B. Temporal-span decay measures the material processed from the moment in time an element was inserted in the representation until the time it is retrieved (Lewis, Vasishth, \& van Dyke, 2006). A missing object is only detectable when the transitive verb is read, thus an empty object position is ceated after the verb is read and this is the point in time that is relevant for object relatives (Figure 3a). Figure 3b illustrates the observation that a sentence-initial object can indicate that the subject is missing from its canonical position, therefore an empty subject position may be created when the object is read and decay will start from that point in time.

Predictions may change depending on reactivation.
C. Reactivation of a constituent can reverse decay, facilitating retrieval (Lewis, Vasishth, \& van Dyke, 2006). Therefore, when a constituent was last reactivated, as opposed to when it was first inserted in the representation, may be a better indicator of temporal decay. In relative clauses in Japanese, both the extraction position and the coargument are reactivated at the embedded verb, but predictions depend on reactivation order. C1. Simultaneous reactivation of the two positions will lead

Figure 3: Temporal decay in Japanese (horizontal lines mark the material that contributes to decay; vertical arrows indicate the point in time the empty position is retrieved from)

\footnotetext{
\({ }^{1}\) If relative clauses and modified nouns are directly associated without the mediation of gaps (Pickering \& Barry, 1991), workingmemory factors predict no extraction advantage in languages with verb-final embedded clauses such as Dutch, German, Japanese.
}
them to have similar activation levels when the modified noun is read, therefore subject and object relatives are predicted to be equally easy to process (Kwon, Lee, Gordon, Kluender \& Polinsky, 2010). But reactivation at the verb is linguistically motivated (as arguments are linked to the verb), and linguistic constraints may affect reactivation order as in the following two alternatives.
C2. Canonical reactivation requires arguments to be reactivated in the canonical, most common, order of the language (i.e., subject and then object). Hence, the object position should have an advantage as the last one to be reactivated and object relatives should be easier than subject relatives.
C3. ObS-based reactivation assumes that the ObS is implemented as a constraint on reactivation. The object is reactivated first to be associated with the verb, then the O-V compound is applied onto the subject, which is thus reactivated last. Hence, subject relatives should be easier to process.
D. Interference from similarity is another factor related to working memory that has been discussed in the literature. Interference should occur when the case marker on the coargument and the modified noun are the same, increasing confusability (Kwon et al, 2010; also Gordon, Hendrick \& Johnson, 2001, for other types of similarity-related difficulty).

The predictions by working memory and accessibility may be obscured by other factors, especially ambiguity.
E. Expectation-based models predict that an interpretation is easier to understand if it is more likely to be generated during production (as measured by, for example, fragment completions). Results in English suggest that object relatives are less predictable because they allow more alternative interpretations as the sentence unfolds, thus requiring longer reading times to zero in on the intended interpretation (Gennari \& MacDonald, 2008; inter alia). But expectation may fail to predict the exact point of greatest difficulty in English (Grodner \& Gibson, 2005) and, in some formulations, expectation is not relevant in long-distance dependencies (Levy, 2008).

Supporting contexts may reduce ambiguity and allow working-memory effects to be measured more clearly. In one such study in Japanese, subject relatives were found to be harder to process than object relatives (Ishizuka, Nakatani \& Gibson, 2006; but see Kwon, Lee, Gordon, Kluender \& Polinsky, 2010, footnote 12, for communication from Edward Gibson reporting failure to replicate and retracting the result; see also Roland, Mauner, O'Meara \& Yun, 2012, for contextrelated factors facilitating object relatives in English, and Sato, 2011, who failed to replicate such effects in Japanese).

We report two self-paced reading experiments confirming the subject advantage for relative clauses in Japanese. The advantage is not explained by previous formulations of working-memory factors (Gibson, 1998; Gordon, Hendrick \& Johnson, 2001; King \& Just, 1991; Lewis, Vasishth, \& van Dyke, 2006; inter alia). Expectation-based models (Gennari \& MacDonald, 2008) are unlikely to be relevant either given the results of two fragment-completion questionnaires.

\section*{Experiment 1}

\section*{Method}

Participants Thirty native Japanese speakers undergraduates at the University of Tsukuba were paid to participate.
Materials Twelve pairs of items (see (3) for an example) were distributed into two lists according to a Latin Square design so that each sentence in a pair appeared in one list.
(3) a. Subject relative clause

Daikigyo-no keesya-o maekara utagatteita
company's manager-acc a while distrusting-was
kanryo-wa totemo mukutida.
bureaucrat-top very quiet-is
'The bureaucrat who has distrusted the company manager for a while is very quiet.'
b. Object relative clause

Daikigyo-no keesya-ga maekara utagatteita
company's manager-nom a while distrusting-was
kanryo-wa totemo mukutida.
bureaucrat-top very quiet-is
'The bureaucrat who the company manager has distrusted for a while is very quiet.'

Each sentence was shown one region at a time on a single line in a non-cumulative fashion using double-byte characters with the uniform-width Japanese font MS Mincho. The segmentation used is indicated with spaces in (3).

Norming 1 The predictions by expectation-based models (Gennari \& MacDonald, 2008) depend on production preferences. Therefore, 42 native Japanese speakers who did not participate in the reading-time study, were shown fragments ending at the embedded verb (e.g., 'distrusting-was' in (3)) and were asked to write completions for them. There were more object relatives than subject relatives (Median of the difference \(=1\); two-tailed Exact Wilcoxon Signed Rank, function wilcoxsign_test in the package coin, R Development Core Team, 2009; Wilcoxon, for short: \(Z_{1}=3.47, P<.001\); \(Z_{2}=2.86, P<.01\); see Ueno \& Garnsey, 2008, for similar results). Contrary to previous reports, the object advantage held even when the comparison was restricted to relative clauses with animate modified nouns, which are the most similar to the items in the reading experiment (Median \(=1\); Wilcoxon: \(Z_{1}=2.41, P<.05 ; Z_{2}=2.59, P<.05\) ), probably because we chose embedded verbs that were biased towards animate objects. Therefore, expectation-based models should predict an object advantage in the reading time data.

Norming 2 To ensure that the two types of relative clauses are equally plausible, simple transitive sentences were created by placing the modified noun in the intended extraction position in the embedded clause. Thirty-two native Japanese speakers, who did not participate in any of the other studies, rated each sentence on a 5-point scale (1 as natural and 5 as
strange). No difference was detected (subject: 1.74; object: 1.66; Wilcoxon: \(\mathrm{Zs}<1\) ).

\section*{Results and discussion}

In the crucial region, the modified noun 'bureaucrat', subject relatives were marginally faster than object relatives \(\left(F_{1}(1,28)=2.96, M S e=92,790, P=.096 ; F_{2}(1,10)=4.94\right.\), \(M S e=15,300, P=.051)\). A spillover was observed in the following region, which contained the same words across the two conditions, and the difference was reliable at this point \(\left(F_{1}(1,28)=11.19, M S e=12,933, P<.01 ; F_{2}(1,10)=6.63\right.\), \(M S e=10,210, P<.05)\).

The results suggest that subject relative clauses are easier to process than object relative clauses, replicating previous results (Ishizuka, Nakatani \& Gibson, 2003; Miyamoto \& Nakamura, 2003; Sheldon, 1976; Ueno \& Garnsey, 2008). This is compatible with accessibility and the ObS in particular, but not with previous formulations of working-memory factors (e.g., Gibson, 1998; King \& Just, 1991).

Temporal-span models (Lewis, Vasishth, \& van Dyke, 2006) can account for the results if reactivation at the embedded predicate obeys the ObS. To date, we know of no other formulation of working-memory factors that has the potential to provide an explanation for the subject preference in the Japanese constructions discussed in this paper. However, even ObS-based reactivation fails to account for other types of relative clauses in Japanese, such as those with the coargument dropped (Nakamura \& Miyamoto, 2013).

Difficulty in object relatives was observed even though they were more expected according to Norming 1 (contra Gennari \& MacDonald, 2008).

\section*{Experiment 2}

The role of the modified noun in the outer clause (usually the matrix clause) has also been implicated in the comprehension of relative clauses. Parallelism predicts facilitation when the extraction site and the modified noun share properties such as grammatical role (Sheldon, 1976). Alternatively, facilitation occurs when the two positions share the same case marker (Sauerland \& Gibson, 1998). This type of case-marking attraction is grammaticalized in some languages so that the case marker on the modified noun can affect the marker on the relative pronoun or vice-versa (e.g., Ancient Greek, Persian; see Keenan, 1981, for examples). We controlled for these factors in this experiment.

\section*{Method}

Participants Thirty-two native speakers of Japanese at the Future University Hakodate, who had not participated in the other studies, were paid to participate in the experiment.
Materials Twelve pairs of items were used with the same procedure as in the first experiment. The following is an example pair.
(4) a. Subject relative clause \(\begin{array}{llll}\text { Kinjono } & \text { obaasan-o } & \text { basutei-made } & \text { miokutta } \\ \text { neighbor-gen } & \text { woman-acc } & \text { bus-stop-to } & \text { accompanied } \\ \text { onnanoko-ni-wa } & \text { sanpochuuno } & \text { inu-ga } & \text { jareteita. } \\ \text { girl-dat-top } & \text { walk } & \text { dog-nom } & \text { frolicking-was }\end{array}\)
'As for the girl who accompanied the woman from the neighborhood to the bus stop, a dog taken for a walk was frolicking around (her).'
b. Object relative clause

Kinjono obaasan-ga basutei-made miokutta neighbor-gen woman-nom bus-stop-to accompanied onnanoko-ni-wa sanpochuuno inu-ga jareteita. girl-dat-top walk dog-nom frolicking-was
'As for the girl who the woman from the neighborhood accompanied to the bus stop, a dog taken for a walk was frolicking around (her).'

Following previous studies (Ishizuka, Nakatani \& Gibson, 2003; Ueno \& Garnsey, 2008), the modified noun ('girl' in (4)) was marked with the dative marker \(n i\) and the topic marker wa. The two combined particles are not shared with either of the extraction positions (the nominative-subject or the accusative-object positions), therefore there should be no interference from attraction (Keenan, 1981; Sauerland \& Gibson, 1998). A sentence-initial animate noun marked with ni is usually interpreted as an indirect object, therefore a strict interpretation of parallelism (requiring the exact same grammatical role for the extraction position in the relative clause and for the modified noun in the matrix clause; Sheldon, 1976) would also predict no difference between the two types of relative clauses. But to the extent that \(n i\)-marked objects are more similar to direct objects than to subjects, \({ }^{2}\) a looser version of parallelism may favor object relative clauses.

Perspective shift elaborates on parallelism by considering whose point of view is adopted as the representation for the event is built. According to work on Hungarian (MacWhinney \& Pleh, 1988), perspective depends on whether the language is subject-prominent (SP; i.e., languages in which sentences are based on the relation between subject and predicate; e.g., Indo-European languages) or topic-prominent (TP; in which sentences are based on the relation between topic and comment; e.g., Chinese; Li \& Thompson, 1976). In TP languages like Hungarian, parallelism is claimed to hold for topics. In particular, a sentence-initial object is the topic in Hungarian, therefore its perspective is adopted, and because of parallelism, there is a preference for relative clauses to be object extracted when they modify a topicalized object (MacWhinney \& Pleh, 1988).

The test sentences in (4) are TP constructions because the dative object 'girl' is topicalized with the marker \(w a\); there-

\footnotetext{
\({ }^{2}\) For example, the object of verbs such as au 'meet', intabyusuru 'interview', denwasuru 'call/phone' is a direct object in English, but it is marked with the dative \(n i\) in Japanese.
}
fore, similar to Hungarian, perspective shift should favor object extraction. \({ }^{3}\)

Norming 3 A new group of 46 native speakers of Japanese participated. As in Norming 1, there were more object relative-clause completions ( \(66.3 \%\) ) than subject relative clauses (52.45\%; Wilcoxon: \(Z_{1}=3.04, P<.01 ; Z_{2}=\) \(2.36, P<.05)\). The same trends were observed when counts were restricted to relative clauses with head nouns depicting humans (object relatives: \(61.7 \%\); subject relatives: \(51.1 \%\); Wilcoxon: \(Z_{1}=2.73, P<.01 ; Z_{2}=2.05, P<.05\) ).

Norming 4 As in Norming 2, no plausibility difference between the subject condition (1.9) and the object condition (1.73; where 1 was natural and 5 was strange; Wilcoxon: \(P \mathrm{~s}>.2\) ) according to 16 native Japanese speakers, who had not participated in any of the other studies reported.

\section*{Results and discussion}

In the critical region ('girl' in (4)), there was a numerical advantage for subject relatives. The difference was reliable in the following region, which contained the same words across the two conditions ( \(P<.05\); function lmer in the package lme4, R Development Core Team, 2009). Moreover, the coargument in five items was a proper name while in the remaining seven items it was a common noun. Because the modified noun was always a common noun, proper names should decrease confusability and facilitate comprehension, but there was no interaction when type of noun was included in the analysis ( \(P>.8\); contra Gordon, Hendrick \& Johnson, 2001).

The results replicated the advantage for subject relatives over object relatives. Because the modified noun was marked dative-topic, factors such as parallelism (Sheldon, 1976), attraction (Keenan, 1981; Sauerland \& Gibson, 1998) and perspective shift (MacWhinney \& Pleh, 1988; Mitsugi, MacWhinney \& Shirai, 2010) incorrectly predict an object preference or no preference between the two types of relative clauses. The subject advantage is not compatible with expectation-based models either (Gennari \& MacDonald, 2008) given that there was an advantage for object relatives in the completion results of Norming 3.

\section*{General discussion}

We can classify languages into four types according to the positions of the relative clause (prenominal or postnominal) and the object ( OV or VO ) as follows: postnominal/SVO (e.g., English, French), postnominal/SOV (Dutch, German), prenominal/SVO (Chinese), and prenominal/SOV (Japanese, Korean, Turkish). Previous discussions of working-memory

\footnotetext{
\({ }^{3}\) Before the topicalized noun is read, the sentences may be mistaken for SP constructions. It has been argued that perspective in SP relatives may remain unspecified after an accusative NP is read, therefore no shift occurs and subject extraction may be relatively easy (Mitsugi, MacWhinney \& Shirai, 2010). However, it is unclear what exactly an unspecified perspective entails for the kind of representation assumed in perspective shift. Even the "neutral" point of view of an uninvolved spectator or the speaker would still require a shift when the perspective of the modified noun is adopted.
}
factors correctly predict the subject advantage in both types of postnominal languages as well as the object advantage in prenominal/SVO languages (Hsiao \& Gibson, 2003; Lin \& Garnsey, 2011; inter alia). The exception is prenominal/SOV languages, for which working-memory factors predict no difference or an object advantage. The results reported confirm the exceptional status of these languages even when ambiguity and expectation are taken into consideration.

We raised the possibility that ObS-based reactivation may explain the subject advantage in Japanese. It is also possible that simultaneous reactivation at the embedded verb cancels out any working-memory difference (Kwon et al, 2010), therefore only accessibility has an effect in Japanese. But there are at least two other alternatives that will also need future research. The first alternative is that the workingmemory load difference is small in Japanese-type languages because linear decay involves only one NP (see Figures 2ab). If so, working memory may not be enough to explain the subject advantage in Dutch and German, for which the difference between subject and object extraction is also of one NP only. This would reinforce the need for another factor such as the ObS to complement working-memory factors in order to explain the subject advantage in these languages.

Another possibility is that closure may be relevant because it flushes out verbatim material out of working memory. Memory load is likely to decrease after closure is performed on a phrase. Moreover, the load may vary across languages depending on the timing of closure. In Japanese, a consistently head-final language, closure is likely to be performed immediately at the end of the phrase (for example at the verb of an embedded clause). In contrast, head-initial languages do not have a marker to indicate the end of the phrase; consequently, closure may be delayed and memory load linger in languages such as English. Mixed languages such as Chinese may also fail to generate closure consistently at phrase end especially if the marker is a short functional word (e.g., de for relative clauses) that can be easily skipped during reading.

In sum, a second factor apart from working-memory constraints is needed to explain the subject advantage in prenominal/SOV relative clauses. This may provide an opportunity to better understand how memory use is affected by processes such as closure during language comprehension.

\begin{abstract}
Sound symbolism or the nonarbitrary link between language sound and meaning are commonly found across many languages of the world. A well-known example is the association between rounded vs. angular shapes and labels (i.e., the Bouba-kiki effect by Köhler, 1929/1947). Previous research has shown that sound symbolic words play facilitative role for preschool children's novel verb learning (Imai, Kita, Nagumo \& Okada, 2008; Kantartiz, Imai \& Kita, 2011), helping children identify what aspects of motion events should be mapped to verbs. In this research, we explore whether sound symbolism may facilitate language learning in human infants who have just begun to learn word meanings. Sound symbolism may be a useful cue particularly at the earliest stages of word learning, because this cue seems to be available without needing prior word learning experience (Gogate \& Hollich, 2010). Using a habituation paradigm and a Bayesian model-based analysis, we demonstrated that 14-month-old infants could detect Köhlertype (1947) shape-sound symbolism, and could use this sensitivity in their effort to establish the word-referent association.
\end{abstract}

Keywords: Sound symbolism; Word learning; Iconicity of language; Origin of language; Multisensory mapping; Bayesian analysis

\section*{Introduction}

Traditional linguistics has long assumed that links between a word's form and meaning are arbitrary (de Saussure, 1916/1983). However, words whose forms are motivated by their meanings (i.e., sound symbolic words) are commonly found across many languages of the world. For example, bump and thump sound like what they mean: an event with an abrupt end (e.g., Firth, 1935). Several languages even have large grammatically defined lexical classes of sound symbolic words (i.e., "ideophones," "expressives," or "mimetics") (Voeltz \& Kilian-Hatz, 2001; Kita, 1997). A well-known example of sound symbolism is the association between rounded vs. angular shapes and labels (Köhler, 1929/1947; see also Ramachandran \& Hubbard, 2001). Given a forced choice, adults and children from different languages (e.g., German, English, and Swahili) much prefer to label rounded objects bouba (or maluma) and angular objects kiki (or takete) (e.g., Davis, 1961; Holland \& Wertheimer, 1964).

Recently, evidence for sensitivity to sound symbolism in young infants is emerging (Penã, Mehler, \& Nespor, 2011; Ozturk, Krehm, \& Vouloumanos, 2012). Ozturk et al. (2012) demonstrated that even 4-month-olds are sensitive to the bouba-kiki sound-shape mappings.
An interesting question is whether sensitivity to sound symbolism is useful for language development. Previous research has shown that sound symbolic words play facilitative role for preschool children's novel word learning, helping children identify what aspects of the world should be mapped to verbs (Quine, 1969, Markman, 1989). For example, Maurer et al. (2006) demonstrated that 2.5-yearold children are likely to match rounded sounding labels with simple, rounded objects and jagged sounding labels with pointy objects (Mondloch \& Maurer, 2004; Maurer, Pathman, \& Mondloch, 2006). In addition, sound symbolism also helps 3-year-olds infer meanings of novel verbs, which are generally more difficult than object names (Imai et al., 2008; Kantartzis, Imai, \& Kita, 2011). Thus, sound symbolism is a good candidate for mappings from word forms to referents in the early stages of development. However, it is not clear whether such sensitivity to sound symbolism in young infants is used for word learning at the initial stage of language development.

Before toddlerhood, it is unknown how the youngest word learners can "break into" the process of mapping words to their referents. For infants just starting to learn words, the induction problem is much harder (Hollich, et al., 2007; Spiegel \& Halberda, 2011), and these infants likely rely more on perceptual regularities, due to limited memory and information processing abilities (Gogate \& Hollich, 2010). In fact, infants between 10- and 17-months of age find it much more difficult to utilize word-learning strategies used by older infants to infer novel word meanings (Woodward \& Hoyne, 1999). At this age, infants may use more perceptual strategies to map words, which can often lead them to the wrong referent (e.g., Hollich et al., 2007).

As with toddlers, however, sound symbolic words may be easier to learn, and these early links may help to scaffold mappings from word forms to referents in the early stages of development. In the present study, we examine whether sound symbolic links can provide early word-referent cues. Specifically, we asked if 14 month-old infants could utilize senseitivity to Köhler-type (1947) shape-sound symbolism
to establish association between a word and a referent object. Here we chose infants at 14 months of age, who are just old enough to learn new words in laboratory tasks, but are at an age when learning is still very fragile, especially when trying to process the precise phonological forms of words (Stager \& Werker, 1997).
We hypothesized that 14-month-olds detect sound-shape correspondence, and that this ability helps these infants make mappings from word forms to their referents. Specifically, we taught Japanese-learning infants two word labels, and then tested whether they encoded these labels in a preferential looking procedure. Half the infants were taught two sound symbolic labels (as rated by adults); half were taught the mismatching labels. We predicted that those in the sound symbolically matching condition would learn labels more easily than those in the mismatching condition.
This report features a Bayesian model-based data analysis. Infants looking behavior-particularly in a preferential looking paradigm, in which infants must compare two objects to make a decision-is very complex: It often shifts dynamically instead of staying stable during a trial. Also, because of the dynamic nature of looking, it is difficult to determine the most appropriate time window prior to the analysis. Furthermore, infants' looking time is "noisy", affected largely by looking profiles inherent in individual infants (e.g., a preference to look at a certain location on the monitor, a preference to look at a particular object, the likelihood to shift eye-gaze, etc.). Ignoring these idiosyncratic looking biases can weaken statistical power. Despite this problem, researchers have traditionally used ANOVA to examine the effect, where infants' looking time is averaged over a pre-set time window and individualbased looking biases are treated as experimental noise. In this research, we employed a Bayesian approach to analyze the data, which offers a new method of data analysis that is more adaptive to complex and dynamic nature of infants' looking behavior (see the Bayesian Data Analysis section for more details).

\section*{Method}

\section*{Participants}

Participants were thirty-four full term, monolingual Japanese 14-month-olds ( \(M=14 ; 16\), range \(13 ; 27-15 ; 9,22\) males). Infants were randomly assigned to either the match or mismatch condition. An additional 11 infants were excluded from data analyses due to experimental error ( \(\mathrm{n}=\) \(1)\), or fussiness during the experiment \((\mathrm{n}=10)\).

\section*{Apparatus}

A black cloth curtain surrounded a 21-inch display where visual stimuli appeared, and a digital video camera was hidden below the screen, relaying video of the infant to the control area. Video was also recorded ( 29.97 fps ) for offline coding of looking.

\section*{Stimulus materials}

Target stimuli consisted of a round versus a spiky shape, as well as audio recordings of two novel words, kipi and moma (Figure 1). Stimuli were constructed on the basis of a pilot study, where we first chose consonants ( \(\mathrm{m}, \mathrm{l}, \mathrm{n}, \mathrm{p}, \mathrm{k}\) ), and vowels (a, o, i) that are related to smooth and jagged shapes according to previous research on sound symbolism (Köhler, 1929/1947; Maurer, et al., 2006; Westbury, 2005). Moma and kipi were selected because our adults frequently chose these as the best match to the smooth/round and spiky/jagged shapes, respectively, and both were nonwords in Japanese. The two shapes were colored to make them more interesting to infants. Colors were chosen not to affect the shape sound symbolism.

During a habituation phase, infants were presented with two pairs of audio-visual stimuli: in the match condition, kipi - spiky, object and moma - round object; in the mismatch condition, kipi - round object, moma - spiky object. Infants were presented with filler stimuli, consisting of colored drawings of a ball, a banana, a car, and a picture book, paired with audio recordings of the corresponding word in Japanese. These items were chosen based on normative data from the Japanese MacArthur-Bates Communicative Development Inventory (J-MCDI) (Ogura \& Watamaki, 2004). A female Japanese speaker recorded the target and filler words, along with all other speech used in the experiment, in an infant-directed speech register.

\section*{Procedure}

Infants were tested individually in a quiet room on their parent's lap, positioned 60 cm from the display. Pretest, habituation, and test phases were presented, each of which contained several trials separated by a short attention-getting movie. Parents were instructed to keep their eyes closed, and also asked to complete the J-MCDI.
Pretest phase Here we presented 4 familiarization and 2 referential trials in random order. Familiarization trials showed side-by-side displays of either filler or target objects. Each trial lasted 8 seconds and was accompanied by, "Mite! Mite!" (Look! Look!). Two referential trials were included to enhance infants' understanding of the referential nature of the labels (Fennell \& Waxman, 2010), and here a single familiar object slowly moved (either up and down, or right and left) on the display, accompanied by the corresponding label in isolation and then in a carrier sentence (e.g., "Kuruma! Kuruma-wo mite!" [Car! Look at the car!]).
Habituation phase The habituation phase consisted of a pseudo-randomly ordered series of trials such that each word-object pairing appeared twice in every block of four trials. In each trial, a single target object moved slowly from right to left in order to maintain infants' attention (Werker et al., 1998), while one of the target words was paired with it (Figure 1). Trials lasted a maximum of 16 seconds and were accompanied by 13 tokens of a target word, each spoken with a different intonation pattern. The habituation criterion was set to a maximum of 24 trials, or a decrease of \(65 \%\) in looking to the longest previous block of 4 trials (Stager \&

Figure 1: Design and Stimuli
Werker, 1997; Yoshida, Fennell, Swingley, \& Werker, 2009).

Test phase The test phase consisted of four filler and four target trials that contained two objects side-by-side, counterbalanced for side over the testing phase. Two filler trials were always shown first, providing infants the opportunity to see familiar objects in the test procedure. The third and fourth trials were target trials, and the remaining four trials alternated between filler ( F ) and target ( T ) trials. All trials lasted 8 seconds, and began with a 3000 ms silent baseline period to measure visual preferences for the objects, followed by a phrase asking infants to look at the correct object (i.e., "X! X wa docchi?" [X! Which is the X?], where X stands for a filler or target word).

\section*{Coding}

Two blind coders classified each video frame as a look to the right, to the left, an ambiguous look, or no look. Fifteen percent of the all samples were coded twice to obtain intercoder reliability. The inter-coder reliability was high, \(\kappa\) \(=.826\).

\section*{Bayesian data analysis}

Data were analyzed using a Bayesian approach. In analyzing infants’ looking behavior, it is customarily assumed that it takes a certain time for infants to process auditory stimuli and/or move their eyes to fixate the target stimulus (e.g., Swingley \& Aslin, 2002). Considering the lag due to auditory and visual processing, a pre-determined time window is set, and infants' looking is averaged throughout this window. The group means are then compared using a linear model (typically a t-test or ANOVA). However, as mentioned earlier, the assumptions in traditional linear models often pose limitations for analyzing infants' complex looking behavior. First, infants' looking to the target often shifts dynamically instead of staying stable during the time course, and hence polynomial functions appear to fit better than a linear function. Second, because
infants' looking behavior may be affected by the nature of the stimuli and experimental settings, it is difficult to determine the most appropriate time window prior to the analysis. Third, although substantial individual difference is expected in infants' looking profiles (e.g., a preference to look at a certain location on the monitor, a preference to look at a particular object, the likelihood to shift eye-gaze, etc.), these response biases are simply treated as experimental noise, which weakens statistical power to detect the experimental effect of interest.

In the current analysis-to rectify these limitations in traditional linear models-we performed a Bayesian modelbased analysis based on Yurovsky, Hidaka, and Wu, 2012. In a Bayesian framework, a hypothetical relationship among a set of experimental factors (e.g., training effects), subsidiary factors (e.g., object-specific bias) and potential patterns of behaviors (e.g., looking time) are expressed as a statistical model with a set of parameters which is estimated through model fitting to a given dataset. In the present analysis, there are two major sets of parameters. The first set includes preference parameters for factors that could potentially affect the looking of a particular AOI at a given moment: individual infants' location preference, object preference, preference to look at the trained object, preference to look at the object that was sound symbolically matching to the label. The second set consisted of group parameters, which classify participants in such a way that within-group similarity in infants' response patterns and across-group differences are simultaneously maximized.

\section*{Results}

Looking data from each of the critical video frames were classified as a look to the left AOI, to the right AOI, or to a 'no-look' AOI. We analyzed infants' looking times (as frame-by-frame counts) as a function of five factors: a location-specific preference, an object-specific preference, a "correct" (trained) object preference, a sound symbolism preference, and the interaction between training and the sound symbolic match. The location-specific preference is defined as a bias to look toward the left or right AOI, relative to the preference for the no-look AOI for each infant independent of the match/mismatch condition. The object preference is a bias to look toward a particular object compared to the no-look AOI (with some other objects). The correct object preference is a preference to look at the object with which the label was associated during the habituation phase. The sound symbolism preference is a tendency to look at the sound symbolically matching object (to the label heard in the trial) after the onset of the speech (i.e., the preference for the spiky object after the onset of speech "kipi," or the preference for the round object after "moma"). Through the process of model fitting, we estimated a set of parameters for all of the five factors above, but we focus only on the three experiment-relevant factors, i.e., training, sound-symbolic match, and training-soundsymbolism interaction factors here.

We first analyzed the effect of the training and that of sound symbolism separately against the baseline preference, to see whether training and/or sound symbolism alone affected infants' looking behavior after the speech onset. For this purpose, we performed a series of models using (Bayesian) hypothesis testing. In Bayesian hypothesis testing, each model specifies a probability of a hypothesis to reproduce the current looking dataset. We tested a contribution of a particular factor, by evaluating the goodness of fit for two models-one with the target factor and one without-by a Bayes factor (Jeffreys, 1961; See also Wagenmakers et al. (2010) for a review in psychological studies). "The Bayes factor (BF) \(X\) of Model \(A\) to \(B\) given a dataset" indicates that the odds ratio for Model \(A\) to reproduce the dataset is \(X\) times higher than that for Model \(B\) to do so under even prior probability for each model \({ }^{1}\). In the present study, we considered a Bayes factor larger than 30 (or equivalently log-Bayes factor larger than 3.4) to be strong evidence in support for the Model A over Model B, based on Jeffreys' (1961) criterion.

Six models were evaluated as shown in Table 1. The first three models-P1-full, P2-full, and P3-full models--were full models in which all of the three experimental factors were included. These three models assumed different levels of complexity in their functions of looking probability. The first order polynomial function was assumed for the P1-full model, and the second- and third-order polynomial functions were assumed for the P2-full and P3-full models, respectively. We then compared the three models to determine the optimal level of complexity of the function in the model. The analysis on the Bayes factors indicates that the middle degree of complexity ( P 2 -full) is strongly favored over both the relatively simple (P2-full to P1-full: 27.5) and complex model (P2-full to P3-full: 247.4). We therefore employed the P2-full model as the baseline model, against which each of the subset models was compared.

To evaluate the effect of the three experimental factors, we calculated the Bayes factors for the three additional models in Table 1, i.e., P2-NoInt., P2-NoSS, and P2-NoTr against the P2-full baseline model (see Table 1 for results and the abbreviations). The analysis of the Bayes factors suggests that the P2-full model was strongly favored over the P2-NoInt (109.6), P2-NoSS (119.6), and the P2-NoTr (92.5). These results indicate that all effects of sound symbolism, training and the interaction between training and sound symbolism significantly contributed to the model fit.

This suggest that infants tended to look at the trained object regardless of whether this object was sound symbolically matching or not. Furthermore, sound symbolism affected infants' looking, regardless of whether infants were trained on a sound symbolically matching object.

\footnotetext{
\({ }^{1}\) According to Jeffreys (1961), BF from 3 to 10 (log-BF from 1.1 to 2.3 ) indicates "substantial" evidence, BF from 10 to 30 (logBF from 2.3 to 3.4) indicates "strong" one, and BF from 30 (logBF greater than 3.4) indicates "very strong" one.
}

Table 1: Summary of the hypotheses testing on the six models.
\begin{tabular}{|l|c|c|c|c|c|c|r|}
\hline \multirow{2}{*}{ Models } & \multicolumn{5}{|c|}{ Models } & \multicolumn{2}{c|}{ Results } \\
\cline { 2 - 7 } & \#P & Tr & SS & TS & Ply & \#G & log-BF \\
\hline \hline P2-full* & 10 & Y & Y & Y & 2 & 7 & 0 \\
P1-full & 7 & Y & Y & Y & 1 & 7 & 27.5 \\
P3-full & 13 & Y & Y & Y & 3 & 6 & 247.4 \\
P2-NoInt. & 8 & Y & Y & - & 2 & 7 & 109.6 \\
P2-NoSS. & 8 & Y & - & Y & 2 & 7 & 119.6 \\
P2-NoTr. & 8 & - & Y & Y & 2 & 8 & 92.5 \\
\hline
\end{tabular}

The abbreviations are as follows: \#P: the number of parameters for each cluster, \(\mathrm{Tr}, \mathrm{SS}\), and TS: whether the model contains preference parameters for trained object, sound symbolism match object, and the interaction between them ("Y" if the model has), Ply: the order of polynomial functions of the looking time courses , \#G: the estimated number of groups of infants, Log-BF: the log-Bayes factor of the P2-full model reproducing the data relative to the compared model. Pn-full: a full-factored model with the \(n\)-th order polynomial functions, P2-NoInt: a model without interaction between training and sound symbolic match, P2-NoSS: a model without the effects of sound-symbolic match, P2-NoTr: a model without the effects of training, *: the best model.

\section*{Discussion}

The present study aimed to clarify the facilitating role of sound symbolism in novel word learning in 14-month-old infants. Although the infants at this age sometimes show difficulty for matching words to their correct referents due to their limited cognitive ability, 14-month-olds could utilize sound-symbolic correspondences between speech sounds and object in this study. By Bayesian analysis, the effects of sound symbolism, training, and the interaction between sound symbolism and training all significantly contributed to the infants' looking behavior.

The current Bayesian data analysis shed light on the issue of how the youngest word learners break into the incredibly difficult process of mapping words to their references. One of the great advantages of Bayesian analysis is that it could wash out the critical experimental effects when traditional averaged analysis are treated as "noise," can be considered. By classifying participants with similar looking patterns into clusters and estimating group parameters, fine-grained response characteristics for a particular subgroup of infants.

The fact that significant contribution of factors sound symbolism, training, and the interaction between sound symbolism and training revealed in early word leaning stage may provide an important clue for solving the difficulty for mapping word to their referents. Sound symbolism may
allow infants to anchor speech to meaning, which in turn helps them obtain "referential insight"--- the insight that language sounds are symbols that represent concepts (Gogate \& Hollich, 2010). Once infants get into soundsymbolically based systems relating surface structure to meaning, they may be able to use this early knowledge to bootstrap themselves to more abstract meanings, needing direct perceptual anchors less and less, perhaps reflecting similar trajectories in language evolution (Kita, Kantartzis, \& Imai, 2010).

\section*{Acknowledgments}

We would like to thank Janet Werker for insightful discussion and advice in designing the experiment. Mamiko Arata, Noburo Saji and Junko Kanero all contributed to the creation and selection of stimuli. Asako Isawa, Kaoru Takata and Satomi Kanbara contributed to the video coding. \begin{abstract}
People's estimations of how certain speakers are of their knowledge (FOAK) match speakers' own estimation (FOK) of how certain they are (Brennan \& Williams, 1995). This is because others can interpret the verbal and nonverbal cues of (un)certainty that a speaker displays (Brennan \& Williams, 1995; Swerts \& Krahmer, 2005). Estimating another's certainty thus seems to be driven by the bottom-up processing of speaker-displayed cues. In this paper, we explore the topdown influence of beliefs about a speaker on judgments of a speaker's certainty. In a perception study, we varied whether a speaker's proclaimed profession would make him an expert or a novice on the topic he was questioned on. Such beliefs were shown to influence participants' ratings of the speaker's certainty, in addition to speaker-displayed cues. Thus, next to the bottom-up processing of speaker-displayed cues, the topdown processing of beliefs about a speaker influences judgments of others' certainty.
\end{abstract}

Keywords: FOK, FOAK, top-down processing, bottom-up processing, speaker-displayed cues, person perception.

\section*{Introduction}

When watching the news on television or online, we often are informed by so-called 'experts' on the current topic, for example, an economist may comment on the Euro crisis and an architect may be interviewed on the progress of a construction site. Often, the person's expertise is displayed in a header once their contribution starts, or announced upfront by the newsreader conducting the interview. Does such knowledge of people's expertise affect our judgment of their certainty? And if so, does this effect depend on whether the expert displays certain or uncertain behavior?
This study assesses the influence of knowing another person's expertise, on the judgment of their certainty when answering questions. We thereby test the influence of this factor relative to the verbal and nonverbal cues of uncertainty displayed by the person answering the questions (henceforth referred to as the 'respondent'). In the following, we first provide an introduction on the production and perception of cues of (un)certainty. Then we discuss the
different types of processing involved in utilizing speakerdisplayed cues, and in making use of beliefs about the speaker. This leads to our research question and hypotheses.

\section*{Displaying (Un)certainty}

Sometimes, when unable to remember the answer to a particular question, we have a strong intuition that we do know the answer, despite our momentary inability to retrieve it from memory. This meta-cognitive phenomenon is known as feeling-of-knowing (FOK), (Hart, 1965). Participants' FOK has been shown to be a reliable predictor of whether they can later recognize the sought-after answer in a multiple-choice test (Blake, 1973; Hart, 1965). This shows that people's intuition on whether particular knowledge is stored in their memory or is absent from it, tends to be correct.
When sharing our knowledge with others, we tend to share our intuition on the certainty of this knowledge as well, by displaying auditory and visual cues of (un)certainty (Brennan \& Williams, 1995; Goffman, 1967, 1971, 1978; Smith \& Clark, 1993; Swerts \& Krahmer, 2005). This may be done to save face in case of being incorrect, or to be as informative as needed, in accordance with Grice's maxim of quantity (Grice, 1989). FOK-ratings can be obtained by asking respondents how certain they are of their answer to particular knowledge questions (Hart, 1965). By matching such ratings to the auditory and visual behavior respondents exhibit while answering, characteristic cues of displays of (un)certainty have been identified. Auditory cues of uncertainty were shown to include: rising intonation, an initial pause, the use of fillers ("um", "uh"), hedging ("I think", "Most likely"), and self-talk ("Let's see, what was that again..."), (Goffman, 1978; Smith \& Clark, 1993). Certainty, on the other hand, is displayed auditorily by the absence of such cues, and a falling intonation.
Visually, uncertainty can be displayed by rising the eyebrows, smiling (when recognizing the answer should be known), producing a marked facial expression (a 'funnyface'), and diverted gaze (Swerts \& Krahmer, 2005).

Certainty is displayed visually by the absence of such cues (e.g., not diverting gaze), although particularly easy questions can also elicit smiles, which then signal certainty.
If these auditory and visual cues serve to convey a level of certainty to an interaction partner, it is expected that people can correctly interpret them.

\section*{Perceiving (Un)certainty}

People are indeed sensitive to the cues of (un)certainty others display. The intuition we have of whether another person is likely to know the correct answer to a question, is known as feeling-of-another's-knowing (FOAK), (Brennan \& Williams, 1995). FOAK-ratings can be elicited by presenting participants with other's answers and asking them how certain they are that the respondent gave the correct answer. This way, answers with rising intonation and longer response latencies were found to elicit lower FOAK-ratings than answers with falling intonation and shorter latencies (Brennan \& Williams, 1995). Also, adding filled pauses to answers led to lower FOAK-ratings than adding unfilled pauses. Participants' FOAK-ratings were found to match respondents' own FOK-ratings (Brennan \& Williams, 1995). Therefore, it seems that people can correctly interpret the auditory cues of (un)certainty others display.

When participants had access to both visual and auditory cues displayed by respondents, the accuracy of their FOAKratings increased as compared to when they had access to either auditory or visual information (Swerts \& Krahmer, 2005). Thus, people can reliably estimate how certain others are of their knowledge, by interpreting their auditory and visual displays of (un)certainty.

\section*{Top-down vs. Bottom-up Processing of Cues}

Next to speaker-displayed cues, more global information about a person's expertise can also inform inferences about this person's knowledge and credibility (for an overview, see Pornpitakpan, 2004). Along these lines, expectations concerning another person's knowledge can be guided by that person's presumed gender (Fussell \& Krauss, 1992), age (Newman-Norlund, et al., 2009), or geographic origin (Isaacs \& Clark, 1987). Also, previous experiences with the person shape expectations about what they are likely to know (Galati \& Brennan, 2010; Metzing \& Brennan, 2003). Beliefs about a person's expertise may therefore influence metacognitive assessments of that person's knowing in a top-down fashion.
In fact, global information may influence the interpretation of locally available verbal and nonverbal displays of (un)certainty. Along these lines, people have been shown to interpret a person's speech disfluencies differently if they can attribute them to a cognitive impairment (Arnold, Kam, \& Tanenhaus, 2007). And speakers interpret their addressees' verbal and nonverbal feedback behavior based on the expected involvement of the addressees in the interaction (Kuhlen \& Brennan, 2010; Kuhlen, Galati, \&

Brennan, 2012). Bottom-up processes informed by locally available verbal and nonverbal displays of knowing may therefore be shaped by top-down processes informed by global information about the respondents' expertise. Investigating how these two processes inform complex social judgments, such as assessing another person's knowledge, will contribute to our understanding of human social cognition.

\section*{Present Study}

The present study assesses whether the top-down processing of global information affects judgments of others' certainty, in addition to the bottom-up processing of locally available cues. To this aim, we manipulated participants' belief about a respondent's expertise, as well as the locally available verbal and nonverbal cues, displayed by the respondent. Based on previous work (Brennan \& Williams, 1995; Swerts \& Krahmer, 2005), we expect the respondent's verbal and nonverbal displays of certainty to influence participants' FOAK-ratings in a bottom-up fashion. In addition, we expect that the interpretation of these displays is influenced top-down by participants' beliefs about the respondent's expertise. Lastly, since displays of certainty have been primarily described by the absence of cues of uncertainty, bottom-up processes may be less important when judging high-FOK as compared to low-FOK displays. Therefore, the top-down processing of global cues may affect FOAK-ratings differently for each type of display.

Below, we first describe how we created stimuli in which a respondent clearly displays verbal and nonverbal cues of high and low FOK. Then follows a description of the main experiment, in which we manipulated participants' beliefs about the respondent's profession, and thereby his expertise.

\section*{Method}

\section*{Material}

Selecting Knowledge Domains To elicit high- and lowFOK answers, a 30 -year-old male tax advisor was interviewed on two domains relating to his interests: gardening and Dutch literature. In two separate pretests, participants were presented with a picture of the respondent and asked how likely it was that he was of certain professions. Ten professions were tested on either pretest, including gardener and Dutch teacher. Each pretest included 16 participants. On a six-point scale, participants rated the possibility that the respondent was a gardener \((M=3.50, S D\) \(=1.14\) ) equally likely to the possibility that he was a Dutch teacher \((M=3.50, S D=1.41), t(31)=.00, p=1.00\).
Participants also rated the professions (ten per test) for how knowledgeable someone of this profession would be in gardening and Dutch literature. A paired samples t-test revealed that on a six-point scale, a gardener was indicated to be more knowledgeable in gardening \((M=5.75, S D=\) .68) than a Dutch teacher \((M=2.69, S D=1.35), t(15)=\)
7.42, \(p<.001\). Vice versa, a Dutch teacher was rated more knowledgeable in Dutch literature ( \(M=5.89, S D=.34\) ) than a gardener \((M=2.00, S D=.63), t(15)=31.00, p<.001\).
Eliciting Audiovisual Displays of High and Low FOK The respondent was asked 40 multiple-choice questions on gardening, followed by 40 multiple-choice questions on Dutch literature. Multiple-choice questions were used to avoid non-answers (e.g., "I don't know") and to manipulate the difficulty of the questions. Each question had four alternatives, see examples (1) and (2). The respondent was instructed to say the answer out loud, e.g., "Blauwe regen". The experimenter asking the questions was located behind the respondent, such as not to give the respondent any cues of the answer being correct or incorrect. Answers were captured with a video camera situated in front of the respondent. After answering, the respondent indicated on a six-point scale how certain he was of his answer being correct, '6' indicating 'definitely correct' and ' 1 ' indicating 'definitely incorrect'. Following Hart (1965), this was taken as a measure of the respondent's feeling-of-knowing (FOK).
(1) Welke plant is giftig? (Which plant is toxic?) A: Blauwe regen, B : Geranium, C: Orchidee, D: Waterlelie
(2) Wie schreef in 1947 de roman 'De avonden'? (Who wrote the novel 'De avonden' in 1947?) A: Jan Cremer, B: Herman Bursselmans, C: Harry Mulisch, D: Gerard Reve.

