and player conditions, especially in the first half of the experiment, in blocks 1 to 3 . In the second half, blocks 4 to 6 , the learning rates do not seem to differ that much. To specifically accommodate for differential learning rates, the factor Block was reparameterized as a new factor Half, with levels 1 and 2 , and
a new factor Block with levels 1, 2, and 3 within each level of Half. The results of the full factorial LME with main and interaction effects of Condition, Half, and Block are discussed below.

The main effects of Half and Block (with linear contrast) are significant, \(\beta=-.22, t=-7.82, p<.001\), and \(\beta=-.18, t\) \(=-5.37, p<.001\), respectively. From the first to the second half of the experiment, and within each half, the RTs decrease linearly. The interaction between Half and Block is also significant, \(\beta=.15, t=3.19, p=.0015\). The decrease in RTs is stronger in the first half of the experiment than in the second half.

Figure 4: Average log-RT across participants plotted against block, separately for the balance scale and player conditions.

The interaction between Condition and Block is significant, \(\beta=.17, t=-3.43, p<.001\). The decrease in RTs in the first half of the experiment is less strong in player condition than in balance scale condition. This finding is partly congruent with the hypothesis that RTs are shortest in the balance scale condition because it requires fewer switches between perspectives than the player condition. There is, however, no main effect of Condition, \(\beta=.14, t=\) \(1.2, n s\). Thus, on average, the RTs do not differ between the balance scale condition and the player condition. However, participants in the balance scale condition do become faster towards the end of the first half of the experiment, whereas participants in the player condition do not become faster. A possible explanation is that participants in the balance scale condition are quicker over the course of playing multiple games to attribute an understanding of gravity to Player 2. In contrast, participants in the player condition need to play more games and test multiple Player 2 perspectives.

The interaction between Condition, Half, and Block is also significant, \(\beta=-.14, t=-2.83, p<.005\). As can be seen in Figure 4, the differential learning rates in the first half of
the experiment disappear in the second half of the experiment, where the RT trends do not differ that much between the balance scale condition and the player condition.

In sum, there is an interaction effect of Condition and Block on the RTs, and this effect is mainly present in the first half of the experiment. There, the RTs decrease more in the balance scale condition than in the player condition. This interaction effect, between Condition and Block, seems to disappear in the second half of the experiment. A possible explanation for the latter finding is that, initially, participants in the balance scale condition settle more quickly on the correct Player 2 perspective than participants in the player condition, who test multiple Player 2 perspectives across multiple games.

\section*{General Conclusions}

In this study we investigated whether ToM requires additional cognitive resources. We presented two types of games that required the same comparisons but differed with respect to the required depth of ToM reasoning: Games in the player condition required second-order ToM , as participants had to reason about a Player 2 that, in turn, reasoned about them; Games in the balance scale condition required first-order ToM, as participants had to reason about a Player 2 that reasoned about a balance scale. Our results show different errors between these conditions, which implies that the reasoning was not the same in the balance scale and player conditions. Moreover, the reaction time trends differed. The learning rate was faster for participants in the balance scale condition than for participants in the player condition. A faster learning rate in the balance condition is congruent with our hypothesis that it is easier to play against a Player 2 that reasons about gravity than playing against a Player 2 that reasons about mental states.

We assumed that games with a balance scale are easier to play because they appear to be more deterministic than games in which Player 1 has the last decision. This assumption is congruent with the RT data: Longer RTs in the player condition could be the cause of participants' testing of multiple possible Player 2 perspectives. Games in the balance scale condition, in contrast, require testing of fewer possible Player 2 perspectives, yielding shorter decision times.

Besides a faster learning rate in the balance condition, we expected a greater proportion of correct decisions. However, the probability of making a correct decision does not differ between the balance scale (i.e., first-order ToM) condition and the player (i.e., second-order ToM) condition. One possible explanation is that knowledge about gravity is not automatically attributed to Player 2. We expected that participants in the balance condition would automatically 'see' how Player 2's decision depends on the outcome of the balance, as young children have already mastered many balance scale configurations (Van Rijn, Van Someren, \& Van der Maas, 2003). However, attributing an
understanding of gravity to Player 2 might be less of an automatic process than reasoning about gravity oneself.

Based on our findings, we conclude that participants do need ToM in Marble Drop games. Sequential games such as Marble Drop can be critiqued for not requiring ToM: If Player 2's strategy is known, the optimal (Player 1) decision can be determined without reasoning about Player 2's reasoning about Player 1's last possible decision. Applying backward induction, an algorithm based on sequential payoff comparisons, would yield the optimal decision. However, Meijering et al.'s (Meijering et al., 2012) eye tracking study shows that participants use more complicated and diverse reasoning strategies, not only backward induction. Moreover, backward induction would not be able to account for different types of mistakes and differential reaction times in the two conditions, as backward induction always works the same, irrespective of condition. Our findings provide strong support for the idea that sequential games are not just a decision-making problem but also evoke reasoning about mental states and thus require ToM.

In fact, it seems that sequential games are a particularly good paradigm to test reasoning about mental states, as they require active application of ToM. If Player 2's strategy is not yet known, participants need to actively find the correct Player 2 perspective. In any given game, multiple Player 2 perspectives might apply, but only that of a rational Player 2 is consistent with Player 2's actual decisions across all games. Active application of ToM is required to test multiple perspectives and find that of a rational Player 2.

To conclude, our findings are congruent with findings from fMRI studies showing that mental state reasoning employs brain regions that differ from the regions involved in cognitive control (Apperly, 2011; Saxe, Schulz, \& Jiang, 2006). Our findings suggest that perspective taking requires additional cognitive resources, as opposed to just greater cognitive control, as one additional switch between perspectives induces not only longer reaction times but also qualitatively different decisions.

\begin{abstract}
The English definite and indefinite articles (also known as \(d e\) terminers) are a useful index of early morphosyntactic productivity in children's speech, and give evidence about children's representation of syntactic abstractions. Previous work (i.e. Pine \& Lieven, 1997) used a measure of productivity that shows a strong sensitivity to sample size and does not account for the relationship between adult input and children's learning. In this paper, we develop a more robust metric by employing a hierarchical Bayesian model to characterize the degree of generalization implicit in observed determiner usage. By inferring parameters for a generative model over longitudinal corpora, we measure the trajectory of grammatical category abstraction. Our results are consistent with the hypothesis that child learners exhibit adult-like patterns of generalization quite early in the acquisition of determiners.
\end{abstract}

Keywords: grammatical productivity; development; syntax; morphosyntax; modeling

\section*{Introduction}

How do children begin to use the rich combinatorial structure of language to express novel thoughts? Nativist accounts propose an innate specification of syntactic categories that allow the child learner to exploit regularities in language structure from birth (Valian, 1986). Constructivist theories, on the other hand, contend that abstract categorical knowledge is built up over time as the child learner generalizes from specific usages to form broader combinatorial rules (Tomasello, 2003). The indefinite determiner "a" and the definite determiner "the"-the shortest and most frequent words in the English language-are a locus of interest for both theoretical viewpoints. Because they are both frequent and obligatory, determiners are an early index of morphosyntactic \({ }^{1}\) productivity that can be observed cross-linguistically.

A context-free grammar production rule (Figure 1) captures the intuition that a noun phrase can be created by choosing a determiner from the abstract DET category and a noun from the abstract N category. This noun phrase in turn combines with other phrase structures, like a verb phrase or preposition, to form higher-order structures. For most singular nouns, a grammatical NP can be formed using either determiner. Furthermore, hearing a novel word with one determiner suggests that use with the the other is also likely grammatical. Hearing someone introduce "a blickmoo" for the first time, you would not hesitate to request "the blickmoo" even if you had never heard that sequence of words before.

\footnotetext{
\({ }^{1}\) In English, determiners and nouns are separate words by linguistic criteria (e.g. an adjective may come between a determiner and a noun). Many other languages use determiners that are morphologically integrated with the noun (see Kramsky, 1972 for an overview).
}

Figure 1: Many noun phrases can be created by combining a word from the abstract categories determiner and noun \((\mathrm{NP} \rightarrow \mathrm{DET}+\mathrm{N})\). It is an open question whether children's early representations are organized around these abstractions.

When do children share that same judgment? Valian (1986) showed that children between \(2 ; 0\) and \(2 ; 6\) demonstrate a variety of productive syntactic categories, including determiners. Using a distributional analysis of children's speech, she found that determiners were used in a fashion consistent with an adult-like grammar. Determiners were never used as the sole content of an utterance, never appeared in a sentencefinal position, and were always sequenced correctly with respect to adjectives and nouns in noun phrases.

Pine \& Lieven (1997) challenged Valian's assertion of adult-like grammatical productivity in children's speech by citing an apparent limit to productivity in determiner use. As a quantitative metric, Pine and Lieven presented the overlap measure for determiners: the number of nouns used with both determiners (in some sample), divided by the number of nouns used with either (in the same sample). For 11 children from \(1 ; 0\) to \(3 ; 0\) this proportion ranged from 0 to .23 , which Pine and Lieven interpreted as being extremely low for a speaker with productive determiner syntax. Rather than making full use of the combinatorial productivity of nouns and determiners, on this metric children thus seemed to be very conservative in their productions and to show a strong tendency to use nouns with only a single determiner. Pine and Lieven interpreted this finding as supporting item-based theories of learning in which there is only gradual generalization from individual instances to abstractions like DET.

Valian et al. (2009) objected that Pine \& Lieven (1997) failed to take noun frequency into account in considering determiner use. Because the overlap measure is necessarily 0 for all nouns that appear only once, Valian and colleagues argued that the overlap measure, especially when calculated over small datasets, under-represents productivity. Highly frequent nouns were much more likely to be used with both determiners: more than \(80 \%\) of nouns used at least 6 times were used with both "a" and "the." Our own analyses of the Providence corpus (Demuth \& McCullough, 2009) confirm

Figure 2: Determiner overlap (proportion of nouns used with both "a" and "the") increases as a function of the number of tokens in a speech sample, as seen from CHILDES files for 4 children from the Providence corpus. Dashed and solid lines show loess smoothers for the child and parent respectively.
this issue: overlap is deeply confounded with sample size. Sample size is the best predictor of both child and parent overlap, regardless of age (Figure 2).

Yang (2010) supplemented this argument by showing that-regardless of sample size-the overlap measure is necessarily low because of the Zipfian distribution of noun frequencies. The Zipfian frequency distribution of nouns results in a long tail of words seen only once, so if overlap is calculated as the proportion of nouns seen with both determiners, it will necessarily be low. Yang additionally observed that nouns vary in their determiner preference (e.g., "the bathroom" is more frequent than "a bathroom", but "a bath" is more frequent than "the bath"), unlike the simplest probabilistic instantiation of a productive context-free rule scheme as in Figure 1, where the probabilities of Determiner \(\rightarrow\) "the" and Determiner \(\rightarrow\) "a" would be independent of the noun's identity (Booth, 1969).

But while the overlap statistic is flawed, there is currently no replacement that directly measures the productivity of children's determiner use. Hence, in the current study, we develop a novel method for quantifying determiner productivity. We use a hierarchical Bayesian model to estimate adults' and children's determiner productivity (metric model) and then develop a variant that estimates the linkage between adult input and child generalization (linking model). In each model, one key parameter can be interpreted as a graded metric of productivity robust to variation in sample size and noun frequency distribution. Bayesian inference gives us the posterior distribution of this parameter given child and adult caregiver production data, allowing us to quantify determiner productivity and examine its developmental timecourse.

Figure 3: Interpretation of the \(v\) parameter, a concise metric of grammatical productivity. At low values of \(v\), little or no information is shared between nouns. At higher \(v\) values, nouns exhibit more consistent usage as a class, indicating the existence of a productive \(\mathrm{DET}+\mathrm{N}\) rule.

\section*{Metric Model}

We model the use of each determiner with a noun as a draw from a binomial distribution (a single weighted coin flip). The use of "the" is heads, and the use of "a," tails. The idiosyncratic determiner preference for each noun can thus be thought of as a coin's weighting, ranging from zero (a noun used only with "a") to one (a noun used only with "the"). We model variability in noun-specific determiner preferences by assuming some distribution underlying these preferences; specifically, we assume that each noun's preference is drawn from a beta distribution with mean \(\mu_{0}\) (the underlying "average" preference across all nouns) and scale \(v\), giving us a hierarchical beta-binomial model (Gelman et al., 2004). \({ }^{2}\)

The scale parameter \(v\) in our model plays a central role in quantifying cross-noun variability and thus gives us a continuous space in which to quantify learner productivity (Figure 3). At one end of the range, when \(v=0\), we have an extreme "island" learner for whom every noun is produced with only one determiner or the other. At the other end of the spectrum, as \(v\) approaches infinity, we have an extreme over-generalizer who has identical determiner preference for all nouns. The \(v\) parameter thus establishes a continuum on which we can place constructivist and nativist hypotheses.

By estimating values of \(\mu\) and \(v\) for individual children over the course of their development, we can examine how these parameters change, potentially reflecting developmental changes in productivity. Here we use the metric model to compare mother and child productivity for the six children in the Providence corpus (Demuth \& McCullough, 2009).

\section*{Model Details}

A full graphical model representation of the linking model is shown on the left side of Figure 4 . We assume that data \(d\)

Figure 4: Graphical representations of the metric and linking model. Shaded nodes indicate observed data (determiner-noun productions) or uninformative priors set by the researcher.
(individual determiner observations) are generated as draws from a binomial with parameter \(\mu_{i}\) for each of \(M\) noun types. These parameters are in turn drawn from a beta distribution with parameters \(\mu_{0}\) and \(\nu\). The \(\mu_{0}\) parameter describes the overall mean determiner preference, and the \(v\) parameterthe central target of inference-describes the degree to which individual noun preferences vary around the overall average \(\mu_{0}\). We complete the model via an uninformative prior distribution over \(\mu_{0}\) and \(v\).

Given a sample of determiner-noun pairings, we can use Bayesian inference to produce full posteriors over \(\mu\) and \(v\). In practice, we perform inference using Gibbs sampling via the JAGS package (Plummer, 2003); grid-sampling of posterior distributions and trace plots confirmed good convergence properties (see also the Appendix).

\section*{Corpus Selection and Extraction}

The Providence corpus (Demuth et al., 2006) consists of longitudinal in-home recordings from six children from New England and contains a relatively high density sample from the onset of single words at about \(1 ; 3\) to \(3 ; 0\). Utterances from each child and their mother were extracted from CHILDESformatted transcripts (MacWhinney, 2000) and augmented with a machine-generated syntax tier in CLAN (Sagae et al., 2010). Using these syntactic trees, we automatically extracted modifiers associated with each noun, as well as their part of speech. For the model input, noun uses were subset to those with a definite or indefinite determiner, yielding \(5-15 \times 10^{3}\) age-referenced DET+N tokens for the mothers and \(1.5-5 \times 10^{3}\) for the children.

For each mother and child, we performed a sliding-window analysis, examining successively older subsections of the corpus. On the basis of artificial corpus simulations (see Appendix), a window size of 1024 tokens was selected. On a linear sequence of tokens, each new window contained 10 new tokens from the full dataset and omitted the earliest 10.

This method yielded on average 150 measures of determiner productivity for each speaker. Additionally, an overlap measure was calculated for each 1024 token window according to the procedure described in Pine \& Lieven (1997).

\section*{Results and Discussion}

An item-based learning theory predicts a developmental increase in children's generalization across nouns (as measured by \(v\) ) as individual item-based constructions give way to a general production rule. In contrast, a theory positing full morphosyntactic productivity predicts no major difference in generalization over development; instead, children and parents will show the same level of productivity from early on.

Our sliding window analysis reveals no clear developmental trend in children's productivity (Figure 5), consistent with the early productivity account. For both the adult and the child, individual conversational bouts show high variance, but \(v\) values for the children are as higher or higher than those in the speech of their mothers, and children exhibit adult-like peaks of noun groupedness from the beginning of production. Nevertheless, for several of the children (e.g. William, Ethan, Violet), it is clear that the amount of data is not sufficient to allow the temporal granularity for a strong test.

Although it gives similar results to the overlap statistic, the \(v\) parameter in our model is preferable. While the overlap measure is confounded by sample size (see above), additional data only improves our estimate of \(v\). Posterior inference gives an explicit representation of the model's uncertainty in a data set, making it readily apparent when the sample size is too small to estimate model parameters.

This property of the model allows us to note that the variability in the estimates of productivity for adults and children seem to be quite reliable. In both cases, there is substantial variability that is not explained by the child's age. We hypothesize that this variability is due to the changing conversational and discourse dynamics between recordings in the

Figure 5: Sliding window analysis results. The metric model shows no clear developmental trend in children's productivity, nor a major difference in productivity between children and their mothers. On the left, black points and vertical gray bars represent the mean of the posterior and the \(95 \%\) highest posterior density interval on \(v\); horizontal gray bars show the temporal extent of the window used in the model at each point.
corpus, leading to the introduction by chance of many nouns with similar or dissimilar determiner preferences in context. Denser data will be needed, however, to test this hypothesis more fully.

\section*{Linking Model}

Although the metric model's results are suggestive of productivity from the earliest ages of children's determiner production, several aspects of the metric model limit the strength of the conclusions we can draw from it. First, the model fails to control for differences in the distribution of nouns for which determiners are produced by the speaker. For example, if children's determiner-noun productions disproportionately involve high-frequency nouns compared with adult productions, and if higher-frequency nouns tend to have more balanced determiner preference, it would inflate the metric model's estimate of children's productivity.

Additionally, an advocate of the island-learner position could justly point out that a child might produce relatively equal numbers of both determiners for a given noun Ywhich disfavors low values of \(v\)-not due to generalization but because the child has learned both "a Y" and "the Y" as islands from the input. Our linking model remedies these shortcomings by explicitly linking the determiner preference for child productions of a given noun to the experience the child has had with that noun in input from the caregiver. In the linking model, \(v\) more directly represents the strength of a child's generalization across nouns: as \(v\) approaches zero, we have a true island learner whose productions for a given noun reflect only experience with that noun from adult input;
as \(v\) approaches infinity, we have a true overgeneralizer for whom noun-specific variabilty in determiner frequencies in input are completely ignored. While it allows for a more nuanced picture of the relationship between a child's input and his or her productions, the linking model does not allow us to compare measures of adult and child productivity directly; in this sense it is complementary to the metric model.

\section*{Model Details}

The generative structure for the linking model is given on the right side of Figure 4. As before, we assume a hierarchical beta-binomial model linking different noun-specific determiner preferences together into a general determiner preference with mean \(\mu_{0}\) and scale \(v\). Here, however, adult determiner productions \(d^{A}\) for a given noun in the child's input contribute explicitly to the child's determiner preference \(\mu\) for that noun. We formalize the effect of the input on the child's determiner preference by assuming that the child acts as an ideal observer. Adult input for a given noun serves as binomial count observations, which the child combines with its beta-prior pseudocounts to yield Bayesian inference on the posterior distribution over the determiner preference for that noun. \({ }^{3}\) We allow adult input to be downweighted by a "for-

\footnotetext{
\({ }^{3}\) Note, however, that while the linking model contains an idealobserver component, it is not an ideal-observer model in its totality. Most critically, \(\mu_{0}\) and \(v\) are not learned by the child from adult data, but rather reflect the relationship between adult input and the child's productions. In principle, the child's productions can even be highly discrepant from the adult input, if \(v\) is large and \(\mu_{0}\) does not match the overall distribution of adult determiner use. Conversely, if the posterior on \(\mu_{0}\) is a close match to adult determiner use, it suggests
}

Figure 6: Linking model results for inference on \(v\) (left) and simulated vs. empirical overlap measure (right). Black points and vertical gray bars represent the mean of the posterior and the \(95 \%\) highest posterior density interval on \(v\), respectively. Horizontal gray bars express the temporal extent of the window used to fit the model at each point.
getting" or "noise" parameter \(\eta\), motivated not only theoretically from the consideration that a child is unlikely to be able to store and learn with perfect fidelity from every determinernoun production in its input, but also empirically: without it, it is hard for even an extreme island learner version of our model to reproduce a pattern sometimes seen in our dataset, where the determiner distribution for a given noun will be relatively balanced for the adult but highly skewed for the child.