This way, 40 answers were collected in each domain. Since the respondent never indicated a FOK-score of 1 , answers with a FOK-score of 2 or 3 were regarded lowFOK and those with a FOK-score of 5 or 6 were regarded as high-FOK. Answers with a score of 4 were few and were disregarded. Sometimes, the respondent's answer contained information about the question being a multiple-choice question, for example "the first one". These responses were disregarded as well. For each domain, ten high- and ten lowFOK answers were then selected, based on their intelligibility and on how clear the displayed cues seemed to be. Whether these clips indeed included clear displays of high- and low-FOK was assessed in a third pretest.
Selecting FOK Displays In the third pretest, 20 native Dutch participants (ten female) watched clips of the 40 selected answers and indicated on a six-point scale how certain they were of the respondent's answer being correct. Following Brennan and Williams (1995), this was taken as a measure of participants' feeling-of-another's-knowing (FOAK). Since participants were only presented with the respondent's answers and not the questions asked, they had to rely on their estimation of how certain the speaker was (FOAK), to tell whether the answer was correct or not.
A \(2 \times 2\) ANOVA with within-factors FOK (levels: high, low) and Domain (levels: gardening, Dutch literature) revealed a main effect of FOK on participants' FOAKratings, \(F(1,18)=157.85, p<.001, \eta_{p}{ }^{2}=.90\), see Table 1 .

Table 1: Mean (SD) FOAK-ratings in the pretest.
\begin{tabular}{llc}
\hline FOK: & Domain: & FOAK \((S D)\) : \\
\hline \multirow{2}{*}{ High } & Gardening \((N=10)\) & \(4.32(.46)\) \\
\((N=20)\) & Dutch Literature \((N=10)\) & \(4.64(.60)\) \\
& Total \((N=20)\) & \(4.48(.11)\) \\
\hline \multirow{2}{*}{ Low } & Gardening \((N=10)\) & \(3.09(.66)\) \\
\((N=20)\) & Dutch Literature \((N=10)\) & \(2.78(.49)\) \\
& Total \((N=20)\) & \(2.93(.10)\) \\
\hline
\end{tabular}

There was no main effect of Domain, \(F(1,18)=.001, p=\) .91. Domain and FOK did interact, \(F(1,18)=17.41, p<\) \(.001, \eta_{p}{ }^{2}=.49\). The difference in FOAK-ratings on highFOK and low-FOK clips was larger for the Dutch literature than for the gardening domain, see Table 1. These results evidence that the clips contained speaker-displayed cues.
For each domain, those sets of clips were selected that participants rated most consistently as portraying either high- or low-FOK answers (assessed by Cronbach's alpha). This way, we could be most certain that our selected FOK displays contained informative cues about the respondent's feeling of knowing. Our final set of stimuli contained seven high-FOK clips for both domains, seven low-FOK clips for the literature domain and five low-FOK clips for the gardening domain. Unfortunately, we did not obtain more suitable low-FOK clips from the gardening domain.

\section*{Task}

Participants' task in the main experiment was to judge the respondent's answers in the selected clips, indicating on a six-point scale how certainly the respondent's answer was correct: ' 1 ' indicating 'certainly incorrect' and ' 6 ' indicating 'certainly correct'. This way, we elicited participants' FOAK-judgments of the respondent's answers.

\section*{Design}

The factors FOK (levels: low, high) and Domain (levels: gardening, literature) were manipulated within participant. The factor Profession (levels: gardener, Dutch teacher, profession not mentioned) was manipulated betweenparticipants. An equal number of men and women participated in each condition. The order in which the two domains were presented was counterbalanced across each condition and across sex. Each participant saw the clips within a domain in a different, randomly generated order.

\section*{Procedure}

The main experiment was conducted as an online survey. Participants received a link through email, which led them to the website of the experiment. Clips were grouped by domain. A short instruction, which announced the domain that the questions were in, preceded the clips in either domain. This instruction also included a description of the respondent, mentioning his age (30) and city of residence (Spijkenisse), along with, depending on the experimental

Table 2: Mean (SD) FOAK-ratings for answers in the Gardening domain.
\begin{tabular}{llc}
\hline Clips: & Profession: & FOAK \\
\hline & Gardener \((N=24)\) & \(3.41(.68)\) \\
Gardening, & Not mentioned \((N=22)\) & \(3.16(.93)\) \\
Low FOK & Dutch Teacher \((N=22)\) & \(2.88(.53)\) \\
\((N=5)\) & Total \((N=68)\) & \(3.15(.75)\) \\
\hline & Gardener \((N=24)\) & \(5.37(.58)\) \\
Gardening, & Not mentioned \((N=22)\) & \(4.99(.64)\) \\
High FOK & Dutch Teacher \((N=22)\) & \(5.08(.57)\) \\
\((N=7)\) & Total \((N=68)\) & \(5.15(.61)\) \\
\hline
\end{tabular}
condition, his profession. The experiment was self-paced and participants could view each clip as often as they wished. They indicated their answer by clicking a radiobutton on a horizontally laid-out six-point scale, before proceeding to the next clip. After all clips had been rated, participants were asked for the respondent's profession (as a manipulation check) and for their own knowledge of gardening and Dutch literature.

\section*{Analyses}

Data of participants who did not correctly remember the respondent's profession (five cases), or who mentioned a profession in the condition in which no profession was mentioned (four cases) were excluded from our analyses. Data from any non-native speakers of Dutch were excluded as well (four cases). Subsequently, data from a minimal number of participants were removed from the sample to ensure counterbalancing of sex, and order of presentation of the domains (seven cases). For this purpose, data from participants who participated last were eliminated first.

\section*{Participants}

Our final sample contained data of 68 native Dutch participants ( 34 female). They were aged between 17 and 37 years old \((M=22.85, S D=3.33)\) and did not take part in any of our pretests.

\section*{Results}

Initially, we conducted a \(3 \times 2 \times 2\) ANOVA, with betweenfactor Profession (levels: not mentioned, gardener, Dutch teacher), and within-factors: Domain (levels: gardening, literature) and FOK (levels: high, low). This revealed a main effect of FOK, such that participants' FOAK-ratings were higher for high-FOK clips ( \(M=5.10, S D=.53\) ) than for low-FOK clips \((M=2.71, S D=.44), F(1,65)=726.14, p<\) \(.001, \eta_{p}{ }^{2}=.92\). We also found a main effect of Domain, such that FOAK-ratings were higher for the gardening domain \((M=4.32, S D=.50)\) than for the Dutch literature domain \((M=3.71, S D=.05), F(1,65)=42.47, p=.001, \eta_{p}{ }^{2}\) \(=.40\). Domain and FOK interacted, \(F(1,65)=34.46, p<\) \(.001, \eta_{p}{ }^{2}=.35\). The difference in rating between high- and

Table 3: Mean (SD) FOAK-ratings for answers in the Literature domain.
\begin{tabular}{llc}
\hline Clips: & Profession: & FOAK \\
\hline Literature, & Dutch Teacher \((N=22)\) & \(2.41(.58)\) \\
Low FOK & Not mentioned \((N=22)\) & \(2.40(.49)\) \\
\((N=7)\) & Tardener \((N=24)\) & \(2.35(.47)\) \\
& Total \((N=68)\) & \(2.38(.51)\) \\
\hline \multirow{2}{*}{ Literature, } & Dutch Teacher \((N=22)\) & \(5.11(.50)\) \\
High FOK & Not mentioned \((N=22)\) & \(5.09(.62)\) \\
\((N=7)\) & Gardener \((N=24)\) & \(4.93(.67)\) \\
& Total \((N=68)\) & \(5.04(.60)\) \\
\hline
\end{tabular}
low-FOK clips was larger for the Dutch literature domain than for the gardening domain, see Tables 2 and 3.
Profession did not exert a main effect on participants' FOAK-ratings, \(F(2,65)=1.01, p=.37, \eta_{p}{ }^{2}=.03\), revealing no overall differences in FOAK-ratings between the three conditions. As expected, Profession and Domain interacted, \(F(2,65)=6.05, p=.004, \eta_{p}{ }^{2}=.16\). Because of the differential influence of domain on our main variables of interest (Profession and FOK), we analyzed each domain separately, by means of a \(2 \times 3\) ANOVA with FOK as within-factor and Profession as a between factor. Pairwise comparisons were performed using least square differences.

\section*{Results for the Knowledge Domain Gardening}

Table 2 provides an overview of the mean FOAK-ratings in the gardening domain. There was a main effect of FOK on FOAK, such that high-FOK clips \((M=5.15, S D=.61)\) were rated as more certainly correct than low-FOK clips ( \(M=\) 3.16, \(S D=.75), F(1,65)=316.78, p<.001, \eta_{p}{ }^{2}=.83\). Profession showed a main effect on \(\operatorname{FOAK}, F(2,65)=4.56\), \(p=.014, \eta_{p}{ }^{2}=.12\). Pairwise comparisons revealed that the respondent was rated as more certainly correct when he was labeled a gardener, than when he was labeled a Dutch teacher ( \(p=.005\) ), or when no profession was mentioned ( \(p\) \(=.033\) ). Ratings between the latter two did not differ significantly ( \(p=.499\) ). The factors FOK and Profession were not found to interact, \(F(2,65)=.89, p=.416\).

\section*{Results for the Knowledge Domain Literature}

Table 3 provides an overview of the mean FOAK-ratings in the Dutch literature domain. There was a main effect of FOK on FOAK, such that high-FOK clips \((M=5.04, S D=\) .60) were rated more certainly correct than low-FOK clips \((M=2.38, S D=.51), F(1,65)=811.92, p<.001, \eta_{p}{ }^{2}=.93\). We did not find a main effect of Profession ( \(F<1\), n.s.), nor an interaction between Profession and FOK ( \(F<1\), n.s.).
To see if the null-result for Profession should be interpreted as evidence against our hypothesis, we conducted a Bayesian analyses on the difference between the Dutch teacher and gardener condition. In the gardening domain, an independent samples \(t\)-test showed higher FOAK-ratings for the gardener \((M=4.55, S D=.44)\) than
for the Dutch teacher condition ( \(M=4.16, S D=.37\) ), \(t(44)\) \(=3.26, p=.002\). In the literature domain, no difference was found between the gardener \((M=3.64, S D=.44)\) and Dutch teacher condition \((M=3.76, S D=.42), t(44)=.961, p=\) .342. Modeling the predicted effect in the literature domain as a normal distribution, with its mean equal to the effect in the gardening domain (.39), and a standard deviation of half this effect (also see Dienes, 2011), rendered \(\mathrm{Bf}=.45\). This indicates that the results from the literature domain do not discriminate between the null-hypothesis and the hypothesis of an effect of Profession on FOAK.

\section*{Results for Participants' Expertise}

A paired samples t-test showed that on a 7-point scale, participants reported to be more knowledgeable in Dutch literature ( \(M=3.90, S D=1.56\) ) than in gardening ( \(M=\) \(2.69, S D=1.25), t(67)=5.35, p<.001,95 \% \mathrm{CI}=(.76\), 1.66). Adding self-reported expertise as a covariate did not reveal an effect of this factor on participants' FOAK-ratings.

\section*{Discussion}

Our results showed strong effects of the respondent's feeling of knowing (FOK) on participants' feeling of another's knowing (FOAK). Following the hypothesis that people make use of verbal (Brennan \& Williams, 1995) and nonverbal (Swerts \& Krahmer, 2005) cues when judging someone's certainty, this indicates that our clips contained clear speaker-displayed cues, which participants used to judge the respondent's certainty.

Going beyond the results of earlier studies, we found that beliefs about the respondent, specifically about the respondent's expertise, influenced participants' judgment of the respondent's certainty as well. When asked questions about gardening, the same respondent was rated as more certainly correct when participants were told he was a gardener, compared to when they were told he was a Dutch teacher, or when no information on the respondent's profession was provided. This shows that, in addition to the information that could be obtained from cues displayed by the respondent, participants' beliefs about the respondent's expertise influenced their judgment of how certain the respondent was of his answers. Therefore, top-down processes informed by global information about a speaker can influence assessments of another person's feeling of knowing too. This top-down effect held both for clips in which the respondent was uncertain of his answer (low FOK) and for clips in which he was certain (high FOK).
Our between-subjects manipulation of expertise allowed us to use the same clips in each condition, ensuring identical speaker-displayed cues and speaker attributes. Participants were randomly assigned to conditions, and our analyses did not show evidence for an overall difference in FOAKratings between the conditions. Hence, we are confident that our results cannot be ascribed to a priori differences between the three groups of participants.

People sometimes use their own knowledge to estimate others' knowledge (Fussell \& Krauss, 1991; Jameson, Nelson, Leonesio, \& Narens, 1993; Nickerson, Baddeley, \& Freedman, 1987). In our study, participants reported having more knowledge on Dutch literature than on gardening. Nevertheless, they rated the speaker to be more certain in the gardening domain than in the Dutch literature domain. Entering participants' self-reported knowledge as a covariate did not render any significant results. Hence, reported effects seem unaffected by participants' own knowledge.
Follow-up studies need to assess if our results generalize to different respondents, domains, and beliefs. In this study, we only found evidence for an additional effect of beliefs about the respondent's expertise in one domain: gardening. We did not find this effect for the literature domain. However, a Bayesian analyses indicated that the results from the literature domain should not be interpreted as evidence against, nor in favor of our hypothesis. It seems that more factors are at play still, which attenuated the effect of beliefs about a speaker in this domain. One difference between the two domains was that the effect of speakerdisplayed cues was even stronger in the literature than in the gardening domain. It may be the case that the role of beliefs diminishes when speaker-displayed cues are very clear. Future studies are needed to uncover what factors moderate the effect of beliefs about a speaker.
Our findings have important implications for our understanding of the social and cognitive processes involved in person perception. From a social perspective, it is striking that simple information, such as labeling someone as being an expert by assigning them a certain profession, can sway perceivers towards judging them to be more knowledgeable in their domain of expertise. This is in line with social psychological literature on persuasion, which shows that perceived experts are expected to provide information that is valid (e.g., Clark, Wegener, Habashi, \& Evans, 2012; Hovland \& Weiss, 1951). Our study thereby contributes to a better understanding of the mechanisms behind perceiving expertise and taking advice from experts (see e.g., Jungermann \& Fischer, 2005). From a cognitive perspective, our study contributes to a growing literature on social cognition showing that the interpretation of social cues cannot be separated from global attributions about the person displaying these cues (Teufel, Fletcher, \& Davis, 2010).

Previous work has suggested that the processing of nonverbal cues is shaped by top-down expectations about the person (Kuhlen \& Brennan, 2010; Kuhlen et al., 2012). In these studies participants responded differently to similar nonverbal behavior of their conversational partners depending on how they had expected their partners to behave. In the present study, it is difficult to disentangle how exactly nonverbal cues are integrated with global beliefs about the respondent. Possibly, evidence from both top-down and bottom-up cues accumulates additively,
swaying the perceiver's judgments in one or the other direction. Future work will investigate further how these two sources of information interact.

\section*{Conclusion}

Our study showed that next to speaker-displayed cues of (un)certainty, beliefs about a speaker can also affect FOAKratings. This shows that people's feeling of another's knowing is affected both by the bottom-up processing of local cues displayed by the speaker and the top-down processing of global beliefs they have about this speaker.

\section*{Acknowledgements}

We thank the reviewers for their insightful comments, Zoltan Dienes for help with the Bayesian analysis, Joe Walther for his advice on the Social Psychology literature, Jacqueline Dake for her assistance with the online surveys, and Paul Eijkenaar for volunteering as the respondent.

\title{
Sharing in the Dark? Target Memory and Risk Awareness in Online Communication
}

\begin{abstract}
A high degree of self-disclosure in Online Social Networks (OSNs) is associated with several risks. This raises an important question: Why don't many users protect their personal data more eagerly? We propose that a lack of memory for what information has been disclosed to which audience contributes to this privacyneglecting behavior in OSNs. We transferred the paradigm of target monitoring to a fictitious OSN and varied the degree of risk associated with selfdisclosure. In a \(2 \times 2\) experiment we varied both audience size (large vs. small) and information intimacy (personal vs. non-personal). We used recognition tests for the association of audience and disclosed information to assess memory performance. Results show that item memory (the memory for what information has been disclosed) exceeded target memory and that target memory improved in vulnerable situations (for large audiences and personal information). Our findings widen the realm of offline memory research and expand our knowledge about which cognitive factors impact privacy-related behavior in online environments.
\end{abstract}

Keywords: Target Memory, Online Self-Disclosure, Risk Awareness

\section*{Introduction}

\section*{Self-Disclosure in OSNs}

Self-disclosure is an important mechanism in relationship formation and trust development (Jourard \& Lasakow, 1958). Lately much research has investigated the benefits of sharing personal information on OSNs-platforms i.e. in terms of self-esteem and identity formation (Valkenburg \& Peter, 2011). At the same time this behavior is associated with several risks. For example, it is not uncommon that employers retrieve information of their job applicants through an online search that includes profile information on OSNs. This information often decides to whom the announced job position is offered (Zeidner, 2007). Interestingly, many users actually are concerned about potential data misuse but nevertheless choose to reveal personal information in OSNs, a pattern that is known as
privacy paradox (Norberg, Horne, \& Horne, 2007). Some scholars argue that privacy related decisions result from a logical calculation in which risks and benefits of selfdisclosure are rationally weighed against each other ( Xu , Teo, Tan, \& Agarwal, 2010). If users self-disclose despite their concerns, the benefits must be larger and/or more probable than the associated risks. However, we argue that privacy-related calculations might be biased, because users could lack important information to assess the actual amount of vulnerability: Online revelation of personal information is usually done over and over again and while the single event is indeed not that risky, its repetition produces a cumulative amount of online information about the user (indicating a corresponding amount of cumulative risk). One important detail that is crucial for the assessment of this cumulative risk is the memory for which information has been disclosed, and to whom it is available.

\section*{Target Memory in Offline Interactions}

Recently it has been shown that people struggle to remember the targets of their messages in offline contexts. For example, in one of their experiments Gopie and MacLeod (2009) investigated how well people remember having disclosed fifty personal facts to pictures of famous people in comparison to impersonal facts. Results show that people successfully identified the facts they had disclosed (item memory) but had problems associating facts and targets (target memory); they did not remember to whom they disclosed what. In another study Marsh and Hicks (2002) let participants repeatedly choose to whom they wanted to give different kinds of objects. The authors conclude that this decisional aspect leads to a deeper elaboration of the situational context which then facilitates subsequent retrieval. Finally, Brown, Hornstein, and Memon (2006) let participants tell various pieces of information to five different celebrity pictures on five subsequent days. On-line and retrospective target memory declined with the number of previous "interactions", indicating a confusion of which information was given to whom.

In the light of these findings it seems plausible to assume that target memory problems also exist online. Therefore, we transferred the paradigm of target monitoring to the environment of OSNs. As a prerequisite for further analysis we assumed that participants remember what information they disclosed but struggle remembering to whom. We thus
hypothesized that item memory exceeds target memory (hypothesis 1).

\section*{Risk Cues in Online Communication}

There has been much discussion on how online environments change the nature of communication and information processing (Kiesler, Siegel, \& McGuire, 1984). However, while OSNs environments are somewhat deprived of conventional context cues that could support the encoding and decoding of information, other situational factors could be more relevant for target memory in OSNs. For example, the elaboration likelihood model (Petty, Cacioppo, \& Kasmer, 1988) argues that when people are motivated they process information in a more elaborate way. It seems plausible that people are more motivated if they feel at risk. People could therefore process risky situations more thoroughly than neutral ones. This could be especially true for online interactions since the accessibility and distribution of information is inherently more difficult to control. Furthermore, studies in associative memory research have demonstrated that the emotional intensity of an event has a major impact on memory performance (LaBar \& Cabeza, 2006). As we can assume that perceived risk does cause some sort of arousal or emotion (Slovic \& Peters, 2006) it seems plausible that risk cues could have a positive impact on target memory performance in OSNs. In this study we focused on two major aspects that could influence perceived vulnerability: a) the kind of information that is disclosed and \(b\) ) the kind of audience that gains access to the information.

Information Gopie and MacLeod (2009) found that target memory performance was worse when people disclosed personal facts in comparison to impersonal facts. In line with Koriat, Ben-Zur, and Druch (1991) the authors argue that revealing personal details increases self-focus which prevents people from integrating the outer environment as a reference point of that event. Impersonal information on the other hand would not trigger the same amount of self-focus resulting in better target memory performance. However, we believe that in OSNs the degree of intimacy of information serves as a distinct risk cue, because disclosing personal information gives the audience's members more opportunities for personal judgment and information misuse. We therefore predicted that target memory would improve when the disclosed information is personal rather than impersonal (hypothesis 2).

Audience Perceived vulnerability does not only vary with the nature of the information but also with the nature of the target. Thus, perceived vulnerability seems to increase with the number of people who have access to this information (Bateman, Pike, \& Butler, 2011). Slonje and Smith (2008) similarly showed that cyberbullying victims experience the unwanted disclosure by others as especially harmful when a large group gains access. Naturally, a larger group is not only more difficult to control but necessarily contains more
members that are less trusted. Publicity thus seems to be an important factor for risk awareness during online selfdisclosure. Therefore, we assumed better target memory for larger than for smaller audiences (hypothesis 3).

\section*{Hypotheses}

To summarize, this study addresses two different aspects of risk awareness and memory performance in online selfdisclosure. On the one hand we assumed that overall target memory problems also exist online. We predicted that people easily remember what information they disclosed (item memory), but not to which audience (target memory; hypothesis 1). On the other hand we presumed that people cognitively react to specific risk cues like the intimacy of the disclosed information (personal vs. impersonal information) and the size of the audience that receives the message (small vs. large audience). We therefore hypothesized that target memory would improve when information is personal rather than impersonal (hypothesis 2 ) and when the receiving audience is large rather than small (hypothesis 3).

\section*{Method}

\section*{Participants}

Participants were senior students from high schools in the area of Münster, Germany. We excluded two participants from data analysis, because they did not follow the instructions as requested. Thus, our sample consists of 99 participants ( 34 males, 65 females) with a mean age of 17.59 years ( \(\mathrm{SD}=2.08\) ).

\section*{Materials}

Scenario Students entered a fictitious social networking site of the local university. Within this site participants entered a sham discussion group where they would be posting information concerning the topic of the group. Students were aware that they were part of an experimental study.

Information In the personal condition students entered the fictitious discussion group "to get to know each other". Items in the personal condition were partly taken from former studies about relationship formation (Joinson, 2001; Jourard \& Lasakow, 1958), partly taken from what is typically disclosed in online profiles (e.g. "your favorite music") and partly self-created (e.g. "what is the meaning of life in your opinion"). In the non-personal condition students entered the sham group "information about the city of Münster". Items in this condition were taken from an online tourist brochure about the city of Münster (e.g. "famous band from Muenster - H-Blockx" or "founding year of the city of Muenster - 793").

Audiences The disclosed information would be sent to either everyone in the students' semester (large audience;

180 people) or only to their future study group (small audience; five people). We defined the size of the audiences to approximate how online social networks are arranged. In 2011 the average network of a Facebook user consisted of around 190 Facebook-friends (Ugander, Karrer, Backstrom, \& Marlow, 2011). Usually, a core group of these people are active contacts the user communicates with on a frequent basis (strong ties). The rest of the network constitutes weak ties - users passively keep in touch with these contacts, but not necessarily interact with them on a regular basis (Ellison, Steinfield, \& Lampe, 2007). Please note that the audiences in this experiment did not constitute strong and weak ties per se since participants had no actual relation to the displayed people whatsoever.

Communication Task The communication task consisted of 20 randomized slides. On each slide students saw two facts at the top of the page (personal or non-personal). They decided which one they wanted to disclose and marked that one. In the personal condition we paired facts with a similar degree of intimacy. In the impersonal condition we paired facts that both contained either numerical or textual information. The audience (small or large) was saliently displayed underneath these two facts via a collection of small-scaled photos that matched the number of the announced audience size. Participants were instructed to choose one of the two facts and disclose it at the bottom of the page where they wrote the information into an empty text field. Ten facts were disclosed to a small target audience, ten facts to a large target audience and thus twenty facts were not disclosed because they were not chosen. While the students could choose which one out of the two facts they wanted to disclose, the audience was predetermined and could not be selected. We incorporated this decisional aspect to enhance the external validity of our experiment: People presumably choose more or less carefully what information they disclose (Marsh \& Hicks, 2002) - not only for privacy reasons but also because this information becomes an inherent part of their selfpresentational strategy. Interestingly, many Facebook users would rather decide what to disclose, instead of to whom, since many report that they make all their information and actions visible to all of their Facebook-friends. Therefore, participants in our experiment could decide what information they wished to disclose but not to which audience.

Memory Task The memory task consisted of 50 randomly presented test slides that contained the forty facts of the communication task plus ten completely new facts. For each displayed fact the students indicated if they had disclosed this fact to a small target audience, a large target audience, if it was a fact they hadn't seen before (new) or if they had encountered this fact but not disclosed it (each of the first three options was correct in 10 times of the cases, the last option in 20 times of the cases). Items that were new or had
not been chosen to be disclosed in the learning phase were treated as distractors. \({ }^{1}\)

Internet Literacy Questionnaire The internet literacy questionnaire (Stodt, Moll, Polzer, Pieschl, \& Brand, 2013) consists of twenty items measuring online literacy in terms of technical skills, online empathy, online interactions, and privacy-related attitudes and behaviors. \({ }^{2}\) This questionnaire was incorporated to create latency between the communication task and the memory task and to thus weaken short term memory effects.

\section*{Procedure}

Students were recruited during an open day of the Westfälische Wilhelms-Universität Münster. Groups of students sat down in front of a computer screen to participate in the experiment. We conducted a \(2 \times 2\) experiment with information (personal versus impersonal) as a between-subject factor and audience size (small versus large) as a within-subject factor. After being welcomed the students were randomly assigned to the information conditions. They received a short description of the scenario and entered the communication task. Afterwards students answered the internet literacy questionnaire as a short filler task, being followed by an explanation on how to work on the subsequent memory task. After this memory task students shortly answered questions about their OSNs-usage and socio-demographic details. After completing the experiment students were offered the chance of winning one out of six gift cards for the online shop Amazon. Students were encouraged to leave an email-address so we could explain the purpose of the experiment after data analysis had been completed. They were then thanked for their participation and dismissed.

\section*{Results}

The random assignment to between-subject conditions was successful. Demographic details in the personal condition ( \(n=49 ; 31\) females, 18 males; \(\mathrm{M}=17.55\) years, \(\mathrm{SD}=1.02\) ) did not differ significantly from the impersonal condition, ( \(n=50 ; 34\) females, 16 males; \(\mathrm{M}=17.62\) years, \(\mathrm{SD}=2.76\) ).

\section*{Target Memory}

As a prerequisite for further analysis we assessed if there actually is a target memory problem in comparison to item memory. In order to do so, we compared the mean number of correct audience identifications (small and large

\footnotetext{
\({ }^{1}\) Additionally, students indicated on 5-point Likert-scales how confident they were about the correctness of each of their answers. These results are not reported here as they addressed a different research question that due to space constraints cannot be reported in this paper.
\({ }^{2}\) The results of this questionnaire are not part of this report as no meaningful factor structure could be found in this sample.
}
audiences) as indicator of target memory with the mean number of correct distractor identifications (not disclosed and new facts) as indicator of item memory in a repeatedmeasure ANOVA. Information was the between-subject factor. Item memory significantly exceeded target memory across both information conditions, \(F(1,98)=262.08\), \(p<.001 \eta_{\mathrm{p}}^{2}=.73\) (see Figure 1), indicating better memory for which information had (not) been disclosed than to which audience it was disclosed.

Figure 1: Percentage of correctly identified audiences and distractors per information condition (error bars indicate standard deviations).

We also found a significant main effect for information, \(F(1,97)=46.25, p<.001, \eta_{\mathrm{p}}^{2}=.32\) as well as a significant interaction between the two factors, \(F(1,97)=19.89\), \(p<.001, \eta_{\mathrm{p}}{ }^{2}=.17\). The difference of correct audience and distractor identification was larger in the personal condition than in the impersonal condition.

\section*{Risk Cues}

To test hypotheses two (target memory improves for personal in comparison to impersonal information) and three (target memory improves for large audiences in comparison to small audiences) we computed a \(2 \times 2\) repeated-measure ANOVA with audience size (small vs. large) as repeated-measure factor and information (personal vs. impersonal) as between-subject factor. Our dependent variable was the mean number of correct target identifications in each condition. We found a significant main effect of information, \(F(1,97)=6.15, p<.015\), \(\eta_{\mathrm{p}}{ }^{2}=.06\). Memory performance in the personal condition exceeded performance in the impersonal condition regardless of audience size (see Figure 2). Furthermore, we found a significant main effect for audience size, \(F(1,97)=51.044, p<.001, \eta_{\mathrm{p}}{ }^{2}=.35\). Memory performance was better when the target audience was large opposed to small - regardless of information (see Figure 2). The interaction of the two factors was not significant, \(F(1,97)=.43, p=.51, \eta_{\mathrm{p}}{ }^{2}=.00\). The descriptive results of the memory test also indicate that students had a general
answering bias; students in both information conditions overall answered "large audience" more frequently than "small audience" (see row "Total chosen" in Table 1).

Figure 2: Percentage of correctly identified targets for the experimental factors audience (X-axis) and information (error bars indicate standard deviations).

\section*{Discussion}

\section*{Overall Target Memory}

Participants correctly identified significantly more distractors (new and not disclosed facts) than they identified the associated audiences of disclosed information (small and large audience). We thus confirmed our first hypothesis that item memory would be superior to target memory: Students struggled to remember what information they had disclosed to which audience. Thus our study shows that target memory problems exist online and might contribute to repeated privacy-neglecting behavior in OSNs: Without the memory of what audience has access to which information the cumulative risk of online self-disclosure must be constructed on an abstract level that is weighed out by the immediate benefits of the same behavior. Our study thus not only expands the realm of target memory research but also contributes to further explanations of the circumstances under which privacy-related decisions are made in online environments. Interestingly, error rate analysis shows that participants mainly confused the audiences or the distractors, but rarely identified a disclosed piece of information as a distractor or a distractor as having been disclosed (see Table 1). Thus participants were well aware of what they disclosed, but had trouble remembering to whom. This finding holds the encouraging notion that OSNs users are not blindly "sharing in the dark" - they are not disclosing information without any memory of past revelations whatsoever.

Table 1: Percentages of chosen options per information condition in the memory task.
\begin{tabular}{|c|c|c|c|c|c|}
\hline & \multirow{2}{*}{Correct Response} & \multicolumn{4}{|c|}{Responses given by participants} \\
\hline & & Small & Large & Not Discl. & New \\
\hline \multirow{5}{*}{\begin{tabular}{l}
Personal \\
Information
\end{tabular}} & Small & 49\% & 43\% & 7\% & 1\% \\
\hline & Large & 27\% & 71\% & 1\% & 1\% \\
\hline & Not Discl. & 3\% & 3\% & 84\% & 10\% \\
\hline & New & 1\% & 0\% & 1\% & 98\% \\
\hline & Total chosen & 17\% & 24\% & 35\% & 24\% \\
\hline \multirow{5}{*}{Impersonal Information} & Small & 44\% & 46\% & 5\% & 5\% \\
\hline & Large & 29\% & 62\% & 6\% & 3\% \\
\hline & Not Discl. & 4\% & 5\% & 51\% & 40\% \\
\hline & New & 1\% & 1\% & 9\% & 89\% \\
\hline & Total chosen & 16\% & 24\% & 25\% & 35\% \\
\hline
\end{tabular}

Note: All percentages pertain to rows; for 'Small', 'Large', and 'New' 10 answers were given per participant, for 'Not Discl.' 20 answers were given; 'Not Discl.' is the abbreviation of 'Not Disclosed'; bold marked numbers indicate percentages of correct identifications.

\section*{The Impact of Risk Cues on Target Memory}

Participants identified more target audiences correctly when they informed the audiences about something personal in comparison to impersonal information. We hereby confirmed our second hypothesis. In line with this finding we also found that distractor identification in the personal condition was superior to the impersonal condition (see Figure 1). In line with hypothesis 3, target memory performance also varied with the target audience of the disclosed message. Participants remembered more targets correctly when the audience was large. Furthermore, response rates show that the risk of disclosing something to a large audience seems to be especially salient, since participants more often chose "large audience" in the memory task than "small audience". We can conclude from our results that people are not oblivious to online risks but show a direct cognitive reaction to situational vulnerabilities like telling personal information or telling something to a large audience. It might be that people process the association of target and information in a more elaborate way when they feel vulnerable or when they cannot trust their interaction partners.

\section*{Limitations}

Naturally, this experiment has limitations that we need to consider when interpreting our results. For one, our sample is a non-representative convenience sample. Thus, we do not know if our results can be generalized to other age and
educational groups. Furthermore, in order to transfer the paradigm of target memory to the environment of OSNs we had to make several alterations from the conventional offline paradigm. These alterations restrict a direct comparison of our findings with results from former studies but substantially enhance the ecological validity of our experiment: First, as we could not find an up-to-date validated collection of intimacy-rated items we created new stimulus material for the information conditions. We thereby focused on information that is typically disclosed in online profiles as well as on details about participants' biographical and attitudinal characteristics. The intimacy of these items varies substantially and further research is needed to assess the perceived intimacy of information in different interaction contexts as well as the role of possible self-reference effects in online environments. Second, we changed the classic operationalization of the target in our experiment. Usually a target consists of one single person represented by a photo or name. However, in OSNs users seldom communicate in one-to-one situations but rather address different kinds of audiences. Therefore, it seemed appropriate to adjust the receiving targets so that information would be disclosed to two different kinds of audiences (small vs. large). In this respect it also seems important to note that our experimental design did not allow manipulations of audience familiarity. Therefore, future research is needed to assess the generalizability of our results to real social network communication where people
usually know their audience's members from offline contexts. Finally, our results do not fully explain the underlying cognitive mechanisms that contribute to better memory performance in risk situations. Future studies should therefore attempt to clarify this issue, for example by controlling for decision times in the communication task.

\section*{Implications}

Our results show that users of OSNs actually do react to specific risk circumstances, if these are salient enough to be grasped. This indicates that users probably do not just claim to be concerned about their data (which often contradicts their behavior) but seem to automatically pay more attention to vulnerable situations in online communication. This possibility of a more thorough elaboration offers a direct practical link: From a technical view, privacy-supporting web applications should work on a less subtle and more realistic representation of the potential audience of the to-be-disclosed information. Furthermore, it seems useful to work on ways in which people get a quick overview about what they have disclosed in the past and to whom it is visible. From an educational standpoint, internet literacy programs should sensitize participants to rather subtle online risk cues, for example the degree of publicity. However, these measures cannot and should not stop users from self-disclosing in OSNs altogether since a considerable amount of research also suggests that OSNs-users benefit both emotionally and socially from their usage. The aim of design alterations and educational measures should rather be to achieve a natural consciousness so that privacy-related decisions can be beneficial after all.

\begin{abstract}
Music is known to have a profound impact on human cognitive and emotional response, which in turn are strongly correlated with physiological mechanisms. This paper presents a system that is designed to create original musical compositions that elicit particular physiological responses. The experiments described below demonstrate that the music generated by this system is as effective as human-composed music in effecting changes in skin resistance, skin temperature, breathing rate, and heart rate. The system is particularly adept at composing pieces that elicit target responses in individuals who demonstrated predictable responses to training selections.
\end{abstract}

Keywords: music; emotion; perception; cognition; physiological response; targeted response

\section*{Introduction}

Music can have a profound impact on human physiology. It affects how we think, how we feel, and how we relate to others. It captivates and holds our attention, stimulating many areas of the brain. From movie scenes to dance floors, the added sensory input of music makes activities and situations more enjoyable and compelling. One study found that pleasurable music activated the same areas of the brain activated by other euphoric stimuli such as food, sex, or drugs. They highlight the significance of the fact that music would have a similar effect on the brain as "biologically relevant, survivalrelated stimuli" (Blood \& Zatorre, 2001).

Music's impact on human physiology may help explain its long-recognized ability to sway human emotion. It provides not only a medium for expressing a particular emotion, but also the accompanying physiological change to add significance and depth to that emotion. According to the SchachterSinger theory, emotion is a function of both physiological arousal and cognitive interpretation of that response. The degree of arousal is associated with the degree of emotional response, but it is up to the individual to label that response according to past experience (Schachter \& Singer, 1962).

Music can also have significant power to calm the body and mind. While relaxation responses such as lowered breathing and heart rate may not be as closely tied with emotional perception and cognition, their elicitation can often have significant therapeutic benefits. Numerous studies have demonstrated the ability of music to induce a relaxation response (e.g White, 1999; Lepage et al., 2001; Khalfa et al., 2002).

Both speed and accuracy of task performance can be enhanced with relaxing music (Allen \& Blascovich, 1994).

While there is little question about whether or not music has an effect on humans, predicting the precise effect is challenging. A few effects, however, do seem to be relatively consistent. For example, one study found that more complex rhythms tended to increase the rate of autonomic functions such as breathing and cardiovascular activity. Silence tended to have the opposite effect-lowering breathing rates and heart rates (Bernardi et al., 2006). White (1999) found that heart rate, respiratory rate, and myocardial oxygen demands were lower among patients recovering from myocardial infarctions; Khalfa et al. (2002) found that arousal responses were more likely with pieces that the subjects found to communicate happiness or fear, while pieces described as sad or peaceful tended to decrease arousal. However, even these results only hold true for a majority of individuals. Finding a piece of music that would reliably effect a desired physiological response in a given individual remains a considerable challenge.

Computer-generated music (Chuan \& Chew, 2007; Cope, 2006) may provide some advantages in addressing this challenge. Computers are well-suited to sifting through a large number of both large-scale and fine-grained musical features and to keeping track of which features will most likely have a particular effect. Indeed, some work has been done in generating music to target a listener emotion or mood (Delgado et al., 2009; Rutherford \& Wiggins, 2003; Oliveira \& Cardoso, 2007). In addition, a human composer might be more biased towards features that would effect his or her own physiology when producing compositions. While a reliance on one's own physiological experiences may be inspiring and helpful in the creative process, when it comes to eliciting physiological responses from others, it may also sometimes result in pieces that are less generalizable. Additionally, once they have "learned" how to do so, computers can generate large quantities of music at virtually no cost in terms of time or effort. A computer would have a much easier time generating a number of different potential compositions to effect a desired result in a given individual until it happened upon the right one. Therefore, the ability of a computer to compose music that elicits a target response could have significant benefits.

This paper presents a system capable of generating selections designed to elicit desired physiological responses. Data collected in biofeedback experiments with 96 different subjects show that the system is able to generate selections that elicit an average change in a target physiological response with roughly the same ability level as a human performing the same task. The system is particularly effective at eliciting such a response if an individual's response to other musical selections is known.

\section*{Methodology}

Our approach can be decomposed into three major components: selection of musical pieces to use as training data for our generative models, construction of those models using the training data and evaluating the effectiveness of the models in eliciting the target response when compared to humangenerated music designed for the same targeting task.

\section*{Training Data Selection}

Seventy-two MIDI files were downloaded from the Free MIDI File Database. \({ }^{1}\) Themes from movie soundtracks were used due to the wider variety of emotional content available in this genre. The first forty-five seconds of each piece was isolated for use in experiments.

Biofeedback experiments were conducted to determine effective candidate training pieces. In our preliminary experiments, forty-eight subjects were asked to listen to a number of different training pieces while their heart rate, breathing rate, skin resistance, and skin temperature were monitored. Physiological responses were recorded using the I-330-C2+ biofeedback machine manufactured by J\&J Engineering. All were university-enrolled students or professors. Subjects ranged in age from 18 to 52, with the average age being 22 . Thirty-four males and 14 females participated.

The seventy-two MIDI selections were split into six groups of twelve selections, and each group of songs was played for eight people. \({ }^{2}\) At the beginning of experiments, forty-five seconds of baseline readings were collected. (Subjects were asked to sit quietly and count upwards in their minds during this time in order to achieve neutral results.) Measurements were sampled at one second intervals. For each of the physiological measures, responses were averaged for the duration of baseline readings and for the duration of each of the fortyfive second song samples. Then, a \(z\)-score was calculated for each of the selections, indicating how many standard deviations the average for a given song varied from the baseline.

Responses were then analyzed to determine which selections were most likely to affect a given physiological response. A corpus of training songs comprised of the selections that elicited the largest average change in response was then created for each of the measures studied.

\footnotetext{
\({ }^{1}\) http://themes.mididb.com/movies/
\({ }^{2}\) While the song grouping could likely have been randomly assigned without significantly affecting the results, an attempt was made to make the groupings as similar as possible.
}

\section*{Automatic Music Generation}

Each generative model (one for each targeted response) is composed of four separate modules, for producing rhythm, pitch, harmony and accompaniment.

Rhythm Generator The rhythm for the selection is generated simply by selecting phrases from randomly chosen selections in the training set and stochastically perturbing them. Each new rhythmic phrase is evaluated by two decision tree Rhythm Evaluators (described below). Generated phrases are only used if they are classified positively by both classifiers.
Pitch Generator Once the rhythm is determined, pitches are selected for the melodic line using a probabilistic \(n\)-gram model of melodic progression built from the training corpus. The system generates one hundred possible series of pitches for each rhythmic phrase, and each of the melodies is evaluated by two decision tree Pitch Evaluators (see below). Generated melodies are only selected if they are classified positively by both classifiers.
Harmony Generator The underlying harmony is determined using a hidden Markov model, with melody notes considered as observed events and the chord progression as the latent state sequence. The probability distributions for populating the model are estimated using statistics gathered from the corpus of music representing the target response.

Accompaniment Planner To generate accompaniment, the system takes as input a measure from a song in the training corpus outlining a characteristic baseline, percussion track, and instrumentation. These act as style files for the computergenerated selections - each measure is transposed according to the generated chord pattern, producing accompaniments in much the same manner as a pianist selecting a given style on an electronic keyboard.

Decision Tree Evaluators A set of two evaluators is developed for interacting with the rhythm module and another set of two evaluators is developed for interaction with the pitch module. The first classifier in each set is trained using analyzed selections in the target corpus (e.g. raise heart rate) as positive training instances and analyzed selections from the other corpora (e.g. the other seven responses, lower heart rate, raise breathing rate, etc.) as negative instances. This is intended to help the system distinguish selections that elicit specific physiological response. The second classifier in each set is trained with melodies from all corpora versus thirty-two unevaluated melodies previously generated by the algorithm. In this way, the system learns to distinguish melodies which have already been accepted by human audiences. An example decision tree (identifying features for eliciting raised heart rate response) developed for evaluating the pitch assignment model is shown in Figure 1.

\section*{Evaluation}

A second round of biofeedback experiments was conducted to evaluate the generated musical selections. Forty-eight ad-

ditional subjects participated in this evaluation phase. Again, all were university-enrolled students or professors. Subjects ranged in age from 17 to 46, with the average age being 22. Twenty males and 28 females participated.

Physiological responses were recorded for twenty-four songs (eight computer-generated selections, eight training selections for reference, and eight human-composed selections). To prevent subject fatigue, selections were divided into two groups, one group consisting of pieces targeted to affect breathing and heart rate and one group consisting of pieces targeted to affect skin resistance and skin temperature, and subjects were only asked to listen to one of the groups. Each subject listened to twelve selections; each piece was played for twenty-four people. A Cronbach's alpha coefficient (Cronbach, 1951) was calculated on the responses of subjects in each group to test for inter-rater reliability. Coefficients for the two groups were both \(\alpha=0.99\). (Values over 0.80 are generally considered indicative of a reasonable level of reliability and consequently, a sufficient number of subjects for testing purposes.)

Baseline readings were collected at the beginning of each recording session. Responses were averaged for the duration of baseline readings and for the duration of each of the selections. Since some individuals were more reactive than others, \(z\)-scores are used in analysis instead of absolute changes in measurement. \({ }^{3}\)

After listening to each selection, subjects were asked to respond to the following questions (on a scale from 1 to 9 ):
1. Did you like the selection?
2. How familiar were you with the selection?
3. How musical was the selection?
4. How original was the selection?

\section*{Results}

This section provides tables reporting the average \(z\)-scores for selections designed to elicit the various target physiolog-

\footnotetext{
\({ }^{3}\) Recall that \(z\)-scores calculate the number of standard deviations an average varies from a given baseline. They are calculated by the formula \(z=(x-\mu) / \sigma\), where \(x\) is the average for a given selection, \(\mu\) is the average for baseline, and \(\sigma\) is the standard deviation for readings taken over the duration of the session. Please note that, while \(z\)-scores are sometimes used to calculate statistical significance, in this case, these measures are only being used to normalize scores from one individual to the next. A high Cronbach's alpha value for a low average \(z\)-score indicates that, while a given selection did not tend to elicit a high magnitude change in a response, it was consistent in eliciting a given change for a significant number of subjects.
}

Table 1: Average \(z\)-scores of computer and human-generated selections designed to affect breathing rate
\begin{tabular}{cccc}
\multicolumn{4}{c}{ Lower Breathing Rate } \\
\hline & Overall & \multicolumn{2}{c}{ Adjusted } \\
Average & Included \\
Computer-Generated & -0.27 & -1.33 & \(29 \%\) \\
Human-Composed & 0.13 & -0.90 & \(29 \%\)
\end{tabular}
\begin{tabular}{cccc}
\multicolumn{4}{c}{ Raise Breathing Rate } \\
\hline & Overall & \multicolumn{2}{c}{ Adjusted } \\
Average & Included \\
Computer-Generated & 0.71 & 1.18 & \(46 \%\) \\
Human-Composed & 0.06 & 0.36 & \(46 \%\)
\end{tabular}
ical responses. In most cases, both the computer-generated and human-composed selections were effective at eliciting arousal responses. However, they were less effective at eliciting relaxation responses. This is not surprising considering findings suggesting that music is often more effective than silence at eliciting an arousal response (Bernardi et al., 2006).

Many of the more conclusive studies on the relaxing effects of music deal with subject-selected pieces. Since both the computer-generated and human-composed selections being evaluated are unique to these experiments, subjects would not associate any of them with previous relaxing experiences and consequently experience a relaxation response due to classical conditioning. It would also be difficult for any of the subjects to identify ahead of time which pieces they would find most relaxing. Instead, we look at how subjects responded to the training selections. Each table also reports an adjusted score, calculated by averaging only measurements for individuals for whom the training selections also had the target effect for the measure being considered (reported in the tables as a percentage of the 24 total people that listed to the selection). While a computer-generated piece may not be able to elicit a particular physiological response in all subjects, this adjusted score allows us to measure whether it elicits a response in a specific group of subjects. (e.g. If it is known that a group of individuals react with a lowered breathing rate to a given song or set of songs, the adjusted score reveals how effective the computer might be in using those training pieces to generate a song that also lowers breathing rate.)

\section*{Breathing Rate}

Breathing rate responses tended to vary by up to one breath per minute. (Considering that normal human breathing rates tend to range from 12 to 18 breaths per minute, an average increase of one breath per minute is non-negligible.) The most significant changes tended towards an increase in breathing rates as compared to baseline.

As shown in Table 1, only the computer-generated selection was able to successfully lower breathing rate on the average for all subjects. However, the magnitude of the change was small enough that the average change was not significantly different from the human-composed selections. With the adjusted scores, both computer-generated and human-
composed songs were able to successfully lower breathing rates. Seven individuals- \(29 \%\) of subjects in this groupresponded as expected to the top training selection for lower breathing rate; four responded similarly to the computergenerated selection.

The computer-generated song designed to raise breathing rate was able to accomplish this task more effectively than the human-composed song. The \(0.71 z\)-score for the computergenerated song corresponds to an average increase of over one breath per minute, and the difference in average \(z\)-scores between this and the human-generated song was significant at the \(p<0.05\) level. A similar pattern is seen with the adjusted scores. The average difference between the computergenerated selection and the human-composed song was also significant. Nine of the eleven individuals who responded with elevated breathing rate to training selections targeted to raise breathing rate responded similarly to the computergenerated selections.

Note that the computer-generated selections designed to lower breathing rate are as effective at doing so as the humancomposed selections. The computer-generated selections designed to raise breathing rate are performing this task at a level that exceeds that of human performance.

\section*{Heart Rate}

Changes in average heart rate were not quite as pronounced. While individual heart rates could vary by up to fifty beats per minute over the course of a session, the average range for a given individual was only ten beats per minutes. When averaged over all subjects, reactions to songs only varied by a couple of beats per minute.

As shown in Table 2, only the human-composed selection was able to reduce average heart rate, although the difference in mean heart rate variation was not significant at the \(p<\) 0.05 level. With the adjusted scores, the computer-generated selection proved more effective at lowering heart rate. For five of the eight individuals whose heart rate lowered for the top training selection, heart rates were also lowered for the computer-generated songs in these categories.

The computer-generated song was the most effective at raising average heart rate for all subjects, though the difference was not statistically significant. The computergenerated song was also more effective at raising heart rate using the adjusted score, but not significantly so. Ten of the thirteen individuals who responded as expected to the training selection for raising heart rate also had their heart rates raised by the computer-generated selection.

As with breathing rate, the computer appears to be addressing the task of composing music that lowers or raises heart rate at a level comparable to that of human performance.

\section*{Skin Temperature}

Skin temperature tended to rise, on average, by two degrees during the course of the session for most subjects, regardless of the piece of music being played. Not surprisingly, all selections were better at raising average skin temperature for all

Table 2: Average \(z\)-scores of computer and human-generated selections designed to affect heart rate

Lower Heart Rate
\begin{tabular}{cccc}
\hline & \multirow{2}{c}{ Overall } & \multicolumn{2}{c}{ Adjusted } \\
Average & Included \\
Computer-Generated & 0.40 & -0.40 & \(33 \%\) \\
Human-Composed & -0.20 & -0.61 & \(33 \%\)
\end{tabular}

Raise Heart Rate
\begin{tabular}{cccc}
\hline & \multicolumn{2}{c}{ Overall } & \multicolumn{2}{c}{ Adjusted } \\
Average & Included \\
Computer-Generated & 0.72 & 1.09 & \(54 \%\) \\
Human-Composed & 0.12 & 0.53 & \(54 \%\)
\end{tabular}

Table 3: Average \(z\)-scores of computer and human-generated selections designed to affect skin temperature
\begin{tabular}{cccc}
\multicolumn{4}{c}{ Lower Skin Temperature } \\
\hline & Overall & \multicolumn{2}{c}{ Adjusted } \\
Average & Included \\
Computer-Generated & 2.18 & -1.22 & \(17 \%\) \\
Human-Composed & 1.23 & -1.84 & \(17 \%\)
\end{tabular}

Raise Skin Temperature
\begin{tabular}{cccc}
\multicolumn{4}{c}{ Raise Skin Temperature } \\
\hline & Overall & \multicolumn{2}{c}{ Adjusted } \\
Average & Included \\
Computer-Generated & 2.22 & 3.03 & \(83 \%\) \\
Human-Composed & 1.75 & 2.49 & \(83 \%\)
\end{tabular}
subjects than they were at lowering it.
However, when individual subjects did have their skin temperature lowered by a training set selection, they also tended to have their skin temperature lowered by pieces generated from those selections. This was true for all four of the individuals whose temperature was lowered by the training selection targeting lower skin temperature. The adjusted score for the human-composed selection designed to lower skin temperature was lower than the adjusted score for the computergenerated piece, but the difference was not statistically significant at the \(p<0.05\) level.

The computer-generated piece was significantly more effective at raising skin temperature than the human-composed pieces when considering both the regular and the adjusted averages. However, this is almost certainly an artifact of the order in which the pieces were played. (The software used in these experiments did not allow for a randomized order of selection presentation that was unique to each subject.)

While it appears that an effective method of raising skin temperature would simply be composing a piece with sufficient duration, the computer seems as competent at the task as a human. Composing music that lowers skin temperature appears to be a much harder task, but again, these experiments show no statistically significant difference between the performance of the computer and the human.

Table 4: Average \(z\)-scores of computer and human-generated selections designed to affect skin resistance

Lower Skin Resistance
\begin{tabular}{cccc}
\hline & \multicolumn{3}{c}{ Overall } \\
Adjusted \\
Computer-Generated & -0.87 & -2.48 & Included \\
Human-Composed & -1.06 & -2.00 & \(63 \%\) \\
\multicolumn{4}{c}{ Raise Skin Resistance } \\
\hline \multicolumn{4}{c}{ Adjusted } \\
Computer-Generated & Overall & Average & Included \\
Human-Composed & -1.06 & 2.27 & \(33 \%\) \\
& -1.03 & 0.21 & \(33 \%\)
\end{tabular}

\section*{Skin Resistance}

Most of the selections were likely to elicit an arousal response (lower skin resistance). However, unlike skin temperature, the effect was not cumulative over the course of the session.

For compositions designed to lower skin resistance, there was no significant difference between the computergenerated selection and the human-generated selection. The training selections lowered skin resistance in fifteen individuals. With the adjusted scores, computer-generated selections were more successful at lowering skin resistance than the human-composed song, though the difference was not statistically significant.

There was also no significant difference between the computer-generated selection designed to raise skin resistance and the human-composed selection. The training selection raised skin resistance in eight individuals and those subjects for whom it did have the target effect also reacted strongly to the selection generated from all the training soundtracks, with the improvement over the humancomposed selection being significant at the \(p<0.05\) level.

As with the other measures, the computer is able to generate music that elicits change in skin resistance as effectively or more effectively than a human composition.

\section*{Subjective Responses}

Average responses to the subjective questions asked after each selection are shown in Table 5. Not surprisingly, the initial training selections and the human-composed selections received higher rating for likability and musicality. However, the computer-generated selections received slightly higher ratings for originality and significantly lower ratings for familiarity than the training selections and human-composed selections-evidence to suggest that the computer is producing genuinely original compositions and not borrowing too heavily from training data.

As shown in Table 6, there was no correlation between subjective responses and physiological changes. While for some individuals, liking a song might result in a more dramatic increase or decrease in a given physiological response, this does not appear to be the case overall.

Table 5: Average results to subjective questions (Responses were measured on a scale of 1 to 9 )
\begin{tabular}{cc}
\multicolumn{2}{c}{ Did you like the selection? } \\
\hline Training Selections & 5.83 \\
Computer-Generated Selections & 3.97 \\
Human-Composed Selections & 5.56
\end{tabular}

How familiar was the selection?
Training Selections \(\quad 5.53\)
Computer-Generated Selections 2.17
Human-Composed Selections 3.01
How musical was the selection?
Training Selections \(\quad 5.35\)

\begin{tabular}{cc}
\hline Training Selections & 6.36 \\
Computer-Generated Selections & 6.97 \\
Human-Composed Selections & 6.70
\end{tabular}

Table 6: Correlations between subjective responses and physiological measures
\begin{tabular}{ccccc} 
& Like & Familiar & Musical & Original \\
\hline Breathing Rate & 0.02 & 0.03 & 0.03 & -0.04 \\
Heart Rate & 0.03 & -0.01 & 0.04 & 0.09 \\
Skin Temperature & 0.04 & 0.04 & 0.00 & -0.06 \\
Skin Resistance & -0.03 & -0.05 & -0.02 & -0.03
\end{tabular}

\section*{Musical Features}

Musical characteristics identified by the evaluating decision trees as being responsible for various physiological responses may be only briefly touched on here. Pieces that raised heart rates tended to have more dissonance and more scale-wise movement. Pieces that lowered heart rate, on the other hand, tended to have less rhythmic variety (perhaps contributing to more flowing rhythms) and a stronger climax.

Melodies that tended to raise breathing rate tended to higher rhythmic variety and either a non-tonal climax note or lower climax strength. Somewhat surprisingly, melodies that lowered breathing rate also tended to have higher rhythmic variety, but also some syncopation and a tendency to upward pitch direction.

Features contributing to a lowered skin temperature response included stability of melodic direction and a non-tonal climax. In other words, upward movement towards a climax that involved a non-tonal suspension note were arousing. A greater pitch range also contributed to lowered skin temperature. Pitch movement by minor tonal step leading to a strong climax tended to contribute to raised skin temperature.

Melodies that tended to lower skin resistance had lower pitch variety and less stability of melodic direction; some of these arousing melodies tended to bounce back and forth between notes. Melodies that raised skin resistance had a greater stability of melodic direction, as well as less rhyth-

Table 7: Ability to elicit arousal response via musical stimuli ( \(\mathrm{RBR}=\) raise breathing rate; \(\mathrm{RHR}=\) raise heart rate; \(\mathrm{LST}=\) lower skin temperature; \(\mathrm{LSR}=\) lower skin resistance)
\begin{tabular}{ccccc}

\hline
\end{tabular}
mic variety and range.

\section*{Conclusion}

Tables 7 and 8 summarize how effective we were at eliciting a change in physiological responses in various situations.

Neither the computer-generated nor the human-composed selections were able to lower average skin temperature, but both computer-generated and human-composed selections designed to elicit the other arousal responses (raised breathing rate, raised heart rate, and lowered skin resistance) were, on average, able to do so successfully. In the case of breathing rate, the computer generated song was able to raise breathing rate more effectively than the human-composed song at a level that was significant (marked with asterisk).

When considering only subjects who responded as expected to the training selections, both the computer-generated and human composed songs were successful at eliciting an average arousal response for all of the measures studied. For breathing rate and skin resistance, the difference between the computer-generated selection and the human-composed selection was significant, the computer-generated one again being more effective at eliciting the target response.

Eliciting relaxation responses proved more challenging for both the computer-generated and human-composed selections. Both were able to raise skin temperature, but neither was able to raise skin resistance. Only the computergenerated selection was able to lower heart rate, and only the human-composed selection was able to lower breathing rate. The difference between the computer-generated and humancomposed songs was not statistically significant.

When considering adjusted scores, both the computergenerated and human-composed selections were able to elicit all target relaxation responses. In the case of skin resistance, the computer-generated song was significantly better at raising average response.

Overall, the system proves itself able to generate songs that elicit target physiological responses with similar effectiveness to songs generated by a human composer. Both still require information about a given individual's physiological responses in order to generate a new piece that also reliably elicits those responses in many categories. However, given the variability of human biofeedback responses, the ability to consistently effect targeted physiological responses under any conditions can be viewed as fairly impressive.

Table 8: Ability to elicit relaxation response via musical stimuli (LBR = lower breathing rate; LHR = lower heart rate; RST \(=\) raise skin temperature; \(\mathrm{RSR}=\) raise skin resistance)
\begin{tabular}{ccccc}

\begin{abstract}
We model the semantic recall sequences of 424 older adults aged between 69 to 103 years in the animal fluency task. Our results suggest that, under normal intellectual functioning, memory search in old age (69-84 years) is consistent with a dynamic process that switches between retrieval probes. With dementia and very old age (85-103 years), however, memory search seems to become more consistent with a static process that activates items in memory as a function of their frequency. The weight that probes have in determining the activation of items in memory seems to be an informative signature of the impact of healthy aging and dementia on memory search. Our results show that, with healthy aging and dementia, the activation of items in memory is increasingly more determined by the frequency of past experience with those items.
\end{abstract}

Keywords: Search; semantic memory; modeling; aging.

\section*{Introduction}

Ronald Reagan became the oldest president elected in American history, when he took office at age 69, in 1981. He was diagnosed with Alzheimer's in 1993, the most common form of dementia, four years after he left office. Yet Reagan's signs of memory decline while in office - like forgetting names and being at a loss for words - have led to much speculation about how early dementia had set in. The question was whether his memory slips were a sign of normal aging or rather the early symptoms of dementia.

Studies using the animal fluency task ("name all the animals you can think of'; Thurstone, 1938) have shown that healthy older adults recall fewer items relative to younger adults within a limited time interval (e.g., Hills, Mata, Wilke, \& Samanez-Larkin, 2013; Kozora \& Cullum, 1995), in much the same way as older adults with dementia produce fewer items compared with healthy older adults (e.g., Beatty, Salmon, Testa, Hanisch, \& Troster, 2000; Epker, Lacritz, \& Cullum, 1999). In this paper, we examine how healthy aging and dementia impact search in semantic memory beyond the sheer reduction in the number of recalls. To this end, we formally model the recall sequences of 424 older adults aged between 69 to 103 years in the animal fluency task. We then examine individual differences in model fit and parameter estimates, as a way of identifying signatures of cognitive decline in memory search with healthy aging and dementia.

\section*{Static and Dynamic Search in Semantic Memory}

Memory retrieval can be viewed as the result of probing a memory representation with one or more probes to activate a response (e.g., Gronlund \& Shiffrin, 1986; Walker \&

Kintsch, 1985). We apply two classes of models based on prior work - static vs. dynamic - that make different assumptions about how retrieval probes are used to search memory in the fluency task (Hills et al., 2013). Consider the following two types of probes. One type of probe, the frequency probe, activates animal names in memory as a function of their frequency of past occurrence. A second type of probe, the similarity probe, activates each item in relation to its semantic similarity to the previously-recalled item. In a static model, search is guided by the same probe arrangement over the entire recall interval (i.e., by either probe alone or by a combination of the two). A dynamic model, on the contrary, switches between a frequency probe and a probe that combines frequency and similarity to traverse clusters of similar items in memory. When leaving a cluster, a dynamic model uses frequency alone to find a new cluster, and goes back to using a combination of frequency and similarity information as the new cluster is entered. Past work has found that, from early to late adulthood, search in memory is overall more consistent with a dynamic search model than with a static model that uses the same probe arrangement during the entire recall sequence (Hills et al., 2013).

In this paper, we examine the relative fit of static and dynamic models in old and very old age, for healthy individuals and individuals diagnosed with dementia. In very old age, do people use memory retrieval probes more in accordance with a dynamic model than with a static model as younger cohorts do? Moreover, we test alternative mechanisms of decline in memory search by investigating individual differences in the use of retrieval probes. We next turn to a brief discussion of the alternative mechanisms of decline in memory search.

\section*{Mechanisms of Decline in Memory Search}

Existing hypotheses proposed to account for age-related differences in the number of items produced in fluency tasks make different assumptions about how memory search declines with aging. The age invariance hypothesis proposes that aging is associated with unaffected semantic processing, and thus predicts no age differences in the use of retrieval probes (Mayr \& Kliegl, 2000). Two alternative hypotheses argue that the impact of aging affects the ability to switch between probes. The cluster-switching hypothesis views memory retrieval as a dynamic process involving a search for semantic categories like "pets", and a search for words within a category (e.g., "dog") (Troyer, Moscovitch, \& Winocur, 1997; Troyer, 2000). A common finding is that aging is associated with fewer total switches between categories, leading to the proposal that aging is associated
with reduced switching between retrieval probes (categories) (Troyer et al., 1997; Troyer, 2000). On the other hand, the cue-maintenance hypothesis (Hills et al., 2013) derives from studies showing that aging is associated with lower working memory capacity, defined as the ability to keep focus on one probe while ignoring distracting ones (e.g., Bopp \& Verhaghen, 2007). Age-related decline in working memory capacity should lead to a loss of probe focus, and therefore to increased switching between probes (e.g., Unsworth \& Engle, 2007). Existing evidence suggests that, from early to late adulthood, age is associated with an increase in switching between probes, per item recalled, in support of the cue-maintenance hypothesis of decline in memory search (Hills et al., 2013).

We examine which mechanism of decline best describes individual differences in switching in old (69-84 years) and very old age ( \(85-103\) years), between healthy individuals and individuals diagnosed with dementia. These mechanisms of decline, which have been proposed to account for age-related differences in fluency performance, can be used to test additional alternative hypotheses regarding memory decline in dementia. One hypothesis holds that memory impairment in dementia results from the acceleration of the same mechanism that leads to memory decline in healthy aging (e.g., Brayne \& Calloway, 1988; Huppert, 1994; Huppert \& Brayne, 1994). On this view, age-related differences in switching among individuals diagnosed with dementia should mirror age-related differences in healthy individuals. According to an alternative framework, however, memory decline in healthy individuals and in individuals with dementia is the product of distinct processes that target different brain systems (e.g., Albert, 1997; Gabrieli, 1996). This framework thus suggests that age-related differences in switching should arise from distinct decline mechanisms in healthy aging and dementia.

To summarize, we examine whether semantic search in healthy old age and dementia is more consistent with a static or with a dynamic model. Moreover, we test different mechanisms of decline in memory search by investigating individual differences in model fit and parameter estimates.

\section*{Methods}

\section*{Participants and Procedure}

The present work uses data from the Berlin Aging Study, a longitudinal study on aging (Baltes \& Mayer, 1999). Specifically, we analyze the animal fluency data that was collected in the first measurement occasion of the study, between 1990 and 1993. In the animal fluency task, participants were asked to respond verbally to the probe "Name all the animals you can think of" within 90 seconds, with their responses being tape-recorded. We retrieved participants' retrieval sequences from the tapes that were still functional, having compiled the responses of 424 individuals, with ages ranging from 69 to 103 (mean \(=\) 84.77, \(S D=8.58\) ). Of these 424 individuals, 91 were diagnosed with dementia (mean age \(=90.31, S D=6.53\) )
according to the guidelines of DSM-III-R, and 333 individuals (mean age \(=83.25, S D=8.45\) ) were considered to have normal intellectual functioning.

\section*{The Representation of Semantic Memory}

The first step towards formalizing search in semantic memory is to provide an explicit representation of the space being searched. We used the semantic representations of animals computed in prior work (Hills, Jones, \& Todd, 2012) using the BEAGLE semantic space model (Jones \& Mewhort, 2007). The BEAGLE model was trained on a subset of Wikipedia, composed of approximately 400 million word tokens and 3 million word types. Once the entire corpus has been learned (see Hills et al., 2012, for a description of the learning process), a word's memory representation is a vector pattern reflecting the word's history of co-occurrence with other words. Words that frequently co-occur end up developing similar vector patterns (e.g., bee-honey), as do words that commonly occur in similar contexts, even if they never directly co-occur (e.g., bee-wasp). Based on the representation learned by BEAGLE, we used the frequency of occurrence of each animal name in the Wikipedia corpus as well as the pairwise cosine similarities between animal names for our comparisons.

\section*{Alternative Models of Semantic Search}

To describe memory retrieval given this well-defined memory representation, we used a model framework similar to the item-level recall probability equation from the Search of Associative Memory model (SAM; Raaijmakers \& Shiffrin, 1981):
\[
\begin{equation*}
P\left(I_{i} \mid Q_{1}, Q_{2}, \ldots, Q_{M}\right)=\frac{\prod_{k=1}^{M} S\left(Q_{k}, I_{i}\right)^{\beta_{k}}}{\sum_{j=1}^{N} \prod_{k=1}^{M} S\left(Q_{k}, I_{j}\right)^{\beta_{k}}} \tag{1}
\end{equation*}
\]
where \(S\left(Q_{k}, I_{i}\right)\) represents the retrieval strength from probe \(Q_{k}\) to item \(I_{i}\) in memory, and \(w_{k}\) represents the saliency or attention directed at the \(k^{\text {th }}\) probe. The probability of retrieving a given item, \(I_{i}\), is given by the ratio of the activation strength of that item and the sum of the activation of all other items in memory given those same probes. Finally, \(\beta\) is a free parameter that indicates how strongly the person's recall was determined by the probe; higher values of \(\beta\) lead items with higher retrieval strengths for a given probe, \(Q_{k}\), to gain a larger share of the recall probability, while lower values of \(\beta\) distribute the probability of recall more evenly over all items.

We considered the frequency probe and the similarity probe introduced earlier in the paper. The frequency probe activates each item in memory as a function of the frequency of occurrence of each animal name in the Wikipedia corpus. The similarity probe activates each item in memory in relation to its semantic similarity to the
previous item recalled. Thus, the most recently recalled item is the probe used to query memory, and activation is defined as the pairwise semantic similarities produced by BEAGLE with all animals yet to be recalled. Given a particular probe arrangement, we can compute the predicted retrieval probability for any sequence of animal names by repeatedly using Equation 1. The \(\beta\) parameters were fit to each participant's data to maximize the observed recall probabilities and produce a maximum likelihood fit.

We tested four models differing in the nature of probe use. All models share the assumption that the probability that an item is the first item recalled is a function of its frequency. From the second recall onwards, the models differ in whether they use frequency and similarity information in a static or dynamic way. Static models use the same probe arrangement over the recall interval. The static frequency model uses a single probe: frequency. This assumes that individuals' recall sequences of animals reproduce their natural strength of activation in memory as a consequence of frequency alone. The static similarity model also uses a single probe: semantic similarity. This assumes that individuals rely only on the previously recalled item as a probe for the next recall, producing a chain of pairwise associated animals. The static combined model represents the simultaneous combination of frequency and semantic similarity. This assumes a process based on semantic similarity to the previous item that is further informed by the frequency of past experience with those items.

The dynamic model switches between a frequency probe and a probe that combines frequency and similarity to traverse clusters of similar items in memory. When leaving a cluster, a dynamic model uses frequency alone to find a new cluster, and goes back to using a simultaneous combination of frequency and similarity information as the new cluster is entered. Transitions are predicted by the model only after they occur, meaning that the model tests where the most plausible locations for transitions are, given the underlying representation. The model switches between retrieval probes wherever a sequence of items \(\mathrm{A}, \mathrm{B}, \mathrm{C}, \mathrm{D}\) have semantic similarities that follow the pattern \(S(A, B)>\) \(S(B, C)\), and \(S(B, C)<S(C, D)\). That is, similarity drops between clusters and then increases again once search resumes with a new cluster (e.g., the sequence DOG, CAT, SHARK, WHALE would have two clusters, divided by a similarity drop between CAT and SHARK).

In our data, healthy aging and dementia are associated with an increase in the proportion of items repeated. For this reason, and in contrast to previous studies (Hills et al., 2012, 2013; Hills \& Pachur, 2012), we did not exclude repetitions from participants' retrieval sequences, nor did we remove items from the memory representation after they were recalled. Although the current models do not distinguish new responses from repeated ones when calculating the retrieval probabilities, we are currently developing a generalized version of the models that takes into account how likely participants are to repeat previous responses.

\section*{Results and Discussion}

Figure 1 shows the mean number of correct responses produced in old and very old age, for healthy individuals and individuals diagnosed with dementia, calculated after excluding repeated items. Throughout our analyses, the group "old age" includes participants with ages between 69 and 84 years, and the group "very old age" includes participants with ages between 85 and 103 years. As expected, age was associated with recalling fewer items \((\mathrm{t}(422)=-11.32, \mathrm{p}<.001, \mathrm{r}=-.48)\). The mean number of correct responses produced decreased with age, both for healthy individuals and individuals with dementia. In addition, individuals with dementia produced fewer correct responses relative to individuals without dementia \((\mathrm{t}(422)=\) \(-12.03, \mathrm{p}<.001, \mathrm{r}_{\mathrm{pb}}=-.51\) ). These results indicate that both healthy aging and dementia are associated with a decline in the number of items retrieved from memory. In what follows, we present our results for the modeling of semantic retrieval in old and very old age.

Figure 1: Mean number of correct responses produced in each group. Error bars represent the standard error of the mean.

\section*{Do people switch between retrieval probes in old and very old age to navigate their semantic memory?}

Table 1 presents the Bayesian Information Criterion (BIC) of the four models. BIC is a commonly used measure to compare the fit of different models while penalizing them for the total number of free parameters that they have, as a way of reducing overfitting (Lewandowsky \& Farrell, 2011). Whereas the static single-probe models have only one free parameter, the models that use both frequency and similarity have two free parameters, each indicating how strongly the person's recall was determined by each type of information. Note that smaller values of BIC indicate a better model fit. Also, due to differences in the number of items recalled, the BIC values for the different models are only informative if compared within groups.

Table 1: Median Bayesian Information Criterion (BIC) of static and dynamic models per group.

& \((95.69)\) & \((92.33)\) & \((54.68)\) & \((79.68)\) \\
\hline
\end{tabular}

Note. Standard deviations are shown in parentheses.
The static, frequency model fit the data of all four groups better relative to the static, similarity model, suggesting that the best single predictor of recall was frequency rather than similarity. The pattern of results is, however, mixed across groups with respect to the fit of the models that use both frequency and similarity. The recall sequences of healthy individuals aged between 69-84 years were better fit by the static, combined model than by the two static single-probe models. Moreover, the model that incorporates dynamic transitions between probe arrangements outperformed the static combined model, being therefore the best fitting model for healthy individuals aged between 69-84 years. This finding is in line with past work showing that younger cohorts search memory according to a dynamic process that switches between a frequency probe and a probe that integrates frequency and similarity (Hills et al., 2013).

For the other groups of participants, however, the results show smaller differences in BIC between the static model that relies exclusively on frequency information and more complex models that use both frequency and similarity in a static or dynamic fashion. This suggests that the static frequency model may give a comparatively better account of memory search in very old age and dementia than for the healthy younger cohort. Yet the smaller BIC differences between models indicate that it is difficult to distinguish between them in very old age and dementia, thus calling for other methods to address the model selection problem.

\section*{How do healthy aging and dementia impact memory search?}

The number of switches per item was essentially unrelated to the total number of items recalled \((\mathrm{t}(422)=-1.21, \mathrm{p}=.22\), \(\mathrm{r}=-.06\) ). Additionally, it was also not related with age \((\mathrm{t}(422)=-1.05, \mathrm{p}=.29, \mathrm{r}=-.05)\), or with the presence of dementia \(\left(\mathrm{t}(422)=.87, \mathrm{p}=.38, \mathrm{r}_{\mathrm{pb}}=.04\right)\). Contrary to the cluster-switching and the cue-maintenance hypotheses, both of which posit specific changes in switching with increased age, these results seem to suggest that there are no differences in the nature of probe utilization with increased age, in support of the age invariance hypothesis. This result
is not consistent with the age-related increase in switching found in previous work for a younger cohort (Hills et al., 2013), suggesting that different mechanisms of decline may be at play in adulthood and later in life. Additionally, the finding that dementia was, as for healthy aging, unrelated with switching suggests that the decline of memory search in dementia may result from the acceleration of the same mechanism that leads to decline in healthy aging.

We believe, however, that there is an alternative, more sensible interpretation of these findings. As seen above, as people age, a static model appears to be better supported relative to a dynamic model. Thus, the number of switches per item recalled may not be an appropriate signature of the impact of very old age and dementia on memory search. A more informative signature of the decline of memory search in old age may be given by the free parameter, \(\beta\), which provides a measure of the deterministic nature of the activation given a specific retrieval probe. Different cohorts of healthy older adults and older adults with dementia may search memory in different ways, and these may influence the estimates of the \(\beta\) parameter. Higher values of \(\beta\) for the frequency probe lead very frequent items to have a larger share of the recall probability. Likewise, higher values of \(\beta\) for the similarity probe give a larger share of the recall probability to items that are very similar to the previouslyrecalled item. Lower values of \(\beta\) distribute the recall probabilities more evenly over all items in memory. Individual differences in the estimates of the \(\beta\) parameter may thus suggest alternative mechanisms of decline of memory search, whereby memory probes are given different weights in determining the recall probabilities.

Figure 2 plots the mean estimates per group for the \(\beta\) parameters corresponding to the frequency probe (panel A) and the similarity probe (panel B) in the static, combined model. Note that the parameter estimates are not comparable between probes due to the different scales of the Wikipediadefined frequencies and semantic similarities.

Figure 2: Mean estimates per group for the \(\beta\) parameters corresponding to the frequency probe (A) and similarity probe (B) in the combined static model. Error bars represent the standard error of the mean.

Figure 2 shows that, for individuals with normal intellectual functioning, there was an age-related increase in the estimates for the frequency probe, and a decrease in the estimates for the similarity probe. This indicates that memory search is more strongly determined by item frequency in very old age, but the weight of semantic similarity seems to decrease. For individuals diagnosed with dementia, the results demonstrate that there are no age differences in the estimates for either retrieval probe. However, the results suggest an association, independent of age, between dementia and the increasing weight of item frequency in determining the probability of recall.

This increase in the saliency of the frequency probe may be related to the observed increase in the proportion of repeated items with age \((\mathrm{t}(422)=6.07, \mathrm{p}<.001, \mathrm{r}=.28)\) and dementia \(\left(t(422)=8.04, p<.001, r_{p b}=.36\right)\). Figure 3 shows the mean of the log-transformed Wikipedia-defined frequencies for newly occurring items and repeated items produced as a function of age (panel A) and dementia diagnosis (panel B).

B

Figure 3: Mean Wikipedia-defined frequencies for new and repeated items produced as a function of age (A) and dementia diagnosis (B). Error bars represent the standard error of the mean.

In both age and dementia groups, repeated items had overall higher frequencies when compared with items recalled for the first time. Moreover, both age and dementia were associated with an increase in the Wikipedia-defined frequencies of the items repeated and, especially, of newly occurring items. Further modeling efforts are required to explore the contribution of repetitions to the higher saliency of the frequency probe in very old age and dementia.

\section*{Conclusion}

Our results suggest that, in the absence of dementia, memory search in early old age is consistent with a dynamic process that switches between a frequency probe and a probe that integrates frequency and similarity to traverse clusters of items grouped in memory by semantic similarity. This finding is in line with past work showing that younger cohorts search memory according to a dynamic process (Hills et al., 2013). However, in very old age and dementia, memory search processes appear to become more static, relying more on frequency to probe memory.

Our results further show that the proportion of switches between probe arrangements is unrelated with age and with the presence of dementia for older individuals. This result is in contrast with findings from previous studies showing that younger cohorts switch more often between probes with increasing age (Hills et al. 2013), thus suggesting that different mechanisms of decline may be at play in adulthood and later in life. Yet the saliency of memory retrieval probes may be a more informative signature of the impact of very old age and dementia on memory search. We have shown that, with healthy aging and dementia, the activation of items in memory is increasingly determined by the frequency of past experiences with those items. This result is consistent with the finding above that, in very old age and dementia, memory search appears to become more consistent with a static process that uses frequency to probe memory. Finally, the increase in the saliency of the frequency probe seems to be related with the increase in the number of repetitions. While age is associated with an increase in the number of repetitions, the items people repeat have a higher frequency of past occurrence compared with items recalled for the first time.

\begin{abstract}
In this study, we tested the hypothesis that social relationships affect the perception of distance. When participants imagined passing through a wall and a disliked-person, they perceived shorter aperture widths than when they intended to pass between a wall and a liked-person. This result was observed only for passable apertures suggesting that social constraints may influence visual perception only when people can actually perform this action. We discuss the results according to an embodied approach to visual perception but also with an alternative explanation in terms of possible demand characteristics. We also discuss some methodological points supposed to improve the validity of such experiments.
\end{abstract}

\section*{Introduction}

According to Proffitt and Linkenauger (2013) the visual perception of space depends on the phenotype of the perceiver. More precisely, the optical information would be scaled on the morphological, physiological, and behavioral properties of the body. For instance, decreasing people's ability to reach an object leads them to perceive it as being farther away (e.g., Lourenco \& Longo, 2009; Morgado, Gentaz, Guinet, Osiurak, \& Palluel-Germain, in press).
Previous works tried to extend this account to the influence of social factors on visual perception (Chambon, 2009; Harber, Yeung, \& Iacovelli, 2011; Morgado, Muller, Gentaz, \& Palluel-Germain, 2011). For example, Schnall, Harber, Stefanucci, \& Proffitt (2008) observed that people underestimate the slant of a steep hill when they are accompanied by a friend instead of being alone. According
to the authors, this difference in slant estimation reflects that social support, as a social resource, can compensate the potential effort associated with climbing the hill and thus reduces its perceived steepness.
In some cases, however, the social constraints associated with a given action constitute a cost rather than a resource. Previous works suggest that people maintain a personal space around them and that they feel discomfort when someone invades this space (Hayduk, 1983). Moreover, this discomfort seems to increase as the physical interpersonal distance decrease (Hayduk, 1981). Interestingly, the discomfort associated with personal space invasion seems to vary according to the social relationship (Sundstrom \& Altman, 1976). Consistent with these findings, we recently observed that people's action-scaled perception of a space between two acquaintances is correlated with the participants' affective closeness toward these acquaintances (Morgado et al., 2011). Indeed, the closer participants felt to their classmates, the more passable the space between the classmates pictures appeared and the less space they needed to pass. These results might suggest that participants perceived the space between the two classmate pictures (i.e., the aperture width) differently because of the closeness feeling.
In the present study, we aimed to investigate further whether social relationships influence the visual perception of an aperture between a wall and an acquaintance. More precisely, participants had to estimate the width of an aperture between the picture of a wall and that of a human figure evoking a liked person or a disliked person. Participants also indicated if the aperture was wide enough to allow them to pass. Our hypothesis was that the participants from the disliked-person group should perceive smaller apertures than participants from the liked-person
group. Moreover, this study aimed to replicate the observed correlation between affective closeness and the passability judgments.

\section*{Method}

\section*{Participants}

Sixty undergraduates ( 52 females; \(M_{\text {age }}=21, S D_{\text {age }}=3\) ) from the University of Grenoble took part in this experiment for course credit. The participants had normal or corrected-to-normal vision, as indicated by self-report. None had participated in our previous study. The present study was conducted in accordance with the Declaration of Helsinki and with the understanding and the written consent of each participant. It was approved by the local ethics committee of the LPNC (CNRS and the University of Grenoble).

\section*{Apparatus and procedure}

To manipulate social relationships, we chose to use a similar mental imagery task as the one used by Schnall et al. (2008). Participants sat down in front of a computer for the mental imagery task. Headphones provided the instructions to the participants who were randomly assigned to the disliked-person or the liked-person group (respectively, \(n=\) 31 and \(n=29\) ). Using headphones enabled the experimenter to be blind to experimental groups while increasing standardization of the instructions.

The instructions indicated that the experiment concerned visual perception of space and that participants would have to estimate the width of an aperture between a picture of a wall and a human figure. Instructions underlined that recent studies indicated that such a task is too difficult in artificial situations. Supposedly to make the task more natural, they had to imagine that the human figure was an acquaintance. At the beginning of the mental imagery task, participants had to complete a relaxation exercise. Then, participants in the disliked-person group had to choose an acquaintance who they did not like at all and who made them uncomfortable. In contrast, participants in the liked-person group had to choose an acquaintance that they liked very much and who made them feel good. Participants could take all the time they needed to choose this acquaintance and they pressed a key to hear the next instructions. Then, they had to imagine the presence of this acquaintance while thinking about their feeling toward this person, while visualizing his or her physical appearance, and while keeping in mind how they usually interact with this person. At the end of this mental imagery task, the instructions indicated that participants had now to estimate aperture width and they had to keep in mind a picture of the chosen acquaintance.
For the perceptual task, participants stood at 3.7 m in front of a white screen on which the picture of a wall and those of a human figure were projected (Figure1). The
dimensions of the two pictures were identical (height: 169 cm , width: 41.5 cm ). The instructions were projected on the screen at the beginning of this task. Throughout this task, participants had to imagine the previously chosen acquaintance in place of the human figure projected on the screen. Since the constraints of a given action influence the perception mainly when people intend to perform this action (e.g., Witt, Proffitt, \& Epstein, 2005), participants had to imagine passing through the aperture between the wall and their acquaintance before each width estimation. Since arm posture seems to influence perceived aperture widths (Stefanucci \& Geuss, 2009), participants had to keep their arms along their body. To estimate the aperture widths, participants completed a visual-matching task (for a similar measure see Stefanucci \& Geuss, 2009). The experimenter stood at 190 cm from the participants' right side and progressively unrolled a tape measure located at 130 cm from the floor. Participants had to stop the experimenter when they considered that the length of the tape measure was equal to the aperture width. To reduce the potential experimenter effect on participants' estimations, the experimenter could not see which aperture width the participants had to estimate. Moreover, the experimenter tried hard to keep his gaze on a fixed point in the wall in front of him while unrolling the tape measure. Neither the experimenter, nor the participants could see the graduation of the tape measure during the estimations. The experimenter could only see the measure after participants were satisfied of their estimation to record it in the computer. Then, participants made a "yes" or "no" passability judgment (Warren \& Whang, 1987) to indicate if the aperture was wide enough to allow them to pass through it without rotating their shoulders. The experimenter recorded this judgment and launched the next trial. Participants completed 32 trials including 4 practice trials and 28 test trials. The actual aperture widths used for the test trials ranged from 30 cm to 95 cm with a \(5-\mathrm{cm}\) step. The actual aperture widths used for the practice trials ( \(31 \mathrm{~cm}, 39\) \(\mathrm{cm}, 52 \mathrm{~cm}, 82 \mathrm{~cm}\) ) were randomly selected among this range of width and were the same for all the participants. The actual aperture widths were randomly presented during the practice and test trials.

Figure 1: Experimental setup and device (P: participant; E: experimenter).

Immediately after the completion of the perceptual task, the experimenter asked participants if the overall procedure was clear and probed them for suspicion about the hypothesis. The experimenter asked two questions to the participants: (1) "In your opinion what hypothesis is tested in this study?" (2) "Do you think that some aspects of the experiment could have influenced your responses? If so, what were these aspects?" Then the experimenter recorded participants' shoulder width as the distance between the tips of the two humerus. Finally, participants sat down and answered a post-experimental questionnaire projected on the screen. The items of this questionnaire were gathered together by themes which were presented in a fixed order: (1) impressions about the mental imagery task, (2) information about the chosen acquaintance, (3) participants' feelings toward the acquaintance, (4) participants' preferred interpersonal distance with the acquaintance (for a similar measure see Pedersen, 1973), (5) participants' physical state, and participants' mood. Items, however, were randomly presented among the themes.