\section*{Dataset, Results and Discussion}

We used the same window size (1024 tokens) as for the metric model for a sliding window analysis using the linking model, but used all parent data up to and including the period of child usages for each window. Results of the linking model indicate that children generalize beyond the input that they receive (Figure 6, left), though there is some evidence of variation across children in generalization strength: the weakest generalizer, Alex, shows a \(v\) around 0.6 , and the strongest generalizer, William at the latest stage in our dataset, shows a \(v\) around 2.3 Posterior means for \(\eta\) varied between 0.071 and 0.599 , with substantial variation between children; posterior means for \(\mu_{0}\) varied between 0.145 and 0.717 . As with the metric model, we observed no evidence for a developmental trend from lesser to greater generalization: while some children (Ethan, Violet, William) seem to show a trend toward increasing \(v\) over time, other children (Naima, Alex) show no directional trend, and one child (Lily) has a decreasing trend.

Finally, although we have argued that the overlap measure is not useful for quantifying productivity across sample sizes, we can use it as a goodness-of-fit metric for our model within a sample. We do this by using the adult data and the joint posterior of the fitted model for each window to generated

\footnotetext{
that the child is indeed generalizing from adult productions across nouns in his or her production behavior.
}
simulated determiner productions for the specific noun distribution in that window, and comparing the overlap measure for the simulated data with the empirical overlap measure in that window. For nearly all windows of all children, empirical overlap falls within the range of simulated overlaps, validating the model's overall fit to the data (Figure 6, right).

\section*{General Discussion}

We constructed two models to quantify the productivity in children's early determiner usage and to compare this to that of their mothers. These models instantiated a statistical tradeoff between memorization of the observed data ("island learning") and extreme generalization. Results from both models suggested that the children in our sample were neither extreme generalizers nor extreme island learners. Contra the constructivist hypothesis, neither model provided clear evidence for developmental change in children's generalization behavior over time, and by the summary measure of productivity furnished by the metric model their speech was not quantitatively distinguished from that of their parents. Yet contra the full-productivity nativist hypothesis, there is clear evidence for item-specific combinatorial preferences between determiners and nouns ( \(v\) values are relatively low in the metric model; compare Figures 3 and 5) and that children are at least somewhat sensitive to the specifics of adult input ( \(v\) values are low in the linking model).

Nevertheless, while the current results are consistent with early productivity, our modeling work leaves unaddressed a number of issues that both preclude a conclusive judgment in this debate thus far and also point the way towards future work. As we alluded to when introducing the linking model, it is difficult to rule out the possibility that apparently "productive" determiner behavior for a given noun may reflect the child's having learned both determiners with that noun as is-
lands. This difficulty is compounded by the fact that though the Providence corpus is extensive, it still records only a small fraction of the total adult input each child in the corpus has received. In the future this difficulty may be addressed by more complete datasets; additionally, our model could be extended by allowing imputation of unrecorded adult data, which would allow our uncertainty regarding the content of this input to be incorporated into inferences about productivity in child behavior.

A second challenge is that an advocate of the fullgeneralization position could reasonably object that nounspecific determiner preferences in child productions that mirror adult input may be driven by other factors to which both adults and children are sensitive in determiner production, such as referential context (e.g., Maratsos, 1979; KarmiloffSmith, 1981). Our model could be extended to account for these effects by conditioning determiner probabilities not only on noun identity but also on other contextual factors recoverable from corpus data; this move might allow a richer investigation of the developmental trajectory of how these aspects of the knowledge underlying fully proficient determiner deteminer use are learned and used in naturalistic production.

The gold standard for demonstrating the existence of productive knowledge of determiner syntax would, of course, be the combination of a novel noun with determiners that the child has not yet heard used with that noun. Regardless of the outcome of such a study, however, we believe that our probabilistic, data-driven approach would retain potential to advance our understanding of how linguistic knowledge develops. The modeling framework presented here provides an alternative to the extreme positions of all memorization or all generalization embodied by constructivist and nativist viewpoints. Although our model contained many simplifying assumptions, including not only those mentioned above but also the restriction to two determiners, it has given initial traction in measuring how experience from local episodes may lead to global generalizations. For the problem of determiner productivity, the simplifying assumptions can be relaxed one by one; and the general architecture can be applied to study a broad range of phenomena beyond the development of determiners, such as the emergence of plural markings and other morphological generalizations. We hope that exploring the space of models that combine the best features of both islandand generalizing-learner accounts may lead to new insights into the emergence of productive language.

\section*{Appendix: Model Validation with Artificial Corpora}

To test the validity of our Gibbs sampling procedure procedure and establish the minimum number of \(\mathrm{DET}+\mathrm{N}\) samples necessary to parameterize the model, we tested the metric model on artificial noun and determiner counts generated according to known statistical properties. We varied \(\mu\) was from .1 to .9 in increments of .1 , and \(v\) at \(.05, .1, .5,1,5,10\), and 50. We additionally varied the number of tokens from \(2^{0}(1)\) to \(2^{24}\left(1.6 \times 10^{7}\right)\) (the upper limit corresponding to the order of magnitude of tokens heard by a child; Frank et al., 2013), with token distributions generated from both uniform and Zipfian word frequency distributions.

As in the main simulations, we estimated posteriors for the parameters \(\mu\) and \(\nu\) and compared with the known \(\mu\) and \(v\) used to generate the input data. MCMC chains here and in the main simulations consisted of 1000 samples after a burn-in of 1000 adaptive samples and 1000 updates, with no thinning. We employed Gelman diagnostics as well as manual inspection of traces to check for sufficient burn-in time and mixing. Grid sampling confirmed that likelihoods were sufficiently peaked to constrain parameter estimates and were consistent with posteriors produced inferred with MCMC. Measures of the reliability of inference (mean and standard deviation in the difference from the true value) helped establish a minimum window size for sliding window analyses to correspond with error less than some fixed value \(\varepsilon\).

\begin{abstract}
The relationship between reasoning and language has been frequently studied. Here we explore principles of spatial reasoning in Germans and Russians. We compared the performance of Russians in three different settings to the performance of Germans. The task was to construct layouts of wooden blocks according to verbal instructions, describing the relations of these blocks. Subsequently pieces of new information, introduced as incontrovertible facts and partly contradicting the initial descriptions, were given. Participants re-arranged the blocks to take into account the new facts. Recent research conducted with Germans has shown that although alternatives are logical equivalent - there are preferences for certain solutions. The question was whether Russians show the same or different preferences. Our results suggest that construction and revision of spatial models follow similar principles. However, we observed differences between the groups regarding the flexibility to apply a principle based on the order of words in a sentence.
\end{abstract}

Keywords: Spatial reasoning; Relational reasoning, Crosscultural similarities; Language; Russia; Belief revision

\section*{Introduction}

Misunderstandings happen so often between people from different countries, triggering the important question: how is language connected to our mental representation of the world? What role does it play in reasoning? Answers suggested to that question are provided by an important theory in that area: the Sapir-Whorf hypothesis affirms that language influences thought (Zvegintsev, 1960; Levinson, Kita, Haun, \& Rasch, 2002; Levinson \& Meira, 2003). On the other hand, there is the view that the mind is organized in a modular way with separate modules dedicated to certain abilities (e.g. Tsimmerling, 2000; Nowak, Komarova, \& Niyogi, 2001; Kulikov, 2012). A further important question, to some extent related to language, is: how do mental representations differ across different cultures? What role do cultural backgrounds play in reasoning? While some studies suggest cultural dissimilarities (e.g. Oyserman \& Lee,
2008), other studies show that there are common cognitive principles used by reasoners of different cultures. Crosscultural similarities have, for instance, been shown in topological reasoning (Knauff \& Ragni, 2011; Knauff, 2013).

The present study is concerned with spatial relational reasoning and the influence of language and culture. We briefly analyze relevant work on linguistic influence on thinking, comparative topology of German and Russian, and spatial relational reasoning. We then present an experiment, designed to investigate the construction and revision of spatial models.

\section*{Construction and Revision of Spatial Mental Models}

Imagine you need to find the house № 28 in a street, unfamiliar to you. You have received the following description of the precise location by friend A , informing you that:
(1) "There is a hotel to the right of a café.", and
(2) "The house № 28 is to the left of the café."

The description allows for one (determinate) model to construct. In order to construct the model, spatial information is inserted successively. Based on the information given by statement (1), the model
(3) "Café - Hotel"
is initiated and extended by (2) "House № 28 ", resulting into the model:
(4) House № 28 - Café - Hotel

A lot of studies have explored factors that influence reasoners when they construct models, among them the order of objects as inserted into the model, and other order effects (e.g. Payne, 1993; Ehrlich \& Johnson-Laird, 1982; Payne \& Baguley, 2006; Bucher, Krumnack, Nejasmic, \& Knauff, 2011; Krumnack, Bucher, Nejasmic, \& Knauff, 2011; Nejasmic, Krumnack, Bucher, \& Knauff, 2011).

Imagine you find out a little later that the information uttered by friend A is unreliable. Friend B - who lives in the street in question - informs you that as a fact:
(5) "The house № 28 is to the right of the hotel."

The more reliable and incontrovertible information partially contradicts friend A's description needs to be taken into account. The following alternatives are possible:
(6) Café - Hotel - House № 28
(7) Hotel - House № 28 - Café

Both variations of the initial model are logically equivalent. Nevertheless, when confronted with ambiguous relational information, human reasoners frequently prefer one alternative over the other (Jahn, Knauff, \& JohnsonLaird, 2007; Krumnack, Bucher, Nejasmic, \& Knauff, 2010; Bucher et al., 2011; Krumnack, Bucher, Nejasmic, Nebel, \& Knauff, 2011; Bucher \& Nejasmic, 2012; Knauff, Bucher, Krumnack, \& Nejasmic, 2013).

\section*{Preferred model revision}

The process of model revision with verbal descriptions, using binary relations \(\mathrm{r}(\mathrm{X}, \mathrm{Y})\) as facts has been shown to rely on the following principle: the functional distinction of X as the "to-be- located object" (LO) in contrast to Y as the "reference object" (RO) specifies the location of the LO relative to the known location of the RO (e.g. Huttenlocher \& Strauss, 1968; Miller \& Johnson-Laird, 1976; Talmy, 1983; Landau \& Jackendoff, 1993). For the revision of horizontal linear arrangements, the following finding concerning reasoners' preferences is characteristic
Initial arrangement \(\quad\) A B C
Counterfact \(\quad \mathrm{C}\) is left of A,
with \(C\) as the relation's \(L O\)
with \(C\) as the relation's \(L O\)
Preferred revision: C A B
Note that the logical equivalent (non-preferred) alternative for revising the initial model by relocating the counterfact's RO (here: A) would results in the revised model: B C A. We refer to the preferred principle as the LO-principle (compared to the RO-principle).

\section*{Linguistic Influence on Thought and Comparative Typology of German and Russian Languages}

The Sapir-Whorf hypothesis postulates that language determines thought or at least that linguistic categories influence thought and certain kinds of non-linguistic behavior (Zvegintsev, 1960). Li and Gleitman (2002) investigated influences of individual languages (e.g. English and Dutch) on spatial reasoning. Chatterjee (2011) studied language as a form of mental representation of space. With the current study, we investigate influences of different languages (Russian vs. German) on spatial mental representations. Moreover, to dissociate between influences that result from linguistic aspects on the one and cultural aspects on the other hand, the study took place in two cultural settings (in Germany and in Russia).

First, we briefly explain the structures of both languages in terms of comparative typology. Both languages are from the Indo-European family. German belongs to the West Germanic family, Russian is a Slavic language. They are inflexional languages (from Lat. Flectivus «flexible»). The term refers to a language, where word-building with inflexions dominates. Inflexions are morphemes which can have much significance; e.g. the article „die" (as in "die Katze", "the cat") in German, indicates the gender (feminine), the case (nominative), and the number (singular). Russian is even more inflexional compared to German. Inflexional languages can be synthetic or analytic. The German language is between the synthetic and analytic languages, it has some characteristics of both language types. In a synthetic language, a word contains all the grammar, e.g., by inflexional endings, prefixes, suffixes. An analytic language is a language which reproduces grammatical relationships syntactically. Accordingly, it uses only unbound morphemes, and only separate words like articles etc. (Anokhina \& Kostrova, 2006). For instance: "хорошая новость" and "eine gute Neuigkeit" ("good news") - in Russian, the ending ,"as", and in German the (additionally needed) article „eine" indicates: feminine, nominative, singular. There are some more differences between German and Russian which we do not want to explain here in detail. What is relevant for the current study is the flexibility in word order in the two languages. In German, the possibility of ordering words within a sentence in a certain way is much more limited compared to Russian. Of course, the "freedom" of word order in Russian is not unlimited and also regulated by semantic and stylistic factors (as in German) (Anokhina \& Kostrova, 2006). An example is given in table 1 .

Table 1. Word order in German and Russians languages
\begin{tabular}{lll}
\hline Russian & German & Exact meaning \\
\hline Я люблю тебя & Ich liebe Dich & I love you \\
\hline Тебя я люблю & \begin{tabular}{l} 
Word order \\
not possible
\end{tabular} & \begin{tabular}{l} 
I love you, exactly \\
you, not another \\
person
\end{tabular} \\
\hline Я тебя люблю & \begin{tabular}{l} 
Word order \\
not possible
\end{tabular} & \begin{tabular}{l} 
I love you, exactly \\
you, not another \\
person
\end{tabular} \\
\hline Люблю я тебя & \begin{tabular}{l} 
Word order \\
not possible*
\end{tabular} & \begin{tabular}{l} 
I love you (with an \\
even stronger \\
significance in the \\
sense that I can do \\
nothing about it)
\end{tabular} \\
\hline Люблю тебя я & \begin{tabular}{l} 
Word order \\
not possible**
\end{tabular} & \begin{tabular}{l} 
You are loved by me, \\
not someone else
\end{tabular} \\
\hline Тебя люблю я & Dich liebe ich & \begin{tabular}{l} 
I love you, exactly \\
you, not another \\
person
\end{tabular} \\
\hline
\end{tabular}
*the word order would be possible in a German question ("Liebe ich Dich?"); **the word order would be possible in a German passive sentence ("Du wirst von mir geliebt.")

Analogously, the Russian spatial language is also more flexible than the German language. For example, dynamic local relations in German indicate source locations ("where from?") and directions of motion ("where to?"), while in Russian such relations have a triple function, they indicate: location ("where"), source location, and direction (Khoruzhaya, 2007).
To summarize, there are major differences between German and Russian. Previous research on spatial relational reasoning suggests that reasoners have strong preferences which are often based on linguistic cues that are connected to the sentence structure. The main finding in a range of experiments on the variation of spatial models (Bucher et al., 2011; Krumnack et al., 2011; Bucher \& Nejasmic, 2012; Knauff, et al., 2013) is that the variation is preferably done by the relocation of objects that are perceived as more flexible compared to other objects. These objects are usually the so called to-be-located objects (LO) of a relational statement as compared to reference objects (RO) which are perceived as more stationary. We refer to this preference as the LO-principle.
The question is whether cognitive principles such as the LO-principle are used independently from linguistic or cultural aspects. Concerning the language aspect, it would be plausible if Russians, i.e. native speakers of a language that is by nature very flexible concerning the word order and sentence structure are accordingly more flexible in the application of such cognitive principles. In this specific case they might use the RO-principle more frequently as an alternative solution in the reasoning task. Culture is another important aspect to look at when we look at similarities of cognitive principles. There are many definitions of culture. Oyserman and Lee (2008, p. 311) say that "culture matters to the extent that individuals living in different societies are likely to have differing experiences". Criado (2009, p. 295) explains that culture is "a set of shared values, beliefs, expectations, customs, jargon, and rituals". What seems to be indisputable is that a cultural environment can have an impact on the way an individual thinks.
In order to explore both, language and culture influence, we conducted the same experiment with native speakers of German and of Russian as participants. Three different samples of Russian participants were tested in two different cultural environments:
1. The first sample was tested in German, in Germany
2. The second sample was tested in Russian in Germany
3. The third sample was tested in Russian in Russia

The purpose was to control for both, the language and the cultural setting.

\section*{Experiment: Construction and Revision of Block Arrangements}

\section*{Method}

The first part of the experiment can be referred to as "construction phase". The task was to physically construct layouts of wooden blocks according to a verbal instruction,
describing the relations of these blocks. The second part can be titled "revision phase". Once a layout was constructed, a piece of new information, introduced as an incontrovertible fact contradicted a part of the initial description. The task was to re-arrange the blocks such that it cohered with the "fact".
Participants Altogether, we tested 76 volunteers who performed in the task either in German or in Russian in Germany or in Russia. All participants gave informed consent to participation. Participants were tested individually. Each participant was tested only once.

Language abilities were assessed by self-report. Russian participants tested in Germany rated their German language abilities as "very good", and reported to be capable of writing and speaking fluently. They were fluent in Russian as their mother tongue and in German as a second language, and have been living and were educated in Germany for a considerable time. Russian participants tested in Russia reported to be not familiar with the German language while German participants reported to be not familiar with the Russian language.

The sample of Germans tested in German in Germany consisted of 11 ( 5 male; age: \(M=24.91 ; S D=2.95\) ) native speakers of German, all students from the University of Giessen. None of them has ever studied Russian.

The sample of Russians tested in German in Germany consisted of 19 ( 3 male; age: \(M=24.05\); \(S D=4.18\) ) native speakers of Russian.
The sample of Russians tested in Russian in Germany consisted of 20 ( 3 male; age: \(M=25.45\); \(S D=5.26\) ) native speakers of Russian.

The sample of Russians tested in Russian in Russia consisted of 26 ( 1 male; age: \(M=20.35\); \(S D=0.63\) ) native speakers of Russian. They were all students from the Federal University of Kazan (among them 19 students of psychology). None of them has ever studied German or has been to Germany.
Materials, Procedure, and Design 32 items were presented, each consisting of two premises and an inconsistent fact. The task was presented on a 19 "-computer screen, using Microsoft PowerPoint (Version 2007) running in the windows environment XP on a standard personal computer. PowerPoint slides were presented by the experimenter in a sequentially and individually adapted manner according to participants' performance.
In all items, the two premises and the contradictory fact (presented in red) had the surface structure as follows: first object - relation (either "left of" or "right of") - second object.

\section*{Example: "Yellow left of red"}

Participants were provided with wooden square blocks (size: \(2.5 \times 2.5 \times 2.5 \mathrm{~cm}\) ), red, green, yellow, and blue colored on a plate in front of them and instructed to construct and subsequently revise their block layouts.
The construction phase: participants were instructed to pick up the colored blocks, one at a time using one hand, and arrange them according to the information provided by
the premises into a linear one-dimensional order. The premises informed about the determinate order of the blocks with the blocks represented by the respective colors (red, green, yellow, and blue).