\section*{Results}

We conducted a set of t-tests to check the effectiveness of our experimental manipulation with Social Relationship as a between-group factor and the different items of the postexperimental questionnaire dependent variables. The participants in the liked-person group indicated more positive feelings toward their acquaintance ( \(M=4.42, S D=\) .34) than those in the disliked-person group ( \(M=2.46, S D=\) .36), \(t(56)=21.32, p<.001, \eta^{2}=.89\). In line with the literature (Sundstrom \& Altman, 1976), participants in the liked-person group preferred keeping a significantly shorter interpersonal distance with the acquaintance ( \(M=30.02, S D\) \(=22.26\) ) than those of the disliked-person group ( \(M=\) \(141.83, S D=44.69), t(56)=-12.19, p<.001, \eta^{2}=.73\). Participants in the liked-person group indicated having more frequent contacts with the acquaintance ( \(M=3.17, S D=\) 1.05 ) than those of the disliked person group ( \(M=1.86, S D\) \(=.85), t(56)=5.19, p<.001, \eta^{2}=.73\). Moreover, participants in the liked-person group indicated that the pictures generated during the mental imagery task were more pleasant \((M=4.6, S D=.49)\) than those in the dislikedperson group \((M=2.11, S D=.59), t(56)=17.28, p<.001\), \(\eta^{2}=.84\). There was no other significant difference for the other items of the post-experimental questionnaire (i.e., duration of the relationship, mood, vividness of the imagery task, easiness to imagine the target person, and easiness to imagine passing through the aperture). It is noteworthy, however, that it was marginally easier to imagine the liked person \((M=3.23, S D=1.22)\) than the disliked one ( \(M=\) 2.64, \(S D=1.25\) ), \(t(56)=1.82, p=.07, \eta^{2}=.06\).

An inspection of the Studentized deleted residuals on the aperture width estimations revealed the presence of two outliers (see Judd, McClelland, \& Ryan, 2009). They were excluded of the subsequent analyses. Two other participants were also excluded because of a power cut during data collection. After these exclusions, it remained 56
participants \(\left(n_{\text {liked }}=29, n_{\text {disliked }}=27\right)\). We considered participants as suspicious when they indicated that they thought that we aimed to test the effect of social relationship on the perception of aperture or when they indicated that social relationship was an aspect that influenced their estimations. In spite of our cover story, \(39.29 \%\) of our participants suspected the true purpose of the study. Moreover, there were more suspicious participants in the disliked-person group ( \(55.56 \%\) ) than in the liked-person group \((24.14 \%), t(54)=2.49, p<.02, \eta^{2}=.10\).

Figure 2. Perceived distance as a function of Actual Aperture Width and Social Relationship. Error bars denote standard errors of the means.

We conducted an analysis of variance (ANOVA) with Social Relationship (liked person, disliked person) as a between-subjects factor and Actual Aperture Width ( 30 cm , \(35 \mathrm{~cm} . . .90 \mathrm{~cm}, 95 \mathrm{~cm}\) ) as a within-subject factor. The Estimated Aperture Width was the dependent variable. Given that the exclusion of all the suspicious participants would lead to decrease dramatically the statistical power of the analysis, we entered Suspicion (suspicion vs. no suspicion) as a covariate in this analysis. We also entered Shoulder Width as a covariate since this variable is known to influence perceived aperture widths. This analysis revealed that participants in the disliked-person group estimated shorter aperture widths ( \(M=58.5, S D=1.35\) ) than those of the liked-person group ( \(M=61.5, S D=1.51\) ). However, this main effect of social relationship was not statistically significant, \(F(1,51)=2.21, p<.14, \eta^{2}=.04\). Neither the main effect of suspicion, nor those of shoulder width were significant ( \(p s>.1\) ). The main effect of Actual Aperture width was significant, \(F(13,663)=7.31, p<.001\), \(\eta^{2}=.13\). Interestingly, the interaction between actual aperture width and social relationship was significant, \(F(13\), 663 ) \(=2, p<.02, \eta^{2}=.04\) (see Figure 2). This seems to reflect the fact that participants in the disliked-person group tended to estimate shorter aperture widths than those of the liked-person group for the aperture judged wide enough to pass, \(F(1,51)=3.08, p<.09, \eta^{2}=.06\), but not for those
judged too small to pass, \(F(1,51)=.68, p<.41, \eta^{2}=.01\). Importantly, the interaction between the actual aperture width and the social relationship did not depend on suspicion ( \(p=.73\) ). Moreover, these results did not change dramatically when we controlled for the easiness to imagine the target person. We also conducted an ANOVA with social relationship as a between-subject factor and the percentage of "yes" passability judgments as a dependent variable. We also entered suspicion and shoulder width in this analysis to statistically control for these variables. Although the percentage of "yes" passability judgments was smaller for the disliked-person group ( \(M=53.32, S D=\) 4.33) than for the liked-person group ( \(M=60.36, S D=\) 4.89), this difference was not significant ( \(p>.74\) ).

Neither the correlation between the familiarity with the acquaintance and the percentage of "yes" passability judgments, nor those between the preferred interpersonal distance and the percentage of "yes" passability judgments were significant ( \(r=-.08, p=.71\) and \(r=-.22, p=.28\) respectively). Interestingly, the correlation between the affective closeness and the percentage of "yes" passability judgments was significant for the participants in the disliked-person group ( \(r=.64, p=.01\) ), but not for those in the liked-person group ( \(r=-.42, p=.23\) ). Importantly, this pattern of correlations remained the same when we statistically controlled for the shoulder width of the participants and for the suspicion.

\section*{Discussion}

When participants intended to pass between a wall and a disliked-person stimulus, they tended to estimate shorter aperture widths compared with when they intended to pass between a wall and a liked-person stimulus, but only for passable apertures. As observed in our previous study (Morgado et al., 2011), we also observed a positive correlation between the affective closeness and percentage of "yes" passability judgments. More precisely, the closer participants felt to the acquaintance, the more passable the aperture appeared. Surprisingly, it was only true for the participants in the disliked-person group, but not for those in the liked-person group. At a first glance, these results seem consistent with the social extension of the phenotypic account of perception (Proffitt \& Linknauger, 2013). According to this account, the anticipation of personal space invasion might lead to perceive shorter aperture widths in the presence of disliked persons than in the presence of liked ones.
The observed interaction between the actual aperture width and the social relationship is consistent with previous results suggesting that the constraints related to an intended action influence visual perception only when people can actually perform this action (Lessard, Linkenauger, \& Proffitt, 2009). The correlation between affective closeness and passability judgments observed only with disliked persons might also suggest that affective closeness is more relevant for passability with disliked persons compared with liked ones.

One might be willing to explain our results in terms of the ease to keep in mind the person stimulus. For instance, it might be easier to imagine the disliked-person than the liked-person given the literature on attention to negative stimuli (e.g., Smith, Cacioppo, Larsen, \& Chartrand, 2003). If so, such a difference might explain our results. The data from our post-experimental questionnaire, however, indicated that the difference between the disliked-person and the liked-person groups for the vividness of the imagery task was not significant. In contrast, it was marginally easier to imagine the liked-person than the disliked one. Importantly, the interaction between the actual aperture width and the social relationship remained significant when we statistically controlled for the easiness to imagine the target person. In the same vein, one might also invoke mood as a potential confound in our results since mood seems to influence visual perception of space (e.g., Riener, Stefanucci, Proffitt, \& Clore, 2011). However, our postexperimental did not provide any support for this alternative explanation.
Durgin et al. (2009) underlined the necessity to take into account the suspicion of the participants in studies about the influence of the action capabilities on visual perception of space. According to their concerns, the large number of suspicious participants in our sample rises another possible explanation for our results in terms of demand characteristics. Demand characteristics refers to the cues which provide an experimental hypothesis to the participants (Orne, 1962). Moreover the large number of suspicious participants in the disliked-person group suggests that these participants were more likely to be affected by demand characteristics. Thus, they could have reduce their width estimations and adjust their passability judgments in line with their guess about our hypothesis. If it was the case, one could argue that the interaction effect between the actual aperture width and the social relationship should depend on whether participants were suspicious or not. Interestingly although the interaction between actual aperture width, social relationship, and suspicion was not significant, the increasing difference with the actual aperture in estimated aperture width between the disliked-person and the liked-person groups seems to be present for the suspicious participants only. Even if these results are only descriptive, it is important to underline the fact that our study was not primarily designed to test such a three-way interaction. Considering our sample size, a lack of statistical power needed to test such an interaction might explain this non-significant result. Another important limit relies on the fact we used very basics questions to probe the suspicion of the participants. Further studies primarily designed to test the relevance of the demand characteristics in perception studies will have to use a more sophisticated postexperimental questionnaire.
One could also argue that the experimental demand in the liked-person and the disliked-person group was the same since the two groups had to imagine the presence of an acquaintance. Yet, we observed more suspicion in the
disliked-person group than in the liked-person one, which means that demand cues are not equally spread into the two groups or at least that the participants' receptivity to these cues are different between the two group. One possible explanation of this asymmetry might rely on an inconsistency between the cover story and the disliked group. More precisely, participants could have found paradoxical to imagine the presence of a dislike person to make the task more natural. Such asymmetry has important implications for studies contrasting positive and negative experimental manipulations and researchers should be encouraged to find a way to rule out this potential confound.
In spite of the limits of our study, it highlights the need of using a systematic and standardized post-experimental questionnaire in perception studies. Indeed, we think that dealing with the demand characteristic explanation need more than just indicating that participants were probed for suspicion. For instance, it seems that participants tend to admit their suspicion more in a computerized postexperimental questionnaire than in a face-to-face interview with the experimenter (Blackhart, Brown, Clark, Pierce, \& Shell, 2012). Thus it is important that the perception researchers take into account such results when they probe their participants for suspicion. One could doubt of the use of questionnaire to deal with the demand characteristics for at least two reasons. The first reason is that if demand characteristics exert an implicit influence on the participants' behavior, the participants should not be aware of this influence. Thus the interest of simply asking people about this influence with a post-experimental questionnaire should be highly limited (e.g., Nisbett \& Wilson, 1977). However, the fact that much of the demand bias should be implicit is not guaranteed. Moreover, even if one considers demand bias as implicit, the demand characteristics which produce this bias can be perceived explicitly by the participants. Thus using a post-experimental-questionnaire remains useful to assess the receptivity of the participants to the demand characteristics. The second reason that can lead scholars to doubt the usefulness of the post-experimental questionnaire is the fact that such questionnaire captures the impression of the participants after the experiment. It is possible that some participants did not think very much about the hypothesis during the experiment and that the post-experimental questionnaire increases their suspicion when they answer to it. Horvat (1986) observed, however, that care in the design of the questionnaire and in the coding of the responses can improve the reporting of true suspicion and decrease the reporting of false suspicion.
The use of theoretical accounts of demand bias to improve post-experimental questionnaire and experimental design is particularly relevant (e.g., Allen, 2004; for a review see also Strohmetz, 2008). According to such accounts, to consider that there is a risk of demand bias, researchers have to consider three critical variables. The first variable is receptivity of the participants to the demand cues. The presence of such cues can lead the participants to guess the hypotheses. We can assess the receptivity of the participants
using a quasi-control group as proposed by Orne (1962) or with a post-experimental questionnaire. Interestingly, we can also reduce the receptivity of the participants to the critical cues by diverting their attention with deceptive cues. With such a "red herring technique", Laney et al. (2008) succeed in reducing the suspicion of the participants about their hypothesis. They used a traditional cover-story to hide the purpose of their study, but in addition they included perceptible cues suggesting that the study had another purpose (i.e., the red herring). Importantly, this red herring cannot be confounded with the true purpose of their studies so that any demand bias in favor of the red herring cannot lead the participants to confirm the true purpose.
The second variable is the participants' motivation to comply with the demand cues. Indeed, without such a motivation, the receptive participants have no reason to comply with demand cues. Allen (2004) in his postexperimental questionnaire used some items about the motivation of the participants to comply or not with what they thought was expected.
The third variable is participants' ability to voluntarily modify their responses according to the demand cues. The question of this ability is highly relevant in behavioral research and seems to be ignored by researchers working on the so called low-level processes. Such tendency might relied on a confusion between what it is studied (i.e., a lowlevel process) and the way by which we have access to this process (i.e., a response). Yet, even if visual perception implies low-level processes that some authors consider as cognitively impenetrable (e.g., Pylyshyn, 1999), the response of the participants might rely on a voluntary motor act. In that case, as in the cases of visual-matching estimate of or affordance judgments, participants might have the opportunity to voluntarily influence their responses. Assuming that any response used to study a low-level process is not sensitive to response bias is a strong claim and had to be examined for each response or at least for each category of response.
Finally, we observed mixed evidences supporting the idea that social relationships influence the visual perception of distance. We have, however, to qualify this conclusion according to the potential implication of a demand bias in our results. To conclude, if overgeneralizing the explanation in terms of demand bias to experiments with very different experimental design is flawed, ignoring the potential presence of a demand bias in an experiment is also an important concern.

\begin{abstract}
According to Margaret Gilbert, a joint commitment (JC) is a commitment of two or more agents, called the parties of the JC, to engage in a common project. Creating a JC often involves an explicit agreement, carried out in a conversational interaction through overt communication. We explored aspects of such interactions that can be considered as complementary to verbal exchanges, focusing on how a JC is managed by the parties by means of emotional and other non-verbal bodily expressions. We analyzed three phases of the JC lifecycle (creation, maintenance, and violation), and in particular the emotional reaction of the participants to two types of violations by the experimenter. In our analysis we used standardized tools such as the Ethological Coding System for Interviews, the Mind Reading Emotional Library, and the Facial Action Coding System. Our results show that certain non-verbal behaviors in the phase of JC creation are characteristic of the participants who later did not fulfill their commitment. Moreover, the participants' emotional reactions to JC violation by the experimenter turned out to depend on the type of violation. Finally, the creation and maintenance of JC, and the emotional reaction to its violation, appear to be independent of the participants' personality and empathic disposition.
\end{abstract}

\section*{Introduction}

The theoretical background of this paper is Gilbert's plural subject theory (Gilbert, 1989) together with some developments by Carassa, Colombetti \& Morganti (2008). Accord-
ing to Gilbert, all genuinely collective phenomena (like joint activities, collective beliefs, group feelings, etc.) involve a special kind of commitment, namely, a joint commitment (JC). An agent may be personally committed to do something as a result of an individual decision; in this case the agent is the only 'owner' of the commitment, and can rescind it as he or she pleases. Contrary to personal commitments, a joint commitment is a commitment of two or more agents, called the parties of the JC, to engage in a common project.

The main feature of JC is that it consists of normative relationships between the parties. If two parties are jointly committed to do something, then each one is obligated to the other one to do their part, and has the right that the other one do their part. Accordingly, a JC is violated when a party does not live up to their obligations.

Gilbert often remarks that making a JC does not necessarily require an explicit agreement: certain subjects may enter a joint commitment by starting to interact in certain ways, without ever trying to describe what they do together as a matter of agreement. Making explicit agreements, on the other hand, is very common in everyday life, and in the current paper we concentrate on this type of situation. According to Carassa \& Colombetti (2009), explicit agreements to joint projects are typically created in a conversational interaction through overt communication, where an agent perform speech acts with a communicative intention, in the

Gricean sense (Grice, 1957), as in the following example: "Can you help me with my homework assignment?" "Yes, sure". Beyond this plain example, it would be undoubtedly interesting to investigate how the making of agreements naturally unfolds in conversations, but our present research is aimed at exploring other complementary aspects of an ongoing face-to-face social interaction of this type. In fact, we want to take into account the role played by intersubjectivity, understood as the broad range of processes and capacities that, according to the enactive approach, allow one to directly perceive, understand and respond to the psychological states of others, without explicitly representing and reasoning upon them (Morganti, Carassa \& Riva, 2008). We believe that such pre-reflective processes need to be investigated to get a comprehensive view of JC creation, maintenance and fulfillment/violation. This means that beyond studying the situated use of language in interaction, we also have to focus on non-verbal behaviors such as facial expressions, gestures, and bodily postures and movements that can be pre-reflectively produced and understood by the interactants. As an example, an interactant can be aware that an agreement has been made verbally, while at the same time perceiving that the other party is not really willing to live up to it. These kinds of behaviors we expect to shape the normative landscape developed by the interactants along emotional and tacit dimensions. In the present research we did not yet analyze, as an enactive approach would require, the participant-experimenter interaction, but we specifically focused on the participant non-verbal behaviors, considering them as components of intersubjective patterns to be further investigated.

The experiment reported in this paper addresses all phases of JC lifecycle: its creation, its maintenance by a participant, and a participant's reaction to a violation performed by the experimenter in two different conditions. To understand if there is a personal predisposition to the acceptance and maintenance of a JC, we made an assessment of personality and of empathic disposition of the participants. This evaluation was justified by the hypothesis that personal predispositions could influence both the acceptance, maintenance and fulfillment/violation of a JC (this hypothesis, however, was not confirmed by our results).

\section*{Materials and methods}

\section*{Subjects}

The experiment involved 35 female participants, all of them students at the University of Bergamo, aged 19-27 ( \(\mathrm{M}=\) 21.11, sd = 1.9).

The sampling was conducted partially at random and the recruitment was voluntary. The experimental phase lasted three weeks between September and November 2011; data analysis was then conducted in a unique solution.

\section*{Materials}

Personality and empathy assessment To analyze the participants' personality, their emphatic disposition and the potential connections with JC creation, maintenance and violation, some questionnaires were distributed. For personality assessment, we used
a) the Eysenck Personality Inventory - EPI (Eysenck,1985), composed by three sub-scales (extroversion/introversion, neurosis, psychosis); and
b) the Mini Questionnaire on Personality Organizations MQOP (Nardi et al., 2012), composed by four subscales (contextualized, normative, controlling, detached).
The latter questionnaire allows one to study personality as a process, by focusing on the relationships between personality and developmental process axes, based on Guidano's theory of Personal Meaning Organization (1987).

Concerning the evaluation of emphatic disposition, two tools have been used:
a) the Interpersonal Reactivity Index - IRI (Davis, 1980, 1983), according to which empathy results from the integration of four factors (fantasy-empathy, perspective taking, empathic concern, personal distress);
b) the Emotional Regulation Questionnaire - ERQ (Gross \& John, 2003), aimed at identifying the strategy of emotional regulation used by the subjects (cognitive reappraisal, expressive suppression).

Joint commitment lifecycle To evaluate the lifecycle of JCs, we used four parallel forms of self-evaluation diaries, based on the structured diary proposed by Oatley and Laroque (1994). The purpose of such diaries was to analyze different possible JC situations, in which the participants could find themselves during the experiment. The diaries proposed to the participants followed the Experiencing Sample Method of Larson and Csikszentmihalyi (1983), which requires participants to describe their experience at certain moments of time.
Non-verbal behaviors We used the coding system proposed by Troisi (1999) to analyze the non-verbal behavior of the participants during the face-to-face meetings in which the JC was created and managed. This method is known as the Ethological Coding System for Interviews ECSI, and includes 37 behavioral patterns, most of them regarding facial expressions and hand movements.

To analyze the participants' reaction to the JC violation performed in the second face-to-face meeting, we used the Facial Action Coding System (FACS) of Ekman and Friesen (Ekman, 1978). We also used the Mind Reading Emotional Library (Baron-Cohen, 2003, 2004) for the classification of the expressions of emotional reaction to JC violation.

\section*{Procedure}

Firstly the questionnaires about personality and empathic disposition were filled in by the participants. This selfassessment, carried out in a quiet room, required about 30 minutes for each participant. Then other three sessions followed:
1. an initial face-to-face meeting between the experimenter and the participant, in which the experimenter purported to describe the goal of the research (see below), the participant's willingness to take part in the research was ascertained, and a JC of the participant and the experimenter was made through an explicit agreement;
2. a one-week period in which the agreed activity was performed and monitored;
3. a second face-to-face meeting in which the JC was violated by the experimenter.
Both meetings were video-recorded by three hidden video cameras, one focused on the experimenter's face, the second on the participant's face, and the third on the body and face of both of them. During the first meeting, all the participants verbally expressed their willingness to participate in the research, and the second meeting was scheduled.
With every participant, the first meeting was divided into three sections:
1. The first section concerned the description of the research. The experimenter told the participant that the research was aimed to analyze the everyday life emotions experienced while performing joint activities with others. In details, she asked the participant to answer some diaries. Every day of the following week, each participant would receive by email 5 diaries per day (for a total of 35 diaries). Furthermore, the experimenter informed the participants that they had to hold a second meeting after one week, in which they would receive comments on their diaries, previously analyzed by the experimenter.
2. The second section consisted in the explicit request to take up the JC, performed by the question "So, do we agree?"
3. The third section consisted in the participant's acceptance of the JC (in fact, no participant refused to take up the JC).
In the week between the first and the second meeting, the 35 diaries were sent to the participants by email, thus living up to the experimenter's obligations deriving from the JC. The explicit purpose of this experimental phase was to collect data about the personal feelings related to different kinds of commitments experienced by the participants during the day. Moreover, the participants had been informed that in this phase the experimenter would have monitored their answers, in order to provide the participants, during the second meeting, with a complete evaluation of their personal 'style of commitment.'

Of the 35 participants (all of whom explicitly agreed to carry out the research), 21 came to the second meeting, which was structured in two sections as follows:
1. In the first part, the maintenance section, the 21 participants, that expected to receive comments on their answers, were asked about their experience during the previous week.
2. In the second part, the violation section, the experimenter told the participants that their diaries had not been examined, thus making all their work useless. The violation of the JC was attributed to two different motivations:
a. to 11 of the 21 participants, the experimenter said that she changed her mind and that she no longer wanted to complete the experiment (we call this the internal attribution of the violation);
b. to the other 10 participants, the experimenter said that it was impossible to complete the experiment, due to the fact that the university refused to approve her project (we call this the external attribution of the violation).
The reaction of the participants to the JC violation was recorded for further analysis. At the end of the meeting the actual design of the experiment was revealed to the participants.

\section*{Data coding}

The non-verbal behaviors displayed in the two meetings were analyzed using the ECSI method. The entire duration of the video-recorded meeting was therefore analyzed by identifying, for each participant, the occurrences of the 37 behavior patterns specified by Troisi (1999).
To monitor the lifecycle of the JC, we examined the participants' answers to the self-evaluation diaries. For each participant, the 35 diaries were coded according to the methodology described by Grazzani-Gavazzi and Oatley (1999). In order to better adapt this methodology to the specific purpose of our research, the items regarding the participants' private emotions during the management of the JC and those attributed by the participant to other people (item 7 and 8) have been coded according to the Mind Reading Emotional Library, and not according to JohnsonLaird's classification as in the original methodology.
In the second meeting, the analysis of the non-verbal reaction to the violation of the joint commitment was conducted using the Action Unit analysis of FACS. We scored the Action Units of the participants occurring in the 30 seconds following the experimenter's violation. Moreover, two independent judges, experts in psychotherapy, were asked to identify the prevalent emotion displayed by each participant as a reaction to the JC violation, and to classify it according to the Mind Reading Emotional Library. The two judges were showed the video-recordings of participants' emotional reaction to the JC violation, but were not explained the situation in which the participants were involved; the
question they were asked was, "These people were told an unexpected piece of news: what kind of emotional reaction are they showing?"

\section*{Results}

To understand which factors may be predictive of the participants' fulfillment of the JC two groups were defined, respectively including the 21 participants who came back to the second meeting (Returned -R ), and the 14 participants who did not come back (Not Returned - NR).
We first analyzed the questionnaires regarding personality (EPI, MQOP) and empathic disposition (IRI, ERQ), to understand whether we could identify a predisposition to maintain the JC. Comparing the questionnaire answers obtained by the R and the NR groups, no significant difference was found.
We then considered the number of occurrences of the 37 ECSI behavior patterns in the different sections of the first meeting. While the comparison between the two groups did not show any significant difference in the ECSI behavior patterns during the description and acceptance sections, in the request section we found significant differences between the groups, concerning 10 of the 37 behavior patterns (see Table 1).
To analyze the lifecycle of the JC, we examined the 408 self-evaluation diaries that were returned by the 21 participants who came to the second meeting. Every participant answered on the average 19.42 diaries ( \(\mathrm{sd}=9.31\) ) of the 35 received during the week. The answers to the diaries did not contain any important information on the participants' emotions concerning JCs in their everyday life.
In any case, we used the diaries as a marker of the participants' commitment, dividing the participants into two groups: \(\geq 25\) answered diaries, \(<25\) answered diaries. In fact, no significant difference between these two groups was observed in the ECSI behaviors exhibited during the first meeting.

Table 1: ECSI behavior patterns at the first meeting: significant differences between the R and NR groups ( \(t\)-test for independent samples).

34. Settle & \(\mathrm{p}<.004\) \\
37. Neutral face & \(\mathrm{p}<.008\) \\
\hline
\end{tabular}

However, we found a significant difference between the two groups in the violation section, where certain behaviors occurred significantly more often in the \(<25\) group (4. Flash, \(\mathrm{p}<.027\); 15. Still, \(\mathrm{p}<.003\); \(t\)-test for independent samples).

As for the second meeting, we first compared the ECSI behaviors in the maintenance and violation sections, for all the 21 participants who came back ( R group). No significant difference was found. For the violation section we conducted a further analysis of ECSI patterns, which revealed significant differences in certain behaviors between the internal and the external attribution groups, as shown in Table 2.

The emotional reactions observed after violation were analyzed using the Mind Reading Emotional Library. The index of agreement between the two judges was evaluated as Cohen's \(\kappa=.79\). The distribution of emotions according to the two types of violation is summarized in Table 3.

Anger (4+5) & Sadness (17) & Hurt \\
Anger (4+5) & Anger (23) & Hurt \\
\hline
\end{tabular}

Excluding the neutral ones (i.e., surprised, disbelieving, and bored) these emotions were classified in two groups: sad and hurt as self-centered emotions, angry and unfriendly as other-centered emotions. The comparison between these two groups of emotions revealed a significant difference between the two types of violation ( \(\chi^{2}\) test with Yates's correction, \(\chi^{2}=4.743, \mathrm{p}<.03\) ), where the selfcentered emotions were predominant in the external attribution group, and the other-centered emotions were predominant in the internal attribution group.
The analysis of Action Units, carried out through FACS and decoded into primary emotional expressions, partially agreed with the Mind Reading analysis, as shown in Table 4. Finally, the emotional reaction to the violation of JC was statistically related neither with personality nor with empathic disposition.

\section*{Discussion}

Our results do not show any effect of the participants' characteristics, such as personality and empathic disposition, on the disposition to maintain or violate a JC. Instead, our data indicate that certain non-verbal behaviors carry relevant information on the subjects' attitude toward the JC they are currently creating. In fact, we observed that some nonverbal behaviors displayed in the first meeting are significantly different between the NR and the R group. It would be interesting to understand whether these behaviors are
voluntary attempts to hide a lack of interest in the joint project (irrespective of the verbal acceptance of the JC), or prereflective bodily expressions of uncertainty about the decision of taking part in the project. In the latter case, the recurring behavioral patterns in the participants who did not come to the second meeting may indicate a feeling of uneasiness concerning the situation they are currently experiencing.
Regarding the lifecycle of the JC, the analysis of the diaries did not yield any important indication on how the commitment was experienced during the week between the two meetings. The average number of diaries answered by the participants who came to the second meeting (19.42 out of 35 , i.e., \(55.5 \%\) ) was rather low, which suggests that even those participants who at least partially fulfilled the JC regarded coming to the second meeting as more important than completing the assignments. The only significant behavioral difference that we found between the \(\geq 25\) and the \(<25\) answered diaries groups occurred during the violation section of the second meeting, where we observed that two non-verbal behaviors (i.e., Flash and Still) were performed more frequently by those who answered less than 25 diaries.

Regarding JC violation, the personality and empathic disposition of the participants did not seem to affect their emotional reaction. On the contrary, the two types of violation (internal vs. external attribution) significantly affected the reactions in the participants, as highlighted by both the behavioral occurrences observed through the ECSI method and the emotional reactions detected by the two judges. Whether such differences were under voluntary control or pertained to the sphere of pre-reflective reactions cannot be established on the basis of our current experimental design.

More specifically, as far as emotions are concerned the Mind Reading analysis carried out by the two judges highlighted two different reactions:
1. In the case of violation with external attribution the most frequent emotions were "sad" and "hurt," which can be regarded as self-centered emotions. This is probably due to the fact that the participants, while feeling frustrated because their work turned out to be useless, were willing to consider the experimenter's violation as excused by the university's refusal to approve the project.
2. In the case of violation with internal attribution, the most frequently observed emotions were "angry" and "unfriendly," which can be regarded as other-centered, as they are directed to another subject. These emotions plausibly reveal a feeling of resentment toward the experimenter, who is considered as fully responsible for the violation of the JC.
We believe that these results may be explained by taking into account the normative structure of JCs, and in particu-
lar their second-personal nature (Darwall, 2006) and their relationships with so-called reactive attitudes (Strawson, 1962). Investigating these aspects of interpersonal normativity is among our future research goals.
Finally, the comparison of the emotions coded through Mind Reading and those coded through FACS only showed partial agreement (for 10 on 21 participants). The reason for this partial agreement may be connected with the different focus of analysis these tools are based on; in fact, whereas FACS focuses on facial micro-expressions that prereflectively arise before a social mediation of the emotion, the Mind Reading coding system also takes social emotions into account.
To conclude, our results allow us to identify some nonverbal behaviors as typical of the participants who, even if they verbally agreed to create a JC, did not fulfill the corresponding obligations. Moreover, our experiment suggests that the type of violation attribution (internal vs. external) is the most significant factor in shaping the reactive emotions, overshadowing the effect of personality and empathic disposition.

\title{
Causal determinism in toddlers
}

\author{
Paul Muentener (pmuenten@mit.edu) \& Laura Schulz \\ Department of Brain \& Cognitive Sciences, MIT, Cambridge, MA 02138 USA
}

\begin{abstract}
Prior research has shown that children hold a belief in causal determinism - the belief that all events are caused - by 4 years of age. In this study we investigate the developmental origins of this belief. We showed toddlers ( 24 months) a spontaneous or explained novel physical outcome (a toy that lit up either spontaneously or upon contact from an experimenter) and then showed them an additional candidate cause (pressing a button) while obscuring the outcome. We asked whether toddlers inferred that the two components (the button and the outcome) were causally linked. We found that toddlers represented the candidate cause as the cause of the novel outcome only when the event spontaneously occurred (Experiments 1-2), and that children spontaneously searched for plausible causes of unexplained outcomes (Experiment 3). These results suggest that toddlers, like older children, believe physical events have causes, and that this belief supports exploration and discovery.
\end{abstract}

Keywords: causal reasoning; determinism; physical causality; prediction; intervention.

Researchers have suggested that children's sophisticated causal inference abilities are at the core of theory development and the many conceptual changes that occur throughout early childhood (Carey, 1985, 2009; Gopnik \& Meltzoff, 1997; Gopink \& Wellman, in press, Schulz, 2012). By preschool, children engage in causal exploration, use conditional probabilities to determine the causal structure of events, and can design appropriate causal interventions (e.g., Bullock, Gelman, \& Baillargeon, 1982; Gopnik \& Sobel, 2000; Gopnik et al., 2004; Kushnir \& Gopnik, 2007; Shultz, 1982).

What drives children's search for causal structure in the world? Although some events in the world involve visible interventions (e.g., human action) and visible outcomes (e.g., objects that move or change state), many events involve unobserved or even unobservable causal mechanisms (e.g., viruses cause disease). Thus, a challenge for theories of conceptual development is to explain how children go beyond the evidence they see.

One possibility is that children are causal determinists. In its most basic form, causal determinism is the belief that all events have causes. If an event appears to occur spontaneously (e.g., a light turns on) adults will typically infer the presence of an unobserved generative cause (e.g., a person activating a hidden switch). A belief in causal determinism could help guide children's search for unobserved variables.

Prior research suggests that by the age of five, children are determinists about physical events. In classic research on causal reasoning, Bullock, Gelman, \& Baillargeon (1982) showed that 5 -year-olds denied that that events could
occur spontaneously. When asked to explain a novel, apparently spontaneous jack-in-the-box event, no child suggested that the event occurred on its own. Rather, all children referred to hidden variables (e.g, wires, remote controls, or "invisible batteries"). More recently, Schulz \& Somerville (2005) found that four and five-year-old children also posited hidden causal variables when outcomes occurred probabilistically.

If a belief in causal determinism is integral to human causal learning and exploration, it might be in place very early in development. Note however, that it is not obvious that the assumption of determinism is necessary either for accurate prediction or effective action. In principle, it might be possible to learn statistical relationships between actions and outcomes (e.g., Blaisdell, Sawa, Leising, \& Waldmann, 2006) and even to innovate causally effective tools (Emery \& Clayton, 2004) without assuming that the world is saturated with causality (though see Gershman, Blei, \& Niv, 2010 for evidence suggesting that inferring latent variables may be integral to causal reasoning broadly). If the assumption of determinism is a relatively late development, children might come to believe that all events have causes only after they have been instructed in unobservable causes like gravity and germs.

Here, we explore the developmental origins of causal determinism by asking whether 18- to 30 -month-old children believe that physical events have causes. We show toddlers an event (a light turning on) that either appears to occur spontaneously or that appears to be caused by the experimenter's preceding intentional action. We then introduce a novel button as a plausible candidate cause for the event (but never show the toddlers any predictive relationship between the button and the light). If toddlers believe that all physical events have causes, then they should ignore the button when the experimenter's intentional action potentially explains the event but reference the button when the event is otherwise unexplained. We test the prediction that toddlers selectively infer causes for unexplained events by investigating toddlers' predictive looks (Experiment 1), their interventions (Experiment 2), and their exploratory behavior (Experiment 3).

\section*{Experiment 1}

\section*{Methods}

Participants Thirty two toddlers (mean: 24 months, range -18-30 months) were recruited at a Children's Museum. An additional 10 toddlers were recruited but not included in the final sample due to: inability to complete the session \((n=4)\), parental interference \((n=4)\), or experimenter error \((n=2)\).

Toddlers were assigned to either the Spontaneous condition or the Explained condition ( \(\mathrm{n}=16 /\) condition). There were no age differences between the conditions ( \(p=n s\) ).

Materials The light box was constructed from a black box ( 6 in \(x 6\) in \(\times 6\) in) with a small blue lamp ( 2 in diameter) emerging from the front panel which was controlled surreptitiously by the experimenter. An orange button box was connected to the black box by a long orange rod (15 in). A black screen served as an occluder throughout the procedure. An additional black screen was placed behind the black box to obscure the experimenter's surreptitious activation of the blue lamp.

Procedure Figure 1 presents a schematic depiction of the procedure from Experiments 1-3. Upon entering the testing space, all children saw the button box connected to the light box. The experimenter directed the child's attention to all components of the novel toy (the button box, the connected rod, and the light box) without labeling the specific items (e.g., "Look at this") (see Figure 1, top panel). The button was then occluded from the child's view with the black screen. In the Spontaneous condition, toddlers saw the light box light up and flash blue ( 4 flashes, approximately 1 s total) apparently spontaneously. In the Explained condition, the experimenter touched the rim of the light and then light box lit up and flashed blue.

In both conditions the experimenter then moved the occluder to reveal the button box and occlude the light box. The experimenter then pushed the button for 1 s .

During the test trial, the experimenter removed the occluder from in front of the light box so that all components were visible to the child. The experimenter pressed the button but the light box did not light up and flash blue. We coded toddlers' first look in the 2 -second window following the button press.

\section*{Results and Discussion}

Figure 2 displays the results from Experiments 1-3. Toddlers in Experiment 1 were significantly more likely to look to the box in the Spontaneous condition (68.75 \%, \(11 / 16\) toddlers) than in the Explained condition ( 25.00 \%, \(4 / 16\) toddlers; Fisher's exact test, \(p<.05\) ) (Figure 2, left panel). That is, toddlers inferred a predictive relationship between a novel event and a candidate cause, but only when the event had no other candidate explanation.

These results are consistent with the possibility that 2 -year-olds believe that physical events have causes. When they saw a novel event that appeared to occur spontaneously and a plausible candidate cause (a button press), toddlers made a predictive look from the candidate cause to the novel event even though they had never seen a predictive relationship between the button press and the light. By contrast, when the novel event could be explained by the experimenter's action, the toddlers did not make a predictive look from the candidate cause to the light.

Figure 1: Procedure for Experiments 1-3.
However, not all predictive relationships are causal relationships. Predictive looking cannot establish that the toddlers in Experiment 1 inferred that the button press was the actual cause of the light activating. Also, in Experiment 1 the experimenter touched the light box in the Explained condition but not in the Spontaneous condition; arguably the experimenter's attention to the light box in the Explained condition drew the children's attention away from the button. In Experiment 2, we matched the experimenter's contact with the light box between conditions and we introduce a stronger test of children's belief in causal determinism: we looked at whether toddlers would selectively intervene on the button. If children believe in causal determinism for physical events, then when asked to turn on the light they should push the button more in the Spontaneous condition than the Explained condition.

\section*{Experiment 2}

Participants Thirty two toddlers (mean: 24 months, range -18-30 months) were recruited at a Children's Museum. Seven additional toddlers were recruited but not included in the final sample due parental interference \((\mathrm{n}=3)\) and failure to intervene \((\mathrm{n}=4)\). Children were assigned to either the

Figure 2: Results of Experiments 1-3.

Spontaneous or Explained condition ( \(\mathrm{n}=16 /\) condition). There were no age differences between conditions ( \(p>.05\) ).

Materials The same materials used in Experiment 1 were used in Experiment 2.

Procedure The procedure was identical to Experiment 1 with the following exception (see Figure 1, middle panel). The experimenter touched the light box in both conditions: in the Spontaneous condition he touched the light box immediately after the light turned on (so that it looked like a response to, rather than potential cause of, the light activating); in the Explained condition, he touched the light box immediately before (as in Experiment 1).

During the test event, the experimenter did not push the button. Instead, he asked the child to "make the light turn on." We coded whether the child first touched the button or the light box within a 30 -second window following the prompt.

\section*{Results and Discussion}

Toddlers were more likely to intervene on the button in the Spontaneous condition ( \(81.25 \%, 13 / 16\) toddlers) than in the Explained condition ( 37.50 \%, 6/16 toddlers; Fisher's Exact test, \(p<.05\) )) (see Figure 2, middle panel). In contrast, toddlers were more likely to initially intervene on the light in the Explained condition ( \(62.5 \%, 10 / 16\) toddlers) than in the Spontaneous condition ( \(18.75 \%, 3 / 16\) toddlers; Fisher's Exact test, \(p<.05\) )). Toddlers seemed to infer a causal relationship between the button and the light only when the light did not already have an apparent cause.

The data from Experiment 2 provide stronger evidence that toddlers believe in causal determinism for physical events. Using interventions as a measure of causal knowledge, toddlers selectively accept candidate causal mechanisms for outcomes only when the event appears to occur spontaneously.

Note that the experimenter contacted both the button and the light in both the Spontaneous condition and the Explained condition. The only difference between the
conditions was whether the experimenter's action on the light could be represented as a cause of the lights flashing; in the Explained condition it could, but in the Spontaneous condition it could not. Thus, the children's tendency to imitate the experimenter's action was influenced by the children's causal attributions.

Experiments 1 and 2 suggest that children's belief in causal determinism affects their search for unobserved causes of physical events. However, neither of these experiments provides a direct test of children's causal exploration. In the prior experiments, toddlers were given a potential causal mechanism (a button) and a relevant action on that mechanism (pressing the button). We do not know whether toddlers in the Spontaneous condition (1) inferred the presence of an external cause and actively searched for it or (2) whether they linked the two subevents of the spontaneous light flash and the button press only after the experimenter directed the child's attention towards the button by acting on it. If a belief in causal determinism guides children's causal exploration, then children might search for a candidate cause even if the experimenter does not direct the children's attention towards it.

This prediction requires a caveat however. Whether a learner actually engages in search depends on many factors, including the learner's prior knowledge, the size of the search space, and exploration/exploitation trade-offs relating the cost and benefit of exploration to the cost and benefit of other actions the learner might take (see e.g., Gittens, 1979). Thus a belief in determinism does not mean that learners will always search for unobserved causes whenever they see unexplained events. Even as adults, we see events every day that we cannot explain; we accept that these events have causes but we rarely bother to seek out the causes ourselves. Nonetheless, if toddlers actively search for plausible candidate causes when events appear to occur spontaneously, then they should be more likely to explore a well-constrained, plausible search space (e.g., the button itself) in the Spontaneous condition than the Explained condition, even if they never observe an intervention on the button. We test this prediction in Experiment 3.

\section*{Experiment 3}

Participants Thirty two toddlers (mean: 23 months, range -18-30 months) were recruited at a Children's Museum. Thirteen additional toddlers were recruited but not included in the final sample due to an inability to complete the session ( \(\mathrm{n}=1\) ), parental interference \((\mathrm{n}=4)\), and failure to intervene \((\mathrm{n}=8)\). Children were assigned to either the Spontaneous or Explained condition ( \(\mathrm{n}=16 /\) condition). There were no age differences between conditions ( \(p>.05\) ).

Materials The same materials used in Experiment 1 were used in Experiment 3.

Procedure The procedure was similar to Experiment 1 except that the toddler did not see the button until the test event (see Figure 1, bottom panel). After the toddler viewed the novel event occur either spontaneously (Spontaneous condition) or as a result of the Experimenter's contact (Explained condition), the Experimenter removed the screen from in front of the button, and then told the child it was his/her turn to play. She did not make any reference to the button and did not explicitly request that the child turn on the light.

We coded whether children intervened on the button within the following 30 -second window.

\section*{Results and Discussion}

Toddlers were more likely to intervene on the button in the Spontaneous condition ( \(81.25 \%, 13 / 16\) toddlers) than in the Explained condition ( 37.50 \%, 6/16 toddlers; Fisher's Exact test, \(p<.05\) ) (see Figure 2, right panel). Even though children had not seen the experimenter act on a plausible candidate mechanism, children selectively explored the candidate mechanism when the novel event seemed to occur spontaneously.

\section*{General Discussion}

The current study suggests that toddlers believe that physical effects have causes. When they saw a novel physical event, they predicted relationships between, intervened on, and explored plausible candidate causes only when the event appears to occur spontaneously. While prior research had shown that four and five-year-olds believe in causal determinism, the current study suggests that the assumption of determinism is present much earlier in development, at least by two years of age.

One possibility is that toddlers' performance in the Spontaneous condition was not driven by a belief in causal determinism, but instead by a prior belief that buttons cause events to happen in the world. That is, toddlers may have made a predictive look towards the light in Experiment 1 because they expected the button press to make something happen rather than because they were looking for a cause of the light. Some evidence that this is not the case comes from the fact that children do not look to the light following the button press when the light's activation can be explained by
another cause. Additionally however, we are currently running a control condition in which toddlers see the button press but never see the light activate. If toddlers look expectantly to the other object on the stage simply because they believe buttons make things happen, they should look in this condition as well. However, preliminary data suggest that toddlers do not make predictive looks following an intervention on the button if they do not have an event to explain.

In the current study, we restricted our investigation of causal determinism to the domain of physical artifacts. Toddlers may assume that events involving artifacts (like a box lighting up) have causes without extending this assumption more broadly. We do not know to what extent children are determinists about naturally occurring physical events. Nor do we know to what extent either adults or children believe in causal determinism for psychological events (e.g., assuming that behaviors like crying, laughing, and thinking always have causes that fully account for their outcomes). The range of contexts under which children believe in causal determinism is an area for future inquiry.

The current research also leaves open the kind of constraints on children's hypothesis space for candidate causes. In this study we provided children with a very plausible, familiar candidate cause: a button. Arguably, as discussed above, children's search for causal structure may rely heavily on the presence of known plausible candidate causes. Alternatively, a belief in causal determinism could guide children's exploration and discovery of genuinely novel causal mechanisms over development. Further work is necessary to know whether toddlers might accept and explore a wider array of candidate causes to account for otherwise unexplained events.

Here, we investigated the simplest form of a belief in causal determinism - that all events have causes. However, a belief in causal determinism can also entail the assumption that causes produce their outcomes deterministically. If events occur probabilistically, a determinist can assume either that a generative cause is sometimes missing or that an inhibitory cause is sometimes present. In related research in our laboratory, we find that toddlers also posit unobserved causes to explain stochastically occurring events. When the event occurs deterministically, they do not make this inference (Wu, Muentener, \& Schulz, 2013; this conference).

Thus a belief in causal determinism may help drive causal learning and exploration starting in early childhood and throughout development. If we assume that all events have causes, then all events are candidates for discovery and exploration, and we can engage in the boundless inquiry that characterizes human cognition.

\begin{abstract}
In the present research we analyze the interrelations of spatial distance and efficaciousness in helping needy others, and we investigate how these factors affect our judgments of moral helping obligations. The main question is under which conditions the location of an agent's means of helping relative to a victim is regarded as morally relevant. We develop a new experimental design that allows us to test our hypotheses concurrently in both separate and joint evaluation modes using a constant procedure across groups. We find that spatial proximity of an agent's means to a victim increases people's sense of obligation only to the extent to which it is indicative of increased efficaciousness or personal involvement.
\end{abstract}

Keywords: moral judgment; spatial distance; means; obligation to help; joint vs. separate evaluation

\section*{Introduction}

The present work explores the relationship between two pervasive moral intuitions. First, we tend to feel more strongly obligated to take care of what is going on near us rather than far from us (see Kamm, 2007). We are more affected by information about harmful incidents occurring in our vicinity than at larger distances and tend to be more inclined to help in near cases. Second, we think that we need to be at least minimally efficacious if we are to be obligated to help others (ought-implies-can principle, OIC; see Vranas, 2007). We usually think we cannot be obligated to do what we cannot achieve. Both intuitions are potentially interrelated: Being near often causes agents to become efficacious in helping a suffering victim. This raises the possibility that the intuition that nearness matters can be reduced to a concrete manifestation of the OIC principle. Near agents may feel more strongly obligated to help not because they are near, but because they perceive themselves to be more efficacious as a consequence of being near. Alternatively, spatial distance might make a difference even at constant levels of efficaciousness (Kamm, 2007).

Nagel and Waldmann (2013) tested this question experimentally. In their Experiment 4, they presented subjects with a case vignette in which a victim was about to be robbed by a thief in a public place. Two agents were standing on the same place, one right next to the victim and the other on the opposite side of the place. Both realized the threat to the victim, and both could do something to prevent the robbery. In one condition, they could walk over to the victim and warn him. Here, the near agent was more efficacious than the far one as the agents needed to traverse the distance in order to be helpful. Spatial proximity caused increased efficaciousness. In the other condition, both agents could send a text message via cell phone in order to
warn the victim. This made both agents equally efficacious, regardless of their distance. It was shown that people judged the near agent to be more obligated than the far one only in the first but not in the second condition. This finding indicates that the effect of the first condition is mediated via efficaciousness considerations. At constant levels of efficaciousness, distance ceases to affect moral judgments.

This conclusion seems to suggest that distance effects can be explained away by efficaciousness. However, the matter is more complicated. Kamm (2007) pointed out that focusing on the distance between agent and victim covers only one way in which distance could matter morally. In addition, agents might be more obligated to victims that are located close to the agent's means, even if they are personally far from both. We conceptualize means as objects with the disposition to bring about an effect intended by an agent in a particular situation. \({ }^{1}\) Both artifacts (e.g., spoons having the disposition to stir liquids) and natural kinds (e.g., tree trunks having the disposition to support ceilings) can serve as means if an agent intends to make them manifest their relevant dispositions. In a typical helping event, an agent intends to bring about a change of state in the victim (from threatened to safe), and he might make certain objects manifest some of their dispositions to achieve this goal. Kamm's (2007) claim is that spatial proximity between such objects and the victim could cause agents to be morally obligated to let these means be used, even if the agent is personally far from both.

This interesting suggestion raises some conceptual problems that have not yet been analyzed. The concept of means is intricately related to both efficaciousness and spatial distance. First, means seem to imply at least a minimal chance of efficaciousness. Second, it seems that most objects have to be (brought) close to the victim at some point during the helping event in order to serve as means. Given these intimate interrelations, how can we separate the claim that nearness of means matters morally from the claim that efficaciousness matters? In what follows, we will offer an analysis of the interplay between distance, efficaciousness, and means. Based on this analysis, we present two experiments testing whether distance between means and victims affects laypeople's moral judgments even at constant levels of efficaciousness.

\section*{Distance, Means, and Moral Obligation}

If you conceive of helping events as causal chains starting at the location of the agent and ending at the location of the

\footnotetext{
\({ }^{1}\) We are not concerned with the special case of using people as means here (see Waldmann, Nagel, \& Wiegmann, 2012).
}
victim, it becomes clear that means can serve two different functions in this process. On the one hand, logistic means enable swift and efficient transport of the causal quantity from agent to victim, making the agent increasingly efficacious across large distances. The cell phones (plus mediating satellite system) from the public place scenario serve this function. Other examples include railroads, electronic media, remote-controls, etc. In order to fulfill this function, such means are often extended in space which makes it difficult to determine their exact location (and thus their distance to the victim). On the other hand, proximate means serve the function to bring about the intended change of state at the victim end of the causal chain. Such objects usually have to be (brought) close in order to become efficacious. Examples for proximate means are headache pills, dollar bills, clothes, organs, etc., depending very much on the specific effect intended by the agent (corresponding to the specific need of the victim). In the above cell phone example, there is no physical object serving this function. Instead, the proximate means would be the text message displayed on the victim's cell phone (changing his state from careless to alert). This exemplifies that logistic vs. proximate means do not correspond to specific kinds of objects. They are differentiated by their function in a specific teleological context. One and the same physical object can serve both functions simultaneously, as when you pick an apple from a high-hanging branch using a rake. You make use of both the logistic disposition of the rake (being long) and of its proximate disposition (having hooks).

Based on this analysis, we can now sensibly ask whether the location of means matters morally independently of efficaciousness considerations. This question refers to proximate means because the location of logistic means often cannot be precisely specified. Proximate means, in turn, need to be (brought) close to the victim in order to be helpful-therefore, they are usually more efficacious when they are near the victim rather than far. However, the presence of efficient logistic means can prevent the detrimental effects of spatial distance on the efficaciousness of proximate means. If the presence of efficient logistic means allows a quick transport of far proximate means to the location of the victim, far proximate means can be as efficacious as near proximate means. Kamm's (2007) claim that means-victim distance matters morally would imply that the location of the proximate means would still make a difference for helping obligations under these conditions. If, by contrast, the location of means mattered only via efficaciousness considerations, the presence of sufficiently efficient logistic means should prevent the location of the proximate means from affecting moral judgments.

\section*{Experiment 1}

In this experiment, we tested whether means-victim distance affects obligation judgments even if the availability of efficient logistic means makes far proximate means equally efficacious to near ones. In the real world, the efficaciousness of proximate means is almost always
reduced if they have to be brought close from a distance. To resolve this confound, we manipulated distance of means (the location of a stick that can be used to rescue a drowning victim) and their efficaciousness (the success probability of the potential rescue action involving the sticks) orthogonally.

\section*{Method}

Participants We obtained data from 183 British subjects (110 female, mean age 38 years) who completed our vignette-based online survey.
Design Our design is based on a classic 2 (Means-Victim Distance: near vs. far) by 2 (Efficaciousness: high vs. low) structure (see the four cells in Figure 1). The scenarios described agents standing in some distance from a canal in which a victim was drowning. They could attempt to rescue the person by running to the canal and reaching out for her with a stick. Our distance manipulation varied whether the stick was located close to the shore and thus near to the victim (near) or next to the agent and thus far from the victim (far). Agents in the far versions had to transport the stick to the shore in order to become efficacious. Our efficaciousness manipulation varied how likely the agent would succeed in his helping attempt. If the stick was located close to the victim (near), it was described as sturdy in the high efficaciousness version (cell a in Figure 1), making it likely that it would carry the victim's weight, and as brittle in the low efficaciousness version (cell b), making it unlikely. If the stick was located far from the victim (far), it was described as light in the high efficaciousness version (cell c), making it likely that it could be brought close in due time, and as very heavy in the low efficaciousness version (cell d), making it unlikely.

We did not simply allocate subjects randomly to one of the four cells. The reason is that we did not want to rely exclusively on a between-subjects variation of the independent variables, as it is well known that between- and within-subjects variations have profoundly different impact on the judgment process (e.g., Hsee \& Zhang, 2010). In the moral domain, we think the most important difference is that the subjects' attention is artificially steered at factors that are varied within-subjects (joint evaluation mode, JE), while the same factor acts as a potentially unattended background condition if it is varied between-subjects (separate evaluation mode, SE; see Nagel \& Waldmann, 2013). As moral judgments in both modes seem interesting, we investigate both concurrently in the present study with a new experimental design that is superimposed on the two-by-two structure described above.

Each scenario contained two agents (instead of only one), Dave and John, standing on opposite sides of the canal. Each agent represented one of two different cells from Figure 1. The agent from each cell was paired with the agent from each of the other three cells, resulting in six conditions (see arrows 1 to 6 in Figure 1). The order in which both agents were described in the scenario was counterbalanced in each of the six conditions, resulting in a total of twelve

Figure 1: Illustration of the experimental design. Numbered arrows correspond to six between-subjects conditions.
scenarios to which our subjects were randomly assigned ( \(n\) s in the six conditions ranging from 29 to 32). Below the scenario description, subjects were presented with two 6point rating scales with which they were to indicate how much they felt both agents were obligated to help. The wording of the two questions was "How strongly do you believe Dave [John] should risk his own life in order to try to save the drowning person?" Each scale was labeled "not at all" at the left hand end (1) and "very strongly" at the right hand end (6). The order of both questions always corresponded to the order in which both agents were introduced in the scenario description.
Analysis The advantage of this procedure is that both within- and between-subjects effects of both factors (distance and efficaciousness) can be concurrently estimated from data that are elicited with a consistent procedure across groups. Each subject judges two agents from different cells, allowing for an estimation of the within-subjects effect of the factor(s) varied between these cells. For example, to estimate the within-subjects effect of distance, we can look at conditions 1 and 2 (see Figure 1) and compare the mean ratings for the near agent with those for the far agent within these groups. This can be formalized as in Equation 1:
\((\) Near/High - Far/High \()+(\) Near/Low - Far/Low \() \neq 0\). [1]
For the within-subjects effect of efficaciousness, we proceed analogously with the efficaciousness contrasts within conditions 3 and 4, that is, we test whether
\[
(\text { Near/High }- \text { Near/Low })+(\text { Far/High }- \text { Far/Low }) \neq 0 \text {. [2] }
\]

At the same time, in conditions 1 to 4 , one of the two factors, distance or efficaciousness, is kept constant at one of its levels within participants. For example, both agents’ means (high and low efficaciousness) in condition 3 are near, whereas both are far in condition 4. Distance is thus a constant background condition within these groups, but is varied between-subjects across the groups. Between-subjects effects of distance can thus be estimated by averaging across both ratings (high and low efficaciousness) for each subject in conditions 3 and 4 and by comparing the means of these averages between these conditions as in Equation 3:
\((\) Near/High + Near/Low \()-(\) Far/High + Far/Low \() \neq 0\). [3]

For the between-subjects effect of efficaciousness, we proceed analogously with the efficaciousness contrast between conditions 1 and 2, that is, we test whether
\((\) Near/High + Far/High \()-(\) Near/Low + Far/Low \() \neq 0\). [4]
Finally, conditions 5 and 6 yield additional information as to how both factors interact when they are concurrently varied in within-subjects comparisons. Condition 5 tests whether subjects make a difference between near/highly efficacious and far/lowly efficacious means, while condition 6 tests whether they make a difference between near/lowly efficacious and far/highly efficacious means. In this last condition, it can be seen if efficaciousness considerations trump distance considerations if both are in conflict.

\section*{Results}

The results are summarized in Figure 2. A three-way mixed 6 (condition 1-6, between-subjects) \(\times 2\) (stimulus i vs. ii, within-subjects) \(\times 2\) (order: i-ii vs. ii-i, between-subjects) ANOVA revealed no main effect of condition, \(F(5\), \(171)<1\), but a main effect of stimulus, \(F(1,171)=25.61\), \(p<.01, \eta_{\mathrm{p}}^{2}=.13\), and a significant Condition \(\times\) Stimulus interaction term, \(F(5,171)=6.67, p<.01, \eta_{p}^{2}=.16\). Order did not affect sense of obligation, \(F(1,171)=1.01, p=.32\), and did not interact with condition, stimulus, or the Condition \(\times\) Stimulus interaction term, all \(F\) s \(<1\). We therefore collapsed the ratings from both order versions for each condition to calculate the specific contrasts from Equations 1 to 4.

The within-subjects contrasts reveal no effect of distance (Equation 1), \(t(171)=-.92, p=.36\), but a significant effect of efficaciousness (Equation 2), \(t(171)=5.08, p<.01\), \(d=.64\). When attending to the content of the varied factors, subjects declare that higher probability of success increases the obligation of an agent to endanger himself in order to help a victim, but that the location of his proximate means is irrelevant given constant efficaciousness. The betweensubjects contrasts reveal no effect of either distance (Equation 3), \(t(171)=.03\), or efficaciousness (Equation 4), \(t(171)=1.34, p=.18\). The results support the conclusion that the location of proximate means relative to a victim does not matter under either evaluation mode. The degree of efficaciousness seems to matter when people compare the obligations of several agents but does not have a measurable influence when varied as a background condition.

When both distance and efficaciousness were varied in a co-acting fashion in the within-subjects contrast (condition 5), people held agents from the near/high efficaciousness cell to be more obligated than agents from the far/low efficaciousness cell, \(t(171)=2.08, p<.05, d=.38\). When both factors were varied in a counteracting fashion (condition 6), people judged agents from the far/high efficaciousness cell to be more obligated than agents from the near/low efficaciousness cell, \(t(171)=4.36, p<.01\), \(d=.81\). Regardless of the location of the means, subjects' moral obligation judgments are tracked by efficaciousness.

\section*{Discussion}

The findings of Experiment 1 suggest that means-victim proximity does not matter morally at constant levels of efficaciousness. Near proximate means only obligate if their nearness implies increased efficaciousness. The fact that efficaciousness exhibited no significant between-subjects effect seems somewhat surprising. Previous research has shown that variations in scope (rather than in quality) are hard to evaluate in SE mode (Hsee \& Zhang, 2010). Accordingly, at constant levels of high or low efficaciousness, our subjects might have merely encoded that both agents can do something to help which is required by the OIC principle. Lacking knowledge about a relevant range of success probabilities in SE mode, subjects might have become insensitive towards variations in degree of efficaciousness beyond this categorical precondition.

\section*{Experiment 2}

In this experiment, we wanted to replicate the basic finding that means-victim distance is irrelevant at constant levels of efficaciousness with a more realistic cover story. At the same time, we wanted to demonstrate that not all effects of the nearness of means are mediated via efficaciousness. Nagel and Waldmann (2013) have argued that spatial proximity between agents and victims is not only indicative of increased efficaciousness, but usually also of increased experiential directness and shared group membership. Similarly, near means do usually not only indicate increased efficaciousness, but also increased personal involvement with the victim. For example, if an agent owns money on a bank account in a faraway country, he is usually more personally involved with this country than if his money was stored elsewhere. Maybe he has visited the country before
and will do so again in the future, or at least he profits from the financial system in the foreign country. If the agent feels obligated to donate this money to sick children suffering in the same foreign country (that is, near his means), this could be due to his increased personal involvement rather than due to means-victim proximity per se.

\section*{Method}

We gathered data from 212 subjects from Great Britain (127 female, mean age 37 years). The experimental design was as in Experiment 1, but instead of efficaciousness we varied personal involvement (high vs. low) orthogonally to meansvictim distance (near vs. far). Efficaciousness was explicitly kept constantly high across all conditions. In this way, it was assured that potential distance effects could not be mediated via efficaciousness considerations. This time, we assigned roughly twice the number of subjects to conditions \(5(n=50)\) and \(6(n=52)\) than to the remaining conditions ( \(n\) s ranging from 26 to 31 ) to have roughly equal numbers of observations in the cell combinations that are compared with each other in the planned contrasts.

The subjects were again assigned randomly to one of the twelve scenario versions resulting from our design (Figure 1). Each scenario contained two British agents having the possibility to donate money (via online banking) to rescue Haitian children who are threatened by a deadly disease. Our distance manipulation varied the location of the agents' money. It was located either at a bank in Haiti (near the sick children), or at a bank in Great Britain (far from the sick children). Our involvement manipulation varied the process by which the agents' means had ended up in their locations. In the high involvement conditions, the agent had personally decided to open an account at the Bank of Haiti and that his money was to be constantly located in a branch of this bank

Figure 2: Results of Experiment 1. Categories on the abscissa represent between-subjects variations, while line graphs correspond to within-subjects variations (cf. Figure 1). C. = condition. Error bars indicate 95\% CIs.
either in Haiti (cell a in Figure 1) or in Great Britain (cell c). In the low involvement conditions, the agent had opened a bank account at an international bank. Employees of this bank regularly transferred the money to the most profitable location, which momentarily happened to be in Haiti (cell b) or in Great Britain (cell d). Note that this is an utterly minimal variation of personal involvement. Neither agent had ever been to Haiti or has had any other personal connection to the country. The only difference was whether a personal decision had caused the money to end up on an account of a bank from the same state as the children.

The wording of the sense of obligation measure was as follows: "How strongly do you believe Dave [John] should transfer \(£ 10\) from his [bank account] in [location] to the donation account?" In the different conditions, the specifications of the bank accounts and their locations were adapted according to the scenario. The scales and the rest of the procedure were identical to those in Experiment 1.

\section*{Results}

The results are summarized in Figure 3. A three-way mixed 6 (condition 1-6, between-subjects) \(\times 2\) (stimulus i vs. ii, within-subjects) \(\times 2\) (order: i-ii vs. ii-i, between-subjects) ANOVA revealed a main effect of condition, \(F(5\), 200) \(=2.29, \quad p<.05, \quad \eta_{p}^{2}=.05, \quad\) and of order, \(F(1\), 200) \(=4.65, p<.05, \eta_{\mathrm{p}}^{2}=.02\), while the within-subjects factor (stimulus) was not significant ( \(F<1\) ). None of the interaction terms approached statistical significance. The order effect resulted from ratings being somewhat higher when stimulus ii was presented before stimulus i. However, since there is no systematic relationship between the underlying factors and the assignment of cells to Stimuli i and ii, and since order did not interact with condition, stimulus, or their interaction (all \(F \mathrm{~s}<1\) ), we collapsed the ratings from both order versions for each condition to calculate the specific contrasts outlined in Equations 1 to 4.

The within-subjects contrasts reveal neither effects of distance (Equation 1), \(t(200)=.00\), nor of personal involvement (Equation 2), \(t(200)=-.16\). When attending to the content of the varied factors, subjects declared that it does not make a difference where the agents' money is located, or how the money ended up in its location. The between-subjects contrasts reveal no effect of distance (Equation 3), \(t(200)=-.16\), but a significant effect of personal involvement (Equation 4), \(t(200)=2.16, p<.05\), \(d=.58\). This shows that our minimalistic variation of personal involvement mattered as a background condition, but was discounted when attention was directed to this factor. Distance, by contrast, did not make a difference in either evaluation mode.

Subjects differentiated between the agents in condition 5, \(t(200)=3.29, \quad p<.01, \quad d=.46\). When proximity and involvement coincided, as in most natural situations, subjects judged the near/highly involved agent to be more obligated than the far/lowly involved agent. However, the null effects of distance in conditions 1 to 4 indicate that this effect cannot be attributed to distance per se. The effect also vanished when both factors were varied in a counteracting fashion (condition 6, \(t[200]=-.02\) ).

\section*{Discussion}

Our findings indicate that spatial distance between an agent's proximate means (his money) and the needy victims does not affect people's sense of obligation if efficient logistic means (online banking) are available, contrary to Kamm's (2007) intuitions which stated that spatial proximity between the agent's means and the victim may increase the agent's obligations to let these means be used, even if the agent is personally far and even at constant levels of efficaciousness. At the same time, people are sensitive to the process by which an agent's proximate means ended up in its location. If nearness between means and victim is at

Figure 3: Results of Experiment 2. Categories on the abscissa represent between-subjects variations, while line graphs correspond to within-subjects variations (cf. Figure 1). C. = condition. Error bars indicate 95\% CIs.
least minimally indicative of an increased personal involvement with the victims (in virtue of having decided to place one's assets in a bank based in their home country), obligation judgments are increased. However, if the nearness between means and victims results from pure coincidence (they are temporally transferred to the near location by a third party), it loses its moral impact.

The effect of personal involvement is limited to SE judgments and disappears in attentive JE mode. Our operationalization of involvement apparently was so minor that people judged it to be irrelevant when attending to it, and yet, it was sufficient to affect their judgments as a background condition. Stronger variations in involvement (e.g., previous visits to Haiti) can of course be expected to be honored in JE mode as well.

\section*{General Discussion}

Previous research suggests that distance between agent and victim is irrelevant for laypeople's judgments of helping obligations (Nagel \& Waldmann, 2013). The present findings extend this conclusion to the more complicated spatial relation between an agent's means and a needy victim, contrary to Kamm (2007) who argued that means of helping that are located spatially close to the victim might increase the agent's obligation to let these means be used at personal costs. In the presence of sufficiently efficient logistic means (making far proximate means efficacious by allowing them to be brought close swiftly), the distance between an agent's proximate means and the victim becomes morally irrelevant, both in separate (SE) and joint evaluation (JE) modes. Means-victim proximity matters morally only when it implies other obligation-inducing factors, such as increased efficaciousness. To the extent that proximity causes efficaciousness, the intuition that we have a strong obligation to help victims near our means can be seen as a manifestation of the ought-implies-can (OIC) principle.

However, we have also seen that not all effects of meansvictim proximity can be explained by the OIC principle. This is because proximity of means is usually not only indicative of increased efficaciousness, but also of increased personal involvement with the victim. In such cases, other cognitive mediators apart from efficaciousness considerations seem to do the moral work (probably emotional engagement and reasons referring to social responsibilities).

The impact of the factors associated with distance was strongly influenced by evaluation mode. Incremental differences in efficaciousness were highly important in the comparison of several agents within a single scenario (JE mode), but they did not affect obligation judgments as a constant background condition (SE mode). Minimal personal involvement, by contrast, was sufficient to increase obligation judgments in SE, but this difference was discounted in JE. These fine-grained observations underline the value of our new experimental design. It allows for a
detailed picture of judgments under different evaluation modes at constant procedural conditions.

The conceptual distinction between logistic and proximate means (which is grounded in their functionally different relationship to spatial distance) does not seem to correspond to a psychologically meaningful distinction. In Experiment 1, subjects did not differentiate between means that were inefficacious due to deficits affecting their potential role as proximate means (i.e., the sticks' brittleness) vs. those that could not be brought close in time with the available logistic means (i.e., because of the sticks' heaviness). What matters morally seems to be the means' reduced efficaciousness in the given context, regardless of the causes for different degrees of efficaciousness and of whether or not these causes are related to distance.

Although the empirical findings are clear-cut, there are some limitations. Our analysis of means seems to be restricted to cases of generative causation, that is, to cases in which a causal chain involving the transmission of a causal quantity is elicited by the agent. It is left unanalyzed what role (if any) means and their location might play in cases of causation by omission (Wolff, Barbey, \& Hausknecht, 2010). A related concern is that our account is mainly tailored to handle cases in which an impending physical harm threatens a victim. It is less clear how the account could deal with moral obligations related to other moral domains (see Haidt \& Graham, 2007). Another special case arises when humans are being used as means. The moral implications of such cases are too far-reaching to be discussed here (see Waldmann, Nagel, \& Wiegmann, 2012, for an overview). As far as obligation judgments in harmbased rescue cases are concerned, however, our findings seem to be clear: Not distance per se but features that are normally associated with distance drive our moral intuitions.

\begin{abstract}
Jones and Rachlin (2008) found that the amount of money a person is willing to forgo in order to give \(\$ 75\) to another person decreased as a hyperbolic function of perceived social distance, in the same way as occurs in intertemporal choice. This study aimed to extend this finding to the domain of social networks, in which social distance is defined by degrees of separation. A total of 334 participants responded to tasks very similar to those in Jones and Rachlin (2008), except that they were required to choose whether they would prefer to receive an amount of money for themselves only or an amount of money for themselves and a person who is \(n\) degrees of separation from them up to six degrees. The results show that the hyperbolic function fit the data well, and that several processes appear to contribute to the judgments made in the experimental tasks.
\end{abstract}

Keywords: social discounting; \(n\) degrees of separation; intertemporal discounting, probability discounting

\section*{Introduction}

In modern society, people must use money to live. However, as a matter of course, people cannot use all their money at once. Rather, people must allocate it between several purposes or several time periods. They distribute money between several stock options so as not to lose all their money at once. They save money for the future to avoid financial difficulties when they are old. Additionally, we also must share money with others in order to prevent poverty. As these examples show, how people use money is of vital importance in life, and appears to be organized according to several dimensions.

According to Julian Simon (1995), a person's allocation of available goods can be described in terms of a three-coordinate system: one is the coordinate of their own current consumption, included in which is the concept that a person has several selves corresponding to their various positions, such as the family self or working self, and so need to allocate goods to these selves. The second is a coordinate of later times, representing sequential temporal persons as different from each other. The third is consumption by other people, according to which the feeling of sympathy between people may be measured by a discount factor. Simon (1995) suggested that this discount function may be similar to that of intertemporal discounting.

Consumption in later time periods corresponds to what is called intertemporal discounting. Many studies have demonstrated that people discount the value of goods as time goes by. Generally, it is known that people prefer small but immediate goods to large but delayed goods (e.g.,

Lowenstein \& Prelec, 1998). To account for this preference, exponential and hyperbolic functions have been proposed.

An exponential discounting function has a form in which the discounted value \(v\) of rewards \(V\) is expressed as follows:
\[
\begin{equation*}
v=V e^{-k D} \tag{1}
\end{equation*}
\]
where \(v\) and \(V\) are the discounted and undiscounted reward values, respectively, and \(D\) is the time delay.

Alternatives to exponential discounting have been proposed by psychologists, behavioral ecologists, and behavioral economists. One major alternative proposal is that the discounting function is hyperbolic (e.g., Mazur, 1987):
\[
\begin{equation*}
v=\frac{V}{1+k D} \tag{2}
\end{equation*}
\]

Until now, many studies have demonstrated that the hyperbolic function, rather than the exponential function, is the most appropriate because it fits the data better than the exponential function, under various experimental conditions (for a review, see Green \& Myerson, 2002).

On the basis of findings within the intertemporal choice literature, Jones and Rachlin (2006) investigated whether discounting similar to intertemporal choice could also be found in Simon's third coordinates. In their experiments, Jones and Rachlin (2006) required participants to imagine that they had made a list of the 100 people closest to them in the world, ranging from their dearest friend at position \#1 to a mere acquaintance at \#100, and then participants answered whether they would forgo a fixed amount of money to give it to another person or not. The results showed that the amount of money people were willing to give to another person decreased as a hyperbolic function of the perceived social distance between them, indicating that the discounting function with regard to social distance is similar to that in intertemporal choice, as Simon (1995) claimed. This study aims to extend the findings of Jones and Rachlin (2006) by considering another type of social distance.

Recent studies in network science have begun to pay attention to the concept of human society considered as a network (Barabasi, 2002; Christarski \& Fowler, 2008; Milgram, 1967). You have a friend, and your friend has a friend. If you do not know the friend of your friend, you can still have a link to the person via your friend. You can extend such connections infinitely. In this vein, our society is a network of friend connections, and much research has
paid attention to various aspects of our society considered as such a network (Barabasi, 2002; Christarski \& Fowler, 2008).

In a social network, the \(n^{\text {th }}\) degree of separation can be considered as one type of social distance between two persons. The degree of separation refers to the number of links via friends between two persons. For example, your friend is a friend of the first order, because there is one link between you and your friends, and a friend of your friend is of the second order because there are two links; one is between you and your friend, and the other is between your friend and the friend of your friend. The number of links ( \(n\) ) between two persons can be increased infinitely, and as \(n\) increases, the social distance from you increases. For example, a second order friend is more remote than a first order friend, because you have not met the former whereas you directly know the latter. In addition, a third order friend is more remote than a second order friend, because even your friend does not know the former person. If the degree of separation is taken as social distance, the following questions arise: Does social discounting also appear with this type of social coordinate? If so, is it hyperbolic or exponential? The first purpose of this study is to address these questions.

A second purpose of this study is to explore the relationship between social ranking and degrees of separation as measures of social distance. Although both social ranking and degrees of separation can be considered as indices of social distance between persons, their meanings are a little different. Whereas the former measure reflects the distance among in-group members because it assumes that the ranking orders the 100 people closest to a person, from the dearest friend to a mere acquaintance, the latter measure contains not only in-group but also out-group individuals, because one cannot know a friend whose degree is of more than two. Thus, even if hyperbolic discounting is found in the \(\mathrm{n}^{\text {th }}\) degree of separation measure, the relationship between social ranking and degrees of separation would still be an interesting question. Therefore, this study also aims to address this issue.

For this research two empirical studies have been performed. Study 1 was to examine whether social discounting occurs with social distance in terms of degrees of separation. Study 2 explored the relationship between degrees of separation and closeness ranking, as used in Jones and Rachlin (2006).

\section*{Study 1}

Study 1 required participants to answer whether they would prefer (a) an amount of money for themselves or (b) an amount of money for themselves and the person who is \(n\) degrees of separation from them, up to 6 degrees of separation. By this procedure, we tried to determine the amount of money forgone to give a person 60,000 yen. This procedure is almost the same as that of Jones and Rachlin (2006), except that the closeness ranking had been exchanged for degrees of separation.

\section*{Procedure}

One hundred and nineteen undergraduates participated in Study 1 for course credits, and all materials and response formats were provided in booklets. The booklets explained the meaning of the degrees of separation on the first page, and the experimental tasks began on the second page. The second page contained the following instructions:

You know a person who is called "your friend." The minimal condition for a person to be called a friend is that you and s/he know each other. In addition, there is a "friend of your friend" who is known to your friend but unknown to you. This "friend of your friend" can also know a "friend of the friend of your friend" and a chain of friends can extend infinitely. Thus, we connect to various people through friends, friends of friends, and friends of friends of friends, and so on, although most of them are unknown to you.

Next, you will be asked to make a series of judgments based on your preferences. On each line, you will be asked if you would prefer to receive an amount of money for yourself or an amount of money for the person listed. Please circle A or B for each line.

Each of the next six pages summarized the above instructions and then presented a list of questions as follows, with a different N -value on each page:

Now imagine the following choices between an amount of money for you and an amount for you and for your friend. Circle A or B to indicate which you would choose in EACH line.
(A) 120,000 yen for you alone
(B) 60,000 yen for you and 60,000 yen for your friend
(A) 110,000 yen for you alone
(B) 60,000 yen for you and 60,000 yen for your friend
(A) 60,000 yen for you alone
(B) 60,000 yen for you and 60,000 yen for your friend

The A-rows listed 9 amounts decreasing by 10,000 yen on each line, from 120,000 to 60,000 yen. Row-B had a different degree of separation on each page. The degrees of separation were from one to six. On each line, the participants were asked to choose between an amount of money just for themselves and 60,000 yen each for themselves and for the person. The degrees of separation were manipulated by adding "of friend" to the sentence in line B. For example, the second order friend was described as the "friend of your friend," and the third order friend as the "friend of the friend of your friend." All participants finished their questionnaire within fifteen minutes.

\section*{Results and discussion}

The crossover point was estimated as the average of the last selfish (row-A) choices and the first generous (row-B) choices, in the same way as in Jones and Rachlin (2006) or Rachlin and Jones (2008). For example, if a participant preferred 90,000 yen for herself to having 60,000 yen and giving 60,000 yen to the \(\mathrm{N}^{\text {th }}\) degree of separation friend, but preferred to have 60,000 yen and give 60,000 yen to the \(\mathrm{N}^{\text {th }}\) friend over having 80,000 yen for herself, then the crossover point was taken as being 85,000 yen for that participant at that N -value. Some participants (the majority at N 51 and N 5 2) chose the generous option even when the alternative was 120,000 yen for themselves. In these cases, a crossover point of 125,000 was assumed. In contrast, many participants chose the selfish option even when the choice was between 60,000 yen for themselves and 60,000 yen for themselves in addition to 60,000 yen for their friends. In these cases, the crossover point was assumed to be 0 .

Figure 1 shows the mean allocation of money to friends who have \(n\) degrees of separation. We fitted both the hyperbolic and exponential functions to this data and compared their performances. The solid line is the best fitting hyperbolic discount function and the dashed line is the best fitting exponential discount function. The fit is remarkably good \(\left(R^{2}=0.995\right)\) when compared with the fit of intertemporal choice (e.g., Rachlin \& Raineri, 1992) or of social discounting (Jones \& Rachlin, 2006).

For comparison, the best fitting exponential discount function is also shown in Figure 1, as the dashed line. Although the fit with exponential discounting is high ( \(R^{2}=0.971\) ), the percentage of variance accounted for by the exponential discount function is less than that of the hyperbolic function. The difference found between the fit of the hyperbolic and the exponential discounting is almost the same as that in Jones \& Rachlin (2006). In sum, these results show that the hyperbolic function provides a better fit to the data than the exponential discount function. Thus, we can conclude that people's discounting in terms of degrees of separation is similar to that of social ranking and intertemporal choice.

\section*{Study 2}

Study 2 was designed to investigate a relationship between n degrees of separation and social rankings. Although the two are similar as they both represent some kind of social distance, they do differ as while the latter distance can only represent the remoteness of in-group members, the former includes that of both in-group and outgroup people. Thus, although Study 1 demonstrated hyperbolic discounting occurs in \(n\) degrees of separation, the way in which social ranking and degrees of separation are similar types of social distance still remains unclear. Therefore, Study 2 required participants to indicate their preference between receiving money for themselves and sharing money with their friends, under both social ranking and degrees of separation types of distance.

Figure 1 Hyperbolic and exponential discount functions under the \(n^{\text {th }}\) degree of separation in Study 1

\section*{Procedure}

Two hundred and fourteen participants answered social discounting tasks using both social ranking and degree of separation conditions. As tasks to explore preferences with social distance as degrees of separation, we employed the same tasks as those in Study 1. For the social ranking tasks, we employed a procedure almost the same as that of Jones and Rachlin (2006). Precisely, the participants were provided with instructions that had been translated into Japanese from the original ones used by Jones and Rachlin (2006). Then participants were required to make choices between receiving an amount of money for themselves or receiving an amount of money for themselves and their friends, using the following response form:

Now imagine the following choices between an amount of money for you and an amount for you and for your friend. Circle A or B to indicate which you would choose in EACH line.
(A) 120,000 yen for you alone
(B) 60,000 yen for you and 60,000 yen for your \#_person
(A) 110,000 yen for you alone
(B) 60,000 yen for you and 60,000 yen for your \#_person
.(continuing down to)
(A) 60,000 yen for you alone
(B) 60,000 yen for you and 60,000 yen for your \#_person

The blanks shown above was replaced by a number ( \(\mathrm{N}=1,2\), \(5,10,20,50\), or 100 ), with a different number used on each of the seven question pages.

Participants answered both the social ranking and degree of separation tasks in random order. All participants completed all the tasks within 20 minutes.

\section*{Results and discussion}

Figure 2 shows the results of both the social ranking and the degree of separation tasks. We found that the hyperbolic function fitted the data better than the exponential function in both cases. The differences between the hyperbolic and exponential discounting in Study 2 are more remarkable than those in Study 1, or in Jones and Rachlin (2006); whereas the \(R^{2} \mathrm{~s}\) of the exponential functions are 0.873 and 0.850 , those of the hyperbolic functions are greater than 0.90 . Additionally, the data points systematically deviate from the exponential functions. Thus, we can conclude that Study 2 replicated the results of Study 1 and of Jones and Rachlin (2006).

To explore the relationship between social ranking and degrees of separation in depth, we performed the following two additional analyses. First, we estimated the \(k\) parameters of hyperbolic functions for the social ranking and degree of separation tasks. There was no relationship ( \(r=-0.03, p>.01\) : Figure 3) between \(k\) parameters in the two tasks (Figure 3), indicating that the steepness of the functions in the social ranking and degrees of separation cases are somewhat independent from each other.

Second, we also performed a factor analysis of the crossover points with promax rotation using the maximum likelihood method. The eigenvalues for the first three factors were \(7.04,2.54\), and 1.35 , respectively. Mainly due to the eigenvalue results, we adopted a three-factor solution pattern for the discounting tasks shown in Table 1, assuming the following interpretations of the meaning of the three factors.

Factor 1 leads mainly to allocations for high ranking friends and first degree friends. To define, these friends can be interpreted as close friends, so we named this factor "close friends." Factor 2 can be considered as the "unknown others" factor, because it strongly influences the allocation to friends who have more than one degree of separation. Logically, one cannot directly know friends who are of more than the second order, and specifically, friends who have more than two degrees of separation are actually unknown because they are not even the friend of a first order friend. Factor 3 mainly impacts friends with rankings higher than \(10^{\text {th }}\), and in particular those who are ranked at \(20^{\text {th }}\) place or higher. These friends are considered as not being so close. Thus, we named this factor as the "acquaintances" factor.
The above results suggest that there are several dimensions to social discounting. Specifically, it is interesting that people have two dimensions of social distance with others who are not so close to them. To examine this indication more precisely, we also performed structural equation modeling and compared models of one, two, and three factors (see Figure 4).

Figure 2 Hyperbolic and exponential functions with data from the \(n\) degrees of separation and social ranking tasks in Study 2: The upper graph shows results in the \(n\) degrees of separation case, and the lower shows those in the social ranking case.

Figure 3 Scatterplot of \(k\) parameter

Table 1 Results of factor analysis
\begin{tabular}{cccc}
\hline & Factor1 & Factor2 & Factor3 \\
\cline { 2 - 4 } Degree of separation & & & \\
1st & 0.78 & 0.12 & -0.07 \\
2nd & 0.35 & 0.43 & 0.10 \\
3rd & 0.11 & 0.75 & 0.07 \\
4th & -0.03 & 0.94 & 0.06 \\
5th & -0.05 & 0.99 & -0.02 \\
6th & -0.06 & 0.99 & -0.03 \\
Social ranking & & & \\
1st & 1.00 & -0.03 & -0.10 \\
2nd & 1.01 & -0.03 & -0.07 \\
5th & 0.79 & -0.06 & 0.23 \\
10th & 0.50 & -0.08 & 0.53 \\
20th & 0.26 & -0.11 & 0.79 \\
50th & -0.09 & 0.05 & 0.97 \\
100th & -0.16 & 0.18 & 0.83 \\
Correlations & & & \\
Factor1 & 1.00 & & \\
Factor2 & 0.36 & 1.00 & \\
Factor3 & 0.53 & 0.49 & 1.00 \\
\hline
\end{tabular}

The one factor model represents a hypothesis that both social rankings and degrees of separation can be summarized by one dimension, that people's dimension of social discounting is unitary. In contrast, the two and three factor models assume that social discounting can be decomposed into several dimensions. The two-factor model entails that social discounting occurs separately in the social ranking and the \(n\) degrees of separation tasks. In other words, this model assumes that participants construct a dimension of social discounting in accordance with experimental tasks. The three-factor model expresses an implication, based on the results of the factor analysis, that the two types of social distance considered in this study can be decomposed into three factors: one influences both social ranking and degrees of separation, and the other two factors affect these two dimensions, respectively.

The results of the structural equation modeling, shown in Table 2, clearly support the three factor model, as all of the fit indices indicate it is superior to the other two models. Thus, we can conclude that although social discounting in social rankings and degrees of separation share the same components, they can be decomposed into several dimensions. That is, while these two types of social distance are similar in how they reflect allocations made to closer friends, they differ in representing the allocations made to others who are not so close.

Figure 4 Three structural equation models: (a) a one-factor model that indicates both the social ranking and \(n\) degrees of separation can be summarized by one dimension; (b) a two factor model that implies participants construct dimensions of social discounting corresponding to the experimental tasks; (c) a three-factor model that reflects the implication of the factor analysis that social rankings and degrees of separation share one common factor ("friend"), but are also individually affected by "acquaintances" and "unknown others" factors, respectively.

\section*{General discussion}

The results of the two studies can be summarized as follows. First, we found that there is hyperbolic social discounting with the \(n\) degrees of separation type of social distance. Recently, many researchers have paid attention to the way in which the structure of our social networks affects human life (e.g., Christarski \& Fowler, 2009). Most of these studies investigate how people's behavior affects others through links between persons. However, previous studies have not considered the way in which people consider others in their social network. In this vein, this may be the
first study that concerns how people consider others who have \(n\)

Table 2 Results of structural equation modeling.
\begin{tabular}{lcccc}
\hline & AIC & BIC & GFI & CFI \\
\cline { 2 - 5 } Model 1 & 311.98 & 497.11 & 0.88 & 0.96 \\
Model 2 & 342.47 & 534.33 & 0.90 & 0.95 \\
Model 3 & 186.37 & 331.11 & 0.94 & 0.99 \\
\hline
\end{tabular}
degrees of separation. Furthermore, as far as we know, this is the first study that shows hyperbolic discounting occurring with social distance other than in closeness rankings. Hyperbolic discounting is found not only in the domain of social discounting but also in probability or intertemporal discounting (Jones \& Rachlin, 2010). Thus, this study applied hyperbolic discounting to another type of social distance and has demonstrated with evidence the hyperbolic function's ability to explain discounting under various types of psychological distance.

Second, from the results of estimating the parameters of hyperbolic discounting and the structural equation modeling, we can conclude that people have two dimensions to their conceptualization of others who are not so close to them: one applies to others who are known but are not so close, and the other applies to those who are unknown. Intuitively, these appear to be quite natural results. However, these results are interesting because hyperbolic discounting occurs under both dimensions, despite them being independent of each other. Additionally, this finding is also of interest because it appears to contradict Simon's (1995) suggestion that social discounting is one-dimensional.

The results of this study may support construal level theory (Trope \& Lieberman, 2010). This theory assumes that people's judgments of various types of psychological distance can be decomposed into two levels of construal: higher and lower levels. The theory claims that high-level construals are relatively abstract, coherent, and superordinate mental representations as compared with low-level construals. It also argues that people use increasingly higher levels of construal to represent an object as the psychological distance from the object increases. The results of our factor analysis and structural equation modeling consistently show that both the social ranking and \(n\) degrees of separation can be decomposed into two factors. One factor reflects allocations made to psychologically close friends, and the other reflects those to psychologically remote friends. This factor structure appears to match the structure entailed by construal level theory.

In addition, what is more interesting in the results of the factor analysis is that the factor reflecting allocations to close friends is related to both the social ranking and \(n\) degrees of separation types of distance. As stated in the introduction, social rankings and degrees of separation are
somewhat different dimensions of social distance: while the former represents distances between known others, the latter contains those between unknown others. In this vein, the results of the factor analysis suggest that the contents of the "friends" factor are richer than those of the other two factors, because this factor influences the two different types of social dimension. If we interpret the "friends" factor as a lower level construal that is psychologically closer, this indication corresponds to a proposition of construal level theory that lower level construals have more complex representations than higher level construals (Trope \& Lieberman, 2010).