Example:
1st premise: "Blue right of red"
2nd premise: "Green right of blue"
Spatial arrangement: red - blue - green
The location of the third object was counter-balanced across all problems. In a recent experiment, very similar to the one reported here, and presented in German to German participants, word order has been shown to be crucial for the physical construction of spatial models (Bucher et al., 2011, Experiment 2). Here, accordingly, based on the description of the \(1^{\text {st }}\) premise, two possible construction orders were possible:
1. Starting on the left side and continue to the right, e.g. (consider the 1st premise from the above example) putting down the red block first and placing the blue block to the red one's right side.
2. Starting on the right side and continue to the left, e.g. putting down the blue block first and placing the red block to the blue one's left side
The resulting orders are describable as \(1-2-3\) and \(2-1-\) 3 , with the numbers indicating the order by which objects had been put down; e.g. red first - blue second - green third (order \(1-2-3\) ) and red second - blue first - green third (order 2-1-3). The question was whether there would be order effects when constructing the arrangements in the Russian samples similar to those found in Germans.
The revision phase: subsequently after participants had constructed the order of the three colored blocks, they were asked to revise their order according to the inconsistent fact.

Example-fact: "Green left of red"
Participants were free with the revision of their initially constructed arrangements. After each trial, the wooden blocks were put back onto the plate by the experimenter. Four practice trials (neither recorded nor analyzed) preceded the experimental trials. Performance was recorded on a video tape by the experimenter and analyzed after the experimental session (Bucher et al., 2011).
In previous experiments, using a very similar experimental set-up, presented in German to German participants, the finding was that of a clear preference (e.g. \(89.52 \%, S D=\) 11.30; see Bucher et al., 2011, experiment 2) of LO relocations as compared to RO relocations. The question was whether participants of the Russian samples would apply the LO-principle similarly to the German participants.

\section*{Results and discussion}

Construction: Mean percentage rate of correctly constructed orders was \(97 \%\) ( \(S D=4.46\) ). There was no difference in number of mistakes in construction between the samples ( \(p>0.30\) ). We analyzed the order of objects put down during the construction in every sample, running Wilcoxon's tests for each sample, separately (Siegal \& Castellan, 1988). In the German sample the 1-2-3-order was
used more frequently compared to the 2-1-3-order ( \(z=-\) 2.01; \(p<0.05\) ). The same applies to the remaining samples: Russians tested in German in Germany ( \(z=-3.93\); \(p<0.01\) ), Russians tested in Russian in Germany ( \(z=-3.97 ; p<0.01\) ), and Russians tested in Russian in Russia ( \(z=-4.49 ; p<\) 0.01 ). Our results provide evidence that the same principle (putting down blocks in word order 1-2-3 rather than in the order 2-1-3) was applied similarly by participants of all four samples. Thus, we can conclude that the cognitive principle is not affected by linguistic aspects. Russians tested in Germany as well as Russians tested in Russia used the same principle, suggesting cross-cultural similarities.
We continued our analysis by comparing the magnitude of the preference applied by Germans and Russians in the different settings. The Kruskall-Wallis test revealed a difference between the samples ( \(\mathrm{p}<0.05\) ). Pair wise comparisons, using Wilcoxon's tests revealed that the group of Germans differed from all Russian samples (all \(p s>.05\) ).
Despite the overall similarities found across all samples, we found that Russians were more strictly in the application of this principle. The Germans performed more flexible in the task, using the alternative word order (2-1-3) more frequently. Figure 1 depicts the result graphically. We continue to discuss this difference in the General Discussion of this paper.

Revision: Mean percentage rate of correctly revised models was \(99.14 \% ~(S D=1.74)\). There were no differences in the amount of mistakes between the samples ( \(p>0.40\) ). Erroneous problems were excluded from further analyses. We ran Wilcoxon's tests for each sample, separately. That was to analyze which principle the revision followed. The tests indicated that in the German sample LOs were relocated more frequently then ROs \((z=-2.95 ; p<0.01)\). The same principle was applied by reasoners in the other samples: Russians tested in German in Germany ( \(z=-3.83 ; p\) < 0.01), Russians tested in Russian in Germany ( \(z=-3.96 ; p\) \(<0.01\) ), and Russians tested in Russian in Russia ( \(z=-4.56\); \(p<0.01\) ). Again, our results suggest similarities across both language groups. There was a clear preference for LO relocations across all samples (figure 2 depicts the results graphically). The principle was equally used by Russian native speakers, who were tested in Russian and in German. This suggests that linguistic aspects were not modulating the effect. Russians tested in Germany as well as

Figure 1. The figure depicts the difference between Germans and Russians during the construction of block arrangements.
The word order effect was more pronounced in Russians than in Germans. Error bars indicate standard errors.

Figure 2. For revision, the LO principle (relocation of the to-be-located object, LO as opposed to the reference object, RO) was preferably applied by participants of all samples. Error bars indicate standard errors.

Russians tested in Russia used the same principle, suggesting similarity across the cultures. We continued our analysis by comparing the magnitude of the preference applied by Germans and Russians in the different settings. The Kruskall-Wallis test revealed that there are no differences between the samples ( \(p>0.30\) ). Unlike the word order effect, the LO effect was equally strong across all groups. This finding further corroborates the assumption of a cross-cultural and cross-linguistc cognitive principle.

\section*{General Discussion}

The present study investigates aspects of spatial relational reasoning in reasoners from Germany and Russia. We explored principles applied for the construction and the revision of spatial models in four types of samples. A sample of German native speakers who were tested in German in Germany, a sample of Russian native speakers, tested under the same conditions, a sample of Russian native speakers tested in their mother tongue but in the German cultural environment, and a sample of native speakers of Russian who were naive to the German language, tested in their native Russian cultural environment.
The study was motivated by recent findings that principles applied by German reasoners in spatial relational reasoning tasks were based on linguistic cues. One study (Bucher et al., 2011) suggests that during the physical construction of spatial (block) arrangements, the word order plays a role in guiding the construction process while for the revision of these models the asymmetry of LOs and ROs of relational statements provide the crucial cues for reasoners (Bucher \& Nejasmic, 2012; Knauff et al., 2013). Here as a novelty, a similar task was presented to native speakers of Russian. We were concerned with the dissociation of linguistic and cultural aspects. In order to dissociate these aspects to a certain degree, we splitted the Russian group into three subsamples, allowing a rough distinction of cultural from linguistic influences. The results indicate cross-cultural similarities for both cognitive principles applied during construction and revision of spatial models. Across all samples (German and Russians), the construction followed the word-order-principle. This effect has been previously shown in Germans (Bucher et al., 2011) and could be repetitively shown here. The revision was found to be
guided by the LO-principle. This principle had been repeatedly shown in German reasoners and here - for the first time - in Russians. The effect was comparable in magnitude across all samples. We conclude that both principles reflect similar mechanisms.

However, Germans used the alternative principle (starting construction with the second object) more often compared to the Russian samples and performed thus construction processes more flexible. Please, note that with the current experiment, it is not distinguishable whether reasoners used the first object mentioned in the premise or the LO as a starting point for their construction, because the first object in a statement was identical with the LO. However, Bucher et al. (2011) argue that different cognitive principles are applied during construction (first vs. second object as starting object) and revision (relocation of LO vs. RO), respectively. The authors also provide empirical evidence for their view. The results of the current study show that German native speakers are more flexible when applying the word order principle, compared to Russians, while the LO-principle is applied equally robustly by both groups. This can be taken as corroborating evidence that the cognitive mechanisms underlying construction and revision are distinguishable, however comparable for Germans and Russians.
Nevertheless, we found differences in the manifestations of the word-order effect between the groups. The effect was stronger in Russians compared to Germans. This indicates that Russians used the alternative word order less frequently than Germans did when they constructed their models. When we bear in mind that the Russian language allows for many variations of word orders in a sentence, the result might look counterintuitive, at the first glance. However, we must note that speakers of Russian already make many decisions when they construct a sentence. Maybe, it is the compensation for this "liberty" in the canonical word order of the Russian language which we find reflected by the high adherence to the word order principle. Also important in the present context is that although we might have found crosscultural similarities between Germans and Russians, as well as cross-linguistic principles that were applied during the construction phase, there is an alternative interpretation of the results. While (as in previous experiments) German reasoners might have based the construction preferably on the word order, it is possible that Russian reasoners applied the LO principle, i.e. put the LO as first object on the table. With the present study we cannot rule out this alternative interpretation but we are currently running experiments designed to look at this problem.

\begin{abstract}
Experiment 1 demonstrates that problem solving knowledge can be applied while a move is in progress in certain Tower of London (ToL) problems. A two-stage move process is often delayed in the second stage when participants have been misled by similarity to a previous problem. We suggest this is indicative of misgivings about the chosen move caused by on-going analysis of the move that is being made. Experiment 2 swapped the stages of the two-stage process and again reported more hesitancy in the second stage when participants had been misled. We conclude that it is desirable for models of problem solving to evolve so that they can apply the same learned problem solving knowledge both before a move is selected and while the move is being made. We then describe a model of ToL problem solving that fulfills these criteria and has been computationally-implemented within an embodied cognitive architecture.
\end{abstract}

Keywords: Problem Solving, Embodied Cognition, Production Systems

\section*{Introduction}

The current paper tries to distinguish between two accounts of how a move (or action) is selected and executed during solving a problem. The first account holds that knowledge about how to solve a problem is used to decide the move and then this move is simply executed. A description of the problem acts as input to the problem solving process (here we term this a situation-only decision process). On this basis an action is selected and then executed. The second account suggests that problem solving occurs after the move has been selected as well as beforehand. In this account problem solving also occurs after an action is selected, immediately prior to and during the execution of said action. The input to this problem solving processes is not only a description of the problem but also a description of the intended action (we term this a situation-action decision process).

Problem solving after a move has been selected is rare in current psychological theories, for example this does not typically occur in ACT-r models (see Anderson, 2007). While theories of problem solving based solely on situationonly problem solving have the advantage of simplicity, they lack the power to use existing problem solving knowledge to evaluate ongoing or imminent actions. Theories featuring situation-action problem solving must necessarily feature some situation-only problem solving in order to derive an action for consideration. However, this situation-only problem solving does not necessarily have to be complex indeed an algorithm that simply picks an action at random
that hasn't been considered before might be sufficient. Some recent theories, particularly those exploring embodied problem solving, favour a combination of simple situationonly problem solving prior to action selection followed by more complex situation-action problem solving afterward (e.g. Miles, 2009, 2011; Schuboltz, 2007), the latter is often based on the mental simulation of the results of the action.

The differences between the two accounts are important because each implies a different form for knowledge about solving problems. Situation-action problem solving representations potentially could replace much of the need for situation-only problem solving representations. A key element of situation-action problem solving knowledge is that it typically either encourages or discourages an already selected action. By contrast situation-only problem solving knowledge is concerned with suggesting an action. Once situation-action problem solving knowledge is added to a theory of problem solving then there is less emphasis on the need to select the correct action first. An unsuitable action can be selected then rejected using situation-action knowledge. Indeed, a situation-action account suggests that people often cycle through a series of possible actions at any given stage of solving a problem, allowing situation-action knowledge to confirm or deny each action.

Hence the two accounts of problem solving are fundamentally different. The traditional model suggests a single decision point, followed by action. The situationaction position suggests a series of tentative decisions regarding possible actions followed by evidence gathering while that action is held in mind. It is notable that the second position is much more temporally scalable than the first. For example it is awkward to model speed-accuracytradeoffs in the first style of problem solving, while the ability to vary the amount of time spent gathering evidence is implicit in the second proposal.

\section*{Empirical Support for Situation-Action Knowledge}

Currently there is only indirect empirical support for the existence of situation-action knowledge. A necessary precondition of this knowledge is the ability to represent an action without necessarily executing that action.

Neuroscience has provided evidence of a representational role for parts of the brain associated with action, for example the premotor cortex (e.g. Decety et al., 1994). The existence of mirror neurons that are activated both by performing an action and observing an action (Gallese, Fadiga, Fogasse, \& Rizzolatti, 1996) suggests that the motor areas of the brain are involved in thinking as well
as doing. Over the last 15 years a large body of work has pointed to the conclusion that motor areas of the brain are used for representational roles as well as for executing actions (see Barsalou, 2009, p. 1285, for a brief review).

If representations in the motor areas of the brain are available to other areas of the brain, then logically these other areas will be able to make use of these representations when deciding what to do. It is exactly this logic that supports the existence of situation-action knowledge. Simply the problem solving parts of the brain are aware of the situation, they are also aware of the action that has been represented in the premotor cortex and related areas. It makes sense for the problem solving areas of the brain to make use of this knowledge regarding the conjunction of situation and action to either spur the motor areas into that action or pull them back from the brink of making an error.

The paper begins by reporting two Experiments that looked for evidence of continuing problem solving in the final stages of move selection in the Tower of London (variant) problem. We then show how these data can be computationally modeled using situation-action knowledge.

\section*{Experiment 1}

The paradigm used in both Experiments reported here works by biasing the selection of a first move in a given Tower of London problem. The bias occurs because participants have earlier solved a problem that is either superficially similar or the same as the target problem. In the repeat condition the bias supports the correct first move (of two possible moves), while in the false-analogy condition the bias supports the incorrect first move (again of two possible moves). These conditions are contrasted with problems where there is no bias.

\section*{Method}

Design: The Experiment was presented in two blocks, firstly of 3-disk problems then of 4-disk problems. Each block featured two training problems, a one minute pause, then two target problems. Each target problem had an inverse version, which although superficially similar has a different optimal first move. In each block one of the target problems was the same as one of the training problems (repeat condition) and one target problem was the inverse of the other training problem (false-analogy condition). Comparisons were planned between these conditions and the unbiased performance on the final training problem (novel condition).

Participants: Twenty-eight undergraduates participated in Experiment 1, each received either 30 minutes course credit or \(£ 2\).

Materials and apparatus: The ToL problems were presented on a desktop computer. Participants responded using a mouse. To move a disk the participants had to click on the disk they wanted to move and then click on the peg they wished to move it to. At the top of the screen the goal state was shown while the current state was interacted with in the main area of the screen. Disks were shown in
different colours and each was labeled with a different letter.

Procedure: At the beginning of each of the two blocks participants were first presented with an orientation task. The orientation task required six moves from a flat start state, with no goal displayed. Instructions were then displayed on the screen for a minimum of 30 seconds.

For 10 seconds prior to all training and target problems, the goal state for the problem was presented, on top of, and obscuring, the initial configuration for the problem. During this period a miniature representation of the start state was shown near the top of the screen, but all the disks in this representation were blocked grey, preventing participants from beginning a solution to the problem. This part of the procedure was designed to act as a cue to the related training problem. This display was then removed revealing the interface.

During the training phase problems the participant was only allowed the number of moves in the optimal solution to a problem. Once they had made this number of moves (and the goal state was not reached) a panel appeared (for 3 seconds) obscuring the problem, with "Try Again!" displayed in large letters. The problem was then reset to its original start state. This restriction was critical in ensuring all participants learned the same correct solution for each training problem (each problem had only one optimal solution path).

Timed lockouts were used between problems and between blocks. Participants were locked out for 30 seconds between all consecutive problems. The pause between training and target phases was one minute. There was also a minute lockout between blocks.

Prior to each target problem in a block a hint was given during the last 15 seconds of the lockout time. In the 3-disk block it was phrased as follows "The next problem will be the same as one you have already done." while in the 4-disk block it was "Note: You will have already solved the next problem". This change of phrasing was designed to increase the salience of the hint in the 4-disk block.

\section*{Results}

All latency data were log transformed for analysis; the raw data are summarised in Table 1. Comparisons were made between i) false-analogy condition and the repeat condition, ii) false-analogy condition and the final training problem (novel condition). The later comparison is subject to order effects, but the order effects (one would expect improved performance with practice) run counter to the predicted effects of condition (false-analogy < novel).

\section*{The 3-disk problems}

No significant effects of condition were found in measures of 3-disk problem solving. Most participants were still learning the basic methods needed to solve the ToL during this block, and this may have disrupted performance on the experimental conditions.

Table 1: Number of optimal first moves (from 28), first click latency (secs), and second click latency (secs) in Experiment 1
\(\left.\begin{array}{lccl}\hline \text { Condition } & \begin{array}{c}\text { No. of } \\
\text { Optimal 1 }\end{array} \\
\text { moves }\end{array} \quad \begin{array}{ccc}1^{\text {st }} \text { Click } \\
\text { latency (SD) }\end{array} \quad \begin{array}{c}2^{\text {nd }} \text { Click } \\
\text { Latency (SD) }\end{array}\right]\)\begin{tabular}{lcll} 
Repeat & 28 & \(5.18(1.66)\) & \(1.33(1.57)\) \\
Novel & 26 & \(6.22(1.66)\) & \(1.39(1.54)\) \\
False Analog. & 12 & \(7.35(1.83)\) & \(1.94(1.84)\) \\
\hline
\end{tabular}

\section*{The 4-disk problems}

Significantly more optimal moves were made under the repeat condition than the false-analogy condition, 28/28 vs. \(12 / 28, \mathrm{p}<.001\). A within-participant T-test found no significant differences between the false-analogy and repeat conditions on measures of the time taken to initiate the first move ( \(\mathrm{t}<1\) ). However participants took less time to complete a move in the repeat condition than they did in the false-analogy condition, \(\mathrm{t}(27)=5.86, \mathrm{p}<.001\).

In the novel condition participants succeeding 26 times on 28 first attempts at the final training problem, this compares to 12 times from 28 attempts of false-analogy target problems, \(\mathrm{p}<.001\). There was no significant difference between the novel condition and the false-analogy condition selection on time taken to initiate the first move by clicking a disk \((\mathrm{t}<1)\) but it took longer for participants to click on the location the disk was to go to in the false-analogy condition, \(\mathrm{t}(27)=2.99, \mathrm{p}<.01\).

Of the 28 participants, two made an error in the 'novel' condition. The remaining 26 were split into those that made an error on the subsequent false-analogy condition and those that did not; groups error \((\mathrm{N}=14)\) and correct \((\mathrm{N}=12)\). These data were analysed in \(2 \times 2\) mixed design ANOVA on disk destination click latency, with condition (false-analogy Vs. novel) as a within participant factor and error group (error Vs. correct) as a between participant factor. There were no interactions with, or main effects of group (all F \(<1\) ). This analysis suggests that hesitancy over the move being made was present both in those who did make the correct move those who didn't.

These results are consistent with the hypothesis that participants were engaged in problem solving during the final stages of completing the move. The hesitancy seen in the final stages of the move in the false-analogy condition is best explained as second thoughts about a move that has previously been decided upon. Despite these second thoughts, the original move is at least sometimes completed, but sometimes an alternative move is chosen (as indicated by the lack of differences in hesitancy between those who made errors and those that made the correct move in the false-analogy condition). This suggests that problem solving knowledge is being used after the first move has been decided upon and initiated.

Our theoretical account assumes that the participants have decided on the move they want to make prior to clicking the disk. Certainly the relative distribution of latency between
first click and second click supports this idea. However to demonstrate that the move has been decided upon prior to the first click, Experiment 2 reversed the order of actions needed to make the move, with the destination selected first and the disk selected second. In the second stage of the move only one disk (the top disk) could be selected, the decision about where to move it having already been made.

\section*{Experiment 2}

As well as changing the order in which the actions needed to complete a move were carried out, Experiment 2 attempted to improve on several elements of the design of Experiment 1. Crucially, only the comparison between the novel condition and the false-analogy condition was explored. It was felt that this comparison best captured the impact of the false-analogy manipulation.

Though the novel condition replaced the repeat condition, Experiment 2 used the same basic design as Experiment 1, with the exception that the two Experimental blocks now used 4 -disk and 5 -disk problems. Prior to this, participants completed a training block of 3-disk problems that facilitated the learning of the main principles of solving Tower of London problems. While the order of actions needed to move a disk were changed, other aspects of the interface remained unchanged.

\section*{Method}

Participants: Sixty-four undergraduates took part in the Experiment, each received 30 minutes credit toward their course requirement.