One important issue for future research regarding social discounting in cases of \(n\) degrees of separation may be its relationship to probability or intertemporal discounting. Jones and Rachlin (2009) reported that the steepness of discounting, represented by the \(k\) parameter, was correlated for probability, intertemporal, and social ranking discounting across participants. The results of Study 2 show that the \(k\) parameter did not correlate between the social ranking and \(n\) degrees of separation experiments, suggesting that the latter dimension may be unique and different from the other three dimensions. If so, what is the meaning of social discounting? Why does the \(n\) degrees of separation differ from delay, probability, and social ranking in its discounting? Pursuing this question may be fruitful in exploring how "social" is represented in the human mind.

\begin{abstract}
We report an experiment in which a change in the context of a stock-flow reasoning problem leads to a \(44 \%\) reduction in the use of an erroneous 'correlation heuristic' response. In its original context - a global warming scenario - the majority of participants pattern-match the output of a system to its inputs (i.e., use a correlation heuristic). In the changed context - financial debt management - the majority reason correctly that in-flows and out-flows must converge to stabilize stock. Potential applications for improving communication of climate change science are discussed.
\end{abstract}

Keywords: stock-flow reasoning; correlation heuristic; climate change

There is overwhelming agreement amongst climate scientists that the globe is warming up, due in large part to increases in the emissions of greenhouse gases (e.g., Anderegg et al., 2010). Despite this consensus in the scientific community, highly divergent opinions about the existence and implications of global warming remain entrenched in the wider community in many countries (e.g., Leiserowitz \& Smith, 2010; Leviston \& Walker, 2011).
The manifold reasons for this 'disconnect' between the science and belief range from fundamental differences in the way people 'view' the world (e.g., Kahan et al., 2012), to the pernicious attempts to manufacture doubt in the science (e.g., Oreskes \& Conway, 2010), to deficits in lay understanding of the mechanisms of global warming (e.g., Bord et al., 2000). Here we focus on this last issue and examine how a change in context might aid understanding some basic science behind how global warming 'works'.
Our experimental task focusses on the relationship between the amount of \(\mathrm{CO}_{2}\) emitted into the atmosphere, the amount of \(\mathrm{CO}_{2}\) absorbed via natural processes, and the resulting 'stock' or concentration of \(\mathrm{CO}_{2}\) that accumulates in the atmosphere. The simple principle that participants
need to appreciate to complete this task successfully is fundamental to any system that involves in-flows, outflows and an accumulating stock. Namely, that a stock will accumulate its in-flows minus its out-flows. Thus water in a bathtub will accumulate the water flowing in from the tap, minus any water flowing out through the drain. If the inflow exceeds the outflow, the tub will continue to fill up with water (e.g., Cronin et al., 2009; Sterman, 2008).
The same principle applies to the simplified climate system we consider in our experimental task: the accumulation of \(\mathrm{CO}_{2}\) in the atmosphere is determined by the in-flow (emissions) and the out-flow (absorptions). If emissions exceed absorptions \(\mathrm{CO}_{2}\) will continue to accumulate; only when emissions and absorptions converge ( \(\mathrm{CO}_{2}\) is entering and leaving the atmosphere at the same rate) will the atmospheric concentration stabilize.
A graphical representation of these relationships is shown in Figure 1 (adapted from Dutt \& Gonzalez, 2012 and Sterman \& Booth-Sweeney, 2007). The top graph shows the accumulated stock of \(\mathrm{CO}_{2}\) in the atmosphere from the period 1900 to 2100 . The stock rises steadily until the final period (between 2090 and 2100) where it stabilizes, i.e., remains constant at 950 GtC .
The bottom graph depicts the absorption of \(\mathrm{CO}_{2}\) (the green line) which is a fixed constant of \(40 \mathrm{GtC} /\) decade across the time period, and the emissions (the black line up to 2000) which steadily increases across time. The task facing participants in our experiment was to complete this emissions line for the remaining time period (2010-2100) so that the concentration depicted in the top graph was achieved; specifically, so that the concentration was stabilized by the final period. The additional lines on the bottom graph show an approximately correct (solid blue line) and a characteristically incorrect (red dashed line) response trajectory.

Your task:

REMEMBER:
The emissions line
shows the number of
gigatonnes of carbon that are added to the atmosphere each decade, due to human activities such as combustion of fossil fuels, and deforestation.

The absorptions line shows the number of gigatonnes of carbon that are removed from that are removed from decade, due to each decade, due to natural
processes such as plant growth, and CO 2 dissolving in the ocean.

The atmospheric CO2 line shows the accumulated total number of gigatonnes of CO 2 in the atmosphere, for each decade.

Next decade

Figure 1: Screenshot showing the Computer Climate Stabilization Task. The participant's task is to complete the emissions trajectory in the bottom graph so that the stabilization of atmospheric \(\mathrm{CO}_{2}\) shown in the top graph is achieved. The solid blue sketched line in the bottom graph shows a correct response trajectory in which the emissions and absorption lines converge at the point of stabilization (2100). The red dashed sketched line is a typical "correlation heuristic" response trajectory in which the emissions line mirrors the trajectory of the accumulation (i.e., continues steadily increasing) - such a response indicates a failure to understand the relationship between emission, absorption and accumulation.

The solid blue line is correct because it takes account of the principle described above. The emission value in each decade is calculated by adding the difference in stock between the current and previous time period to the absorption rate. Thus reading from the top graph in Figure 1 for the first estimate, the stock in 2000 is approximately 770 GtC and in 2010 it is approximately 800GtC. To achieve a net increase of 30 GtC in the atmosphere, 70 GtC must be emitted, 40 GtC of which is absorbed via natural processes (the green flat line in the bottom graph). Thus the correct response is 70 GtC which is approximately the value of the blue line for that decade. The red-dashed trajectory is incorrect because it fails to take account of the principle rather, the trajectory simply mirrors that of the accumulated stock, a steady increase.

Despite the apparent simplicity of stock-flow relationships (we all know how to run a bath without flooding the house), participants presented with tasks like that shown in Figure 1 overwhelmingly produce responses akin to the red-dashed line instead of the blue line (e.g., Cronin et al., 2009; Sterman \& Booth-Sweeney, 2007). The standard explanation of such erroneous responding is over-reliance on pattern-matching or use of a 'correlation heuristic' whereby participants reason that the output of a system
should "look like" (be positively correlated with) its inputs (Cronin et al., 2009; Sterman, 2008).
In the climate task such reasoning leads to people to think that if the concentration is 'going up' then so too should the emissions and thus they sketch a rising emissions trajectory that looks like the accumulation line in the top graph. Such reasoning is not confined to the climate task, however. Responses consistent with the adoption of a correlation heuristic have been observed across a range of task contexts (e.g., water tanks, bank accounts, people entering and leaving a shop) and formats (bar graphs, line graphs, tabulated numbers, and even simple text descriptions) (e.g., Cronin et al., 2009; Sterman \& Booth-Sweeney, 2007).

Couching the explanation of this erroneous behavior in terms of a heuristic begs the question of why the heuristic response is so readily adopted. Heuristics are typically invoked in an attempt to reduce the effort associated with performing a task (e.g., Shah \& Oppenheimer, 2008). One account (Kahneman \& Frederick, 2002) suggests that heuristic responding combines elements of attribute substitution and natural assessment. A participant faced with a hard question about a particular target attribute (e.g., the emissions trajectory) tends to answer a different but easier question (e.g., what does the concentration trajectory look like?). Thus the question about the target attribute is responded to by substitution of a more readily accessible
heuristic attribute. The accessibility of this heuristic attribute is determined by the extent to which its properties are naturally assessed - that is via some routinely used cognitive procedure (similarity, fluency, availability, etc.). The visual availability of the accumulation trajectory in the climate task (i.e., the functional form of the line in the top graph of Figure 1) may well contribute to it being readily 'substituted' for the correct attribute.

This visual similarity cannot, however, be the only trigger to adoption of the correlation heuristic because, as noted earlier, its use has been observed in other contexts and in non-graphical tasks (although the majority of studies have used some kind of graphical representation, e.g., Cronin et al., 2009). Thus a more likely candidate for the prevalence of such heuristic responding is simply that stock-flow tasks are not the kinds of things that we think about regularly, thus we find them difficult, and readily revert to simpler solutions. While we may be able to run a bath - thus exhibiting behavior consistent with understanding the principle of accumulation - it does not necessitate an abstract appreciation of such knowledge.

Furthermore our experience with such systems does not typically involve making sequences of decisions about the rates of change of in-flows and out-flows across time. Rather they involve a single decision within a particular time period. For example, when running a bath we know that we need to put the plug in, turn the tap on and then turn it off before the tub overflows. While this involves (periodic) monitoring of the water level, there is only one interaction with the system (turn off the tap) and the outflow is typically constant (i.e., zero, unless we have a leaky bath).
This analysis of so called 'stock-flow-failure' (Cronin et al., 2009) suggests two aspects that might be important for reducing reliance on a correlation heuristic response. First, the elements of the problem need to be sufficiently accessible or familiar that participants answer the question they are being asked rather than an 'easier' but wrong one. Second, the problem needs to be one in which people have some experience in dealing with the elements across time and preferably one that involves multiple decision points.

We reasoned that a candidate scenario that features many of these desirable attributes is financial debt management. Most of us can readily intuit that if we spend more than we earn then we will get in to debt, and that if we keep spending more than we earn that debt will continue to increase. Unlike the bathtub, debt management involves sequential, discrete monitoring of income and expenditure and is something that many of us grapple with across time ("I will pay off that credit card by the end of year!"). Figure 2 shows how the climate task depicted in Figure 1 can be readily transformed into a 'financial' debt management task.

The top graph in Figure 2 depicts the size (in dollars) of the debt incurred by an individual across a period of 21 weeks. Just like the \(\mathrm{CO}_{2}\) accumulation in Figure 1, the debt increases from just over \(\$ 600\) in Week 1 and then stabilizes at \(\$ 950\) in Week 21. The bottom graph of Figure 2 depicts the amount the person earns (the green line) - which is fixed
at \(\$ 40\) per week, and the amount the person is spending. The amount spent gradually rises to a peak at \(\$ 90\) by Week 11.

Figure 2: The Financial Task: A participant's task was to complete the 'amount spent' line in the bottom graph to ensure stabilization of the debt depicted in the top graph. A correct response required the 'amount spent' and the 'amount earned' lines to converge by 'week 21'.

The task facing the participant is to complete the 'amount spent' line to reflect the debt trajectory shown in the top graph. To do this successfully requires realizing that the 'spending' and 'earning' lines need to converge by Week 21. (For simplicity, participants were told that their debt incurred no interest.)
It is clear that the fundamental (deep) characteristics of the problems illustrated in Figure 1 and Figure 2 are the same, only the surface characteristics have changed (cf., Gonzalez \& Wong, 2011). Both tasks require understanding the relations between in-flows (emissions or spending), outflows (absorption or earnings), and stock ( \(\mathrm{CO}_{2}\) concentration or financial debt). Despite these basic similarities, we hypothesized that the financial debt scenario would trigger the correct intuition more readily (i.e., stop spending more than you earn) than the climate scenario and thus inhibit 'correlation' heuristic responding. In short, participants should be more accurate in plotting the trajectory when given the financial context than the climate context.

We tested this hypothesis in two ways: first we compared participants given only the climate task depicted in Figure 1 with participants given only the financial task in Figure 2. Second we developed another version in which
another group of participants were given the climate task but were invited to think about it as one of financial debt management. In other words, we provided explicit links between the two contexts (e.g., "You might find it helpful to think about emissions as the amount you are spending", etc.). We predicted that participants in this additional condition would perform more accurately than those given the 'pure' climate task and possibly as well as those given the 'pure' financial task. This latter prediction was based on related work on analogical encoding (Gentner, Loewenstein, \& Thompson. 2003), in which people are better at solving a problem when they are able to compare similar analogous cases prior to undertaking a target task. If the explicit links to the financial debt scenario facilitate abstraction of the basic principle (i.e., that in-flows and out-flows need to converge in order for stock to stabilize) then performance might be commensurate with the 'easier' version of the task.

We report these three conditions as a single experiment to facilitate presentation, although in reality they were run sequentially.

\section*{Experiment}

\section*{Participants}

Seventy-five undergraduate students from the University of New South Wales took part in the study in return for course credit. There were 44 females and the mean age was 19.92 ( \(\mathrm{SD}=3.40\) ). Each condition was run sequentially over a 4 month period, so participants were not randomly allocated to conditions. No participant completed more than one condition.

\section*{Experimental Design and Procedure}

Participants were given one of three versions of the basic stock-flow tasks described in the introduction (see Figures 1 and 2). For the Climate Task the graphs were adapted from ones used by Dutt and Gonzalez (2012). In each condition the main task was to complete the trajectory in the bottom graph of the display. This was done via moving on-screen slide controls that plotted the line for each time period discretely. Thus participants made 10 predictions in total. At the conclusion of these predictions participants were invited to make a second attempt (if they wished to) and could readjust any or all of the sliders before finalizing their response.

Participants in the Climate Task and Climate Financial Context condition were given some initial introductory text about climate change and global warming (adapted from Dutt and Gonzalez, 2012). Those in the Financial Task received no additional information. Participants in the Climate Financial Context condition were given additional instructions drawing explicit links between financial debt management and the climate task. These instructions appeared first on a preliminary screen and then alongside the graphs (to the left of the display shown in Figure 1) and remained there throughout the prediction attempts.

Prior to making the predictions participants in all conditions answered three comprehension questions that required reading off some numbers from both the upper and lower graphs in the display and typing in the responses.

\section*{Results}

All participants answered the comprehension questions correctly, suggesting that they were able to read the graphs accurately.

The key dependent measure of interest is the emissions/spending estimate made for each decade/week. Each participant made 10 initial estimates and then had the opportunity to change each estimate on a second attempt. Figure 3 shows the mean estimates for the 10 time periods averaged across both attempts by participants in the three conditions (very few participants changed their initial answers when given the opportunity to make adjustments). The figure also plots the correct trajectory calculated by adding the difference in stock between the current and previous time period to the out-flow (see introduction for an example).

Figure 3: The mean emission/spending estimates for each time period averaged across the two attempts made by participants (error bars are SEM). The asterisks are the correct values for each time period - see text for details. Financial refers to the debtmanagement task, Climate to the standard task and Climate Fin Context to the climate task with instructions inviting participants to consider the problem as one of debtmanagement.

Three features of the data are noteworthy: 1) participants given the 'pure' financial debt management task perform most accurately (on average) showing the correct downward trajectory; 2) those given the pure 'climate frame' display (on average) an upward trending 'correlation heuristic' response; 3) those participants given the standard climate task but with instructions to consider it as a debt-
management problem (Climate Fin Context) fall in-between the two other groups in terms of accuracy.

Figure 4: A boxplot showing the average MSD between the correct response and the estimates (average across the two attempts) in each condition. Solid line is the median response.

These general impressions are confirmed in an alternative way of graphing the data shown in Figure 4. To examine whether the differences apparent in Figure 4 were statistically reliable we used a default Bayesian t-test (Rouder, Speckman, Sun, Morey, \& Iverson, 2009). We assume, for fairness, that the null hypothesis and the alternative hypothesis are equally plausible a priori. The ttest then allows us to determine the posterior plausibility of the null hypothesis and the alternative hypothesis. We denote the posterior probability for the null hypothesis as \(p_{\text {BayesHo }}\). When, for example, \(p_{\text {BayesHO }}=.9\), this means that the plausibility for the null-hypothesis has increased from .5 to . 9.

As predicted, participants given the Financial context made significantly better (lower MSD) estimates than those given the standard climate task ( \(p_{\text {BayesH0 }}=.01\) ). In addition, participants given the Climate task with the financial context as a guide made more accurate estimates than those given the standard climate task \(\left(p_{\text {BayesHo }}=.24\right)\). For the difference between the Financial condition and the Climate Financial Context the null hypothesis is more plausible ( \(p_{\text {BayesH0 }}=.75\) ).

The data in Table 1 showing classifications of individual performance supports the interpretation provided by Figures 3 and 4 . When a correct response is coded as ensuring that in-flow and out-flows converge by the final time period, over half (52\%) of the participants given the 'pure' Financial task showed correct stabilization compared to only 2 people given the pure climate task (8\%). In addition 7 participants given the climate task with the financial context instructions achieved the correct stabilization pattern.

Table 1: Classification of Individual Responses as achieving correct stabilization of the system (i.e., in-flow and out-flow converge by the final time period).
\begin{tabular}{lcc}
\hline \multicolumn{3}{l}{ Correct Stabilization (N of Participants) } \\
\hline Experiment & Correct & Incorrect \\
\hline Financial & 13 & 12 \\
Climate & 2 & 23 \\
Climate + Fin & 7 & 18 \\
\hline
\end{tabular}

\section*{Discussion}

Our experiment sought to address reasons for the welldocumented 'stock-flow failure' observed when participants are asked to make judgments about changes to in-flow, outflow and accumulated stock across time.

In the first instance we showed a clear replication of participants' inability to 'solve' the stock-flow task when it is presented in the context of the climate system. This result dovetails neatly with those reported in the literature (e.g., Sterman \& Booth-Sweeney, 2007) and suggests that procedural differences between our and previous studies are not crucial for eliciting correlation heuristic-consistent responding.

In particular, our task differed from those used before in that we required participants only to make estimates of the emissions (in-flow) rather than both emissions and absorption rates (out-flow) (see Sterman \& Booth-Sweeney, 2007). We suspected that this change might make the task somewhat easier but it appeared not to affect performance. Likewise the fact that our 'stabilization period' was not as long as in previous studies (i.e., only one time period) did not appear to affect the failures to stabilize. (Note that the instructions stated explicitly that the emissions stabilized by 2100, and the comprehension questions suggested that participants could read this aspect of the graph.) Finally, the change to a computer interface rather than the hand-drawn sketches used previously (e.g., Dutt \& Gonzalez, 2012), appears to be a useful progression that allows a more accurate quantitative approach to analysis while not affecting the over-all pattern of responding.

In contrast to the relatively negative conclusions that can be drawn from the climate task, an optimistic (glass half full) interpretation of the Financial Task context is that (some) participants can 'do' stock-flow reasoning. Given the low-base of accurate performance in these tasks (e.g., Cronin et al., 2009), any manipulation which leads to over \(50 \%\) of the sample getting the answer (approximately) correct is newsworthy. Our working hypothesis is that the financial context helps because the familiar principle (don't spend more than you earn if you want to avoid debt) is readily intuited thereby inhibiting the correlation heuristic response (cf. Kahneman \& Frederick, 2002; Shah \& Oppenheimer, 2008). Moreover, the familiarity of projecting thoughts about debt management across time - because people often cannot pay off a debt in one go - helps understanding of the in-flow, out-flow and stock relationship.

Clearly though the familiar context on its own is not enough for all participants - just fewer than \(50 \%\) still failed to stabilize, and most of those gave responses consistent with a correlation heuristic response. As related literature has shown, the relationship between context familiarity and accuracy on these tasks is not straightforward (e.g., BoothSweeney \& Sterman, 2000; Brunstein et al., 2010; Moxnes \& Saysel, 2009) and more research is needed to identify exactly which aspects of context facilitate reasoning, and why.

This sentiment is borne out by the results of our third condition - climate with the financial context as a guide. Provision of the 'readily intuited principle' (don't spend more than you earn) was enough for just over a quarter (28\%) of the sample to understand the task, and led to significant improvements in accuracy relative to the climate task instruction alone. Thus for these participants at least, the additional explanation in terms of a familiar context seemed to improve the understanding of one aspect of the science behind global warming. However, the remaining participants could not (or did not) apply the principle correctly to the unfamiliar context.

An important question arising from this work is whether participants who perform the climate tasks accurately differ in attitudes towards taking action on global warming from those who exhibit 'stock-flow failure'. As noted in the introduction, although some authors argue that differences in 'world view' are more important than scientific understanding (e.g., Kahan et al., 2012), other studies suggest positive correlations between understanding and willingness to act (e.g., Leiserowitz \& Smith, 2010). Indeed Sterman (2008) argued that failures in stock-flow reasoning may well contribute to the tendency to take a 'wait-and-see' approach on addressing global warming.

Although we collected some data on attitudes and intentions to behave pro-environmentally, the paucity of accurate performers on the climate versions of our task, made it difficult to draw any strong conclusions in this regard. Future work will attempt to address these limitations by building on the successful context manipulations found here and by targeting more heterogeneous (non-student) populations with more divergent opinions about global warming. Such studies could provide important findings to help in getting the message about global warming both heard and heeded (cf., Newell \& Pitman, 2010).

\title{
Non-parametric estimation of the individual's utility map
}

\begin{abstract}
Models of risky choice have attracted much attention in behavioural economics. Previous research has repeatedly demonstrated that individuals' choices are not well explained by expected utility theory, and a number of alternative models have been examined using carefully selected sets of choice alternatives. The model performance however, can depend on which choice alternatives are being tested. Here we develop a non-parametric method for estimating the utility map over the wide range of choice alternatives. The estimated maps are compared against the three of the most well-known models of risky choice: expected utility theory, cumulative prospect theory, and the transfer of attention exchange model. Model comparison indicates that cumulative prospect theory provides a better prediction of individuals' choices, but the estimated maps show that the overall shape of utility map is different from what the model predicts.
\end{abstract}

Keywords: decision making; risky choice; utility; MCMC with People; expected utility; cumulative prospect theory; transfer of attention exchange

\section*{Background}

Understanding how people trade off risk and reward is a fundamental goal of behavioural economics. The most common approach to modelling how people make decisions between risky alternatives is based on the idea of utility: individuals integrate the probability of reward with the utility of the reward to produce an expected utility that describes how well the alternative is preferred. The alternative with the highest utility is most often chosen.
The normative calculation of utility that maximizes longterm gain is to multiply the probability with the utility of the associated outcome and to derive the expected utility. For an illustration, suppose an individual is considering a choice alternative with three possible outcomes: \(£ 20, £ 10\), and \(£ 0\). This particular alternative has a \(20 \%\) probability for \(£ 20\), \(40 \%\) for \(£ 10\), and \(40 \%\) for \(£ 0\). Then, the expected utility is \(20 \% \times u(£ 20)+40 \% \times u(£ 10)+40 \% \times u(£ 0)\), where \(u\) is the function to map the monetary value to the utility.

However, previous research has demonstrated that an individual's choice frequently deviates from the predictions of expected utility theory (for review, Schoemaker, 1982). To explain the deviations, descriptive models of how risk and reward are integrated have been developed (for review, Starmer, 2000). A common and useful way to visualize the predictions of these models is to look at the indifference lines, which connect choice alternatives of equal utility, over a MarschakMachina probability triangle (Marschak, 1950; Machina, 1982). The probability triangle is a two-dimensional space which maps alternatives with varying probabilities for the same set of three potential outcomes. Throughout this pa-
per, we use \(£ 20, £ 10\), and \(£ 0\) as the potential outcomes from a choice alternative.

Figure 1 displays the predicted utility maps from three of the most well-known models of risky choice: expected utility theory, cumulative prospect theory (Tversky \& Kahneman, 1992) and transfer of attention exchange (TAX) model (Birnbaum, 2008). In the probability triangle, the probability of attaining the best outcome ( \(£ 20\) ) is represented in the vertical axis, and the probability of the worst outcome ( \(£ 0\) ) is represented in the horizontal axis. The probability for the other outcome ( \(£ 10\) ) is represented as the distance from the diagonal boundary along the horizontal axis. The diagonal boundary ensures that the sum of the probabilities for \(£ 20\), \(£ 10\) and \(£ 0\) does not exceed 1 .

The red area in the triangles indicates the area of high utility, and the blue area is the area of low utility. Also, the coloured lines connect the alternatives of equal utility. These indifference lines highlight the differences between expected utility theory and the two descriptive models. Expected utility theory predicts indifference lines that are parallel and straight. Both cumulative prospect theory and the TAX model predict concave lines in the top corner of the triangle but convex lines in the lower right corner.

The usual experimental practice is to investigate choices in the regions of the triangle where models most differ from each other (e.g., Wu \& Gonzalez, 1998). When the models are tested in this way, the "best" model may not predict choices away from the diagnostic regions well. For instance, Harless (1992) suggests that cumulative prospect theory outperforms expected utility theory only at the edges of the triangle. Thus, the model comparison could benefit from being tested on the whole area of triangle. One way is to estimate the utility map over the whole triangle and compare the estimated map against the model prediction. However to the best of our knowledge, the available estimation methods impose an assumption on how subjective value and probabilities are integrated (e.g., Abdellaoui, 2000), which could favour the model with the identical assumption.

To this end, we develop a non-parametric method to estimate entire utility maps, an extension of Markov chain Monte Carlo (MCMC) with People (Sanborn, Griffiths, \& Shiffrin, 2010). We have modified MCMC with People to investigate the regions of the probability triangle where the choice alternatives are less preferred. The new method is tested in a simulation to show that it can deliver useful results within a reasonable number of trials. We then estimate utility maps from human. Finally, we discuss the results and future applications for this approach.

(A) Expected utility theory with the identity value function

(B) Cumulative prospect theory with parameters \(\alpha=0.88\) and \(\gamma=0.52\)

(C) The transfer of attention exchange model with parameters \(\beta=1, \gamma=0.7\), and \(\delta=1\)

Figure 1: Theoretical predictions

\section*{Markov chain Monte Carlo with People}

Markov chain Monte Carlo (MCMC) is a common method for drawing samples from a distribution. It has been widely used to perform probabilistic inference especially when solving the exact function of interest is computationally difficult (Neal, 1993).

MCMC begins in a start state \(z\). A sample \(z^{\prime}\) is first drawn from the proposal distribution \(q\), and then \(z^{\prime}\) is evaluated with the function of interest, \(\pi\), to determine whether to accept \(z^{\prime}\) as a new state or discard it and retain the current state \(z\). The sequence of accepted samples forms a Markov chain, and after this Markov chain converges, accepted samples can be regarded as samples from the \(\pi\) distribution. To ensure that the Markov chain converges to \(\pi\), it is sufficient to satisfy detailed balance (as well as ergodicity):
\[
\begin{equation*}
\pi(z) q\left(z^{\prime} \mid z\right) A\left(z^{\prime}, z\right)=\pi\left(z^{\prime}\right) q\left(z \mid z^{\prime}\right) A\left(z, z^{\prime}\right) \tag{1}
\end{equation*}
\]
where \(q\left(z^{\prime} \mid z\right)\) is the probability of drawing \(z^{\prime}\) when the current state is \(z\) and \(A\left(z^{\prime}, z\right)\) is the probability of accepting proposal \(z^{\prime}\) over the current state \(z\).
Throughout the paper, we assume a symmetric distribution for \(q, q\left(z^{\prime} \mid z\right)=q\left(z \mid z^{\prime}\right)\), so Equation 1 becomes
\[
\begin{equation*}
\pi(z) A\left(z^{\prime}, z\right)=\pi\left(z^{\prime}\right) A\left(z, z^{\prime}\right) \tag{2}
\end{equation*}
\]

Detailed balance can be satisfied by carefully designing the acceptance function \(A\). The most commonly used function is the Metropolis acceptance function (Metropolis, Rosenbluth, Rosenbluth, Teller, \& Teller, 1953), but the Boltzmann acceptance function (Flinn \& McManus, 1961) is of interest here:
\[
A\left(z^{\prime}, z\right)=\frac{\pi\left(z^{\prime}\right)}{\pi(z)+\pi\left(z^{\prime}\right)}
\]

If an individual is asked to make a choice between alternatives \(z^{\prime}\) and \(z\), then the Boltzmann acceptance function can
model that individual's choice. This is because the Boltzmann function is equivalent to Luce's choice rule (Luce, 1959), which has been frequently used to model risky choice (e.g., Blavatskyy \& Pogrebna, 2010). As a result, by sequentially presenting pairs of choice alternatives to an individual (where the new alternative \(z^{\prime}\) is selected by the computer), the collection of choice alternatives chosen by the individual can be treated as samples from the probability distribution whose density is proportional to the individual's utility (Sanborn et al., 2010).

\section*{Extending MCMC with People}

However, sampling from the individual's utility distribution does not necessarily serve to estimate the shape of the utility map: pilot work confirms that all of the samples will be concentrated around the most favourable alternative ( \(100 \%\) probability of \(£ 20\) in the triangle), and that it would take a very large number of trials to explore the rest of the utility map. To enable the reasonable estimation of the utility map, the stationary distribution needs to be more diffused, so that the Markov chain travels better around the triangular space.
For this purpose, we implement a latent agent in the experimental program. This agent makes an independent choice between the same alternatives as the participant, and only when the agent and the participant both select the new choice alternative does the new alternative become the new state. Otherwise, the current state remains the same and another alternative is generated from the proposal distribution.

When the agent is implemented in this way, the acceptance function becomes a joint function of the participant's and the agent's choices. Specifically, the acceptance function is defined as
\[
A^{*}\left(z^{\prime}, z\right)=\frac{f\left(z^{\prime}\right)}{f(z)+f\left(z^{\prime}\right)} \frac{g\left(z^{\prime}\right)}{g(z)+g\left(z^{\prime}\right)}
\]
where \(f\) is the utility function for the participant and \(g\) is the
agent's utility function. Here, both the participant and the agent follow the Boltzmann acceptance function. Then Equation 2 becomes
\[
f(z) g(z) A^{*}\left(z^{\prime}, z\right)=f\left(z^{\prime}\right) g\left(z^{\prime}\right) A^{*}\left(z, z^{\prime}\right)
\]

With the implementation of the agent, the trajectory of the Markov states depends on both the participant's and the agent's choices. If the agent's utility is the lowest at the top corner of the triangle, the Markov chain would be pushed away from that region. With this extended method, the stationary distribution of the Markov chain is the joint utility function of the participant and the agent, \(f g\). The participant's utility map can subsequently be recovered by dividing the joint utility by the latent agent's known utility, \(g\).

\section*{Simulation}

To demonstrate that the developed method can estimate a participant's utility map within a reasonable number of trials, we conducted a simulation.

\section*{Method}

The simulation used two of the utility functions in Figure 1: the latent agent's utility function, \(g\), was set to the inverse of expected utility theory, and the simulated participant's function, \(f\), was cumulative prospect theory:
\[
g=\frac{1}{20 \times p(£ 20)+10 \times p(£ 10)}
\]
and
\(f=20^{\alpha} \times w(p(£ 20))+10^{\alpha} \times(w(p(£ 20)+p(£ 10))-w(£ 20))\),
where \(p(£ 20)\) is the probability of attaining \(£ 20\), and \(w(p)=\) \(\frac{p^{\gamma}}{\left(p^{\gamma}+(1-p)^{\gamma}\right)^{1 / \gamma}}\). The parameter values for \(\alpha\) and \(\gamma\) were 0.88 and 0.52 , respectively. The proposal distribution, \(q\), was uniform over the triangular space. The possible outcomes were fixed to be \(£ 20, £ 10\) and \(£ 0\), and hence, the agent and the simulated participant repeatedly made choices between two alternatives with varying probabilities for fixed outcomes: e.g., a choice between an alternative with a \(30 \%\) probability for \(£ 20\), \(40 \%\) for \(£ 10\) and \(30 \%\) for \(£ 0\), and another alternative with a \(10 \%\) probability for \(£ 20,60 \%\) for \(£ 10\) and \(30 \%\) for \(£ 0\).

With the above specifications, a choice trial was simulated as follows. First, the agent used the \(g\) function to evaluate each alternative and used the Boltzmann acceptance function to select between the current state and the proposed alternative. If the agent preferred the current state over the proposed alternative, another alternative was sampled from the proposal distribution. If the agent chose the new alternative over the current state, the simulated participant used the \(f\) function to make a choice between the same two alternatives.

Although the agent and the simulated participant could have made a choice at the same time over the same two alternatives, we had the agent decide first: if the agent does not select the new alternative, the previous state remains the state
regardless of the choice the participant makes. This reduces the number of choices the participant must make.

Each simulation consisted of three chains: one chain started with the Markov state of \(60 \%\) of \(£ 20,20 \%\) of \(£ 10\) and \(20 \%\) of \(£ 0\). Another chain started with the state of \(20 \%\) of \(£ 20,60 \%\) of \(£ 10\) and \(20 \%\) of \(£ 0\). The final chain started with \(20 \%\) of \(£ 20,20 \%\) of \(£ 10\) and \(60 \%\) of \(£ 0\).

\section*{Results and Discussion}

The first 100 trials were considered to be trials before convergence of the Markov chain (burn-in period) and were discarded from each chain. The remaining samples from the three chains were pooled and smoothed by kernel density estimation. Because of the triangular boundary of the estimation space, it is actually quite difficult to produce unbiased indifference lines. We chose to use a Dirichlet kernel, an extension of the Beta kernel (Chen, 1999) to the triangular space, because it produced less bias than the other alternatives we investigated. The Dirichlet kernel is defined as
\[
\hat{f}(x) g(x)=\sum_{i} \operatorname{Dir}\left(z_{i} \mid \alpha_{1}, \alpha_{2}, \alpha_{3}\right)
\]
where \(z_{i}\) is the \(i\) th state in the Markov chain, \(x\) is a vector of probabilities for three outcomes, and \(\alpha_{j}\) is \(x_{j} / \min \left(h, x_{j}, 1-\right.\) \(x_{j}\) ). The kernel width \(h\) was set to 0.09 . This smoothed joint distribution is then divided by \(g\) to derive the estimation \(\hat{f}\).
To assess the similarity between \(f\) and \(\hat{f}\), we computed Kullback-Leibler (KL; denoted as \(\operatorname{KL}(f \| \hat{f})\) ) divergence (Kullback \& Leibler, 1951), which measures how much information is lost in the estimation process.
The KL divergences for different sample sizes are plotted in the left panel of Figure 3. This figure illustrates that the estimation shows the increasingly smaller divergence within the first few hundred trials. The estimation becomes reasonably accurate on average after 700-800 trials.

The middle and right panels of Figure 3 display the estimations after 1,000 trials. The estimation with the smallest KL divergence among the 10 simulation runs is in the middle panel, and the right panel show the estimation with the largest KL divergence. Both panels show the key property of cumulative prospect theory: the indifference lines show fanningout property from the lower left corner toward the diagonal boundary.
Thus, the simulation demonstrated that the proposed method with the Dirichlet kernel density estimation can recover the key characteristic of the utility map using a reasonable number of samples.

\section*{Experiment}

\section*{Method}

Participant Ten participants were recruited through the subject panel at the University of Warwick. One participant did not complete the experiment, leaving nine (five male and four female) participants. Their age ranged from 19 to 30 with a mean of 22.9.

Figure 2: The KL divergences between \(f\) and \(\hat{f}\) for various numbers of trials. The solid line represents the mean measurement of the 10 simulation runs, and the dotted lines are maximum and minimum values archived in the simulations.

Figure 3: Estimation of cumulative prospect theory with 1,000 trials

Procedure The experimental procedure closely followed that of the simulation. The agent's utility function, \(g\), was set to the inverse of expected utility theory raised to the power of 8 , and the proposal distribution, \(q\), was uniform over the triangular space. The possible outcomes were fixed to be \(£ 20, £ 10\) and \(£ 0\), and hence, the agent and the participant repeatedly made choices between two alternatives with varying probabilities for fixed outcomes.

In each trial, the agent made a decision first, and a new alternative was drawn until the agent chose the new alternative. Three chains with the same start states as the simulation were run interleaved until participants had made 1,000 choices per chain. In addition, 50 catch trials were inserted into the experiment, so that we could assess whether participants were engaged in the task. In each catch trial, one alternative had larger probabilities for both \(£ 20\) and \(£ 10\). If a participant was not engaged with the task and randomly making choices, it is expected that he or she would occasionally not select the non-dominant alternative.

The experiment presented a choice alternative as a pie chart with three slices. Each slice represented one possible outcome, and the size of the slice was proportional to the probability of the outcome. Participants were forced to log out from the online experiment and take a break after spending one hour on it. After the minimum break of three hours, participants were allowed to \(\log\) in again and resume the experiment.

The choices participant made were incentivized: we invited participants to the lab when participants completed the experiment. At the lab, we randomly selected one trial from the experiment and played the selected alternative for real. Participants were paid what they earned from the play.

\section*{Results and Discussion}

All the nine participants selected the dominant alternative in all of the catch trials, which was evidence that all participants understood and were engaged in the task.

Utility maps were estimated as in the simulation study. All participants show a sharp peak at the top corner of the triangle in the estimated maps. The sharp peak makes it difficult to see the shape of the map, and thus for illustration purposes, we spaced out the indifference lines by taking the natural logarithm of the estimation. As a result, differences in small utilities are exaggerated, but the shapes of the indifference lines are not affected. The resulting maps are displayed in Figure 4. Each panel in the figure corresponds to one participant's map.

The estimated maps show the steep indifference lines, especially where the probability of \(£ 0\) is small. The steep lines indicate aversion to the worst outcome (c.f., Tversky \& Kahneman, 1992; Birnbaum, 2008), where the increment in probability for the worst outcome needs to be compensated with a larger increment in probability for the most desirable outcome. The steepness tends to be lessened near the lower right corner of the triangle. As a result, for Participants A, D and H in particular, the indifference lines show the fanning-out property. The fanning-out suggests that participants more willingly accept an increment in probability for the worst outcome when the probability is already large. The fanning-out is consistent with the prediction from cumulative prospect theory and the transfer of attention exchange (TAX) model.
The estimated maps also show the convex indifference lines throughout the triangle. The convexity makes the estimated maps appear rather different from the predicted utility maps from cumulative prospect theory and the TAX model, which expect the concavity toward the top corner of the triangle (Figure 1).

To quantitatively assess the model performance, we fit the models to the individuals' choices by maximizing the likeli-

Figure 4: \(\ln (\hat{f})\)
hoods. When fitting the model, we used the power law utility function for expected utility theory: \(u(s)=s^{\alpha}\). The range of parameter values are restricted to be between 0 and 1 for all the parameters. Also, each model included one additional parameter to raise the predicted utility. This exponent controls how steep the peak is toward the most favourable alternative.

The value for this exponent parameter is restricted to be nonnegative.

Bayesian information criteria (BIC) indicates that the choices are best predicted by cumulative prospect theory for seven out of nine participants (Panels A through G). The TAX model achieves smallest BIC for one of the remaining partic-
ipants (Panel H), and the expected utility theory has smallest BIC for the other participant (Panel I).

\section*{General Discussion}

Previous research has demonstrated that individuals' choices deviate predictions from expected utility theory, and variety of descriptive models have been proposed. However, the deviation from expected utility theory has often been studied with relatively limited range of choice alternatives. The present study developed the non-parametric method to estimate utility maps over the whole probability triangle.

The curvature of the indifference lines in the estimated maps implies differences to the predictions from the existing models: The lines tend to be convex where concavity is expected. Even though cumulative prospect theory (CPT) does not predict this curvature, CPT provides a better fit to the choice data than expected utility theory or the attention exchange model does for the majority of participants. Thus, a new model could explain the choices better than CPT, if the new model produces a utility map similar to the estimated maps.

In developing such a model, it is useful to identify choice alternatives where the CPT prediction differs from the individuals' choice behaviour. To this end, the estimation method that we have developed can be further extended. As the developed method lets the MCMC chain converge to the joint distribution of the individual's and the agent's utility, manipulation of agent's utility function can reveal interesting joint distributions. For instance, by setting the latent agent's utility to the inverse of the CPT prediction, the MCMC chain converges to the distribution whose density is proportional to the individual's utility divided by the CPT prediction. The condensed area in this joint utility distribution is where the CPT prediction is smaller than the individual's utility (i.e., the area where CPT underpredicts the utility), and the thin area is where the CPT prediction is larger than the individual's utility (i.e., the area where CPT overpredicts the utility).

To conclude, we have developed the method for estimating the utility map. The developed method can be further leveraged in future study.

\begin{abstract}
Decision making from sequential sampling, especially when more than two alternative choices are possible, requires appropriate stopping criteria to maximize accuracy under time constraints. Optimal conditions for stopping have previously been investigated for modeling human decision making processes. In this work, we show how the \(k\)-nearest neighbor classification algorithm in machine learning can be utilized as a mathematical framework to derive a variety of novel sequential sampling models. We interpret these nearest neighbor models in the context of diffusion decision making (DDM) methods. We compare these nearest neighbor methods to exemplar-based models and accumulator models, such as Race and LCA. Computational experiments show that the new models demonstrate significantly higher accuracy given equivalent time constraints.
\end{abstract}

Keywords: sequential sampling; decision making; diffusion decision making model; \(k\)-nearest neighbor classification; evidence; sequential probability ratio test

\section*{Introduction}

Whenever a faster decision is required to save time and resources, the decision making process should focus on choosing whether to proceed with a decision in light of the given information or to postpone the decision in order to collect more information for a higher confidence level. In many previous and recent psychology works, various computational models have been introduced seeking to explain the speed-accuracy tradeoff and to understand the decision making process in humans. However, apart from the understanding of individual models, there has been little systematic way of understanding these models in one mathematically unified framework. Moreover, multiple-choice problems were not discussed intensively in any of the methods.

The optimality in decision making with sequential sampling is discussed with the optimality in speed-accuracy tradeoff. In other words, the objective of the present work is to seek the fastest decision with the same average accuracy or the maximum accuracy if the same average decision time is used. Sequential sampling methods such as Race (Smith \& Vickers, 1988; Vickers, 1970), diffusion decision making (DDM) (Ratcliff, 1978; Ratcliff \& Rouder, 2000; Shadlen, Hanks, Churchland, Kiani, \& Yang, 2006; Ratcliff \& Mckoon, 2008), and leaky competing accumulator (LCA) (Usher \& McClelland, 2001; Bogacz, Usher, Zhang, \& McClelland, 2007) are all interested in explaining this optimality in the
speed-accuracy tradeoff. In these methods, one or more variables are commonly introduced for accumulating sampled information, and a criterion is used to determine whether to continue collecting more information or to make a decision with given information. Here, we propose a common mathematical framework combining these methods and providing a systematic explanation for understanding different methods.

Our framework combining sequential sampling methods is the \(k\)-nearest neighbor ( NN ) classification in machine learning. The sequential sampling situation with multiple choices is explained as the multiway \(k\)-NN classification from the theoretical analysis on \(k\)-NNs in the asymptotic situation. Due to this connection, we can interpret all different types of sequential sampling methods as different methods of choosing \(k\) adaptively in \(k\)-NN classification. By further analyzing the strategy of choosing \(k\) in \(k\)-NN classification using the Sequential Probability Ratio Test (SPRT) (Wald \& Wolfowitz, 1948) and Bayesian inference, we can obtain five different accumulating variable and stopping criteria for optimal tradeoff. Interestingly, all these five optimal methods are interpreted as different kinds of DDM strategies.

Our work is directly applied to a recently reported neuroscientific decision making mechanism. The proposed mechanism considers an output neuron which sends out a decision result. By collecting Poisson spike trains from different neurons, the output neuron makes a decision about which neuron gives Poisson spikes at the highest rate (Shadlen \& Newsome, 1998; Ma, Beck, Latham, \& Pouget, 2006; Beck et al., 2008; Zhang \& Bogacz, 2010). The output neuron can achieve optimality by using our proposed strategies.

The proposed method can be compared with traditional exemplar models which explain memory retrieval using similarity weighted voting based on stored exemplars. Our work is different from this line of research by using majority voting of adaptively chosen \(k\) number of NNs. We discuss the advantages and disadvantages of our method when it is applied to the memory retrieval problem.

The rest of the paper is organized as follows. We introduce the sequential sampling problem in Section 2 especially from the point of view of multiple-choice. In Section 3, we introduce problems to which sequential sampling methods can be applied, and we show how \(k\)-NN classification can be natu-
rally introduced as a common framework for explaining these problems. In Section 4, we derive the examples of two- and multiple-choice evidence for DDM in light of \(k\)-NN classification. After we explain the relationship between our method and other exemplar methods in Section 5, we present simulation experiments in Section 6. Finally, we conclude with discussion in Section 7.

\section*{Computational Methods in Sequential Sampling Problems}

Sequential sampling methods consider decision making using incoming information over time. With unlimited time, the decision can be made late enough to increase the expected accuracy. However, if the decision should be made as soon as possible, there is a trade-off between the speed and accuracy of the decision. In order to address this tension, decision making strategies introduce criteria to determine whether or not to make a decision at a certain time.

Accumulator Model: One simple method of determining whether the accumulated information has reached a certain level of confidence is the accumulator model. This model considers one variable for each choice and accumulates information separately in favor of each choice. Once one of the accumulating variable reaches a predefined threshold, the decision is made immediately thereafter.

This simple model with no interaction between different choices is known as suboptimal. This method can be compared with the DDM strategy in the next section, where the accuracy of the accumulator model is always less than the accuracy of the DDM model (Zhang \& Bogacz, 2010). This model of doing race between accumulators is also called the Race model.

Diffusion Decision Making (DDM) Model: In this model with two choices, one variable is introduced to collect information and diffuse toward one of the choice. This variable, also known as the evidence, represents the bias in the preference of accumulated information toward a choice. Finally, once the evidence reaches a pre-defined level of any choice, it stops diffusing and selects the choice.

A canonical method of determining the evidence variable and stopping criterion uses the sequential probability ratio test (SPRT) (Wald \& Wolfowitz, 1948; Dragalin, Tertakovsky, \& Veeravalli, 1999; Zhang \& Bogacz, 2010). Previous work using this test has considered two incoming Poisson signals aiming to determine the signal with the higher Poisson rate from the accumulation of signals. In this case, the diffusing evidence is just the difference in the number of signals within a certain time, and the decision is made once this difference exceeds a threshold. This method is known to be optimal among sequential sampling methods such as Race and LCA (Bogacz, Brown, Moehlis, Holmes, \& Cohen, 2006; Bogacz et al., 2007).

Leaky Competing Accumulator (LCA): LCA uses one variable for each choice similar to the accumulator model,
but it considers the interaction between the variables. LCA considers the dynamics of activation with the decay of the activation as well as the inhibitory interaction between activation variables. This LCA dynamics is very flexible in that the strategy can be either similar to Race or DDM as its special case, but the maximum performance is known to be that of DDM (Bogacz et al., 2007).

\section*{Multiple-Choice Extension}

Among the aforementioned sequential sampling models, the multiple-choice extension of the Race and LCA models is straightforward, by just increasing the number of accumulating variables. However, the extension of DDM is more complex. Fortunately, the Multiple SPRT (MSPRT) method was previously developed by extending the SPRT method using the number of signals (Dragalin et al., 1999; Zhang \& Bogacz, 2010). In addition to this MSPRT result, we also provide different criteria for multiple-choice DDM using derivations from other approaches of MSPRT and Bayesian inference. Our result provides an evidence diffusing in a \(C-1\) dimensional space for a \(C\) alternative choice problem.

\section*{Sequential Sampling Problems}

Decision making problem using sequential sampling can be found in many examples. Here we introduce two exemplary problems. One example can be found in neuronal decision making as in the left figure of Fig. 1. When an output neuron tries to make a decision as to whether one incoming signal has a higher Poisson rate than the other has, the output neuron can collect signals until the accumulated information reaches a certain level.

Another example can be found in a Bayes classification problem where we only have data generated from unknown underlying density functions. Bayes classification selects the class having the highest underlying density, but the classifier in this case cannot directly access the underlying density information. A surrogate method of determining the class of highest density is through \(k\)-NN classification. By collecting more nearest neighbors, the confidence of choosing a class of the highest density is expected to increase to a targeted level.

Here, we show that the two problems are in fact exactly the same by explaining several theoretical results on \(k-\mathrm{NN}\) classification in the asymptotic situation:

Majority Voting Rule in \(k\)-Nearest Neighbor Classification: When there are \(N\) number of training data with labels, \(\mathcal{D}=\left\{\mathbf{x}_{i}, y_{i}\right\}_{i=1}^{N}\), where each datum \(\mathbf{x}_{i} \in \mathbb{R}^{D}\) is represented as a \(D\)-dimensional vector, and the label has one of \(C\) labels, \(y_{i} \in\{1, \ldots, C\}, k-\mathrm{NN}\) classification assigns class \(y\) to a classunknown datum \(\mathbf{x}\) according to the majority voting with \(k\) labels of nearest data in \(\mathcal{D}\) :
\[
\begin{equation*}
y=\arg \max _{c} \sum_{i=1}^{k} \mathbb{I}\left(y_{n(i)}=c\right) \tag{1}
\end{equation*}
\]
with nearest neighbor index \(n(i), i=1, \ldots, k\). The theoretical study of this majority voting strategy originates from Cover

Figure 1: Diffusion decision making (DDM) in neurons determines the input neuron with the higher firing rate, and its analogous \(k\)-NN classification determines the larger class-conditional density function
and Hart (Cover \& Hart, 1967; Cover, 1967), and in their work, once there are enough data, the expected error monotonically and asymptotically decreases with the number of \(k\) :
\[
\begin{equation*}
E(k=1) \geq E(k=2) \geq \ldots \geq E(k=\infty) \tag{2}
\end{equation*}
\]
for \(k \ll N\). This continuous decrease of error will encourage the use of more nearest neighbors, which explains the tradeoff between the number of nearest neighbors \(k\) and the classification accuracy.

Distance Comparison Rule of \(k^{\prime}\)-th NNs of Each Class: If we consider a strategy of comparing two \(k^{\prime}\)-th NN in class 1 and class 2 , we can easily prove that this strategy is equivalent to the majority voting rule with \(k=2 k^{\prime}-1\) NNs.

Proof: Consider a comparison between \(k^{\prime}\)-th NN of class 1 and another \(k^{\prime}-t h N N\) of class 2. If \(k^{\prime}\)-th \(N N\) in class 1 is closer than \(k^{\prime}-t h N N\) in class 2 , then we can say that the \(k^{\prime}-t h\) \(N N\) in class 2 can never be included in the closest \(\left(2 k^{\prime}-1\right)\) \(N N s\), because at least \(k^{\prime}\) number of NNs in class 1 and \(\left(k^{\prime}-1\right)\) number of NNs in class 2 have less distance than the \(k^{\prime}\)-th NN in class 2. Therefore, comparing strategies of \(k^{\prime}-t h N N\) in each class is the same as majority voting with \(\left(2 k^{\prime}-1\right)\) nearest neighbors.

Therefore, the monotonic increase of accuracy is also satisfied with the increase of \(k^{\prime}\).

Two Sequential Sampling Methods in \(k\)-NN Classification: From the monotonic increase of the accuracy with the increase of \(k\) (or \(k^{\prime}\) ), we can make two different sequential sampling methods showing the speed-accuracy tradeoff.

First, we can consider the majority voting strategy using number of NNs within a certain distance from the testing point. If we do not have enough accuracy with the current distance, we can increase it to use more resources. Another example can be designed by considering the distance to the same \(k^{\prime}\)-th NN in each class and making a decision by comparing the distances.

The first design corresponds to the sequential sampling
with continuous time and discrete accumulation of information, because the accumulation variable is the function of the number of NNs. In contrast, the second design uses the discrete time and continuous accumulation of information.

Distribution of the distances: Now, we show that \(k\)-NN classification is in fact equivalent to sequential sampling for determining the signal with the highest Poisson rate.

A recent study discussed the distribution of the distance to the NNs when there are enough data (Leonenko, Pronzato, \& Savani, 2008). Instead of directly dealing with the distribution of distance, they changed the random variable to \(u=N V\), with volume \(V\) of \(D\) dimensional hypersphere having the distance to the \(k\)-th NN as a diameter multiplied by the number of data \(N\). Then the distribution of samples approaches the Erlang density function:
\[
\begin{equation*}
\rho(u \mid \lambda)=\frac{\lambda^{k}}{\Gamma(k)} \exp (-\lambda u) u^{k-1} \tag{3}
\end{equation*}
\]
with a parameter \(\lambda\), which is the probability density \(p(\mathbf{x})\) at \(\mathbf{x} \in \mathbb{R}^{D}\). Moreover, this special Erlang function implies the Poisson distribution of the number of NNs \(k\) within a specified volume of the hypersphere (Wasserman, 2003):
\[
\begin{equation*}
\rho(k \mid \lambda)=\frac{\lambda^{k}}{\Gamma(k+1)} \exp (-\lambda) \tag{4}
\end{equation*}
\]

This equation shows that the number of NNs within a growing hypersphere at a constant rate in volume is a Poisson process.

Comparing this Poisson process interpretation with the aforementioned neuronal decision making, we can draw several corresponding analogies. The firing rate of the Poisson signal corresponds to the underlying density function in \(k-\mathrm{NN}\) classification, the number of spikes corresponds to the number of NNs, the time within which spikes are counted corresponds to the volume of the hypersphere within which we count NNs, and as a consequence, determining a choice with the highest firing rate corresponds to the problem of deter-
mining the class with the highest underlying density function, which is also known as the Bayes classification.

The correspondence shows that these two very well-known methods from different disciplines can share optimal strategies as well as theoretical knowledge. However, the study of a method in one field is rarely investigated in another; the strength of the correspondence suggests that whenever a good strategy is found for DDM, a corresponding strategy should be examined for machine learning. Conversely, when a new strategy is provided for the \(k\)-NN method, its relevance to psychology should also be investigated.

\section*{Derivation of Stopping Criteria}

In this section, we now derive stopping criteria from \(k\)-NN classification using MSPRT and Bayesian inference for a multiple-choice problem.

\section*{Multiple Sequential Probability Ratio Test}

One simple statistical test for determining whether one of \(C\) different choices has the highest probability density is the MSPRT. MSPRT uses fixed parameters of densities \(\lambda_{+}\)and \(\lambda_{-}\)where \(\lambda_{+}>\lambda_{-}\), it calculates the likelihood that the first data came from the density \(\lambda_{+}\)and others from \(\lambda_{-}\), and then compares those likelihoods.

Without loss of generality, we consider the likelihood that the highest density \(\lambda_{+}\)is occupied by \(\lambda_{1}\). In other words, \(\lambda_{1}=\lambda_{+}\), and \(\lambda_{c}=\lambda_{-}\)for \(c=2, \ldots, C\). Because of the independence between classes,
\[
\begin{align*}
& \log P\left(k_{1}, \ldots, k_{C}, u_{1}, \ldots, u_{C} \mid \lambda_{1}=\lambda_{+}, \lambda_{2}=\lambda_{-}, \ldots, \lambda_{C}=\lambda_{-}\right) \\
& \quad=\log \rho\left(k_{1}, u_{1} \mid \lambda_{+}\right)+\sum_{c=2}^{C} \log \rho\left(k_{c}, u_{c} \mid \lambda_{-}\right) \tag{5}
\end{align*}
\]

The posterior \(P_{1}\) that \(\lambda_{1}\) occupies \(\lambda_{+}\)is proportional to this likelihood Eq. (5). From the Poisson distribution in Eq. (4) with \(k_{c}\), the number of NNs of class \(c\) within the same volume, we can obtain the log of posterior:
\[
\begin{equation*}
\log P_{1}=g^{*} k_{1}-\log \left(\sum_{c=1}^{c} \exp \left(g^{*} k_{c}\right)\right) \tag{6}
\end{equation*}
\]
with a predetermined ratio \(g^{*}=\log \left(\lambda_{+} / \lambda_{-}\right)\). If we consider the volume distribution for the same \(k\)-th NNs, the equation for the posterior also becomes
\[
\begin{equation*}
\log P_{1}=-h^{*} u_{1}-\log \left(\sum_{c=1}^{c} \exp \left(-h^{*} u_{c}\right)\right) \tag{7}
\end{equation*}
\]
with \(h^{*}=\lambda_{+}-\lambda_{-}\). We call Eq. (6) "DN", which considers the difference in the number of NNs within a specific volume of the hypersphere and Eq. (7) "DV", which considers the difference in the volumes of the same \(k\)-th NNs. In order to make a decision with confidence, we can first increase the volume of hypersphere or increase the number of NNs until the criterion exceeds a pre-defined confidence level, then
we can decide the choice. For two-choice problem \((C=2)\), comparing the MSPRT criteria with a certain value reduces to a simple comparison whether \(g^{*}\left(k_{1}-k_{2}\right)\) and \(h^{*}\left(u_{2}-u_{1}\right)\) is greater than a certain confidence threshold, for Eq. (6) and Eq. (7), respectively.

For DV, an additional conservative method can be considered. The decision can be made more carefully for the class of interest (here, class 1 ), by using the maximum possible volume containing \(k\)-th NN , in other words, the volume of the hypersphere of \((k+1)\)-th NN of class 1 instead of the volume of \(k\)-th NN. We call this strategy "conservative DV" (CDV), and in CDV, an additional NN is always used to calculate the accumulated information.

\section*{Bayesian Inference}

Another method of utilizing the Bayesian method is to use the prior density function for \(\lambda\) with parameters \(a\) and \(b\) :
\[
\begin{equation*}
p(\lambda)=\frac{b^{a}}{\Gamma(a)} \lambda^{a-1} \exp (-\lambda b) \tag{8}
\end{equation*}
\]

With conjugacy relationship, we can calculate the posterior probability that the underlying density of choice \(1, \lambda_{1}\), is greater than the underlying densities of the other choices \(\lambda_{2}, \ldots, \lambda_{C}\) with given condition \(D\) on nearest neighbor information. The calculation of \(P\left(\lambda_{1}>\lambda_{2}, \ldots, \lambda_{C} \mid D\right)\) is performed using the probability primitives such as \(P\left(\lambda_{1}<\lambda_{2} \mid D\right)\), \(P\left(\lambda_{1}<\lambda_{3} \mid D\right), \ldots\), and \(P\left(\lambda_{1}<\lambda_{2}, \ldots, \lambda_{C} \mid D\right)\) :
\[
\begin{gather*}
P\left(\lambda_{1}>\lambda_{2}, \ldots, \lambda_{C} \mid D\right)=\int_{0}^{\infty} d \lambda_{1} p\left(\lambda_{1} \mid D\right)\left(1-\int_{\lambda_{1}}^{\infty} d \lambda_{2} p\left(\lambda_{2} \mid D\right)\right) \\
\ldots\left(1-\int_{\lambda_{1}}^{\infty} d \lambda_{C} p\left(\lambda_{C} \mid D\right)\right)  \tag{9}\\
= \\
1-P\left(\lambda_{1}<\lambda_{2} \mid D\right) \ldots-P\left(\lambda_{1}<\lambda_{C} \mid D\right)+  \tag{10}\\
\ldots+(-1)^{C-1} P\left(\lambda_{1}<\lambda_{2}, \ldots, \lambda_{C} \mid D\right) .
\end{gather*}
\]

When the condition is on the number of nearest neighbors \(k_{1}, \ldots, k_{C}\) within a certain volume, the general form of primitives is presented with multinomial coefficients:
\[
\begin{align*}
& P\left(\lambda_{1}<\lambda_{j_{2}}, \ldots, \lambda_{j_{L}} \mid k_{1}, \ldots, k_{C}\right)=  \tag{11}\\
& \quad \sum_{i_{j_{2}}=0}^{k_{j_{2}}} \cdots \sum_{i_{j_{L}}=0}^{k_{j_{L}}} \frac{1}{L^{\left(k_{1}+1+\sum_{c=2}^{L}\left(k_{j_{c}}-i_{j_{c}}\right)\right)}}\binom{k_{1}+\sum_{c=2}^{L}\left(k_{j_{c}}-i_{j_{c}}\right)}{k_{j_{2}}-i_{j_{2}}, \cdots, k_{j_{L}}-i_{j_{L}}}
\end{align*}
\]
where \(L\) and \(j_{1}, \ldots, j_{L}\) are determined according to the primitives in Eq. (10). In addition, when volume information \(u_{1}, \ldots, u_{C}\) is given for \(k_{1}, \cdots, k_{C}\)-th NN in each class, respectively, the primitives are
\[
\begin{align*}
& P\left(\lambda_{1}<\lambda_{j_{2}}, \ldots, \lambda_{j_{L}} \mid u_{1}, \ldots, u_{C}\right)=  \tag{12}\\
& \quad \sum_{i_{j_{2}}=0}^{k_{j_{2}}} \cdots \sum_{i_{j_{L}}=0}^{k_{j_{L}}}\binom{k_{1}+\sum_{c=2}^{L} i_{j_{c}}}{i_{j_{2}}, \cdots, i_{j_{L}}} \frac{u_{1}^{k_{1}+1} \prod_{c=2}^{L} u_{j_{c}}^{i_{j_{c}}}}{\left(u_{1}+\sum_{c=2}^{L} u_{j_{c}}\right)^{k_{1}+\sum_{c=2}^{L} i_{j_{c}+1}}}
\end{align*}
\]
for \(L\) and \(j_{1}, \ldots, j_{L}\) determined from the primitive. Now, Eq. (10) with primitives in Eq. (11) can be considered as a

Figure 2: Examples of diffusion of evidence for three-choice decision making. The diffusion of posteriors, \(P_{1}\) and \(P_{2}\), are plotted on the horizontal and vertical axes. The threshold is set to 8 .
criterion "PN" and Eq. (10) with primitives in Eq. (12) can be considered as a criterion "PV." Here, we used \(a=1\) and positive small value \(b\).

For a two-choice problem, with \(k_{c}\)-th NNs in \(c\) class within the same hypersphere, the probability result becomes a very simple equation
\[
\begin{equation*}
P\left(\lambda_{1}>\lambda_{2} \mid u_{1}, u_{2}\right)=\sum_{m=0}^{k}\binom{2 k+1}{m} \frac{u_{1}^{m} u_{2}^{2 k+1-m}}{\left(u_{1}+u_{2}\right)^{2 k+1}} \tag{13}
\end{equation*}
\]
from Eq. (11). Similarly, with \(u_{1}\) and \(u_{2}\) of \(k\)-th NN in each class, Eq. (12) becomes
\[
\begin{equation*}
P\left(\lambda_{1}>\lambda_{2} \mid k_{1}, k_{2}\right)=\frac{1}{2^{k_{1}+k_{2}+1}} \sum_{m=0}^{k_{1}}\binom{k_{1}+k_{2}+1}{m} \tag{14}
\end{equation*}
\]

Both Eq. (13) and Eq. (14) are the sums of binomial distributions which can be interpreted analogous to coin tossing problem with a biased and an unbiased coin. Eq. (13) corresponds to the probability of having heads less than or equal to \(k\) among \(2 k+1\) tosses of a biased coin, and Eq. (14) corresponds to the probability of having heads less than or equal to \(k_{1}\) among \(k_{1}+k_{2}+1\) tosses of an unbiased coin.

We can note that all derived stopping criteria have a posterior representation where the sum over classes equals one. Therefore, we can consider a \(C-1\) dimensional simplex and the diffusion of the posterior within this simplex. Therefore, a vector with posterior elements for all candidate classes extending Eq. (10) can be considered as a diffusing evidence in a DDM model, and all criteria derived in this work can subsequently be considered as DDM models.

\section*{Relationship with other Exemplar Methods}

One typical method of learning with exemplars is utilizing the similarity measures with exemplars (Nosofsky, 1986; Shepard, 1987). Recently, this model was connected to kernel learning methods in machine learning (Jäkel, Schölkopf, \& Wichmann, 2008), which connected the similarity notion to an associated reproducing kernel Hilbert space as well as to Bayesian inference (Shi, Griffiths, Feldman, \& Sanborn, 2010). These similarity-based methods utilizing exemplars are computationally well-integrated with various machine learning methods.

However, majority voting with equal weights, which is proposed in this work, is a completetly different approach of

Figure 3: Performance of adaptive \(k\)-NN classification using PN, DN, Race, and a machine learning criteria, "Cons." Accuracy is plotted with an average number of NNs used for various thresholds of confidence. Cons makes a decision when the number of recent consecutive NNs of the same class exceeds a threshold (Ougiaroglou et al., 2007).
utilizing exemplars, where the theoretical explanation shows optimality in certain situations (Bailey \& Jain, 1978). Our model is also different from the random walk model using conventional exemplar models (Nosofsky \& Palmeri, 1997). The random walk is performed according to the random retrieval from already generated data, while our model directly considers the underlying density function and uses the generated data without any additional randomness. A severe problem in the memory retrieval of Nosofsky and Palmeri is that a repetitive retrieval of one very similar exemplar will affect the decision predominantly where a noise on this particular exemplar can severely affect the decision accuracy.

\section*{Experiments with Simulation Data}

The examples of diffusion of the evidence for each criteria are shown in Fig. 2. In this experiment, the proposed five examples of evidence PV, PN, DV, CDV, and DN, diffuse with the same NN information. In the figure, all five examples diffuse differently, but they reach the same threshold. The parameters used are \(\lambda_{1}=.25, \lambda_{2}=.35\), and \(\lambda_{3}=.4\), and the decision threshold is .8. Though they diffuse differently, CDV shows a smoother diffusion than the others, and PN and DN show more sampling-wise configuration.

Figure 4: Performance using volume evidence. The CDV with smooth diffusion is slightly better than DV, while PV outperforms both CDV and DV with large margins.

The performance evaluation of the methods is shown using \(k\)-NN classification. We first generated data randomly from three uniform probability densities, \(\lambda_{1}=.2, \lambda_{2}=.7\), and \(\lambda_{3}=.1\), and compared the adaptive \(k-\mathrm{NN}\) classification method between the proposed criteria and other criteria from psychology and machine learning models. In Fig. 3, as expected in our analysis, the Race accumulator model without interaction does not outperform the criteria from statistical tests, PN and DN, although using a Race criterion does give a better performance than a simple majority voting method with fixed \(k\). We also compared our results with a conventional machine learning method, which considers the number of recently appeared NNs belonging to the same class.

In Fig. 4, three criteria using volume information, PV, DV, and CDV, are compared. According to a few realizations in Fig. 1, the diffusion of CDV is in general much smoother than that of DV, and the CDV criterion shows a little better accuracy than DV. PV shows better performance than either DV or CDV.

\section*{Conclusion}

In this work, a general framework integrating decision making with sequential sampling is proposed based on its relationship with the exemplar-type machine learning algorithm, \(k-\mathrm{NN}\) classification. In contrast to previous research on suboptimal weighted voting, we have shown how \(k\)-NN majority voting can be used to better understand the sequential sampling decision making process. Using an adaptive \(k\)-NN classification framework, we also showed how the proposed five examples of optimal criteria are derived for multiple-choice decision making, minimizing the error for any given average resource that can be used. Our future work includes extending this relationship among decision making methods to form a scaffold of understanding within the mathematical framework of \(k\)-NN methods.

\title{
Where What You Count is What Really Counts
}

\begin{abstract}
We noticed that human subjects were notably faster and more accurate in concurrent counting of three location-based events while they ignored the identity of targets, compared to concurrent counting of three identity-based events while they ignored the locations. In a control experiment, subjects performed a location-based triple counting task, while now also paying attention to the target identity. This did not incur any additional cost, compared to the cost of the location-based counting. Performing each of these tasks relies on maintaining three running numerical counters, and on switching between them to increase each one. Our results suggest that switching between these counters has lower cost when they are associated to spatial locations, compared to when they are associated to identities. This difference is not affected when additionally processing the identity of items. We argue that this might be related to the advantage of the space in switching attention between internal representations.

\section*{Introduction}

The challenge of many non-trivial intellectual symbolic working memory tasks lies in the difficulty of juggling several residents of working memory at the same time; there are one or two items that are being acted upon while a few others are actively maintained and kept apart for future steps of the process. For example think of adding 34 to 89 mentally while looking away from the paper or the screen. During early mathematics education, students are taught to perform this task in a sequential way, and by several calls on the addition table for single-digit numbers. In this example, while 3 and 8 (or 30 and 80 ?) are maintained for the next step of the operation, 9 and 4 are the ones that are acted upon first.

Due to the increasing role of abstract representations in solving difficult problems, intellectual symbolic tasks such as this example have become increasingly important as a part of necessary mental skills for a civilized individual in modern time. Understanding our limitations in maintaining and manipulating mental concepts that are needed for intellectual tasks is key to understanding our cognitive limitations, and to possibly improving individuals' performance. This in turn poses the question of how we manage to keep some items in our working memory, and how we can handle selecting them for the right operation at the right time.

The common metaphor among cognitive psychologists, which captures the selectivity of operations on several actively maintained items, is the shiftable spotlight or focus of attention. Attention in this sense refers to the special treatment that a few representations receive, which in turn makes it possible to be acted upon (or processed) with more agility (in terms of response time or accuracy).

Cowan goes even further and uses the concept of attention to directly relate working memory representations to longterm memory representations. In his view, residents of working memory are those representations in long-term memory which have received attention. He states that this attention may apply to only four items at a time, and hence the number of representations in working memory is limited to four (Cowan, 1999). Some other researchers have mentioned that indeed the spotlight of attention is even narrower than four items, and there is room for only one representation (Garavan, 1998; McElree, 2001). Experimental support for this claim comes from the observation that the most recently attended resident of working memory is privileged in terms of processing speed (McElree \& Dosher, 1989; Mcelree, 2006; Garavan, 1998; Voigt \& Hagendorf, 2002). For example Garavan studied the execution time of human subjects in a self-paced dual counting task where subjects had to keep count of how many of two possible visual shapes (triangles versus squares) had been presented. The sequence of switching between internally maintained counters is dictated by the stimulus sequence of triangles and squares. Garavan noticed that updating a recently updated counter (e.g., when two squares or two triangles are presented consecutively) is significantly faster than updating alternative counters (e.g., when a square is presented after a triangle or vice-versa). Garavan showed that this speedy update of a recently updated internal counter is not related to the perceptual priming in detecting the associate signal. He posited that the execution time difference between updating one counter twice and updating two different counters is related to the cost of shifting the focus of attention from one counter to the other one.

Oberauer has tried to reconcile Cowan's concept of attention with the single spotlight focus of attention, to establish a framework that explains storage and processing as two features of working memory (Oberauer, 2002). While the concept of shifting the focus of attention seems to capture the dynamics of working memory during mental processing, one question remains to be answered: what is the underlying mechanism for switching between two working memory representations? In particular, is there a unitary system for switching attention between items of working memory, either in space or in other dimensions?

For this matter, some researchers have looked at brain activities of human subjects during tasks that involve reconfiguration of cognitive resources by switching between different representations. Yantis and his colleagues, in a series of fMRI studies, have compared BOLD signals during switching attention in the visual-spatial domain or in other representation domains. They have identified a fronto-parietal net-
work which is common among different tasks (Shomstein \& Yantis, 2006; Tamber-Rosenau, Esterman, Chiu, \& Yantis, 2011; Greenberg, Esterman, Wilson, Serences, \& Yantis, 2010; Chiu \& Yantis, 2009). Among these regions, the superior parietal lobule (SPL) of the posterior parietal cortex (PPC), which is also known for its role in shifting visual attention and eyes in space, is shown to be engaged in all of the studied switching tasks. Based on this evidence, Yantis proposes a general-domain switching mechanism (Chiu \& Yantis, 2009).

Yet, an important question is whether such a switching mechanism is indeed a domain-independent machinery, or is in fact a part of an evolutionary older system that is lent or co-opted for use in different domains. It is important to distinguish between these two alternative views as they propose two different views of the evolution of human cognition. On the one hand, the domain-independent machinery may sound more appealing to some researchers in terms simpler description of the functioning mind. On the other hand, the idea of co-opting evolutionary older systems (e.g., sensory-motor systems) for switching is more plausible from an evolutionary perspective (Dehaene \& Cohen, 2007; Paillard, 2000) and provides an opportunity to ground working memory machinery in perceptual-motor systems in line with more recent trend in grounded and embodied cognition (Lakoff \& Núñez, 2000; Barsalou, Simmons, Barbey, \& Wilson, 2003; Damasio \& Damasio, 2006; Dehaene \& Cohen, 2007).

As an example of a grounded model for working memory processing mechanisms, Noori and Itti (Noori \& Itti, 2013a, 2013b, 2011) propose a framework for management of working memory items which relies on the role of sensory-motor working memory systems for manipulation of working memory items, even in the context of symbolic and abstract items. They assume that manipulation of memory items is facilitated by a registry of memory items to spatial locations, accessible to visuospatial attention mechanisms. Switching spatial attention between those locations, is then based on operational schemas, similar to what Arbib has proposed in the perception-action domain (Arbib, 1992). Their proposal suggests the performance on mental operations that need memory manipulation, even in the case of abstract and symbolic representations, would depend on how those sensory-motor systems are utilized.

To test the dependency of switching between working memory representations on utilization of space, we studied speed and accuracy of our subjects in performing a modified version of Garavan's task (Garavan, 1998). We arranged two versions of a triple counting task: identity-based counting (counting appearances of three possible symbols) and location-based counting (counting any symbols appearing in three possible locations). A domain-independent account predicts that the switching time between internal counters should be independent of our counting paradigms. Our results do not favour this prediction.

Figure 1: Schematic view of both triple-counting paradigms. Nine target presentation events (at the center of the diagram) is similar for both paradigms.

\section*{Experiment 1}

The first experiment compares the cost of switching between different running counters in a concurrent triple counting task for an identity-based and a location-based mental counting. Subjects in both versions of the task maintain three running counters in their memory. These counters are associated to three different events.

In both versions of the task, an event is a subject-initiated brief visual presentation of a keyboard character in a box on the screen. In the case of location-based counting, the difference between events is defined based upon the location of the character, while the identity is irrelevant. In contrast, in the identity-based counting version, the difference between counting events is defined based on the identity of characters, and the location is irrelevant. Counters should be updated upon perceiving their associated signal. Since a signal presentation is initiated by the subject, the task progresses with a pace determined by the subject, which allows us to measure execution times.

We measured the time between two consecutive signal initiations and analysed them based on similarity or dissimilarity of counting-relevant and counting-irrelevant features of two consecutive events, to explore the effect of type of counter-event binding. Moreover, we analysed the error rates in counting using different measures, to explore possible effects of counter-event binding on the accuracy of counting.

\section*{Method}

Apparatus Stimuli were displayed on a 46-inch LCD monitor (Sony Bravia XBR-III, \(89 \mathrm{~cm} \times 50 \mathrm{~cm}\) ), 97.8 cm in front of participants (corresponding field of view is \(54.7^{\circ} \times\) \(32.65^{\circ}\) ). To control the viewing distance, subjects used a chin
rest to maintain their head position during the experiment. A gray background \((0.62 \mathrm{~cd} / \mathrm{m} 2)\) was displayed during the experiment.
Subjects Seven female and four male undergraduate students with normal or corrected to normal vision, participated for course credit. Subjects' ages ranged between 19 to 21 ( \(M=19.7, S D=0.78\) ).
Procedure Figure 1 depicts a schematic view of the triple counting paradigm for both identity and location based concurrent counting. Events for both types of counting paradigm presented in a similar way: one of three keyboard characters \(\$\), \# or ? would be selected to appear in one of three fixed boxes located in three of four main quadrants randomly and upon subject's press of any of keys on the keyboard. In each trial boxes centered at vertices of a virtual square with sides that would appear \(3.5^{\circ}\) wide from subject's view point. In each trial three out of four possible boxes were selected randomly and remained on screen throughout the counting process. In trials of location-based counting boxes appeared on the screen from the beginning of the trial and during presentation of the initial counters.

Each trial started by presenting three initial counters. Initial counters were either 0 or 1 which were selected randomly. During trials of counting identity-based events each item was presented next to its initial counter at the center of screen and during trials of location-based counting initial counters appeared at the center of boxes. Each trial included nine counting events. The pace of counting was determined by subjects. At the end of ninth counting event subjects reported the counters using the keyboard and in the same order of initial counter presentation.

Independent of the type of the counting task the identity and the location of target character changed randomly and independently. The identity of two consecutive characters changed with \(50 \%\) of the chance and the location of two consecutive character presentation changed with \(50 \%\) of the chance. This arrangement roughly balanced the change in counting-relevant and counting-irrelevant features.

Five trials of each counting paradigm defined a block. The type of counting paradigm change in two consecutive blocks. Each subject performed between 20 to 30 blocks which left us between 50 to 75 trials of each counting paradigm. At most 10 blocks were performed in each session. A five minute break administered between each two consecutive sessions.
Results Tables 1 and 2 summarize the results of experiment 1. Table 1 shows the average execution time for four possible combinations of changing the location or the identity of two consecutive signals separated based on the type of concurrent counting paradigms.

The effect of three factors on execution times were examined: a. the type of concurrent counting (with LBTC and IBTC as its two levels), b. change in the counting-relevant feature (the location in LBTC and the identity in IBTC) for two consecutive signals (changed or same as two levels) and
\begin{tabular}{ccc}
\hline \hline \multicolumn{3}{c}{ Location Based Counting } \\
\hline & Same Location & Changed Location \\
\hline Same Id & \(0.834 \pm 0.077\) & \(1.552 \pm 0.136\) \\
\hline Changed Id & \(0.889 \pm 0.102\) & \(1.564 \pm 0.116\) \\
\hline \multicolumn{3}{c}{ Identity Based Counting } \\
\hline & Same Location & Changed Location \\
\hline Same Id & \(1.126 \pm 0.135\) & \(1.198 \pm 0.143\) \\
\hline Changed Id & \(2.122 \pm 0.190\) & \(2.120 \pm 0.205\) \\
\hline
\end{tabular}

Table 1: Mean \(\pm\) SE of the execution times (experiment 1).
c. change in the counting-irrelevant feature (the identity in LBTC and the location in IBTC) for two consecutive signals (changed or same as two levels). The execution time data with these three factors was submitted to a \(2 \times 2 \times 2\) withinsubjects ANOVA.

The analysis revealed a significant main effect of the type of counting task \([F(1,10)=16.4, p=0.0151]\), with a faster response time for the location-based triple counting ( \(M=\) \(1.2100 s, S E=0.055\) ) compared to the identity-based triple counting ( \(M=1.6415 s, S E=0.0819\) ). The main effect of change in the counting-relevant feature also proved to be significant \([F(1,10)=171, p=0.0009]\). A change in countingrelevant feature requires switching between the counters, and the average execution time for this case was higher than when two consecutive signals shared the same counting-relevant feature (i.e., the same counter is updated twice in a row). However, for the counting-irrelevant feature whose change does not require switching between counters, no significant impact was observed \([F(1,10)=1.9237, p=0.1956]\).

The analysis also revealed a significant interaction between the type of the double counting task and the change in counting-relevant feature with \(F(1,10)=24.1, p=0.0006\). A further analysis showed that indeed the change in countingrelevant feature resulted in a larger difference in execution times for IBTC compared to LBTC. All three other possible interactions were non-significant.

We quantified counting errors using four different measures: a. the proportion of trials that had at least one mistake in the reported counters (Incorrect Trials), b. the absolute difference between the reported values and the actual values (Counter Error), c. the absolute difference between reported values and actual values, after sorting both the counters and the reported values (Sorted Counter Error) and d. the absolute difference between the sum of reported values and the sum of actual counters (Sum Error). Among these four measures, a. and \(b\). are the most sensitive measures, while c. discounts any error in incorrectly reporting the order of counters, and d. is the least sensitive measure as it does not account for any error in adding to the right counter or in reporting the counters in the correct order.

Table 2 shows mean \(\pm\) standard error values for each of these error measures for two types of concurrent triple counting. To assess the significance of the effect of the type
\begin{tabular}{c|c|c|c}
\hline Error Type & LBTC & IBTC & Sig. \\
\hline Trials with Error & \(20.5 \% \pm 5.4 \%\) & \(39.3 \% \pm 7.1 \%\) & \({ }^{* *}\) \\
Value Error & \(0.11 \pm 0.03\) & \(0.31 \pm 0.07\) & \({ }^{* *}\) \\
Sorted Value Error & \(0.10 \pm 0.03\) & \(0.22 \pm 0.04\) & \({ }^{* *}\) \\
Sum Error & \(0.24 \pm 0.08\) & \(0.40 \pm 0.09\) & \(*\) \\
\hline
\end{tabular}

Table 2: Mean \(\pm\) SE of error measures (experiment 1). ** means \(p<0.01\), * means \(p<0.05\)
of the counting task on each of these four measures, the data of each error measure was submitted to a separate oneway within-subject ANOVA. A significant main effect of the counting type on the error rates was revealed, for all four measures of error. The significance of this impact on the first measure is quantified by \([F(1,10)=20, p=0.0012]\); for the absolute difference, this significance is quantified by \(F(1,10)=15.4, p=0.0028\); for the absolute difference in sorted sequence of counters and reported values, the significance is quantified by \([F(1,10)=17.2, p=0.00197]\); and finally for the absolute difference between the sum of counters and the sum of reported values, the significance of the main effect is quantified by \([F(1,10)=9.11, p=0.0129]\).
Discussion Changing the counting-relevant feature in two consecutive events for both counting paradigms requires increasing a counter which is different from the previously increased counter, and thus involves switching to a different counter. We observed that, independent of what defines the counting-relevant feature (location or identity of items), switching between counters results in a significantly lower speed for counting. Thus, we could replicate what Garavan had previously reported in the case of an identity-based dualcounting task (Garavan, 1998). However, compared to Garavan's study, our subjects were slower than his (both in updating one counter in a row or switching between counters and updating). This difference might be related to the fact that we had three counters, which might have had an extra load for maintaining the items. Moreover, our subjects needed to switch between two different counting paradigms frequently, and this might have had some impact on the execution time. Finally, we did not impose a delay between blocks of different counting paradigms, and subjects were only notified about the change in the counting paradigm by displaying a message on the screen.

However, the striking result of this experiment is related to the significant difference in execution time and counting errors of our two paradigms. Compared to the identity-based paradigm, the location-based paradigm proved to be both faster and more accurate. Even when the sums of reported counters were compared to the sums of actual counts, subjects were significantly more accurate in the location-based counting. Note that this measure for counting error is not even sensitive to the counting-relevant feature, and yet identity-based counting is significantly slower and less accurate with respect to this measure. This reveals that the slower execution time
in identity-based triple counting is not the result of a trade-off between accuracy and speed.

Another striking result was related to the fact that not only the overall execution time during LBTC was less than the execution time during IBTC but also the switching cost was significantly less for LBTC. This is related to the fact that in our analysis we observed a significant interaction between switching condition and the counting paradigm. While updating the same counter during LBTC was about 300 milliseconds faster than IBTC, updating a different counter, which involves switching between counters, was about 560 milliseconds faster. This result suggests that using location as the counting-relevant feature has saved on the switching cost rather than a cost associated to maintaining or updating counters. We discuss the significance of this result in the general discussion.

\section*{Experiment 2}

In our second experiment, we test whether the higher cost for both counting and switching in the identity-based concurrent counting is indeed the result of differences in character versus location perception. It is known that processing visual forms and locations engages two different pathways; the ventral pathway specialized in identifying visual forms, which serves object perception, and the dorsal pathway specialized in identifying spatial locations, which serves action (Goodale \& Milner, 1992). One may argue that the observed differences between execution times in two concurrent counting paradigms is indeed related the processing of the visual input, and before the processing of the counters. To test the effect of identity recognition on the counting cost, we replaced the Identity-Based Triple Counting task with a modified version of the Location-Based Triple Counting task which involves identification of characters. In this paradigm, the running counters are still associated to locations; however, an occasional appearance of a dummy target can change the counter values and the rule of the concurrent counting thereafter. Thus, every time a valid target appears at a location, its identity should be checked before updating the counter associated to the target presentation location. We call this task IdControlled Location-Based Triple Counting or IC-LBTC for short.

\section*{Method}

Subjects Seven female and four male undergraduate students with normal or corrected to normal vision, participated for course credit. Subjects' ages ranged between 19 to 24 ( \(M=20.1, S D=1.4\) ).
Procedure In this experiment \# and ? were targets for incrementing a counter and \% was used as the dummy character. Subject were instructed that trials were arranged in two type of blocks, no-dummy blocks and dummy-possible blocks. In no-dummy blocks which contained 5 trials, only \# and ? could appear in boxes and all events had to be counted. However, in \(50 \%\) of the dummy-possible blocks, at some ran-
\begin{tabular}{ccc}

\hline Same Id & \(0.719 \pm 0.068\) & \(1.214 \pm 0.105\) \\
\hline Changed Id & \(0.716 \pm 0.071\) & \(1.285 \pm 0.105\) \\
\hline \multicolumn{2}{c}{ Id-Controlled Location Based Counting } \\
\hline & Same Location & Changed Location \\
\hline Same Id & \(0.724 \pm 0.071\) & \(1.205 \pm 0.113\) \\
\hline Changed Id & \(0.710 \pm 0.060\) & \(1.285 \pm 0.104\) \\
\hline
\end{tabular}

Table 3: Mean \(\pm\) SE of the execution times (experiment 2).
dom time the character \% would appear only once in a box; in this case, the counter for that box had to be reported as 0 (i.e., reset and ignored during subsequent stimulus presentations). In the beginning of each block, subjects were notified about the type of block by a written message appearing on the screen.

Thus each trial of a IC-LBTC block could be similar to trials of the LBTC or could have the dummy character appearing only once in one of the boxes. Choosing to include the dummy character in a IC-LBTC trial was decided randomly and with \(50 \%\) of the chance.

Given that blocks of different counting paradigms were similar in every sense we imposed a 10 second delay with a message on the screen informing the subject about whether in the next block there will be dummy characters or not.
Results Table 3 shows the average execution time for four possible combinations of changing the location or the identity of two consecutive signals, separated based on the type of concurrent counting paradigms. For the controlled locationbased counting, only those trials without dummy characters were included in the analysis.

To assess the significance of the effect of controlling for the identity of characters during the triple concurrent task, switching locations and switching identities, execution times were submitted to a \(2 \times 2 \times 2\) within-subject analysis of variance with type of counting, switching location and switching identity as three factors. The analysis showed no effect of attending to the identity of characters on the execution times \([F(1,10)=0.011, p=0.92]\). A significant effect of changing the location of target in two consecutive events on the execution times was observed \([F(1,10)=53.9, p=0.00557]\) and marginally-significant effect of switching the identities was observed \([F(1,10)=4.13, p=0.07]\).

The data for all measures of error were separately submitted to within-subject one-way ANOVAs with type of counting as the main factor to assess the impact of attending to the identity of characters on the error rates. None of the analyses returned a significant main effect of the counting paradigm on the error rates.

Except for one subject, all subjects correctly reported the incidence of appearance of the dummy character with \(100 \%\) accuracy.
\begin{tabular}{c|c|c|c}
\hline Error Type & LBTC & IC-LBTC & Sig. \\
\hline Trials with Error & \(19.1 \% \pm 3.9 \%\) & \(18.1 \% \pm 4.1 \%\) & n.s. \\
Value Error & \(0.11 \pm 0.02\) & \(0.10 \pm 0.03\) & n.s. \\
Sorted Value Error & \(0.08 \pm 0.02\) & \(0.07 \pm 0.02\) & n.s. \\
Sum Error & \(0.21 \pm 0.05\) & \(0.17 \pm 0.04\) & n.s. \\
\hline
\end{tabular}

Table 4: Mean \(\pm\) SE of error measures (experiment 2). n.s. : nonsignificant

Discussion The analysis of both execution times and error measures showed that compared to LBTC, attending to the identity of characters during IC-LBTC incurred no extra cost. This suggests that attending to the identity of the items in IBTC does not seem to be the source of extra cost of IBTC counting paradigm relative to LBTC.