Apparatus: The apparatus and software was the same as it had been in Experiment 1. In all stages of the Experiment the method for moving the disks was altered. Now the participant had to click on the location they wanted the disk to go to. When this was done the peg they had pointed to was highlighted (turned from black to yellow). At this stage the participant then clicked on the disk they wanted to move to this peg. If the next click was not on a disk that could be legally moved to the highlighted peg then the highlighting on the chosen peg was removed, thus allowing participants to change their mind on the desired move.

A set of 5-disk problems was introduced for Experiment 2. It was reasoned that these would be sensitive to our Experimental manipulations in the same way as the 4 -disk problems were in Experiment 1 (and the 'too simple' 3-disk problems were not). Each problem again had an inverse counterpart that was used in the false-analogy condition. The use of different problems was balanced across the Experimental conditions for both 4-disk and 5-disk problems.

Procedure: Many elements of the procedure were the same as they were in Experiment 1, though the block structure of the experiment was altered. Initially participants completed a block of four 3-disk problems. Following this block the two Experimental blocks were presented. The first used 4-disk problems in the same basic structure as was used in Experiment 1 (orientation task - two training
problems - pause - orientation task - target problems). In each Experimental block one of the target problems was Novel and one a false-analogy to a training problem (order of conditions was counterbalanced). A 5-disk block followed the 4-disk block, using the same structure.

Table 2: Number of optimal first moves (from 128), first click latency (secs), and second click latency (secs) in Experiment 2
\begin{tabular}{lccl}
\hline Condition & \begin{tabular}{c} 
No. of \\
Optimal 1 \\
moves
\end{tabular} & \begin{tabular}{c}
\(1^{\text {st }}\) Click \\
latency (SD)
\end{tabular} & \begin{tabular}{c}
\(2^{\text {nd }}\) Click \\
Latency (SD)
\end{tabular} \\
\hline Novel & 104 & \(5.35(1.71)\) & \(1.17(1.66)\) \\
False analog. & 86 & \(4.73(1.77)\) & \(1.34(1.85)\) \\
\hline
\end{tabular}

\section*{Results and Discussion}

Descriptive data for Experiment 2 are shown in Table 2. We combined data from the two Experimental blocks with latency data log transformed. There were significantly fewer correct first moves in the false-analogy condition in comparison to the novel condition (proportionally .67 vs . .81 respectively), \(\mathrm{p}<.05\). Comparisons on latency measures were made using a data set reduced by two, as two of the data points in the 5 -disk block showed zero values for first-click latency (126 paired comparisons remained). This was due to participants clicking prior to the interface becoming active causing a zero to be recorded for first click latency. The effects on the counter-balancing of the Experiment were thought to be minimal. The expected simple effect, i.e. false-analogy slower, was found in the second stage latency, i.e. disk-selection, \(\mathrm{t}(125)=2.00, \mathrm{p}<\) .05. There was no significant difference in the time taken to initiate the move.

The data confirm that problem solving knowledge is being applied after a move has been decided upon in the Tower of London. We argue in the next section that these data and those from Experiment 1 are best accommodated by a cognitive architecture that primarily uses situationaction knowledge to solve problems.

\section*{Modeling Problem Solving Following Action Selection}

Problem solving knowledge has often been modeled in production system architectures, a tradition with its origins in Newell \& Simon's (1972) seminal book Human Problem Solving. Recently the ACT-r cognitive architecture has been used to produce production system accounts of problem solving. In traditional problem solving accounts, situation-only knowledge is represented in the following format: IF situation THEN action.

The model presented (TOL-GLAM) here is coded in the Glamorgan Problem Solver (GLAM-PS) architecture. This is notable because it doesn't use amodal representation and doesn't have a dedicated mechanism for processing goals (see Miles, 2011). TOL-GLAM is thus an example of an
embodied account of problem solving in the Tower of London, with emphasis placed on representation in the motor and perceptual systems used to complete the task. In terms of the representation of knowledge about solving the ToL, much of what TOL-GLAM knows is stored in the format: IF situation AND action THEN inhibit/activate action. This knowledge verifies the appropriateness of an already selected action, rather than specifying what action should be taken in a particular situation.

\section*{The TOL-GLAM Model}

In the GLAM-PS architecture there are modules dedicated to visual perception, ocular movement and motor actions. There are also modules dealing with other functions, for example auditory perception, speech production and bodily movement. Each module has its own production memory, working memory and production matching bottleneck.

Executive control within a GLAM-PS model emerges from the interaction of distributed subsystems (a similar idea was explored by Barnard, 1991). This control is based on each module's ability to see what is happening in all the other modules. So a production in the motor action module can match to working memory representations in other modules as well as working memory representations in the motor module itself.

\section*{Situation-Only Problem Solving in TOL-GLAM}

There are examples of situation-only and situation-action problem solving knowledge in TOL-GLAM. In the two Experiments the first move is restricted to two possibilities. The disk that is to be moved is always known (as it is on top of all the other disks in a tower configuration), the only question is the disks destination.

The situation-only algorithm used by TOL-GLAM begins by generating an action plan for moving a disk. This action plan is represented in the motor module, within a hierarchical structure. An example is given below (with only key attributes shown):
\begin{tabular}{|c|c|}
\hline \multicolumn{2}{|l|}{Action_plan1} \\
\hline Type & Action_plan \\
\hline First_element & disk_click1 \\
\hline Last_element & destination_click1 \\
\hline \multicolumn{2}{|l|}{Disk_click1} \\
\hline Type & click_on_object \\
\hline Location & diskA_location \\
\hline Super_element & Action_plan1 \\
\hline \multicolumn{2}{|l|}{Previous_element none} \\
\hline Next_element & destination_click1 \\
\hline \multicolumn{2}{|l|}{Destination_click1} \\
\hline Type & click_on_object \\
\hline Location & Peg2_location \\
\hline Super_element & Action plan1 \\
\hline \multicolumn{2}{|l|}{Previous_elementDisk_clickl} \\
\hline Next_element & none \\
\hline
\end{tabular}

This initial action plan will often not involve the movement of the top disk. Typically TOL-GLAM, will first represent the movement of the bottom disk in the tower to its goal location. This reflects a means-ends analysis of the ToL problem where the bottom disk is prioritized as the biggest difference between the start state and goal state. While the GLAM-PS architecture doesn't feature explicit goal representation, what is happening is that TOL-GLAM is effectively 'subgoaling' the bottom disk. The model then represents a move of the top disk (the first blocking disk) to the peg where the 'subgoaled' disk is not going (in order to remove the block).

An exception to this process occurs when TOL-GLAM recalls a previous problem that was apparently the same as the current problem. In this case the first move that was made successfully in the previous problem is used to determine where the top disk should go.

TOL-GLAM will now have a representation of a potential first move in its motor module. It is at this point that situation-action knowledge is used to determine the appropriateness of the action, either increasing its activation till it is executed, or blocking its execution.

\section*{Situation-Action Problem Solving in TOL-GLAM}

The situation-action algorithm used in TOL-GLAM is based upon forward search, and makes use of representational simulation of the results of the move that is being considered.

The process begins after a potential move of the top disk has been represented in the motor module. At this point productions in the visual module are able to match to this motor module representation and simulate the result of this action. In Miles (2011) visually simulated interim stages were utilized in a model of offline algebra problem solving, what the TOL-GLAM model does is very similar, essentially looking ahead to see what the results of the action that is being considered will be.

Simulation of the results of the move involves the creation of a projected representation of the disk being moved in its new location, and the inhibition of the representation of the disk in its current location. Once the move has been simulated in the visual module, the motor module is now able to consider the next move that will be made after the current one. The productions that do this match both to simulated and actual visual representations.

At this stage an action plan will be generated for the second move and typically, any conflict with the first move will often become apparent to TOL-GLAM. This is particularly the case if the first move blocks the ideal second move. A production looks for incompatibilities between the two moves being considered. On the other hand if the first move doesn't block the ideal second move then it is taken as providing evidence that the first move is a good one.

\section*{Executing an Action in TOL-GLAM}

Key features of the GLAM-PS architecture determine the process of action execution in TOL-GLAM. One of these is the Action-Execution Threshold (AET), a level of activation that must be reached before an action or action plan will be executed. The AET is an important element of GLAM-PS because it allows actions to be represented without necessarily being executed (Miles, 2009). Within the TOLGLAM model it allows a move to be represented and then evidence gathered about the suitability of the move. There is no limit in GLAM-PS to the number of productions that can match if those productions change an existing representations activation level. This means that in TOLGLAM the representation of a move can be simultaneously inhibited and activated by competing productions. It is the relative strength of the competing productions that will determine whether the action representation will continue to increase in activation until it surpasses the AET, or be inhibited.

\section*{Simulating the Results of Experiment 1 and 2 in TOL-GLAM}

To simulate the results of Experiments 1 and 2 TOLGLAM was setup with productions that represented knowledge gained from previous training problems, which were added to the productions that model normal problem solving in the ToL.

The additional productions, modeling knowledge from specific previous problems, trigger when TOL-GLAM is faced with a problem that has the same initial configuration and goal configuration as the previous problem in terms of number of disks on each peg in each configuration (so an exact match wasn't necessary). The identity of the first disk to be moved must also match. These encodings of solutions from previous problems result in the first move used in the previous problem first being represented in the motor module and subsequently quickly gaining activation.

The performance of the model was tested on simulation runs of the 84 problems from which data were taken for Experiment 1 ( 28 each in the repeat, novel and falseanalogy conditions) and the 256 problems from Experiment 2 (128 novel, 128 false-analogy).

In GLAM-PS each production has a strength value, this strength modifies the impact of the production - so a strong production will increase the activation of an action representation more than a weak one. The strength of the productions modeling knowledge from the previous problem was systematically varied through a single parameter beta, which multiplied the strength of productions activating a representation of the action used previously. The beta values used conformed to a Gaussian distribution, meaning that in some case the influence of previous problems was strong, but in others the influence was weaker. A second parameter theta modified the strength of productions that solved the problems, this was a free parameter with a single value across all simulations runs used to maximize the match between model and data.

Another free parameter was AET, the level of activation at which an action was executed in the motor module. Additional parameters included the time taken to initiate problem solving and the time taken to execute a mouse click.

A comparison of the models performance to the latency and accuracy data showed relatively strong fits, \(\chi^{2}=.72\) and \(\chi^{2}=.83\) respectively. The matches of model to data do show some differences with the model making fewer errors than participants did in Experiment 1, but more errors than seen in Experiment 2. The timing of the mouse clicks was simulated more closely, partially reflecting the availability of parameters that varied the timing of the models performance.

A key purpose of the model was to simulate the differences in latency seen in the false-analogy condition (as compared to Repeat and Novel problems). In this respect the model is very successful, showing the same differences as participants.

\section*{General Discussion}

Experiments 1 and 2 provide evidence of problem solving occurring after move-selection in the Tower of London (ToL). The TOL-GLAM model accounts for this data through a mechanism based around situation-action knowledge. This knowledge is encoded in TOL-GLAM as production rules that increase or decrease the activation of a particular motor action, depending on the apparent suitability of this action. The delays seen in move completion during the false-analogy condition in Experiment 1 and 2 are explained as TOL-GLAM having 'second thoughts' about the suitability of an already selected move. Our findings are similar to those of Walsh and Anderson (2009) who demonstrated how participants adaptively 'changed their minds' about the best strategy to solve a multiplication problem after a quick initial choice.

The way problem solving knowledge is structured in TOL-GLAM is noteworthy, relatively simple situation-only productions suggest a possible action, while more complex situation-action productions contain much of the knowledge that TOL-GLAM possess of how to solve ToL problems.

The notion that actions are selected and then evaluated is found in other theories. However in most existing theories this evaluation occurs in a single cycle of the system, and is only necessary if there is a conflict between two or more possible actions. For example in SOAR (Newell, 1990) preference rules are used for conflict resolution, while in ACT-r (Anderson, 2007) the relative utility of actions is considered. In TOL-GLAM, and more generally in the GLAM-PS architecture, the evaluation of an action is a protracted process, typically involving the evaluation of a single action, rather than multiple competing actions.

Although the current research focuses on a simple knowledge-lean domain (ToL), the issue explored is fundamental to understanding human thought. Current accounts (e.g. ACT-r, SOAR) appear to suggest that we think about situations, reason about them and only then
select an action. The suggestion here is that much of human thought begins with a possible action, and is followed by reasoning about the suitability of this action for the current situation.

\title{
A Mechanistic Account of Computational Explanation in Cognitive Science
}

\author{
Marcin Miłkowski (mmilkows@ifispan.waw.pl) \\ Institute of Philosophy and Sociology, Polish Academy of Sciences \\ ul. Nowy Świat 72, 00-330 Warsaw, Poland
}

\begin{abstract}
Explanations in cognitive science rely predominantly on computational modeling. Though the scientific practice is systematic, and there is little doubt about the empirical value of numerous models, the methodological account of computational explanation is not up-to-date. The current paper offers a systematic account of computational explanation in cognitive science in a largely mechanistic framework. The account is illustrated with a short case study of modeling of the mirror neuron system in terms of predictive coding.
\end{abstract}

Keywords: computation; computational modeling; explanation; mechanism; levels; information-processing.

\section*{Importance of Computational Modeling}

Computational modeling plays a special role in contemporary cognitive science; over 80 percent of articles in theoretical journals focus on computational \({ }^{1}\) models (Busemeyer \& Diederich, 2010). The now dominating methodology forcefully defended by (Marr, 1982) has turned out to be fruitful. At the same time, the three-level account of Marr is not without problems. In particular, the relationship among the levels is interpreted in various ways, wherein the change of level is both the shift of grain and the shift of the boundary of the system under explanation (McClamrock, 1991); it is not at all clear what is the proper relation between competence and its realization or whether bottom-up modeling is entirely mistaken; and, last but least, whether one model should answer how, what and why questions related to the explanandum.

My goal in this paper is to offer a descriptive account, which is close in spirit to the recent developments in the theory of mechanistic explanation (Bechtel, 2008; Craver, 2007; Glennan, 2002; Machamer, Darden, \& Craver, 2000). According to mechanism, to explain a phenomenon is to explain the underlying mechanism. Mechanistic explanation is a species of causal explanation, and explaining a mechanism involves the discovery of its causal structure. While mechanisms are defined variously, the core idea is that they are organized systems, comprising causally relevant component parts and operations (or activities) thereof. Parts of the mechanism interact and their orchestrated operation contributes to the capacity of the mechanism. Mechanistic explanations abound in special sciences and it is hoped that the adequate description of the principles implied in explanations generally accepted as sound will furnish researchers also with normative guidance.

\footnotetext{
\({ }^{1}\) I am not using the word 'computational' here in the sense used by Marr to define one of the levels in his account.
}

The claim that computational explanation is best understood as mechanistic gains popularity (Piccinini, 2007), and I have defended it at length against skeptical doubt elsewhere (Miłkowski, 2013). Here, I wish to succinctly summarize the account and, more importantly, add some crucial detail to the overall mechanistic framework proposed earlier. I cannot discuss Marr's theory in detail here (but see (Miłkowski, 2013, pp. 114-121)) and it is used only for illustration purposes. My remarks below are not meant to imply a wholesale rejection of his largely successful methodology.

Marr's account did not involve any theory of how computation is physically realized, and it is compatible with a number of different accounts. I will assume a structural account of computational realization here, defended also by Piccinini (2008) and Chalmers (2011). For an extended argument, see also (Miłkowski, 2011, 2013).

One particular claim that is usually connected with the computational theory of mind is that the psychologically relevant computation is over mental representation, which leads to the language of thought hypothesis (Fodor, 1975). Here, no theory of mental representation is presupposed in the account of computation, one of the reasons being that representation is one of the most contentious issues in contemporary cognitive science. As the present account is intended to be descriptively adequate, assuming one particular theory of representation as implied by computation would make other accounts immediately noncomputational, which is absurd. Another reason is that mechanistic accounts of computation do not need to presuppose representation (Fresco, 2010; Piccinini, 2006), though they do not exclude the representational character of some of the information being processed. In other words, it is claimed that only the notion of information (in the information-theoretic sense, not in the semantic sense, which is controversial) is implied by the notion of computation (or information-processing).

\section*{Explanandum phenomenon}

Marr stressed the importance of specifying exactly what the model was supposed to explain. Specifying the explanandum phenomenon is critical also for the mechanistic framework, as several general norms of mechanistic explanation are related to the specification of the capacity of the mechanism. All mechanisms posited in explanations have an explanatory purpose, and for this reason, their specification is related to our epistemic interest. For the same reason, the boundaries of the mechanism, though not entirely arbitrary, can be carved in different ways depending on what one wishes to explain.

The explanandum phenomenon has to be described precisely in a mechanistic model; otherwise, the model's use and value will be unclear. The specification of the model is not to be confused with raw, unrefined observation or common-sense intuition about the capacity under consideration. The specification of the capacity may be (and usually is) improved during the modeling process, wherein the model allows to understand the capacity better. What the mechanistic model explains is the real mechanism, but how the explanandum phenomenon is delineated is decided in what was called "the model of data" in philosophy of science (Suppes, 1962). For example, models of language production usually presuppose that user's productivity is the phenomenon to be explained, even though it is impossible to empirically observe a language user producing an infinite set of sentences. If there are theoretical reasons to believe that language users have this capacity, it will be described in a model of data. In this respect, mechanistic explanation is in accord with Marr's plea for explicit specification of what is computed.

To some degree, the specification of the explanandum phenomenon corresponds to description of the cognitive competence (understood generically as the capacity of the mechanism). However, in contrast to traditional competence accounts, descriptions of the explanandum need not be idealized. Also, the competence is explained with realization, and its realization by underlying levels of the mechanism is explanatorily relevant. This stands in contrast to traditional symbolic cognitive science.

\section*{Explanatory focus and target}

In the context of computational modeling, which nowadays uses different computer simulations and embodied robots, it becomes clear that properties of a model are not limited to the ones related directly to the explanandum phenomenon. For example, a robotic model of cricket phonotaxis (Webb, 1995) has to include, for technical reasons, a circuit board even if there is nothing that corresponds to the board in the cricket. Such boards are ignored when evaluating the adequacy of the robotic explanation. I propose to distinguish the explanatory focus of the model from its target, which is the real robot. In particular, all embodied mechanistic models are complete with respect to the capacities of the target, while their explanatory focus may still include gaps: we may still not know how certain properties of the insect give rise to the explanandum phenomenon even if we have a robotic replica. The same goes for purely computational models that contain numerous ad hoc additions (Frijda, 1967; Lewandowsky, 1993). These additions are not parts of the explanatory focus.

Whenever the causal model of the explanatory focus of the mechanism is complete with respect to the explanandum phenomenon (note: not complete in an absolute sense), the model is a mechanistic how-actual explanation; if the model includes some black boxes, whose function is more or less well-defined, it is a mechanism schema; otherwise, it
remains a mechanism sketch. \({ }^{2}\) Note that even a grounded, embodied, robotic model of visual perception may still be a mechanism sketch with respect to human vision. Also, a model in which the explanatory focus is just a minor part of the mechanism, while the parts included in the target are predominant, violates the principle of parsimony.

\section*{Three levels of constitutive explanation}

Constitutive mechanistic explanation is the dominant form of computational explanations in cognitive science, and I will focus on it in what follows. This kind of explanation includes at least three levels of the mechanism: a constitutive ( -1 ) level, which is the lowest level in the given analysis; an isolated (0) level, at which the parts of the mechanism are specified along with their interactions (activities or operations); and the contextual (+1) level, at which the function of the mechanism is seen in a broader context (e.g., the context for cricket phonotaxis includes the dispersion of sound in the air). In contrast to how Marr (1982) or Dennett (1987) understand them, levels here are not just levels of abstraction; they are levels of composition. Hence, they are tightly integrated but not entirely reducible to the lowest level.

Computational models explain how the computational capacity of a mechanism is generated by the orchestrated operation of its component parts. To say that a mechanism implements a computation is to claim that the causal organization of the mechanism is such that the input and output information streams are causally linked and that this link, along with the specific structure of information processing, is completely described (for more on various mathematical notions of information, see Miłkowski (2013, chap. 2); note that I do not presuppose Church/Turing thesis). Importantly, the link might be cyclical and as complex as one could wish.

There are two ways in which computational models may correspond to mechanisms; first, they may be weakly equivalent to the explanandum phenomenon, in that they only describe the input and output information; or strongly equivalent, when they also correspond to the process that generates the output information. Note that these notions have been used in methodology of computer simulation since 1960s (Fodor, 1968, chap. 4). Only strongly equivalent models are explanatory according to the mechanistic framework.

\section*{Mechanistically adequate model of computation}

The description of a mechanistically adequate model of computation at the 0 level usually comprises two parts: (1) an abstract specification of a computation, which should include all the causally relevant variables; (2) a complete blueprint of the mechanism at this level of its organization. I will call the first part formal model of the mechanism and

\footnotetext{
\({ }^{2}\) These distinctions were used by Craver (2007), but were unrelated to the distinction between the target and the explanatory focus.
}
the second instantiation blueprint of the mechanism, for lack of a better term. While it should be clear that a formal model needs to be included, it is probably less evident why the instantiation blueprint is also part of the mechanistically adequate model. The causal model must include all causally relevant parts and operations without gaps or placeholder terms (think of generic and unspecific terms such as "representation" or "activation"). Yet formal models cannot function as complete causal models of computers. For example, to repair a broken old laptop, it is not enough to know that it was (idealizing somewhat) formally equivalent to a universal Turing machine. Similarly, how mental deficits will manifest themselves is not obvious based on a description of ideal cognitive capacity. One needs to know its implementation.

Hence, the mechanistic model of a computational phenomenon cannot be limited to its formal properties. Accordingly, merely formal models of, say, linguistic competence, which abstract away from its realization, are assessed as essentially incomplete. They are either mere specifications of the explanandum phenomenon, but not explanatory in themselves, or, when accompanied with a rough theory of how they are related to experimental data, mechanism sketches (Piccinini \& Craver, 2011). This means that computational explanations of psychological capacities need to be integrated, for completeness, with models of their realization. Otherwise, they may posit epiphenomenal entities without any causal relevance. Contrary to the functionalist theory of psychological computational explanation (Cummins, 1983), mechanism requires it to be causal. It follows that some symbolic models in psychology, even if they are weakly equivalent to the model of input/output data, are not considered to be fully explanatory because of the inherent danger of positing entities that are causally irrelevant.
Just because the usual description of the computational mechanism usually involves two different models, the formal one and the instantiation blueprint, and these may be idealized, computational modeling requires complex integration, similar to one described as multiple-models idealization (Weisberg, 2007).

Note that my mechanistic account of computation does not stipulate that there be a single formal model of computation that would fit all purposes. Rather, it adheres to transparent computationalism (Chrisley, 2000): any formal model that can be specified in terms of informationprocessing is fine here, be it digital, analog, or hybrid, as in contemporary computational neuroscience (Piccinini \& Bahar, 2012).

The empirical adequacy of the mechanistically adequate model of computation can be tested. As such models are strongly equivalent to processes being modeled, usual process-testing methods apply, including chronometry (Posner, 2005), various kinds of experimental and natural interventions (Craver, 2007), brain imaging - though with usual caveats (Trout, 2008), and task decomposition (Newell \& Simon, 1972). All in all, the more independent
observables are tested, the more robust the model. Note that the phenomenological validation modeled after the Turing test (Turing, 1950) is not taken to be evidence of the model's empirical adequacy.

\section*{Marr's cash register}

The account may be illustrated with the example used by Marr (1982, pp. 22-24): a cash register in a supermarket. The explanandum phenomenon is the capacity to add prices of individual items and determine the overall sum to be paid. At the contextual level, one describes the cash register as playing a certain role in the supermarket, by allowing easy calculation of the sum to be paid, and making the work of the cashier clerk easier. This includes a bar-code scanner, a conveyor belt, etc. At the isolated level, a dedicated computer using special software is described. The constraints mentioned by Marr, such as commutativity or associativity of addition, are included in the description of the software. Yet without describing the machine that can run the software, this level of description is incomplete. Various failures of the cash register (e.g., dimming of the display), can be explained not only in terms of the software bugs but also as hardware failures. Also, the particular display configuration, which can be related to user preferences at the contextual level, is usually not described fully in the software specification. It is the isolated level where one describes the physical machine that can display the product name for the cashier clerk and, more fundamentally, can run code by reading it from external memory (not all computers do so; a mechanical cash register, even if it performs computations, cannot run different software). The formal description, usually in terms of the programming language or diagrams, is put into correspondence with the machine. At the constitutive level, the operations of the electronic parts of the machine are explained by reference to their properties, relationships, and organization. Just because vast differences between different types of registers are possible (witness the differences between the self-checkout register and the ones used during the American Civil War), the exact explanations will differ. Also, self-checkout machines will have the capacity to collect cash automatically, which needs to be explained as well (the explanandum will be different), and so forth.
The purpose of this toy example is to show that the mechanistic explanation differs a bit from Marr's account by explicitly tightly integrating the levels. Also, at all levels one can ask the why-question: why is the design appropriate for the user? Why does the cash register appropriately display figures on the screen? Why does it save energy? The how-answer is specified at a lower level, and the lowest level depends on our epistemic interest. The what-question also concerns operation of all levels.

\section*{Case study: Predictive coding in mirror neurons}

To demonstrate what methodological guidance is offered by the mechanistic account of computational explanation, let
me briefly describe a recently proposed model of actionunderstanding in terms of predictive coding (Kilner, Friston, \& Frith, 2007). Predictive coding is one of the Bayesian frameworks and is gaining now considerable recognition (Clark, 2013). In the model, it is presupposed that this capacity is realized by the mirror-neuron system (MNS henceforth). \({ }^{3}\) The explanandum phenomenon, or action understanding, is described at four levels of hierarchy: (1) the intention-level, which includes long-term goals of actions; (2) the goal-level, which includes short-term goals necessary to realize (1); (3) the kinematic level, which is the shape of the movement of limbs in space and time; and (4) the muscle level, which is the pattern of muscle activity underlying the action (Hamilton \& Grafton, 2006). People have visual access only to (3) of other agents. Moreover, the same kinematic level information is correlated to different intentions: Mr. Hyde might hurt someone with a scalpel by making the same movements as Dr. Jekyll (Jacob \& Jeannerod, 2005). What needs to be explained, therefore, is how one understands actions, given ambiguous visual information; the constraint of the model is that such understanding is to be realized by MNS. Naturally, given relatively scarce evidence about the details of MNS, the model might be currently only biologically plausible. In mechanistic terms, it cannot be a how-actually model, as we lack observables that could confirm that causal factors in the model are actual. We may have only a how-plausible model (for more on this distinction, see (Craver, 2007)), which should ascribe a precise computational role for MNS.

Kilner, Friston \& Frith note that other similar explanations of action in terms of MNS posit forward or generative models. Yet these explanations cannot deal with the fact that people easily distinguish between the action of Dr. Jekyll and Mr. Hyde. In other words, they do not explain one important part of the phenomenon.

The contextual level of the proposed predictive coding mechanism includes the context in which the action is observed (e.g., the operation theatre vs. dark streets of London). The context of action, which is not coded by MNS, is hypothesized to be represented by other parts of the larger hierarchy, where intentions are encoded (Kilner et al., 2007, p. 164). Note that such hierarchy can be naturally accounted for in the mechanistic framework, while in the Marrian methodology, nested hierarchies of mechanisms are still analyzed merely on three levels, which are not levels of composition, as in Kilner et al.'s paper (this makes the analysis of the model in Marrian terms all the more difficult).

The 0 level of the mechanism is then described as performing predictive coding of action, i.e., the mechanism predicts the sensory consequences of movements, and the prediction error is minimized through recurrent or reciprocal

\footnotetext{
\({ }^{3}\) For my purposes, it is quite irrelevant whether this account of MNS is correct or not (but see (Lingnau, Gesierich, \& Caramazza, 2009)). I am merely interested in how the model is vindicated by its authors and how it should be evaluated from the mechanistic standpoint.
}
interactions among levels of a cortical hierarchy. This means that the mechanism posited by authors comprises more than just three levels, which is the minimal number for constitutive explanations. Here, the upper level mechanism employs a generative model to predict representations in the level below. Backward connections are used by the upper level to convey the prediction to the lower level, which is used to produce information about prediction error. The instantiation blueprint of the mechanism includes this hierarchy whose architecture allows adjusting the neural representations of actions in terms of sensory representation of causes of action if prediction error is found. The architecture is self-organizing, and the reciprocal exchange of signals continues until the error is finally minimized.

The formal model of the neural architecture is described here in terms of empirical Bayesian inference (Friston, 2002, 2003, 2005): the prior expectations are generated by the self-organizing information-processing architecture. In other words, this model includes, as usual, two complementary parts: the instantiation blueprint, characterized in terms what is known about MNS, and its formal computational specification. Quite obviously, contrary to the programmable cash register, no storedprogram computer is posited.

The constitutive level is merely touched upon; there is no extensive discussion of the precise realization of predictive coding by elementary entities of the neural system. Thus, this model is, at best, a mechanism schema, because it does not explain how MNS comes to operate as it does. The authors stress that to test the model, one would need to characterize the nodes of the cortical hierarchy anatomically and functionally, and such characterization is not available.

The neural plausibility of the predictive coding and its relation to empirical Bayesian modeling is the focus of much current discussion (Blokpoel, Kwisthout, \& Van Rooij, 2012). In particular, the question whether the biologically plausible implementation of the predictive coding is equivalent to empirical Bayes or not (it may somewhat approximate it). The mechanistic explanation requires that the mechanisms be not idealized in such a way that would require to ignore tractability questions (Van Rooij, 2008). The data in the original paper makes it impossible to answer critical questions about the mechanism in this context, such as the number of inputs in the Bayesian network, which is essential in assessing the parametrized complexity of the algorithm.

Were the model implemented on the computer, the results of the simulation could be compared to those observed in humans or in macaque monkeys. Alas, no such results are reported by Kilner et al., and since without implemented models detailed testing of hypotheses is impossible, the empirical adequacy of the explanation is not entirely clear. To assess the adequacy properly, one should rather implement several comparable models of the same explanandum phenomenon, which can also help in avoiding the confirmation bias to which researchers are prone (Farrell \& Lewandowsky, 2010; Miłkowski, 2013, p. 86).

Some Bayesian theories in psychology were recently criticized as fundamentalist, i.e., dogmatically trying to model behavior as rational and without mechanistic constraints (Jones \& Love, 2011). Note that this is not true of the model under consideration; Bayesian modeling in neuroscience is obviously related to functioning of the brain. Instead of stressing the contrast between the mechanistic account of computational explanation and Bayesian modeling, my intention is to show that the mechanistic framework can be used to evaluate the contribution of the given model to progress in understanding of the explanandum phenomenon.

Summing up this part of the discussion, the mechanistic framework makes it easy to assess the maturity of the model in terms of its completeness and empirical adequacy. Because the computer implementation is lacking, it is impossible to say whether the model contains a lot of empirically undecided decisions that are needed to make it run (hence focus/target evaluation is impossible). At the same time, there is no information about the constitutive level. On the contextual level, placeholder terms such as "intention encoding" are used and they need further explanations in other models. Thus, the model does not include a complete specification of the mechanism.

Also, it is not at all clear how long-term goals might be understood in terms of mere sensory input prediction. Dr. Jekyll's intention to heal a patient (long-term goal) does not seem, prima facie, to be represented just in sensory terms. If it is actually so represented, the model does not explain how. This makes it a mechanism sketch, so its explanatory value is, qualitatively speaking, on the par with traditional symbolic models of competence. (Quantitative evaluation is impossible here, as no results of experiments on computer implementation were reported.)

\section*{Conclusion}

The mechanistic account of computational explanation preserves the insights of Marr but is more flexible when applied to complex hierarchical systems. It may help integrate various different models in a single explanation. Mechanistic methodological principles are inferred from research practice in life sciences, neurosciences, and cognitive science. Also, by subsuming computational explanation under causal explanation, the mechanistic account is naturally complemented by methodology of causal explanation (Pearl, 2000; Spirtes, Glymour, \& Scheines, 2000; Woodward, 2003).

By allowing multiple nested hierarchies, the standard three-level constitutive explanation is naturally expanded when needed. There is also no danger in preferring only the contextual level in the explanation, as it does not furnish us with the constitutive causal factors. The constitutive level will also not obviate the need for the contextual level as it does not contain some of the entities which are found at the contextual level. For example, the encoding of intention is not realized by MNS only, so its explanation cannot be 'reduced' to the description of the lower levels.

The present theory is not intended to settle debates over matters in which modelers explicitly disagree; the only goal is to make as much sense of various modeling approaches as possible, and make cross-approach comparisons possible by showing the common ground between them.

It is also not presupposed that computational explanation is the only proper way to explain cognition (Miłkowski, 2012). On the contrary, only some part of the mechanism model is strictly computational (i.e., uses vocabulary of the theory of computation). The constitutive level of the mechanism has to be framed in non-computational terms; otherwise, the computational operations of the isolated level are not explained, and may turn out to be spurious (Miłkowski, 2013, pp. 82-3). At the same time, the present account leads naturally to explanatory pluralism, as the only requirement for the theoretical frameworks used to describe various levels of composition of mechanisms is that they include causally relevant factors.

\begin{abstract}
Performing inductive generalizations is critical for learning, yet there is much debate regarding the mechanisms underlying this ability. One view posits that similarity-based induction, utilizing perceptual features, may allow for increased encoding and higher memory accuracy on recognition tests. While category-based induction, utilizing semantic information, may result in limiting encoding of perceptual detail, thus resulting in decreased memory accuracy. In Experiment 1, we attempted to impair spontaneous categorization by presenting a second Working Memory load task. In Experiment 2, we attempted to impair perceptual processing by introducing a second Visual Search task. Results indicate that adult participants can rely on either mechanism when performing induction.
\end{abstract}

Keywords: Induction; Learning; Memory.

\section*{Introduction}

The ability to generalize from the known to novel is a critical aspect of cognition - this ability allows expanding knowledge to new situations. At the same time, the learner may not know how far new knowledge can be expanded outside of the learning situation. Suppose that one learned that adenosine promotes myelination in the brain of the Capuchin monkey. Should this knowledge be generalized to New World monkeys, all monkeys, all primates, or all mammals? One way of generalizing knowledge is by identifying a common category that licenses such generalization. For example, one may decide that MONKEY is such a category and generalize knowledge to all monkeys. However, while knowledge of categories is useful, it is not necessary for inductive generalization. For example, one may decide that animals share a property to the extent their similarity exceeds some criterial value.

The latter mechanism seems to be a good candidate for generalization early in development, whereas the former could be a product of development. However, despite the fact that inductive generalization exhibits early onset (Baldwin, Markman, \& Melartin, 1993; Gelman \& Markman, 1986; Sloutsky, Lo, \& Fisher, 2001; Welder \& Graham, 2001), the mechanisms underlying early induction are hotly debated.

According to the naïve theory approach (see Murphy, 2002, for a review) induction is a two-step process: children first identify encountered entities as members of categories, and, if entities belong to the same category (say, the same natural kind), then infer that these entities share many properties. The inference is licensed by children's assumptions that members of some categories (such as, for example, natural kinds) share many properties. Given that children are more likely to know basic-level categories (e.g., MONKEY) than superordinate categories (e.g., MAMMAL), they are more likely to generalize properties within basic-level categories.

According to another position (i.e., the similarity view), induction is a generalization process, and young children generalize on the basis of multiple commonalities, or similarities, among presented entities (e.g., Jones \& Smith, 2002; McClelland \& Rogers, 2003; Sloutsky, Fisher, \& Lo, 2001; Sloutsky, 2003, Sloutsky \& Fisher, 2004a, 2004b). This view does not attribute conceptual assumptions to young children.

In an attempt to address these issues, Sloutsky and Fisher (2004b; Fisher \& Sloutsky, 2005) introduced Induction-then-Recognition (ITR) paradigm. The idea is based on the following reasoning. There is a well-known "level-of-processing effect" - deeper semantic processing facilitates correct recognition of presented items, increasing the proportion of "hits" (Craik \& Lockhart, 1972; Craik \& Tulving, 1975). At the same time, deeper processing also results in higher levels of memory intrusions - false recognition of non-presented "critical lures" of semantically associated or categorically related items (e.g., Koutstaal \& Schacter, 1997; Rhodes \& Anastasi, 2000; Thapar \& McDermott, 2001). Due to elevated levels of false alarms, the net result of deep semantic processing on recognition accuracy (i.e., Hits - False Alarms) is negative. At the same time, it is known that focusing on perceptual details of pictorially presented information leads to more accurate recognition (Marks, 1991) - although hits might be slightly lower, false alarms are significantly lower than under deep semantic processing. Therefore, these memory findings suggest that categorization (which is a variant of deeper semantic processing) would result in a higher level of memory intrusions and thus in lower recognition accuracy
than shallow perceptual processing (see also Brainerd, Reyna, \& Forrest, 2002, for related arguments).

Thus, a memory test administered after an induction task may reveal differential encoding of information during induction: if participants perform category-based induction, they should be engaged in deep semantic processing, and therefore exhibit low discrimination of studied items from critical lures during a memory test (compared to a noinduction baseline condition). On the other hand, if participants perform similarity-based induction, they should be engaged in shallow perceptual processing, and as a result their memory accuracy should not decrease compared to the baseline. Because, unlike adults, young children were expected to perform similarity-based induction, this reasoning led to a nontrivial prediction that after performing induction, young children may exhibit greater memory accuracy (i.e., have fewer false alarms) than adults.

These predictions have received empirical support: the pattern of results reported by Sloutsky and Fisher (2004a; 2004b; Fisher \& Sloutsky, 2005) indicated that while adults perform category-based induction, young children perform similarity-based induction. In particular, after performing inductive generalizations about members of familiar animal categories (i.e., cats, bears, and birds), adults’ memory accuracy attenuated markedly compared to the no-induction baseline, and, these effects of induction were robust across a wide range of animal categories (Fisher \& Sloutsky, 2004). At the same time, young children were accurate in both the baseline and induction conditions, exhibiting greater accuracy in the induction condition than adults.

Although these findings are compatible with the idea of different mechanisms of induction across development (i.e., similarity-based early induction and category-based mature induction), a number of alternative explanations have been proposed. In particular, Wilburn and Feeney (2008) and Hayes, McKinnon, \& Sweller (2008) suggested that the mechanism of induction does not change across development (with induction being category-based) and the higher memory accuracy of children simply reflects their inability to filter out irrelevant perceptual information. In other words, whereas adults process primarily category information, young children cannot focus efficiently, and, as a result, they process both category and perceptual information. Although there are several phenomena that this idea cannot explain (see Sloutsky, 2008), we deemed it necessary to address the issue directly.

To do so, we created a new paradigm to examine the issue. The underlying idea is to selectively impair either categorical or perceptual processing and to examine induction and memory performance. If participants can rely on either information (which we believe is the case with adults), then neither manipulation should have an effect on induction. If participants rely primarily on perceptual information (which we believe is the case with children), then impairing perceptual processing should impair induction.

Each manipulation should also have a different effect on memory. Impairing categorical processing should force participants to process items perceptually, thus potentially increasing memory accuracy after performing induction. At the same time, impairing perceptual processing should force participants to process items categorically, thus potentially decreasing memory accuracy.

In research reported here, we tested this paradigm with adults. The main idea is to introduce a second task when participants perform induction. To impair categorical processing, we introduce a working memory task, whereas to impair perceptual processing, we introduce a visual search task.

In what follows, we report two experiments: In Experiment 1, the second task is a working memory task, whereas in Experiment 2, the second task is a visual search task. We compare performance on these experiments with performance reported by Sloutsky and Fisher (2004), when no secondary tasks were introduced.

\section*{Experiment 1: Induction with Working Memory Load}

The experiment was a replication of Sloutsky and Fisher (2004b) ITR paradigm with one difference: during the study phase participants were presented with a second task, whose goal was to increase working memory load.

\section*{Method}

Participants. Sixty-two introductory psychology students participated in the experiment for class credit. Twenty-six participants were excluded due to low accuracy on check trials in the recognition portion of the experiment.

Materials, Design and Procedure. Visual Stimuli consisted of 44 color photographs of animals on white backgrounds (see Figure 1 for examples). Auditory Stimuli consisted of ten familiar words (e.g., one, two, three, four, five, six, seven, eight, nine, ten) presented through headphones between 68-72 dB.

Similar to Sloutsky and Fisher (2004b), the experiment included two between-subjects conditions: Memory and Induction. In both conditions, the experiment was divided into two phases: the study phase and the recognition phase.

During the study phase of both conditions, participants received a working memory (WM) task. For the WM task, participants were initially presented with five randomly selected Auditory Stimuli and asked to listen for one of the words to be played more than one time on each of the subsequent study phase trials. At the end of each trial participants were asked if one of the words had been repeated and were provided with Yes/No feedback.

The primary task of interest differed across the conditions: in the Induction condition participants were asked to generalize properties and in the Memory condition, they were asked to remember the items as accurately as possible.

Study Phase: Induction Condition. During the study phase, participants were presented with 30 pictures of animals, one at a time, in a random order. The animals were selected from 3 categories: 10 bears, 10 birds, and 10 cats. The pictures were presented centrally on a 22 " wide screen monitor for 2750 ms each. After being introduced to the WM task, participants were then shown a picture of a cat and were told the cat had "beta cells in its blood." Throughout the study phase of the Induction condition, participants were first asked after each trial whether one of the words had been repeated and Yes/No feedback was provided. They were then asked to decide whether each presented animal also had beta cells. Yes/No feedback was provided indicating that only cats had beta cells.
Study Phase: Memory Condition. The Memory condition was similar to the Induction condition, with a single difference: instead of performing an induction task, participants were asked to remember the items as accurately as possible. They were also warned about the upcoming memory test.
Recognition Phase. The recognition phase was identical across both conditions. The recognition phase immediately followed the study phase. During recognition, participants were presented with 28 images, 14 of which had been presented in the study phase and 14 of which were new images. Participants were instructed to determine whether each image had been presented during the study phase and neither feedback nor secondary task was given.

Figure 1: Examples of Visual Stimuli

\section*{Results and Discussion}

In this experiment, it was expected that spontaneous categorization would be hindered due to increased working memory load. Therefore, compared to a single task condition in Sloutsky and Fisher (2004b), the dual task condition may increase the overall task difficulty thus attenuating recognition accuracy in the Memory condition. At the same time, it may block categorization, thus increasing recognition accuracy in the Induction condition. The average rate of correct induction was over \(98 \%\), compared to over 75\% induction accuracy in Sloutsky and Fisher (2004b).

To analyze recognition memory accuracy, Hit and False Alarm (FA) rates were calculated (see Table 1). Also in the Table are Hit and FA rates from Sloutsky and Fisher (2004b). Because these researchers did not use a secondary WM task, we will refer to their experiment as "Baseline".

To further examine the ability to discriminate old items from critical lures, we computed memory sensitivity \(A^{\prime}\) scores. \(A^{\prime}\) is a nonparametric analogue of the signal detection statistic d' (Snodgrass \& Corwin, 1988; Wickens, 2002). If participants do not discriminate old items from critical lures, \(A^{\prime}\) is at or below .5. The greater the discrimination accuracy, the closer \(A^{\prime}\) is to \(1 . A^{\prime}\) scores for Experiment 1 are presented in Figure 2 alongside \(A^{\prime}\) scores for Experiment 2, as well as the results of the Sloutsky and Fisher (2004b) Baseline data.

Data in the figure were submitted to a 2 (Experiment: Working Memory vs. Baseline) by 2 (Condition: Induction vs. Memory) ANOVA. The analysis revealed a significant interaction between experiment and condition, \(F(1,80)=\) 5.58, \(p=.02\) as well as a significant main effect of condition, \(F(1,80)=14.38, p<.000\). Independent samples t-tests indicated that memory accuracy in the Memory condition of the current experiment was lower than that in Sloutsky and Fisher (2004b), \(t\) (35) \(=-2.23, p<.05\). At the same time the opposite was true for the Induction condition, in which the WM load of the current experiment resulted in marginally higher memory accuracy than a single task induction accuracy reported in Sloutsky and Fisher (2004b), \(t(45)=1.54, p=.13\).

Table 1
Mean Proportions of Hits and False Alarms (FA) and Mean Accuracy
\begin{tabular}{lccc}
\hline \hline Condition & Hits & FA & \begin{tabular}{c} 
Accuracy \\
(hits-FA)
\end{tabular} \\
\hline WM-Ind & \(.78(.16)\) & \(.59(.26)\) & .19 \\
WM-Mem & \(.77(.14)\) & \(.52(.22)\) & .24 \\
\hline *S\&F-Ind & \(.83(.20)\) & \(.76(.25)\) & .07 \\
*S\&F-Mem & \(.89(.10)\) & \(.47(.31)\) & .42 \\
\hline \hline
\end{tabular}

Note. WM - working memory; *S\&F - Sloutsky \& Fisher (2004b); Standard deviations are in parentheses.

Taken together results of Experiment 1 indicate that impairing categorization by introducing a secondary WM task does not affect induction accuracy, but it does affect memory accuracy. Most importantly, memory accuracy in the Induction condition increased somewhat, compared to the memory accuracy in the single-task Induction, which was not the case for the Memory condition. These results confirm that if categorization is impaired, adults can rely on perceptual information to perform induction. In Experiment 2, we attempted to impair participants' perceptual processing.

\section*{Experiment 2: Induction with Perceptual Load}

The experiment was similar to Experiment 1, with one critical difference: the second task was a visual search task, whose goal was to impair perceptual processing rather than categorization.

\section*{Method}

Participants. Fifty-six introductory psychology students participated in the experiment for class credit. Thirty participants were excluded due to low accuracy on check trials in the recognition portion of the experiment.

Materials, Design and Procedure. Visual Stimuli consisted of the same 44 color photographs used in Experiment 1. Visual Search Stimuli consisted of a total of 16 red or black " + " and " 0 " symbols. These stimuli were presented in random sequence by Rapid Serial Visual Presentation, with items being displayed for 250 ms each and having an inter stimulus interval of 250 ms . Visual Search stimuli were presented in the upper right hand corner of the screen with eccentricity of approximately \(23^{\circ}\) visual angle and subtending approximately \(1.4^{\circ}\) of visual angle. Experiments were conducted on a Dell Optiplex 790 computer and were programmed in E-Prime Professional 2.0 software.

Similar to Experiment 1, this experiment included two between-subjects conditions: Memory and Induction. Also, similar to Experiment 1, the two conditions differed only in the Study phase, while having identical Recognition phase.
The Study phase of each condition was similar to the respective condition of Experiment 1, with a single difference. The second task in Experiment 2 was a Visual Search (VS) task.

During the study phase of both conditions, participants were presented with Visual Search stimuli in the upper right corner of the monitor and asked to watch for red " + " signs on each of the subsequent study phase trials. The Visual Search stimuli preceded the onset of animal pictures by 3000 ms and continued 2000 ms after the picture of the animal disappeared. The study phase consisted of the same 30 pictures of animals as in Experiment 1 and were presented centrally on a 22 " wide screen monitor for 2750 ms each. After each study phase trial, participants were first asked whether a red "+" sign had been presented. In both
conditions, participants were instructed to not look directly at the animal pictures. Participants' eye gaze was monitored by an experimenter and verbal corrective feedback was provided. Immediately following the last Visual Search stimuli on each trial, participants were asked whether they had seen any red "+" signs and Yes/No feedback was provided.
Study Phase: Induction Condition. During the Induction Condition, participants were first asked whether they had seen any red "+" signs and were provided with Yes/No feedback. They were then asked whether the animal had beta cells and were given Yes/No feedback indicating that only cats have beta cells.
Study Phase: Memory Condition. The Memory condition was similar to the Induction condition, with a single difference: instead of performing an induction task, participants were asked to remember the items as accurately as possible.
Recognition Phase. The recognition phase was similar to that in Experiment 1: in the Memory condition participants were told in advance about the upcoming recognition phase, whereas in the Induction condition, no advanced warnings about upcoming recognition were given. The recognition phase immediately followed the study phase. During recognition, participants were presented with the same 28 images that were presented in Experiment 1, 14 images had been presented in the study phase and 14 were new images. Participants were instructed to determine whether each image had been presented during the study phase and neither feedback nor secondary task was given.

\section*{Results and Discussion}

In this experiment, it was expected that perceptual processing would be impaired due to the demands of the Visual Search task. The average rate of correct induction was over \(94 \%\), compared to over \(75 \%\) induction accuracy in Sloutsky and Fisher (2004b).

Hit and false alarm rates are presented in Table 2 and \(A^{\prime}\) scores for Experiment 2 are presented in Figure 2 alongside \(A^{\prime}\) scores for Experiment 1, as well as the results of the Sloutsky and Fisher (2004b) Baseline data. Hit and false alarm percentages for Experiments 1 and 2, as well as the Sloutsky and Fisher Baseline percentages are presented by condition in Table 3.

Table 2
Mean Proportions of Hits and False Alarms (FA) and Mean Accuracy
\begin{tabular}{lccc}
\hline \hline Condition & Hits & FA & \begin{tabular}{c} 
Accuracy \\
(hits-FA)
\end{tabular} \\
\hline VS-Ind & \(.71(.20)\) & \(.59(.28)\) & .12 \\
VS-Mem & \(.58(.22)\) & \(.39(.23)\) & .18 \\
\hline *S\&F-Ind & \(.83(.20)\) & \(.76(.25)\) & .07 \\
*S\&F-Mem & \(.89(.10)\) & \(.47(.31)\) & .42 \\
\hline \hline
\end{tabular}

Note. VS - Visual Search; *S\&F - Sloutsky \& Fisher (2004b); Standard deviations are in parentheses.
\(A^{\prime}\) scores shown in Figure 2 were submitted to a 2 (Experiment: Visual Search vs. Baseline) by 2 (Condition: Induction vs. Memory) ANOVA. The analysis revealed a significant interaction, \(F(1,70)=4.65, p<.05\), as well as a main effect for condition, \(F(1,70)=10.08, p=.002\). Furthermore, two tailed independent samples t-tests indicated a significant decrease in memory accuracy in the Memory condition of Experiment 2 compared to Sloutsky and Fisher (2004b), \(t(29)=-2.38, p<.05\); but not in the Induction condition \(t(41)=.60, p=.55\).

Figure 2. Memory Sensitivity scores (A') across experimental conditions. The dashed line represents the point of no sensitivity. Error bars show standard errors of the mean.

Table 3
Mean Proportions of Hits and False Alarms (FA) and Mean Accuracy
\begin{tabular}{lccc}
\hline \hline Condition & Hits & FA & \begin{tabular}{c} 
Accuracy \\
(hits-FA)
\end{tabular} \\
\hline WM-Ind & \(.78(.16)\) & \(.59(.26)\) & .19 \\
WM-Mem & \(.77(.14)\) & \(.52(.22)\) & .24 \\
VS-Ind & \(.71(.20)\) & \(.59(.28)\) & .12 \\
VS-Mem & \(.58(.22)\) & \(.39(.23)\) & .18 \\
*S\&F-Ind & \(.83(.20)\) & \(.76(.25)\) & .07 \\
*S\&F-Mem & \(.89(.10)\) & \(.47(.31)\) & .42 \\
\hline \hline
\end{tabular}

Note. Standard deviations are in parentheses.
*Indicates data from Sloutsky \& Fisher (2004).

Overall, results of Experiment 2 indicate that impairing perceptual processing does not impair inductive inference in adults, while significantly impairing recognition accuracy in the memory condition.

\section*{General Discussion}

The two reported experiments introduce and test a new paradigm for studying the mechanism of induction. Experiment 1, attempts to impair semantic categorization by introducing a secondary Working Memory task, while Experiment 2 attempts to impair perceptual processing by introducing a secondary Visual Search task. Results indicate that whereas participants were able to perform inductive inference in both conditions, each manipulation somewhat differently affected recognition accuracy in the Memory and Induction conditions.

First, both tasks impaired recognition accuracy in the Memory condition compared to a single task Baseline, perhaps more so in the Visual Search than in the WM condition. Note that when Visual Search was the secondary task, recognition memory in the Induction condition (similar to the Baseline) was not different from 0.5 ( \(p>.12\) ), which indicates no discrimination between old items and critical lures. At the same time, when working memory was the secondary task, recognition memory in the Induction condition was above \(0.5(p<.05)\) In addition, the WM task (whose goal was to block semantic categorization) increased somewhat memory accuracy in the Induction condition.

The reported results support the idea that adults may perform inductive inference by relying on either conceptual or perceptual information. In future research, we plan to present these tasks to children. If mechanisms of induction in children are equivalent to those of adults, then, similar to adults, children should be able to perform induction in either condition (although their memory accuracy may attenuate due to increased task demands). In contrast, if children rely on perceptual (but not conceptual) processing when performing induction, their induction performance should drop in the Visual Search, but not in the WM condition. We believe that the new paradigm presented here can address these issues.

\begin{abstract}
Does the typicality of an object affect how we identify it? When we produce initial reference to a visible object, we are influenced by a variety of factors, including what is visually salient (bottom-up influences) as well as our previous experiences with the object (top-down influences). In this study, we seek to understand how the top-down influence of typicality affects initial reference to an object. We use real world, everyday objects, and focus on the visual properties of SHAPE and material. Our findings suggest that there is a tendency to select the atypical over the typical. But we have only begun to scratch the surface of understanding reference to real world objects. The annotated corpus from this study is made available for future research on modeling reference in visual domains. \({ }^{1}\)
\end{abstract}

Keywords: referring expressions; description; reference; vision; typicality

\section*{Introduction}

I never saw a purple cow.
I never hope to see one, But I can say this anyhow:
I'd rather see than be one. - Gelett Burgess

When we identify an object for a hearer, we have a number of choices to make about what to mention. When the object is visible to both speaker and hearer, properties that help guide visual attention, such as color and size, are particularly informative (Treisman \& Gelade, 1980; Wolfe, 2006). Properties that are salient to the discourse or relevant to the speaker and hearer's previous interactions also affect what we will mention and describe (Clark \& Wilkes-Gibbs, 1986; Brennan \& Clark, 1996; Clark \& Krych, 2004).

We hypothesize that when we generate initial reference to an object for a hearer, our knowledge about objects of the same type is also likely to affect what we mention. In other words, our understanding of what is typical for an object category influences the selection of modifiers - the adjectives and longer descriptive phrases - that we produce when we first describe an object. This understanding of what is typical for an object category may stem from stored object prototypes (Rosch \& Mervis, 1975; Rosch, C. Mervis, W. Gray, Johnson, \& Braem, 1976) or mental representations of similar objects in previous situations (Yeh \& Barsalou, 2006; Wu \& Barsalou, 2009). Because of typicality, we know that the purple cow mentioned in the example above is remarkable.

Previous work on reference has paid little attention to the role of typicality. This is equally true for psycholinguistic

\footnotetext{
\({ }^{1}\) http://m-mitchell.com/corpora/typicality_corpus/
}

Figure 1: Example scenes from the GRE3D3 Corpus and the TUNA Furniture sub-corpus. Participants produce referring expressions such as yellow ball on top of the red cube (GRE3D3) or small fan (TUNA).
work (Arnold, 2008) and for work on computational models of reference (Dale \& Reiter, 1995; Krahmer, van Erk, \& Verleg, 2003; Krahmer \& van Deemter, 2012). The present study addresses what we believe to be a significant gap in our understanding of reference.

We examine the role of typicality in reference to real world, everyday objects, focusing on material and shape properties. Objects are presented so that one of these two properties will distinguish the object. We test whether there is a significant difference between groups when participants in one may choose between atypical shape or typical material to describe target objects, while participants in a second group may choose between typical shape or atypical material to describe target objects. Our findings suggest that there is a tendency to select the atypical over the typical.

Although this study focuses on shape and material typicality, we release the full corpus from our experiments, annotated with a variety of visual properties, in hopes of helping further work in constructing models of reference to real objects. Current available corpora for reference to visible objects, such as the GRE3D3 Corpus (Viethen \& Dale, 2008) or the TUNA Corpus (van Deemter, Gatt, van der Sluis, \& Power, 2012), were built from reference elicited to graphics of simple objects presented on a computer screen (see Figure 1). In this work, we seek to better understand the rich details of reference in real world visual domains, where a multitude of different visual properties interact. This opens up several aspects of reference that have not been researched before and gives rise to further questions about the factors influencing initial reference and visual object descriptions. We discuss some of these issues, and their implications for a computa-
tional model of reference.
To establish what properties are typical for an object, we use semantic feature production norms. Semantic feature production norms provide a set of common properties for basiclevel concepts, and are collected to explore conceptual representations such as typicality (Rosch \& Mervis, 1975) and semantics (Wu \& Barsalou, 2009). We use McRae's norms (McRae, Cree, Seidenberg, \& McNorgan, 2005; McRae, 2011), which to our knowledge is the largest source of production norms to date. McRae's norms were collected by providing participants with 10 blank lines for each basic category and asking them to list features for each, such as physical (perceptual) properties (how it looks, sounds, smells, feels, and tastes), functional properties (what it is used for and where and when it is used), and other information, such as encyclopedic facts (e.g., where it is from).

For this study, we are interested in perceptual properties, specifically shape and material properties, which are available from the norms. \({ }^{2}\) For example, objects belonging to the bowl category are listed as typically having a "curved" or "round" shape, and made of a "ceramic" or "plastic" material. We consider atypical properties to be properties (1) mentioned by no participants for the object, and (2) difficult to find during our object collection period.

Our initial list of possible objects included all inanimate objects from McRae's norms that could fit on an experiment table, and this set was narrowed down by availability and our abilities to control the visual properties of the objects. The final set of test objects are listed in Table 1, along with their typical and atypical shapes and materials. The full set of objects used in this study are shown and labeled in Figure 3.

\section*{Using Real World Objects}

A notable complication in this study is that we seek to use a variety of everyday objects, while controlling the typicality of particular properties of those objects. This means that the objects must look relatively commonplace, matching as closely as possible on every visual property except for shape/material; and for these properties, one must be clearly atypical while the other must be clearly typical. Finding everyday objects that fit within these rigid constraints is difficult. In some cases (bowl, mug, screw), we colored the objects to match one another, while in other cases (atypical envelope, key, ruler), we physically created the objects in order for them to have all the desired properties. Real world objects bring with them a set of complications for any model of reference, and we discuss some of these briefly. Although we cannot address all of the issues we list, we hope to provide evidence for a preliminary model of typicality in reference while bringing to light areas for further research.

\section*{Cultural and Individual Differences}

What is typical for an object varies person to person, culture to culture. This study was conducted with a range of students

\footnotetext{
\({ }^{2}\) We use McRae et al.'s "external_surface_property"/"external _component" labels for shape and "made_of" labels for material.
}
and professionals in two countries (the U.S. and the U.K.), but ideally in testing and modeling the production of reference, the set of typical properties would be defined with respect to a culture or group of people, or tailored to a specific person. For our study, we use one set of objects, without changing typical/atypical properties.

\section*{Interconnection}

It is clear that there is an interconnection between different visual properties. For example, material often entails color and texture. An object made of wool is fuzzy or rough (texture values), while an object made of wood is usually tan or brown, and for everyday objects, tends to be smooth (color and e.g., smoothness values). Ideally, participants would refer only to those properties that we vary; but they may instead refer to interconnected properties, calling a woolen bowl "coarse" or "flexible", or a mug made of ceramic but painted silver a "metal mug".

\section*{Lexicalization}

Another competing factor in this study is how easy a property is to lexicalize. Some shapes (e.g., "square") are common and may be quick to access, while other shapes (e.g., "octagonal") may take longer to produce, affecting the object description. Further complications may arise when there is competition over whether to use a prenominal modifier ("the flower-shaped bowl") or a postnominal modifier ("the bowl that looks a bit like a flower").

\section*{Shapes, Parts, and Object Categories}

Figure 2: Bowl, Sugar Bowl, Creamer, Teacup, Mug, Pitcher: Similar objects with different shapes tend to have different names.
An object's shape is often indicated by its name (Markman, 1989; Landau \& Jackendoff, 1993), and therefore an object designed to have an atypical shape may instead appear to belong in an entirely different object category (see Figure 2). For some objects, we found that changing its full shape made it unclear what the object was, or else created a subtype of our target basic-level object category; in a few cases, we therefore manipulated a part of the object's shape. Rather than a round head of a key, the head was square; the straight rectangular center of a ruler was cut out with geometric shapes; and the circular head of a screw was made atypically oval.

\section*{The Objects}

The objects used in the study, as they were presented to participants (without the superimposed identifiers), are shown in Figure 3. Test objects are listed in Table 1 along with their shapes and materials. Those values in italics could not be found in McRae's norms and were added based on intuition and object availability. Filler objects are listed in Table 2.

Figure 3: Objects used in study, keyed to descriptions in Tables 1 and 2 below.

Table 1: Test objects with shapes and materials. Values listed in italics were provided by the authors because they were not listed in the McRae et al. (2005) norms.

* These objects were varied by color/size/type as part of a separate pilot experiment.

Figure 4: Subjects sat across from an assistant, with objects between them. An experimenter sat at the head of the table, moving objects to their original positions between trials.

Figure 5: Example stimuli, Atypical Shape group. Here, the test object is the square envelope.

\section*{Experiment}

Participants sat at a table across from an assistant (Figure 4), with a variety of objects on the table between them (Figure 3). Subjects were asked to explain to the person sitting across how to recreate images of the objects grouped in different patterns (Figure 5). There were two objects for each test object category on the table, matched for color and size. One object had atypical material and typical shape; the other had atypical shape and typical material. Subjects could therefore not distinguish a test object to the hearer by its type alone, but could distinguish it by mentioning its shape or material.

Atypical feature is a grouping variable both by subjects and by materials. For the ATYPICAL SHAPE participants, shape properties of the test objects were atypical, while material properties were typical. For the Atypical Material participants, material properties of the test objects were atypical, while shape properties were typical.

\section*{Method}

Participants Thirty native English speakers with normal or corrected vision in the United States and the United Kingdom were paid for their participation ( \(\$ 5\) or \(£ 5\) ). Subjects were recruited through word of mouth and online ads, 17 males and 13 females, aged 20-55, and randomly assigned to one of the two experimental groups, (1) ATYPICAL SHAPE or (2) Atypical Material. Four male subjects and one female subject were randomly removed to a held-out set to balance gender, leaving 6 female and 6 male subjects in each group (24 subjects total).

To check for possible outliers in each group, we calculate the average number of references with shape, and the average number of references with material. Participants whose total number of references with shape or material were more than two standard deviations from the mean for that property were identified as possible outliers. We found no outliers in the Atypical Material group, and two possible outliers in the Atypical Shape group. The data for these two subjects (one male, one female) were removed and replaced with gender-matched data from the held-out set.

Materials Participants sat in front of a large set of everyday objects (rulers, envelopes, pins, etc., as shown in Figures 3 and 4), with test objects and fillers mixed. Test objects for the two experimental groups with their corresponding shape and material properties are listed in Table 1.
Procedure \& Design All participants consented to participate in the study. The experiment followed a director-matcher paradigm, where the director (the participant) instructed the matcher (the assistant). Participant and assistant sat opposite one another while the experimenter sat on a third side of the table. Participants alone viewed pictures on a laptop (positioned so screen was not visible to the assistant). Each participant saw 8 pictures in randomized order including a different atypical stimulus each time (see example in Figure 5). On each trial, the participant viewed the picture and explained to the assistant where each pictured object should go on the grid laid out on the table between them. At the end of each trial, the experimenter returned objects to their original positions. Participants' instructions were recorded onto the laptop.

\section*{Results}

Annotation Annotations are provided by the first author. To test for adequacy of the annotation system, a second annotator annotated a random subset of 20 references to the test objects. The annotator was given mark-up instructions and examples of a variety of visual properties (shown in Table 3), and told to mark which words referred to which properties as best they could following their understanding of the examples. Treating shape and material as binary categorical variables, Cohen's \(\kappa\) is very good for shape ( \(\kappa=.894\) ) and good for material ( \(\kappa=.798\) ) between annotators. Disagreements were over whether "metallic" in "the non-ribbed metallic cup" was a material or a texture, whether "heart" in "a heart-shaped box" was a shape or a type, and whether "silver" in "a silver round cup" was a color or a material. The total number of expressions produced for test items with shape and material modifiers in each experimental group is shown in Figure 6.
Analysis We see a tendency to choose the atypical over the typical in both groups. In the Atypical Shape group, 54 expressions contain a shape modifier while 36 contain a material modifier; in the Atypical Material group, 28 expressions contain a shape modifier while 41 contain a material modifier (see Figure 6). There is a slight preference for shape over material across the groups; 82 expressions contain a shape modifier while 77 contain a material modifier.

We are interested in understanding whether there is a significant difference in the selection of modifiers between groups. For each participant, we subtract the number of test object expressions containing a modifier for the object material from the number of test object expressions containing a modifier for the object shape. In other words, for each participant \(p\), given the number of expressions with material modifiers \(M_{p}\) and the number of expressions with shape modi-

Table 3: Attributes annotated and example surface forms.

Figure 6: Number of expressions with shape and material modifiers in each experimental group.
fiers \(S_{p}\), we calculate \(V_{p}=S_{p}-M_{p}\). This provides a vector for each group with differences in the number of modifiers for shape and material. For participants in the Atypical Shape group, where shape is atypical, we expect positive values for \(V_{p}\). For participants in the Atypical Material group, where material is atypical, we expect negative values for \(V_{p}\).

An independent samples t-test was conducted to compare the effect of property typicality on the production of modifiers between groups. There is a significant difference at \(\alpha=.01\) between the Atypical Shape group ( \(\mathrm{n}=12\), mean \(=1.50, \mathrm{sd}=1.62\) ) and the Atypical Material group \((\mathrm{n}=12\), mean \(=-1.08, \mathrm{sd}=2.07) ; \mathrm{t}(21)=3.406, \mathrm{p}=0.003\).

\section*{Discussion}

\section*{Current Study}

These results suggest that atypicality affects object reference. We find a tendency to select the atypical property over the typical one, with participants in the ATYPICAL SHAPE group preferring shape modifiers, and participants in the ATYPICAL Material group preferring material modifiers. This difference is significant between groups.

Shedding further light on these findings, when material was included in a reference in the Atypical Material group, it was often incorrect. Figure 7 illustrates how frequently subjects were correct and incorrect in the description of an object's material. In the Atypical Material group (Figure 7a), the plastic screw was called "metal", the paper ruler was called "wooden". The ruler in particular gave rise to incorrect material modifiers - it was printed on paper with a wood print,

Figure 7: Number of participants who included material modifiers that were correct, incorrect, or did not use a material modifier at all (neither). In the Atypical Material group (a), ruler tends to evoke incorrect material modifiers. The ruler, envelope, and screw had no correct material modifiers. In the Atypical Shape group (b), the mug, box, and bowl tended to evoke incorrect material modifiers. The mug (painted silver) had no correct material modifiers.
so it was called "wooden". Most participants in the Atypical Material group did not use material modifiers for the envelope and the screw, which may be partially due to the fact that the screw was painted black and so was not clearly plastic; and the envelope was made of foam, which may have not been clear without physically touching the object. Some examples of expressions in the ATYPICAL MATERIAL group that do not include material modifiers are given in Table 4.

A similar tendency to refer to incorrect material emerged in the Atypical Shape group (Figure 7b), where the ceramic mug painted silver was called "metal" or "steel", the ceramic bowl was called "plastic", and the cardboard box was called "wooden". In contrast, subjects were rarely incorrect about shape (Figure 8). The only exception to this is the atypically shaped mug (Figure 8b), which was called "octagonal" (correct), "hexagonal" (incorrect) and "septuplet" (incorrect).

These trends suggest that material is not purely visual, but may also be guided by our tactile sensations of the objects; without tactile input, our expectation of the typical material for the object may be used in our reference rather than its actual material, or we may disprefer material altogether. It is not enough to judge whether a visual property is atypical or not; it must also be judged whether that value is visually clear, and whether other properties suggest another interconnected

Figure 8: Number of participants who included shape modifiers that were correct, incorrect, or did not use a shape modifier at all (neither). In the Atypical Material group (a), there were no incorrect shape modifiers. In the ATYPICAL SHAPE group (b), only the mug received incorrect shape modifiers (e.g., "hexagonal" rather than "octagonal").
property (which may not actually be true of the referent, as when subjects use incorrect modifiers).

Future work could shed more light on these issues with a variant of the experiment in which we look at how reference here compares to reference towards objects of the same category that have typical shape and typical material, and likewise, atypical shape and atypical material. This should also provide useful data on how to separate general preference for shape or material versus a preference for atypical properties.

\section*{Towards a Model of Reference}

As discussed in the introduction, current research on reference production has focused on very simple, constrained domains. In this work, we propose taking the object's typicality into consideration when deciding which properties to add to an initial description. In a computational model, typical information may be made available in a knowledge base queried at runtime. As part of the reference production process, the target object category could then be compared against a stored object category. Property selection in such a model could be a function of the typicality of the property for the object, as well as, e.g., its contrastive value against the other objects. This offers an extension to current models of referring expression generation (e.g., Dale and Reiter (1995)), and may help to further explain the process of reference generation.

\end{tabular}

Table 4: Examples of references without material in the Atypical Material group. We see underspecified references and references describing the object's size.

\section*{Conclusions and Future Work}

This study has sampled a handful of real world objects to understand the role that typicality plays on reference. We have focused on two visual attributes, shape and material, in a visual scenario where either may be used to identify an object. We see a tendency to select the atypical property over the typical one, and find a significant difference between the selection of atypical shape over typical material versus typical shape over atypical material between groups.

Our study has focused on relatively crisp properties of objects. It would be interesting to explore whether our findings extrapolate to properties that come in degrees, such as height, weight, age, and so on. Based on our study, we hypothesize, for example, that the length of a screw is more likely to be mentioned if it is unusual (e.g., unusually long or unusually short) than if it is not. In line with this, gradations of atypicality for an attribute may also affect reference; some values may be more atypical than others, and thus more likely to be included in a final description.

This study leaves many further open questions. To fully model reference production to real world, visible objects, we must better understand how the production of visual modifiers is affected by interconnection and lexicalization issues, and how notions of typicality are changed culture to culture.

In future work, we aim to focus directly on interconnection, understanding how the degree of correlation between properties affects description. We would like to extend our set of objects in order to examine reference when both properties are typical, or both atypical. There may be a tendency to select the atypical over the typical, but we have only begun to scratch the surface of the factors at play when we refer to real world objects.

\begin{abstract}
Stoic behavior is defined as a behavior in which students tend not to seek help with a challenge. We investigated two types of stoic behavior: keeping-off behavior, in which students restrain themselves from requesting help, i.e., keep levels of help support at a minimum, and self-fading behavior, in which students voluntarily lower levels of support on their own volition. Three experiments were conducted. Overall, results showed that the participants actually exhibited stoic behavior when learning in an actual classroom setting. Self-fading was more difficult than the keeping-off behavior. The participants who maintained levels of support at a minimum through exhibiting active keeping-off behavior achieved greater learning gains, suggesting that stoic behavior resulted in positive impacts on learning. However, our experiment did not detect this effect for self-fading behavior. These experimental results were discussed with the assistance dilemma problem, generally occurring in instruction by intelligent tutoring systems.
\end{abstract}

Keywords: Intelligent tutoring system; Help seeking; Assistance dilemma.

\section*{Introduction}

Recent intelligent tutoring systems include highly interactive features. Such systems give participants various types of feedback such as verification, correct response notification, try again encouragement, error flagging, and elaboration messages (Shute, 2008). In this context, the assistance dilemma has been recognized. Koedinger \& Aleven (2007) asked a crucial question: How should learning environments balance assistance giving and withholding to achieve optimal learning? (Koedinger \& Aleven, 2007) High assistance sometimes provides successful scaffolding and improves learning, however, it may also elicit superficial responses without consideration from the students. In contrast, low assistance sometimes encourages students to make great efforts to learn, while at other times it results in enormous errors and interferes with effective learning. To resolve this issue, the levels of support (LOS) must be adaptively controlled by tutoring systems.

Equipping tutoring systems with intelligent functions for help control and optimization of feedback information for participants are important issues. However, students must seek help intelligently. From this perspective, in this study, we investigate students' active help-seeking behaviors rather than passive help-receiving behaviors, which were managed by intelligent tutoring systems. Razzaq \& Heffernan (2011) (Razzaq \& Heffernan, 2010) confirmed that active hintseeking, in which on-demand hints were given, was more ef-
fective for learning than passive hint-seeking, in which participants were given hints proactively when facing errors.

Help-seeking is a representative metacognitive activity in learning behavior. Help-seeking is valuable, not only for maximizing learning effects but also for acquiring a domainindependent meta-learning strategy. Some trials have instructed students using such metacognitive abilities. A domain-independent agent, called Help Tutor, for teaching better help-seeking skills by tracing students actions, was developed (Roll et al., 2006). Such help-seeking support was successful in improving students’ declarative help-seeking knowledge, but did not improve their overall learning (Roll, Aleven, McLaren, \& Koedinger, 2007). In more recent trials, the Help Tutor improved students' help-seeking behavior, and the improved help-seeking skills are transferred to learning new domain-level content during the month following the intervention (Roll, Aleven, McLaren, \& Koedinger, 2011). To instruct such metacognitive activities, we must learn more about the nature of students' help-seeking behavior.

Students themselves have to manage their help-seeking behavior to maximize learning effects. However, previous studies have demonstrated that students' help-seeking behavior does not follow rational principles (Wood \& Wood, 1999). Hint abuse is a representative irrational behavior that appears in hint-seeking whereby students tend to seek the most specific hints to find answers rather than acquiring understanding (Aleven \& Koedinger, 2000).

In this study, we focus on stoic behavior in hint seeking. Stoic behavior is defined as behavior in which students tend not to seek help for their challenge. We will investigate two types of behavior: the keeping-off and self-fading behaviors. Keeping-off behavior is defined as behavior in which students try to solve problems by themselves without a system's assistance. Students restrain themselves from receiving help from a tutoring system even when permitted to do so. This is regarded as a type of behavior with the purpose of avoiding the hint abuse. On the other hand, we define self-fading behavior as one in which students voluntarily decrease an LOS by their own volition. This behavior is recognized, along with scaffolding, as a central concept for effective learning. To enable students to effectively learn, scaffolding should be eliminated gradually as learning progresses. In learning by examples, fading methods have also been used as an effective principle
for controlling the flow of learning (Atkinson, Renkl, \& Merrill, 2003).

In this study, we investigate the following two research questions: Do students exhibit stoic behavior in hint seeking when learning with an intelligent tutoring system in classroom settings? and does such stoic behavior in hint seeking promote learning gains? We examined these research questions through three empirical studies.

\section*{Learning System and Task}

We investigated participants' help-seeking behavior using a relatively complex learning task in which participants learned natural deduction (ND). Natural deduction is a kind of proof calculus in which logical reasoning is expressed by inference rules closely related to a natural way of reasoning. The following is an example solution process of an example problem: inducing a proposition \(\neg Q \rightarrow \neg P\) from a premise \(P \rightarrow Q\).
\begin{tabular}{lll} 
(1) & \(P \rightarrow Q\) & Premised \\
(2) & \(\neg Q\) & Assumption \\
(3) & \(P\) & Assumption \\
(4) & \(P \rightarrow Q\) & Reiteration of (1) \\
(5) & \(Q\) & \(\rightarrow\) Elimination from (3) and (4) \\
(6) & \(\neg Q\) & Reiteration of (2) \\
(7) & \(\neg P\) & \(\neg\) Introduction from (3), (5), and (6) \\
(8) & \(\neg Q \rightarrow \neg P\) & \(\rightarrow\) Introduction from (2) and (7)
\end{tabular}

Participants learned inference rules and strategies for applying the rules. Participants in this study learned eight basic rules and four strategies, which are the fundamental basis of ND ; the majority of problems can be solved using these rules and strategies.

Our tutoring system, which was developed for teaching ND to university undergraduates, has two important features.

First, it does not have a database that contains a set of ND problems and their solutions. Our system solves each problem on demand. It includes a production system model, which consists of the working memory, whose layout is consistent with the structure of ND problems, and production rules, which correspond to the inference rules and strategies for solving ND problems.

As a second feature, our system was established based on a server-client framework. Miwa et al. developed a webbased production system architecture called DoCoPro that enables such a system design to be established (Miwa, Morita, Nakaike, \& Terai, 2013). A problem solver constructed on a server performed the complex inferences in ND. Client computers connected to the server performed easy processing for the interface. Using this server-client framework, our system can operate in any educational environment where various types of computers, e.g., high performance, poorly performing, and on different types of operating systems. Participant learning processes are saved as \(\log\) data on the server.

Figure 1 shows a screenshot of the tutoring system. The system provides the participants with lists of the inference rules and strategies. They select one of the rules or strategies from a list, and the system automatically runs the rules and presents partial or complete results of inference. The system

Figure 1: Example screenshot of the tutor terminal.
scaffolds the students by providing helpful information about the selection of the rules and strategies.

The LOS can be controlled from two viewpoints: rule selection and application.
LOS for rule selection: Level 3 (high): The system presents applicable candidates (rules and strategies) and the propositions to which the rules should be applied. For example, in the middle window in Figure 1, the system proposes that three highlighted inference rules and one strategy could be applied. When " \(\rightarrow\) Elimination" is selected, \(P\) and \(P \rightarrow Q\) are highlighted in the left window, indicating that the selected rule should be applied to these propositions. Level 2 (middle): The system presents only applicable candidates (rules and strategies). When this level is selected, students are required to find the propositions to which the selected rule should be applied without receiving support from the system. Level 1 (low): The system presents only a set of inference rules and strategies (no support is provided).
LOS for rule application: Level 2 (high): The system infers a proposition and automatically presents it in the left window. Shortly after students select an inference rule and the propositions to which the rule will be applied, the system displays the current status of deduction. Level 1 (low): The system infers a proposition, but presents only partial information of the inferred result. Students are required to complete the inference process by filling terms in blank spaces of a template.

\section*{Experiment 1}

In Experiments 1 and 2, the initial setting of LOS at the beginning of solving each problem was lowest. Once a new problem was set, the LOS was initialized to Level 1. The participants were required to determine whether to raise an LOS from the initial setting while solving each example problem. Therefore, Experiments 1 and 2 investigated the participants'
keeping-off behavior in help-seeking. We will investigate the self-fading behavior in Experiment 3.

Experiment 1 was a preliminary experiment. Experiment 1 was performed in a laboratory setting; Experiments 2 and 3 were performed in a real classroom setting.

\section*{Participants and Procedure}

Thirty-three participants joined Experiment 1. In the initial phase of the experiment, the participants learned the basics of ND through handout materials and an instructional video. They learned eight inference rules and four strategies without the tutoring system. After the participants were instructed on how to use the tutoring system, they learned ND by solving six example problems with our tutoring system through the \(80-\) min learning phase. Two of the problems were difficult and required a second-order subproof, and two were easy and either did not require a subproof or required only a first-order subproof. The data recoreded in this phase were analyzed.

\section*{Results}

We focused on two kinds of help control behavior. One is a relatively simple behavior. In our experiments, participants were allowed to solve problems at their own pace. Some participants quit solving a problem, moved to other problems, and then revisited the initial problem and attempted to complete it. Our first hypothesis is that participants in the second and following attempts, compared to the first attempt, would not raise it for their challenge. The other is a more sophisticated behavior: we expected that participants would adopt an LOS according to the degree of difficulty of each problem. Our hypothesis is that participants solving easy problems would select a lower LOS than when solving difficult problems, despite the fact that they were permitted to receive help if they wished.

We compared the average LOS of the first attempt with that of the second-and-following attempts. In certain cases, the participants attempted to solve a problem more than twice. In such cases, we used the average score of the second-and-following attempts. Figure 2 shows the result of analysis about the LOS control between the first and second-andfollowing attempts. A t-test revealed a significant difference between the first and second-and-following attempts in rule selection \((t(116)=6.10, p<0.01)\), but not in rule application \((t(115)<1\), n.s. \()\).
Figure 3 shows the result of analysis about more sophisticated behavior, i.e., the LOS control when solving easy and difficult problems. A t-test revealed a significant difference between the easy and difficult problems in both rule selection and application \((t(31)=2.59, p<0.05) ; t(31)=4.58, p<\) \(0.01)\).

The above results indicated that the participants kept an LOS at low in the second and following attempts, relative to the first attempt, but only in rule selection, and did not raise it when solving easy problems compared to when solving difficult problems. These results supported our hypotheses about the participants' keeping-off behavior in help-seeking. This

Figure 2: Levels of support versus number of attempts in Experiment 1.

Figure 3: Levels of support versus problem difficulty in Experiment 1.
stoic behavior was observed greatly in rule selection than application.

\section*{Experiment 2}

In Experiment 2, we performed both pre- and post-tests, before and after the learning phase, to examine the relationship between help-seeking behavior and the learning effects. We also focused on whether the participants' stoic help-seeking behavior depends on their problem solving ability. In Experiment 1 , we confirmed that stoic behavior was greatly observed in rule selection; therefore, in Experiments 2 and 3, the LOS in rule application was fixed at Level 1, and only the LOS in rule selection was investigated.

\section*{Participants and Procedure}

Forty-nine participants from a cognitive science class joined the 2011 experiment. Three lessons were assigned to learn ND. In the first lesson, an instructor lectured on the basics of formal inference systems and ND as an example of such systems.
In the second lesson, the participants initially solved six problems while learning how to use the tutoring system. First, the instructor presented an example flow of problem solving. Then, participants followed the flow and reached the solution using the system. After the initial training, the participants were given two new problems to solve. Finally, the

Figure 4: Levels of support versus number of attempts in Experiment 2.
participants were given a paper test in which they solved a test problem; we used this test as a pretest in the following analysis.
The log data from the third lesson were analyzed. The participants solved eight problems at their own paces and selected an LOS. Three of the eight problems were easily solved by applying the basic rules learned in the first lesson. However, three problems were relatively difficult, and their solutions required more complex rules and solution strategies, such as subgoal settings. The learning session lasted for an hour. After the learning session, a post-test was performed.

\section*{Results}

To investigate whether the participants' help-seeking behavior is dependent on their problem solving ability, we divided the participants into two groups on the basis of their pre-test scores, and formed lower- and higher-score groups.
Figure 4 shows the results of analysis on simple help management behavior, i.e., the LOS control between the first and second-and-following attempts. A two (attempt: first and second-and-following) x two (ability: high and low) ANOVA revealed that the main effect of the attempt factor reached significance \((F(1,158)=136.93, p<0.01)\), but the main effect of the ability factor \(\operatorname{did} \operatorname{not}(F(1,158)=1.54\), n.s.). There was no interaction between the two factors \((F(1,158)<1\), n.s.).

Figure 5 shows the results of analysis on more sophisticated behavior, i.e., the LOS control when solving the easy and difficult problems. A two (problem: easy and difficult) \(x\) two (ability: high and low) ANOVA revealed that the main effect of the problem factor reached significance \((F(1,44)=\) \(33.02, p<0.01\) ), but the main effect of ability factor did not \((F(1,44)<1\), n.s.). There was no interaction between the two factors \((F(1,44)=2.96\), n.s. \()\).

The above results duplicated the participants' stoic behavior captured in Experiment 1. Additionally, the same tendency was observed in both low- and high-score groups, meaning that such help-seeking behavior does not depend on the participants' problem solving ability.

Next, we focus on the analysis of the relation of helpseeking behavior and learning effects. We hypothesize that a lower LOS may provide greater learning effects and a higher

Figure 5: Levels of support versus problem difficulty in Experiment 2.

Figure 6: Levels of support versus learning gains in Experiment 2.

LOS may obstruct effective learning. We divided the participants into two groups on the basis of their average LOS during problem solving in the learning phase. The problem used in the pre-test was different from those used in the posttest; therefore, we cannot directly compare the scores of the two tests. Accordingly, we transferred the test scores to the z -scores in each of the two tests and calculated the gains of the z -score from the pre- to post-tests.

Figure 6 shows the results of the analysis. A two (LOS in learning phase: high and low) x two (ability: high and low) ANOVA revealed that both the main effects of the LOS factor and the ability factor reached significance \((F(1,45)=8.28, p\) \(<0.01 ; F(1,45)=26.98, p<0.01)\). There was no interaction between the two factors \((F(1,45)=1.44\), n.s. \()\).
The result shows that the participants who learned with a lower LOS in the learning phase gained greater learning effects. This means that stoic behavior, especially the keepingoff behavior in this case, promoted learning.

\section*{Experiment 3}

In Experiment 2, we focused on the keeping-off behavior. Experiment 3 investigated the self-fading behavior in helpseeking,

\section*{Participants and Procedure}

Twenty-eight participants from a cognitive science class joined our 2012 experiment. Three lessons were assigned for learning ND and the learning content and procedures were almost identical to Experiment 2. The crucial differ-

Figure 7: Levels of support versus number of attempts in Experiment 3.

Figure 8: Levels of support versus problem difficulty in Experiment 3.
ence was that the initial setting of LOS at the start to solve each problem was the highest (Level 3) in Experiment 3. The participants were required to determine whether to lower an LOS from the initial setting, while solving example problems. Therefore, Experiment 3 investigated the participants' selffading behavior in help-seeking.

\section*{Results}

Figure 7 shows the results of analysis on the LOS control between the first and second-and-following attempts. A two (attempt: first and second-and-following) \(x\) two (ability: high and low) ANOVA revealed that the main effects of both the attempt and ability factors reached significance \((F(1,54)=\) \(34.43, p<0.01 ; F(1,54)=4.98, p<0.05)\). There was significant interaction between the two factors \((F(1,54)=4.47\), \(p<0.05\) ). The simple main effect of the ability factor at the first attempt was not significant \((F(1,108)<1\), n.s. \()\), but the effect at the second-and-following attempts was significant \((F(1,108)=9.41, p<0.01)\).

Figure 8 shows the result of analysis about the LOS control when solving the easy and difficult problems. A two (problem: easy and difficult) x two (ability: high and low) ANOVA revealed that there was neither a main effect of the problem factor nor a main effect of the ability factor \((F(1,25)<1\), n.s.; \(F(1,25)=2.67\), n.s.). There was no interaction between the two factors \((F(1,25)<1\), n.s.).

In Experiment 3, we confirmed the stoic behavior only in the LOS control between the first and second-and-following attempts, but not in the LOS control when solving easy and difficult problems. In the former case, the higher abil-

Figure 9: Levels of support versus learning gains in Experiment 3 .
ity participants greatly lowered the LOS in the second-andfollowing attempts compared with the lower ability participants.

Next, we focus on the analysis of the relationship between the self-fading behavior and learning effects. The same analysis as in Experiment 2 was performed. Figure 9 presents the results of the analysis. A two (LOS in learning phase: high and low) \(x\) two (ability: high and low) ANOVA revealed that there was neither a main effect of the LOS factor nor interaction between the two factors \((F(1,24)<1\), n.s.; \(F(1,24)<\) 1 , n.s.). However, the main effect of the ability factor reached significance \((F(1,24)=5.09, p<0.05)\). Learning effects by the stoic help-seeking behavior were not confirmed in Experiment 3.

\section*{Discussion and conclusions}

The first research question we posed was: Do students exhibit stoic behavior in hint seeking? We examined two types of stoic behavior: Experiment 2 investigated the keeping-off behavior, and Experiment 3 investigated the self-fading behavior. We hypothesized that participants would lower an LOS with the development of learning (i. e., from the first to the second-and-following attempts). This hypothesis was fully supported in both Experiments 2 and 3. More specifically, with regard to self-fading, high ability participants more actively lowered the LOS in the second-and-following attempts compared with the lower ability participants. The second hypothesis was whether participants would adaptively manage their help-seeking behavior based on the degree of problem difficulty. We expected that they lower an LOS or would not raise it when solving easy problems, compared to when solving difficult problems. This hypothesis was supported only in Experiment 2, indicating that the participants kept an LOS at low (Experiment 2), but that they did not reduce an LOS from high to low (Experiment 3) when solving easy problems, which suggests that the keeping-off behavior was confirmed, though the self-fading behavior was not.

These results imply that the self-fading behavior, as an adaptive behavior in help-seeking, was more difficult for the participants than the keeping-off behavior. The latter behavior comes from a strategy to set the LOS at low by stopping action (i.e., stopping raising an LOS). However, the former
behavior comes from a strategy to set the LOS at low by performing an action (i.e., beginning to reduce an LOS). The latter is relatively passive, while the former is an intentional and active behavior. These results suggest that an active type of stoic behavior was more difficult for users.

The second research question was: Does the stoic behavior in hint seeking promote learning gains? This relates to a trade-off of selecting either the problem-solving or the learning goal. Participants learn while solving instance problems given by a tutoring system. Attaining the problem-solving goal means solving such instance problems as accurately and rapidly as possible. However, the learning goal requires another attainment that is usually more essential. The primary objective is not to solve instance problems, but to learn by solving instances. Dweck classified two types of goals: learning and performance (Dweck, 1986; Ames, 1992). Highly motivated children tend to set learning goals in an effort to increase their competence levels for understanding or mastering something new rather than simply solving problems. Our previous study confirmed that high learning supports promote the problem solving goal setting, and refrain the learning goal setting (Miwa, Terai, \& Nakaike, 2012). In the high LOS situation, participants may solve training problems accurately and rapidly in the learning phase, but tend to learn least from the training.

The assistance dilemma hypothesizes an optimum point of learning effects. Koedinger et al. (2008) demonstrated a reverse U-shape learning curve as a function of cognitive load (Koedinger, Pavlik, Mclaren, \& Aleven, 2008). This means that extremely lower and higher cognitive loads result in negative impacts on learning. The levels of help support are correlated with learners' cognitive load while learning. Much help reduces their cognitive load for problem solving in the learning phase where students simply respond to help indications from a tutoring system, e.g., a direct instruction about what to do next, without deeper consideration. From this viewpoint, our experimental results are considered to capture the right side of the reverse U -shape. We compared learning effects when the participants learned with a low and a high LOS. In the right half, the reversed U-shape predicts that a lower LOS provides more learning effects; Experiment 2 supported this prediction. However, we also expected that the effects of learning decrease gradually, in the left side of the reverse U-shape, as the LOS is reduced. In another experiment (Miwa et al., 2012), we confirmed this prediction using the same tutoring system, in which we set up two experimental conditions. In the system condition, the participants learned ND using our tutoring system. They were permitted to control the LOS. In the control condition, i.e., the paper-and-pencil condition, participants learned ND without a tutoring system, instead they learned ND using only a textbook. The latter was the no support condition. Results showed that learning effects in the system condition were greater than in the paper-and-pencil condition. In this experiment, no support relates to the leftmost side of the reversed U -shape.

\title{
Unmet Expectations in the Comprehension of Relative Clauses in Japanese
}

\begin{abstract}
In two self-paced reading experiments, subject relative clauses (e.g., 'the woman who saw the man') were read faster than object relative clauses ('the woman who the man saw') in Japanese. Previous formulations of working-memory factors do not predict the patterns observed. A preference to complete fragments as object relative clauses indicates that ambiguity and expectation are unlikely to explain the reading-time data. The results support the proposal that accessibility of the position relativized affects how natural the relative clause is as a statement about the modified noun.
\end{abstract}

Keywords: relative clauses, Japanese, subject, object

\section*{Introduction}

An accessibility hierarchy of grammatical roles has been shown to constrain the grammaticality of relative clauses in 49 typologically distinct languages (Keenan \& Comrie, 1977; also Comrie, 2007, for a recent summary). Subjects are ranked higher than objects to reflect the observation that more languages allow subject relative clauses than object relative clauses. Postnominal relative clauses as in (1) follow the modified noun woman (brackets mark the boundaries of the embedded clause; the extraction site or gap is coindexed with the modified noun, or filler).
(1) a. Subject relative clause (postnominal) the \(\operatorname{woman}_{i}\) [that \(g a p_{i}\) saw the man]
b. Object relative clause (postnominal)
the woman \(_{j}\) [that the man saw gap \(_{j}\) ]
In languages that allow both alternatives, subject relatives are predicted to be easier to understand, that is, comprehension is facilitated when woman is interpreted as the subject of the embedded verb saw as in (1a). The subject advantage is well-documented for constructions in which both nouns are animate (man and woman in (1); Dutch: Mak, Vonk \& Schriefers, 2002; English: Traxler, Moris \& Seely, 2002; inter alia). We report evidence supporting accessibility as a factor in the comprehension of relative clauses in Japanese.

Japanese is an SOV (subject-object-verb order) language and relative clauses are prenominal as they precede the modified noun as in (2).
(2) a. Subject relative clause (prenominal)
[ gap \(_{i}\) dansei-o mita] josei \({ }_{i}\)
man-acc saw woman
'the woman that saw the man'
b. Object relative clause (prenominal)
[dansei-ga \(g a p_{j}\) mita] josei \(_{j}\) man-nom saw woman
'the woman that the man saw'
The words and their order are exactly the same except for the case marker on the coargument, 'man' (i.e., the argument inside the embedded clause). When the coargument is an accusative object, extraction is from subject position; when it is a nominative subject, extraction is from object position. This similarity allows for a cleaner comparison between the constructions as it avoids comparing words with different parts of speech as is often the case in languages such as English.

As a universal constraint, the accessibility hierarchy predicts subject relatives to be easier to understand in Japanese. The prediction is supported by off-line judgments (e.g., difficulty ratings, Sheldon, 1976) and self-paced reading (Ishizuka, Nakatani \& Gibson, 2003; Miyamoto \& Nakamura, 2003; Ueno \& Garnsey, 2008, Experiment 1, also Experiment 2, for event related potential data). But these studies fail to address alternative explanations, especially those related to ambiguity factors, which we discuss later in this introduction. Moreover, some aspects of the preference are better explained by a new type of accessibility.

\section*{The object before subject preference}

Although often described as taking two arguments, transitive verbs are more closely associated with their direct objects than their subjects (Marantz, 1984; the verb-object bonding principle, Tomlin, 1986). A transitive verb can thus be represented as a function that takes the direct object as its only argument to yield a one-place predicate, which in turn takes the subject as its argument. Hence, the semantic role of the object is assigned by the verb, and the role of the subject is assigned by the verb-object compound (Marantz, 1984).

This subject-object asymmetry leads to a processing preference to assign the role of the object more locally than the role of the subject (the object before subject bias or ObS). Locality is assumed to be determined by clause structure. Relative clauses are statements about the modified noun, that is, they are functions that are applied onto the modified noun. Intuitively, we must understand what the statement means (e.g., determine the semantic roles of the coargument) to apply the statement to the modified noun.

In subject relative clauses, the object is in the same clause as the verb and receives its semantic role first. Next, the
object-verb complex assigns a semantic role to the subject (see the left-hand side of Figure 1). Therefore, the semantic role assigned to the modified noun is congruent with the statement that the relative clause makes about this noun.

Object RC

Figure 1: Order of semantic-role assignment in Japanese
In object relative clauses, the verb assigns a semantic role to the modified noun (its object) and only then the object-verb as a unit assigns a role to the coargument inside the relative clause (the subject; see Figure 1). The statement that the reladive clause makes about the modified noun is complex in that it is partly based on the modified noun itself and it does not match the order in which roles are assigned by the verb.

The ObS maintains the intuition from traditional accessibility that extraction position affects the naturalness of the relative clause as a statement about the modified noun. But in traditional accessibility the hierarchy is fixed (Keenan \& Comrie, 1977) and it incorrectly predicts that subject extraction is always favored (Nakamura \& Minamoto, 2013).

\section*{Ambiguity in relative clauses in Japanese}

There are no markers in Japanese that differentiate relative clauses from simple clauses (i.e., clauses without extractions such as adjunct, matrix or complement clauses). The relative clauses in (2) can be initially interpreted as simple clauses with an argument left implicit or dropped. Subject extraction is less likely to be affected by this type of ambiguity because the relative clause may be detected as soon as the coargument is read for the following reasons. First, the object coargument is an early indicator that there is no subject in the clause (although possible, a subject rarely follows an object; e.g., less than \(2 \%\) of accusative objects are followed by a subject in a newspaper corpus, Miyamoto \& Nakamura, 2005). Second, in a null context, the missing subject lacks a referent, therefore the relative-clause interpretation has been claimed to be favored so that a referent can be provided (Ishizuka, 2005).

In object relative clauses, the subject coargument provides little information about an upcoming object NP. It is only at the predicate (e.g., 'saw' in (2b)) that it is clear that the object is missing. In short, subject relatives may be detected as soon as the coargument NP is read, while object relatives may not be noticed until past the embedded predicate.

\section*{Alternative explanations}

One line of research has articulated a compelling alternative to accessibility models by proposing that working-memory factors such as decay and interference increase the difficulty in creating the dependency between the modified noun and the extraction position. In English, more material intervenes
a. Object relative clause: man-nom saw woman \(_{i}\) \(\uparrow\) \(\qquad\)
b. Subject relative clause: man-acc saw woman \(_{i}\) \(\uparrow\)

Figure 2: Linear decay in Japanese (horizontal lines mark the material that contributes to decay; vertical arrows indicate from where in the sentence retrieval occurs)
from the modified noun to the object position than to the subject position, therefore these proposals correctly predict more difficulty in object relative clauses such as (ib). \({ }^{1}\) The following is a summary of working-memory factors proposed in the literature and their predictions for Japanese.
A. Linear-span decay is based on the material in the sentence intervening between the modified noun and the extraction position (metrics based on number of words, King \& Just, 1991; new discourse referents, Gibson, 1998). For Japanese, greater difficulty is predicted for subject relatives than for object relatives (see Figure 2).