However compared to the LBTC in experiment 1, subjects were significantly faster in LBTC trials of the second experiment. Given that subjects had to switch between LBTC and IBTC in the first experiment and LBTC and IC-LBTC in the second experiment, the faster execution time in the second experiment might have been related to a lower cost for switching between the two tasks in the second experiment. This difference might be related to either the 10 second imposed delay between blocks of experiment 2 , or the fact that both tasks in the second experiment are indeed two versions of the same counting paradigm, and thus switching between blocks of experiment 2 is less costly. Furthermore, since there was no significant interaction between the identity of experiments and changing counting-relevant factor in both LBTC trials, the effect of switching between blocks of tasks seems to have had equal effects on both updating the same counter in a sequence or updating two different consecutive counters. This suggests that the extra cost on switching between counters during IBTC counting is not likely related to the cost of switching between blocks of experiment 1 .

\section*{General Discussion}

The goal of this study was to test the dependency of putative switching mechanisms for managing working memory in the internal domain and in a seemingly abstract and symbolic context, on the explicit utilization of space. We analysed our subjects' execution time in two concurrent counting tasks that differed in their reference to spatial locations. In one version of the task, where counting events were associated to spatial locations on the screen, subjects were faster and more accurate than when the identity of visual targets was the basis for the counting events. More importantly, not only the speed of counting in the location-based counting paradigm was generally faster, but also this speed was significantly faster when subjects had to switch between internal counters. Below, we argue that a faster switching between internal counters indicates that the source of speedup indeed is not related to a verbal shortening effect in rehearsing.

In Garavan's process model for a dual-counting task, each counting event consists of a sequence of five steps: 1. stimu-
lus identification, 2. orientation of attention, 3. updating the associated count, 4. rehearsing the other count, 5 . key-press. He suggests that the source of a 300 to 400 msec difference in updating the same counter subsequently versus updating two different counters is related to the cost of the second step: a recently attended resident of the working memory is privileged in terms of processing speed or accuracy (Garavan, 1998), and thus updating a counter which was just updated saves on the cost of bringing the item of working memory into the focus.

This model could be adopted for the triple-counting task by considering a third counter which needs to be included in the switching and the rehearsing steps. This model does not assume that the second step of this process, which accounts for the extra switching cost between two different counts, is dependent on perceptual aspects of the counting tasks. Likewise, no other model of working memory, to our knowledge, in which the focus of attention plays a critical functional role in regulating the process, assumes that the second and the third steps of this process are relevant to the perceptual aspects of the counting task. Hence, according to this process model, steps 2,3 and 5 should be independent of the type of counting events. Our second experiment controlled for the influence of potential effects of perceptual differences, and showed that the source of speed difference in two paradigms cannot be attributed to the perception of events. Consequently, according to this model, the only source of difference in counting speed might be in rehearsing other counts (step 4). However, this effect would affect the speed of counting in a similar way for both updating the same counter or updating counters alternatively. Moreover, the analysis of errors adds another dimension to our argument: even when misplaced counters and signals are discounted in the error calculation, the location-based counting is still significantly more accurate. In sum, we argue that a model that confers a special role to space (unlike Garavan's process model), may be necessary to fully explain our findings.

Noori and Itti's spatial registry framework for manipulation of information in working memory is an example of a model where space plays a special role. According to this model, which assumes that working memory items are bound to spatial locations, accessing items in the internal domain draws on shifting spatial attention to different locations. In the case of location-based counting, counters can be directly bound to the location of boxes, and thus attending to the visual stimulus will automatically draw attention to the location of counters for accessing the counter value. In contrast, during the identity-based triple counting, each signal will draw spatial attention, but the signal location is not correlated with its identity and thus with the associated counter, thus likely a second shift of attention is required to point attention to the correct counter. When items need an update, two shifts in spatial attention may thus be required. The extra shift of attention may account for the slower response time during the identity-based triple counting.

\begin{abstract}
We measured the sensitivity in detecting a change in the location of one of two visual targets over a short period of time to investigate the impact of a secondary intellectual symbolic WM task on the visuospatial short-term memory, in a dual-task paradigm. We observed that engaging in a WM task that involves manipulation of symbolic information impacts the ability to detect a location change, and this impact does not change when more time is allocated to the WM task. Furthermore, we observed that the impact of a mental sorting task on the ability to detect location changes is spatially selective to the horizontal orientation. Our results suggest a possible role for sensory-motor working memory, which supports perceptionaction schemas in manipulation of information during the intellectual symbolic working memory tasks.

\section*{Introduction}

The quality of our modern life has become so dependent on the ability to perform intellectual tasks with symbols (e.g. addition or subtraction) that we force our children to spend a big chunk of their life on learning them at school and home. Effective assessment of individuals' ability in performing these tasks has become a constant occupation of mind for some cognitive psychologists among which some have suggested that the ability of management of working memory (WM) is an indicator and the key to understanding individuals' ability in performing these tasks (Conway, Kane, \& Engle, 2003). Suggestions such as this, have created a motivation for understanding mechanisms of WM management.

Better understanding the human ability for maintaining and manipulating symbolic content poses the question of which brain mechanisms may be recruited by these tasks. From an evolutionary standpoint it is not easy to entertain the idea that our brain has evolved a dedicated system for maintaining and manipulating symbolic concepts in mental schemas, which are indeed very recent cultural inventions (e.g., numbers in mental arithmetic). Meanwhile, humans often perform daily sensory-motor routines that require temporary maintaining and manipulating of information gathered from the environment and relevant to the task. Robust maintaining of task-relevant information for performing perception-action schemas provides an adaptive value, which might have led to evolution of sensory-motor working memory. For instance think of the adaptive advantage of the ability to temporarily maintain the location of a targeted prey which is momentarily out of sight until the right moment for attack.

As suggested by some researchers, it is conceivable that evolutionary older systems for encoding, maintaining and manipulating of information for rudimentary tasks are coopted or reused for the intellectual tasks with newly invented
concepts (Paillard, 2000; Dehaene \& Cohen, 2007). For example, some researchers have entertained the idea of using space in the representation of numbers (Knops, Thirion, Hubbard, Michel, \& Dehaene, 2009; Wood, Willmes, Nuerk, \& Fischer, 2008).

However, studying capacities for maintaining and manipulating of information in the intellectual domain and in the sensory-motor domain are traditionally pursued in different research communities, with not much of cross-talk. Hence, studying the possibility of reusing sensory-motor working memory in intellectual symbolic tasks has not been fully explored yet.

The goal of the present study is to investigate the possibility of involvement of visual-spatial short-term memory in manipulation of information during intellectual symbolic working memory tasks. Short-term memory of the location of a visual target is a component of sensory-motor working memory and is crucial for performing a range of visual-motor tasks. We measured the impact of two different intellectual symbolic tasks on the ability to maintain the spatial information of the location of visual targets.

Similar attempts with an opposite goal have been made to pinpoint the role of the central executive (CE) as the supplier of executive attention (Repovs \& Baddeley, 2006) during maintaining visuospatial short-term memories (Phillips, 1983; Logie, Zucco, \& Baddeley, 1990). In those studies, spatial span - the maximum size of a matrix of symbols which can be recalled better than a threshold performance - is used as a measure for the capacity spatial memory. Any change in the memory span as the result of engagement of the CE would be interpreted as evidence for a role for executive resources in maintaining spatial information. Meanwhile, engaging CE is mostly achieved by engaging subjects in intellectual symbolic working memory tasks, known as executive working memory tasks.

These studies have been equivocal in their conclusions about the role of executive resources in maintaining spatial memory. Phillips has reported that performing a mental arithmetic task reduces the visual/spatial span (Phillips, 1983). He concluded that maintaining spatial information is facilitated through an active mental imagery process which is inhibited by the load of the mental arithmetic. Logie, Zucco and Baddeley (Logie et al., 1990) compared the effect of both a mental arithmetic and a mental imagery task, on both visual and word spans, and showed that the the mental imagery task impairs the visual span to a greater extent, while mental arithmetic impairs the word span to a greater extent. However, they still observed an impact of mental arithmetic on visuospatial span and stated that "the impairment in short-term visual memory
resulting from secondary arithmetic reflects a small general processing load".

However, later on, Baddeley and Repovs summarized the results of many dual-task studies, pinpointing the role of CE in maintaining and manipulating information in components of Baddeley's multi-component model of working memory. They concluded that simple representation and maintenance of information may be independent from the CE (Repovs \& Baddeley, 2006). This conclusion includes maintaining spatial information tested in measuring spatial span which is contrary to Baddeley's previous note on the impact of mental arithmetic on spatial span.

In the present study, we use the sensitivity of subjects in detecting a change in location of two dots to measure the ability of retaining visual-spatial information. This requires retaining an amount of spatial information which is below the capacity of normal subjects (Luck \& Vogel, 1997). In other words, instead of using a fixed threshold for performance in measuring the span of short-term memory, we used a fixed amount of information load below the normal capacity of our subjects, to measure the effect of a secondary intellectual working memory task. Although this paradigm does not measure the spatial working memory capacity in its conventional definition yet, it reflects the general capacity of maintaining spatial information over a short period of time. Moreover, this measure tests the spatial short-term memory in a way that is closer to the use of spatial information in daily perception-action routines. Finally, this paradigm can be easily used to test the spatial selectivity of any potential impact on the spatial short-term memory. This paradigm can be deployed in fixed-length blocks which eliminates the influence of the training factor.

Using this sensitivity measurement paradigm, we inspected the influence of two different symbolic working memory tasks on the short-term spatial information retention. In our first experiment, we used a dual-counting task in which two running counts need to be maintained and updated upon presentation of two distinguishable audio signals. We use the rate of signal presentation as a parametric feature to change the amount of time that is allocated to this task. This allows us detect any impact onto spatial short-term memory caused by decaying information as the result of performing the symbolic working memory (SWM) task.

In our second experiment, we used mental reordering versus retaining of four random alphabetical characters (presented auditorily) as our symbolic working memory tasks. We compared their impact onto retaining spatial information along either the horizontal or vertical orientation. This allowed us to test the spatial selectivity of the impact of mental reordering of characters compared to maintaining them.

\section*{Experiment 1}

We asked our subjects to perform a mental dual counting task of two audio signals, while they were also retaining visualspatial information. The goal was to test whether this sym-

Figure 1: Schematic view of the experimental paradigm.
bolic working memory task could interfere with retaining visual-spatial information as simple as the spatial locations of two visual targets. We also aimed to test whether a possible interference is due to competition over scarce executive resources that might be needed for both the manipulation of working memory content and the retention of visual-spatial information.

Mental dual counting involves maintaining two running counters, associated with two signals, in working memory, and, each time a new signal is perceived, incrementing the associated counter. The rate of updating of the internal counters can be adjusted by the rate at which audio signals are presented. This allows manipulation of the total amount of time that putative executive resources may be free and available for other tasks (e.g., active retaining of spatial short-term memory), which in turn may affect the sensitivity measure. We chose two different rates for presenting audio signals for the dual counting task. In separate blocks, we asked subjects to ignore versus count the signals while retaining the visualspatial information.

\section*{Method}

Apparatus Visual-spatial stimuli were displayed on a 46inch LCD monitor (Sony Bravia XBR-III, 1,016 \(\times 571.5\) mm ), 97.8 cm in front of participants (corresponding field of view is \(54.7^{\circ} \times 32.65^{\circ}\) ). To control the viewing distance, subjects used a chin rest to maintain their head position during the experiment. A gray background \((0.62 \mathrm{~cd} / \mathrm{m} 2)\) was displayed during the experiment. A headphone was used for presenting audio stimuli. Our stimulus presentation program was developed using iLab Neuromorphic Toolkit (iNT) and operated on a Linux 64bit machine.

Subjects Fourteen female and one male undergraduate students with normal or corrected to normal vision, participated for course credit. Participants' ages ranged from 18 to 23 years \((M=20.9, S D=1.6)\).

Procedure Figure 1 displays a schematic view of the experimental paradigm. Visual-spatial stimuli consist of two separately displayed red dots, each one placed randomly on an imaginary circle at center of screen with a diameter of \(3.125^{\circ}\) angle of view. Each dot stayed on the screen for 500 ms and a 500 ms blank screen separated the display of red dots. On the virtual circle, dots were at least \(90^{\circ}\) and at most \(120^{\circ}\) apart. Subjects had to retain the location of red dots for about 10 seconds during which they were supposed to engage in a symbolic working memory task.

During a 10 second period after the removal of the second dot, audio signals of two easily distinguishable types were played in a random order either in a slow tempo or a fast tempo. We used two 250 ms long, 50 Hz tones as audio signals; a soft tone (sine wave) and a rough tone (square wave). For the slow tempo condition, four signals were played with a random ISI of 3000 ms to 3600 ms , and for the fast tempo condition 8 signals were played with ISI of 1330 ms to to 2000 ms .

In all trials, subjects were given an initial set of 3 separate digits (each could have initial value between 0 and 3 ). In half of the blocks, subjects were asked to ignore audio signals and to keep repeating three random digits played before the onset of visual targets. We refer to this task condition as the ignore condition (IC). Under this condition, subjects had to report these same three digits at the end of the trial. In the counting condition, subjects were asked to increment the first digit upon hearing the soft tone, to increment the last digit upon hearing the rough tone, and to remember the middle digit unchanged. All three digits were reported at the end of trial. We refer to this condition as the engage condition (EC).

The memory of the location of targets was probed at the end of a 10 second retaining period by presenting two probe targets simultaneously. Probe targets were presented either on the exact same location as the initial targets (with \(50 \%\) chance), or the location of one of the probe targets was shifted along the imaginary circle at least by \(45^{\circ}\) and at most \(60^{\circ}\) away from the location of the initial target. Subjects were supposed to respond whether both probe targets appeared at the same locations as the original stimuli. During the retaining period, a fixation cross remained at the center of the screen. Subjects fixated the fixation cross during the SWM task execution period. Subjects reported their three digits by mouse clicks on a virtual keypad after responding to the visuospatial probe.

We administered the experiment in separate blocks of 20 trials for the engage and ignore conditions. Each block contained equal numbers of trials with each possible tempo. Each subject performed two blocks of trials for each engagement condition.

Results Sensitivity of subjects in detecting matching probes was used to measure the impact of the symbolic working memory (SWM) task onto the visual-spatial short-term memory (VSSTM) task. Figure 2 demonstrates the mean value of sensitivity \(\left(d^{\prime}\right)\) in identifying matching visuosptial

Figure 2: Impacts of task condition and audio signal rates on the sensitivity measure (experiment 1 ).
probes, for different conditions. To determine the significance of the impact of task and tempo factors, \(d^{\prime}\) values were submitted to a two-way ANOVA with repeated measures on both factors.

The analysis revealed a main effect of task at significance level \(p<0.0001[F(1,14)=37.69]\). The tempo of audio signals did not show a significant main effect \([F(1,14)=\) \(0.504, p=0.49]\). No significant interaction between factors was observed \([F(1,14)=0.11, p=0.74]\).

Further analysis revealed that sensitivity was higher in identifying identical probe targets when subjects ignored audio signals \((M=2.46, S D=1.29)\), compared to when subjects were engaged in dual counting of audio signals ( \(M=\) \(1.57, S D=1.21\) ). Moreover, increasing the tempo of audio signals decreased the mean value of \(d^{\prime}\) for both task conditions; however, this change did not reach a significant level.

To measure the engagement of subjects in the counting task we compared the number of counted signals for both tempos. The difference between the sum of reported counters and the sum of initial counters was used as the measure of counted signals. The average counted signals for fast tempo was \(6.7 \pm 1.2(M \pm S E M)\) and the average counted signals during the slow tempo was \(3.8 \pm 0.2(M \pm S E M)\), which was significantly less than the counted signals for the fast tempo \([F(1,14)=131.04, p<0.0001]\).

Discussion Our results indicates that, first, the sensitivity measure is sufficiently sensitive for detecting the impact of a secondary working memory task such as the dual counting, even though the load on the VSSTM appears to be half of the capacity of visual-spatial short-term memory in normal subjects (Luck \& Vogel, 1997). Second, the double counting task can impair the retention of visual-spatial information over a short period of time. A significant impact on the sensitivity measure with such a low amount of spatial information suggests that the dual counting task, independent of the tempo, can potentially impact the spatial span too.

One may maintain that this effect is caused by engaging

CE in the dual counting task. However, on the basis of the sensitivity measure, increasing the rate of dual counting neither showed a main effect nor an interaction with the VSSTM task. Based on this result, one may come to the conclusion that increasing the tempo indeed does not change the complexity of the task, and thus does not add to the load on the central executive.

In this sense, the double counting might use a specific amount of executive resources in lapses associated to each signal presentation event. Garavan has proposed a model for a self-paced version of dual counting task which consists of five steps (Garavan, 1998): 1. stimulus identification, 2. orientation of attention to the associated counter, 3. updating the count, 4. rehearsing the other count, 5. key-press. The first four steps can be used as a model for our version of the dual counting task. Previous research suggests that executive attention does not play a direct role in the first step (He \& McCarley, 2010). Also, verbal rehearsing in step 4 is suggested not to be dependent on executive resources (Repovs \& Baddeley, 2006). Additionally one may maintain that rescheduling the sequence of rehearsing in the case of switching between different counters (Garavan, 1998) may also draw on executive resources.

Involvement of executive resources in updating counters may result to unavailability of necessary resources for retaining visuospatial information over a refractory period (Pashler et al., 1994). Hence, a higher rate of signal presentation in fast tempo trials hypothetically would occupy a larger fraction of retaining period with a refractory condition.

Yet, one needs to establish how executive resources may play a role in retaining location of two visual targets to leverage a refractory explanation for the impact of dual counting on the sensitivity in location change detection. One may propose that retention of VSSTM requires active maintenance through a rehearsing process (Awh, Jonides, \& ReuterLorenz, 1998; Awh et al., 1999), which according to Jonides is a "controlled sequence of retrievals and re-encoding of items into the focus of attention" (Jonides et al., 2008). This may also draw on general executive resources needed for manipulation of information in symbolic working memory tasks. This argument hinges on this assumption that rehearsing prevents VSSTM traces from decay, so that interrupting the rehearsal process results in decaying traces of spatial short-term memory. Yet, this would imply that the more the rehearsing is interrupted, the more the effect of decay is pronounced. This in turn suggests that adding to the rate of dual counting may affect the performance on the visual-spatial task, which is not supported by our results.

Without CE as the shared scarce commodity between the SWM task and spatial information maintaining process, one should consider another source of conflict between manipulation of information in the SWM task and retaining spatial information. One source of conflict could be that visuospatial short-term memory is indeed used during the SWM task.

The use of space for the manipulation of information has
been previously discussed for specific SWM tasks such as immediate reverse recall (Rudel \& Denckla, 1974) and mental sorting of numbers (Noori \& Itti, 2011). One may imagine a use of space as natural addressing system for the content of SWM, which can be used as a handle to shift processing to different items of working memory (Noori \& Itti, 2011).

Our next experiment explores this matter in the case of a mental sorting task by measuring the sensitivity in detecting a location change along the horizontal versus the vertical directions. An account based on a bottleneck in executive resources for the impact of SWM on retention of spatial information maintains that interrupting the CE would affect VSSTM independently of the spatial location of visual targets. Hence, our second experiment provides us with another opportunity for testing the role of CE in retaining visualspatial information.

\section*{Experiment 2}

To test whether the observed influence of the SWM task on VSSTM is due to utilization of space for active manipulation of symbolic working memory content, we examined the selectivity of the impact of a mental sorting task on VSSTM. In particular, we used two visual-spatial targets either along the horizontal orientation or the vertical orientation. Subjects performed a sorting task on a random list of English letters during the visual-spatial information retaining period.
Subjects Eleven female and three male native English speaking undergraduate students with normal or corrected to normal vision participated for course credit. Participants' ages ranged from 19 to 22 years \((M=20.39, S D=1.4)\).
Procedure The procedure for this experiment is similar to experiment 1, except for the location of visual targets and the symbolic working memory task ( see Figure 1 ). Visual targets were two red dots presented either along a horizontal line or a vertical line passing through the center of screen, each dot on one side of the center, and between \(1^{\circ} \ldots 4.9^{\circ}\) angle of view away from the center. Visuospatial probe targets were presented simultaneously in the same locations as target stimuli with \(50 \%\) chance, otherwise, one of probe targets was displaced by \(1.4^{\circ}\), either inward or outward along original presentation direction so that two probe targets remained on two sides of the center cross along the direction of initial presentation.

Before the onset of the red dots, four randomly selected English letters were presented aurally to be maintained in the same presentation order (during maintaining trials), or sorted in alphabetical order (during sorting trials), within a 10 second period. At the end of the delay period, subjects first responded to the visuospatial query, followed by reporting four characters by mouse clicks on a virtual keypad displayed on the screen.

We administered the experiment in separate blocks of 20 trials for the maintaining and sorting conditions, but each block contained equal number of trials for each different di-
rection for the presentation of visual targets. Each subject performed two blocks of trials for each task condition.

Figure 3: Average sensitivity measure for two tasks and two target orientations (experiment 2).

Results Figure 3 demonstrates the mean value of sensitivity \(\left(d^{\prime}\right)\) in identifying matching visuosptial probe targets for different conditions of SWM task (Maintaining vs. Sorting) and visual target orientations (Horizontal vs. Vertical). To determine the significance of the impact of task and target orientation factors \(d^{\prime}\) values were submitted to a two-way ANOVA with repeated measures on both factors.

The analysis revealed a main effect of the task \([F(1,13)=\) \(8.43, p=0.012]\). No significant main effect of target orientation was determined \([F(1,13)=3.12, p=0.10]\) while the interaction was marginally significant \([F(1,13)=4.3, p=\) \(0.058]\). A post-hoc correlated-samples one-way ANOVA revealed a simple effect of the task, only for horizontal targets \([F(1,13)=15.26, p=0.0018]\), and no simple effect of the task condition at the level of vertical visual targets was observed \([F(1,13)=0.03, p=0.86]\).

Moreover, further analysis for exploring simple effects of orientation at different task levels showed that under the maintaining condition subjects demonstrated a higher sensitivity in detecting identical horizontal probe targets ( \(M=\) \(2.02, S E=0.19)\) compared to identical vertical probe targets \((M=1.28, S E=0.29)\). A correlated-samples one-way ANOVA revealed that the simple effect of orientation during the maintaining task is significant \([F(1,13)=5.11, p=\) 0.041].

Discussion As the analysis revealed, compared to maintaining of four characters in their original order for a later recall, sorting them into an alphabetical order could significantly influence the sensitivity measure. This result again demonstrates the capacity of the sensitivity measure in registering the impact of a secondary SWM task on temporary retention of spatial information. Given our significant results under the low amount of load on VSSTM in our location change detection, one would also expect an impact on spatial span tasks (higher load) due to engaging in a mental sorting task.

However the striking result was that the impact of the sort-
ing task on the sensitivity measure is only significant for visual targets that are spanned along the horizontal direction. Switching task condition did not change the average sensitivity to shift in location of targets along the vertical direction.

The sensitivity to change of location for vertically spanned visual targets was significantly above chance and, unlike the horizontally spanned targets, switching to the sorting task did not decrease sensitivity. This is consistent with the finding of the previous experiment, in that the influence of SWM task on the retention of spatial information is not caused by involvement of executive resources in spatial information retention; otherwise, one would expect an influence on the sensitivity for vertically distributed visual targets too. The initial sensitivity along vertical orientation was lower than along the horizontal orientation, hence one may raise the point that there was less room for decreasing the sensitivity along the vertical direction, and detecting a change would need more space. Controlling for the influence of this initial difference on the sensitivity in location change detection remains to be tested in a separate experiment, with a setup that can balance the sensitivities for detecting target locations along the vertical and horizontal directions during the list maintaining task.

\section*{General Discussion}

The goal of this study was to explore the influence of intellectual working memory tasks devoid of visual and spatial features on the ability of retaining visuospatial information over a short period of time. We used a measure which is different from the actual capacity of spatial memory for holding spatial information. Instead we used the ability to detect a change in spatial location of one of two simple visual targets. In both experiments we observed that engaging in active manipulation of working memory content results to a decrease in the sensitivity of subjects in detecting a change in location of targets which needs to be explained.

Theories of working memory in the realm of cognitive psychology -independent of what they assume about the nature of representation in WM - usually assume a specific execution model based on separation of storage and execution. As such, a conflict between two tasks is either associated with sharing storage or with drawing on limited executive resources. Given that the WM tasks in our study are devoid of immediate visual features, one may conclude that the source of conflict is the the dependency of the retention of visualspatial information and WM task on the CE. Yet, one should be clear as to how CE explains this conflict rather than - as Baddeley and Repovs have stated (Repovs \& Baddeley, 2006) - using CE as a homunculus which has an undisclosed role in everything.

As we discussed in our introduction Baddeley's latest account assumes no role for the CE in retention of spatial information as simple as we tested in our experiment.

We also discussed that the proposal of Awh and his colleagues for engagement of a rehearsing mechanism in maintaining visuospatial information (Awh et al., 1998, 1999),
and Jonides' account for the dynamic of rehearsing process (Jonides et al., 2008), may suggest a role for the CE in retention of visuospatial information. Our experiments were able to test this hypothetical role and our results did not support it.

Another view of working memory, proposed by Cowan (Cowan, 2001), has recently gained popularity in the cognitive psychology community. According to Cowan, working memory content is a part of long-term memory in a heightened state and under attention (Cowan, 2001). He explains the limitation in the capacity of working memory by the limitation of the internal attention in covering only four items at a time. The role of CE in this schema is to dynamically dispatch attention between representations in the long term memory, to make them available for processing. Accordingly, one might say that attention might be shared between information about the locations of two dots and the identities of four characters of the sorting task, which would exceed the capacity limit of 4 items proposed by Cowan. Yet, this explanation lacks sufficient detail to explain why adding to the rate of double counting and fastening this juggling of content of working memory under the watch of attention has no impact, or, in our second experiment, the effect of sorting characters in memory is limited to the sensitivity in detecting changes along the horizontal orientation.

Finally, there is another explanation, previously proposed by Noori and Itti (Noori \& Itti, 2013, 2011), which falls out of the realm of models of working memory that assume separation of execution and storage. According to Noori and Itti, manipulation of information during symbolic intellectual working memory tasks (e.g., mental sorting or mental arithmetic) is made possible by re-using those sensory-motor working memory systems that evolutionarily have been developed to support perception-action routines (such as the occulomotor system). They argue that the capacity of maintaining information about locations of objects in space, in preparation for action on these objects, may provide a capacity for an internal binding of working memory task items for further manipulation. They assume that the management of working memory is made possible through an operational schema. In a way that was specified by Arbib's schema theory, operational schemas eliminate the need for a general-purpose CE in charge of management of working memory content, by instead defining explicit mechanisms that range from simple action-perception routines in catching a prey (Arbib \& Liaw, 1995) to high-level language production (Arbib, 2005).

According to this account, one may assume that visuospatial short-term memory which maintains information about the whereabouts of real objects (e.g., locations of dots in our experiments), is also being utilized for the manipulation of working memory for the intellectual symbolic task (e.g., keeping two running counts separate and yet accessible) by binding symbolic items to space. This assumption may explain the observed effects as the result of a retroactive interference which masks memory of stored information about the location of dots.

\begin{abstract}
Negation is one of the most important concepts in human language, and yet little is known about children's ability to comprehend negative sentences. In this experiment, we explore how children's comprehension of negative sentences changes between 2- to 4-year-old children, as well as how comprehension is influenced by how negative sentences are used. Children between the ages of 2 and 4 years watched a video in which they heard positive and negative sentences. Negative sentences, such as "look at the boy with no apples", referred either to an absence of a characteristic or an alternative characteristic. Older children showed significant improvements in speed and accuracy of looks to target. Children showed more difficulty when the negative sentence referred to nothing, compared to when it referred to an alternative. In addition, children showed an early tendency to look towards the named noun, even when that noun was negated. This study contributes to our understanding of children's comprehension of negative sentences, as well as our understanding of the conceptual structure of negation.
\end{abstract}

Keywords: Negation; language development

\section*{Introduction}
"No" is among the first words that children learn, as well as one of the most important. Negation is a fundamental element of human language - it is essential to logical systems, allows us to evaluate whether a statement is true or false, and it gives us a way to express concepts such as nonexistence. Negation is also challenging for language users; adults take longer to process negative sentences than positive ones (Clark \& Chase, 1972; Just \& Carpenter, 1971, 1976; Carpenter \& Just, 1975). These findings lead us to an apparent paradox - how is that negation is difficult for adults, yet acquired at such a young age? By examining children's acquisition of negation, we can explore the origins and development of logical concepts.

Not all uses of negation are the same; words like "no" and "not" allow us to express multiple concepts. Three primary categories have been identified in children's early negative utterances: nonexistence, rejection, and denial/truth-functional (Bloom, 1970, 1993; Pea, 1980). A child expressing rejection might say "no go outside" when they want to stay inside, while a child who says "no more juice" to describe an empty cup is expressing nonexistence (Bloom, 1970). Denial involves making a statement about falsehood; a child might say "that not lollipop" if they believe a candy has been falsely identified as a lollipop. Additional types of negation have been identified as well. Pea (1980) identified two additional categories - self-prohibition, used when the child is about to engage in a forbidden action, and unfulfilled expectations, used when an expected action/object is not present. Choi (1988) identified a full 9 categories of negation, including failure, inability, epistemic negation (e.g. "I don't know"),
and inferential negation (i.e. negation of inferred beliefs of others). Regardless of taxonomy, negation is used in a variety of contexts to express a range of different thoughts.

The relationship between different types of negation is unknown. One possibility is that distinct categories of negation belong to a single cohesive concept. Even pre-linguistically, nonexistence, rejection, and denial could all fall under a superordinate conceptual category of negation. It is also possible, however, that these types of negation represent fundamentally different concepts. For example, the situation in which a child expresses a dislike for going outside (rejection) is very different from a child commenting on an empty juice cup (nonexistence). Perhaps it is only the common language used to describe these events that unites these concepts. One way of untangling these possibilities is by examining children's understanding of different negative concepts, and exploring how their conceptual structure changes as they develop the language to express these thoughts.

The acquisition of linguistic negation follows a long developmental trajectory. As early as 12 months, children produce negation in the form of the word "no", typically to express nonexistence and rejection (Bloom, 1970, 1993; Pea, 1980). Denial doesn't emerge until almost a year later, between 19 and 23 months (Pea, 1980). Cross-linguistic studies suggest that this stratification by type, with certain negative categories produced earlier than others, can be seen across languages (McNeill \& McNeill, 1968). Even after age 2, children continue to learn about negation, showing improvements in syntactic form (Klima \& Bellugi, 1966; CameronFaulkner, Lieven, \& Theakston, 2007) as well as increases in the frequency with which they produce spontaneous negatives (Pea, 1982). Furthermore, children as old as 4 years continue to have difficulty with implicitly negative terms such as marked adjectives (e.g. less) (Donaldson \& Balfour, 1968; Klatzky, Clark, \& Macken, 1973). Thus, although "no" is among the first words that children produce, they continue to grapple with the nuances of negation for several more years.

Nearly all prior research on the acquisition of negation has focused on production. Very little work has examined children's comprehension of negative sentences (cf. de Villiers \& Tager-Flusberg, 1975). While production can tell us about the contexts in which children use negation, it does not reveal the extent to which children understand concepts underlying negative sentences. Children may already have a sophisticated understanding of different types of negation before they start producing negative utterances. Alternatively, children's conceptual understanding may change as they develop linguistic negation. By examining the development of children's com-
prehension of negative sentences, we can begin to tease apart the relationship between children's conceptual understanding of negation and their linguistic abilities.

Our primary goal in this initial study was to address the lack of work on children's comprehension of negation. We conducted a study of children's understanding of negative sentences, using eye-tracking to test comprehension. Eyegaze measures are ideally suited to our goal, because gaze following requires limited cognitive resources (Fernald, Zangi, Portillo, \& Marchman, 2008). Because our ultimate goal is to understand the conceptual structure of negation, we measured comprehension of two types of negative sentences: those that refer to nothing (nonexistence), and those that refer to an alternative (similar to denial). By examining comprehension, we hoped to gather a more nuanced picture of the acquisition of negation as well as gain insight into children's conceptual understanding of different types of negative sentences.

\section*{Method}

This study was designed to examine the development of the comprehension of negation from ages \(2-4\) years. Children watched a video in which they were asked to "look at the boy with/with no X". This type of negative construct was used because it involves "no", the negative element emerging earliest in children's speech (Klima \& Bellugi, 1966; CameronFaulkner et al., 2007). Plural items were used instead of singular items to maintain maximum consistency between positive and negative sentences. Prior to each test trial, children viewed a context slide designed to set up expectations about the characters in the trial. This context was included due to work suggesting that contextual support facilitates negation processing in adults (Wason, 1965; Glenberg, Robertson, Jansen, \& Johnson-Glenberg, 1999; Lüdtke \& Kaup, 2006) as well as children (de Villiers, J. and Tager-Flusberg, H.B., 1975). Following each trial, Elmo appeared next to the target, to motivate children to look towards the correct character. In order to capture different types of negation, we created two between-subjects conditions. In the nothing condition, negative sentences referred to people with no items at all (e.g. a boy holding nothing compared to a boy holding apples). In the something condition, negative sentences referred to people with alternative items (e.g. a boy holding presents compared to a boy holding apples). By measuring children's comprehension of negative sentences in different contexts, we hoped to learn more about the types of negation that children understand between ages 2 and 4 .

\section*{Participants}

Families visiting the Children's Discovery Museum in San Jose, CA were invited to participate in this study. Our final sample was comprised of children who were exposed to English at least \(75 \%\) of the time, as indicated by their parents, and who were attentive for the initial calibration phase of the experiment. This resulted in a sample of 111 children, 49 2 -year-olds (mean age \(=2 ; 5\), range \(=2: 0-2 ; 11,22\) female) and 623 -year-olds (mean age \(=3 ; 5\), range \(=3 ; 0-3 ; 11\), 21

Figure 1: An example of context, trial, and feedback from the nothing and something conditions.
female). In exchange for participation, children were given a sticker and a certificate.

Of these initial 81 children, only those who completed at least 8 of the 16 trials were included in analysis. Four 2-yearolds and 53 -year-olds were rejected due to this criterion. A further 42 -year-olds and 43 -year-olds were rejected due to loss of gaze data in more than \(30 \%\) of the experiment. Finally, individual trials with more than \(30 \%\) missing gaze data were excluded from analysis. This left a total of 91 participants whose data was analyzed; 20 2-year-olds in the nothing condition and 21 in the something condition, and 263 -year-olds in the nothing condition and 27 in the something condition.

\section*{Stimuli}

We created 16 items, each presented as an individual trial. Items consisted of boys or girls either holding nothing or holding different items (e.g. two apples). Each trial was paired with a positive or a negative sentence. Sentences were of the form "Look at the boy who has/has no apples".

Each trial contained three parts: a context, a test trial, and feedback (see Figure 1):

Context: The context consisted of three characters, two holding two target items each, and the other character holding either nothing (in the nothing condition) or two alternative items (in the something condition). A pre-recorded voice said e.g. "See these boys?". Each context lasted 5 seconds.

Test trial: Each trial consisted of two new characters, one holding two target items and one either holding nothing (in the nothing condition) or two alternative items (in the something condition). The images were presented in silence for two seconds, after which a pre-recorded voice said a positive or a negative sentence (e.g. "Look at the boy with/with no apples"), followed by an additional tag sentence (e.g. "Can you find him?"). Each trial lasted 7.5 seconds.

Feedback: Feedback involved Elmo appearing next to the target character with a chiming noise lasting 1.5 seconds.

Figure 2: Proportion of 2-year-old and 3-year-old children looking to the target picture as the sentence unfolds. Nothing trials are shown above, and something trials are shown below. Error bars represent 95\% C.I.

\section*{Procedure}

Parents and children were led to a small research room. Children sat in a booster seat approximately 60 cm from the monitor of an SMI RED 120 Hz corneal reection eye-tracker mounted on an adjustable arm. Some children sat on a parent's lap, depending on the child's age and level of comfort.

The experiment was presented in the form of a short video. The video began with a short Elmo clip, during which any necessary adjustments to the eye-tracker were made. This was followed by a 2-point calibration and validation of the calibration points. After calibration, children were introduced to Elmo and told that "Today, Elmo is going to visit some of his friends. Do you want to meet Elmo's friends? Let's go!". This opening sequence was created to give the video a more "story-like" feeling, and to motivate children to look to the target characters during the test trials.

Following this introduction, children saw three gazecontingent practice trials, designed so that the video would not advance until the child looked at the target item. Practice trials involved only the trial + feedback (no context). The first practice item had only one character, while the next two practice items had two characters, as in the test trials.

The rest of the video consisted of 16 trials, as well as 6 filler pictures of Elmo and 4 Elmo video clips. Filler videos were advanced by the experimenter after a variable length of time depending on the child's attentiveness, making the video length slightly different for each child; in general the video lasted approximately 6 minutes. Two orders were created for the test videos, such that trial types were counterbalanced and trial order pseudo-randomized across the two orders.

Table 1: Coefficient estimates from mixed-effects models predicting proportion of looks to target in an early window (600-1600 ms after noun onset) and a late window (16002600 ms after noun onset).
\begin{tabular}{rrrr}
\hline & Coefficient Std. err. t value \\
\hline (Intercept) & 0.83 & 0.04 & 22.81 \\
Sentence (Negative) & -0.55 & 0.06 & -9.03 \\
Condition (Something) & -0.20 & 0.05 & -4.12 \\

\section*{Results and Discussion}

We first examined developmental changes in children's ability to comprehend negative sentences between ages 2 and 4. Next, we explored the contrast between types of negation (i.e. the nothing condition and the something condition). Finally, we examined how gaze changes over the course of a trial.

Developmental changes Children's ability to process negative sentences increases considerably between ages 2 and 3 . This increase can be seen both in children's accuracy and reaction time in response to negative sentences.

Figure 2 shows the proportion of children who looked to the target picture over the course of a trial. The majority of

Figure 3: Reaction times of children who were looking at the distractor picture at the onset of the noun to orient towards the target picture. Error bars represent \(95 \%\) C.I.

\end{tabular}
children in both age groups and conditions responded correctly to positive sentences. However, a difference in accuracy can be seen in response to negative sentences between the two age groups. While 2 -year-olds show very little comprehension of negation in this paradigm, 3-year-olds show a noticeable increase in looks to target following the onset of the noun. We ran a linear mixed-effects model analyzing the effects of sentence type, condition, age group, and time window (early: 600-1600ms following noun onset; late: 16002600 ms following noun onset) on the proportion of children looking to the target (Table 1). \({ }^{1}\) Results of this model indicate a significant interaction between sentence type and age group, such that 3-year-olds are more likely to look to the target in response to negative sentences than 2-year-olds.

Reaction time (RT) was measured by looking at trials in which children who were originally fixating on the distractor (non-target) picture at the onset of the noun, and calculating how long it took these children to make their first shift to the target picture (Fernald et al., 2008). Two-year-olds showed larger RTs in response to negative sentences compared to positive sentences (Figure 3). However, 3-year-olds were surprisingly quick to orient to the target picture, only slightly slower than in response to positive sentences and much faster than

\footnotetext{
\({ }^{1}\) All mixed-effects models were run using the Ime4 package in R version 2.15.2. The random effects structure for this model was as follows: \((\) sentence + window|subject \()+(\) sentence + condition + age group + window \(\mid\) item \()\)
}

2-year-olds. Results from a linear mixed-effects model are reported in Table 2. \({ }^{2}\) Note that the decrease in 3-year-olds' RTs in response to negative sentences is not due to a general increase in processing abilities; our model found no main effect of age, only an interaction between sentence type and age, such that 3-year-olds process negative sentences nearly a full second faster than 2 -year-olds.

Types of negation Our results suggest that children have more difficulty identifying the referent of a negative sentence when it refers to nothing than when it refers to an alternative object. While 3-year-olds increase their looks to target following noun onset in the nothing condition, this does not increase above \(50 \%\) (Figure 2). However, in the something condition, nearly \(70 \%\) of children look to the target following negative sentences. This increase is seen in the later window of time, \(1600-2600 \mathrm{~ms}\) following the onset of the noun. This can be seen in the results of our model reported in Table 1; there is a significant 4 -way interaction such that 3 -year-olds' responses to negative sentences in the later window of the something condition show an increase in looks to target.

Onset-contingent plots (Figure 4) provide another way of looking at children's gaze behavior. These plots split trials based on whether the child was looking at the target or the distractor at the onset of the noun, and plot the proportion of children who shift their gaze to the opposite item. Children who are initially looking at the distractor should show rapidly increasing shifts, whereas children who are initially looking at the target should continue to look at the target (Fernald et al., 2008). Note that responses to the positive sentences are typical of what these plots normally look like.

Responses to the negative sentences, however, deviate from the typical pattern. For 2-year-olds in both conditions and 3-year-olds in the nothing condition, the pattern seen is the reverse: if children are looking at the target picture, they orient away, and if they are on the distractor, they stay. 3-year-olds are slightly better, with about \(50 \%\) orienting away from the distractor, but still the majority orient away from the target. However, 3-year-olds in the something condition show a different pattern; initially, children continue to fixate on the distractor and shift away from the target, but after approximately 1600 ms this pattern reverses and children shift away from the distractor and back towards the target. Thus, it is only 3-year-olds (and only in the something condition) who exhibit increased looks to target in response to negative sentences.
Real-time processing of negative sentences The data here reveal that children show a tendency to initially orient away from the target object, looking towards the negated noun, even amongst children who eventually do look to the target.

Two-year-olds do not look to the referent of negative sentences in either condition. Note that in the nothing condition, this preference could be explained by children's lack of interest in the boy with nothing, but in the something condi-

\footnotetext{
\({ }^{2}\) The random effects structure for this model was as follows: \((\) sentence \(\mid\) subject \()+(\) sentence + condition + age group \(\mid\) item \()\)
}

Figure 4: Onset-contingent plots of children's looking behavior starting at the onset of the noun. Nothing trials are shown above, and something trials are shown below.
tion both characters are equally salient. Thus, it appears that when 2-year-olds hear a named noun, they prefer to look at that noun, even if it has been negated.

In the earlier window of Figure 2 (600-1600 ms following the onset of the noun), 3-year-olds in the something condition show a similar pattern, showing a preference to look incorrectly to the negated noun. In the later window, however, the opposite pattern is seen: now children appear to look reliably to the target picture. This pattern can be seen more clearly in Figure 3. If children are looking at the distractor at the onset of the noun, about \(50 \%\) linger until 1600 ms , when suddenly the majority of looks shift to the target. Conversely, if children are looking at the target at noun onset, the majority of children shift away from the target, fixating on the distractor until 1600 ms , when they look back to the target. Again, this indicates a tendency for children to initially look to the negated noun, even when both options are equally salient.

\section*{General Discussion}

Little is known about children's comprehension of negative sentences, a surprising fact given the universality of negation and its importance in logical reasoning. Previous work on production suggests that children are continuing to learn about negation between 2 and 3 years of age (Klima \& Bellugi, 1966; Cameron-Faulkner et al., 2007; Pea, 1982), but few studies have explored how children's comprehension changes over this period. We conducted a study of children's comprehension of negation, examining negative sentences that referred either to nothing or to an alternative. We found that 3-year-olds were much faster and more successful than 2-year-olds at correctly looking at the referent of negative sentences. In addition, we found that children at both
ages struggle to identify the referent of negatives that refer to nonexistence, as opposed to referring to an alternative.

An additional and surprising finding of this study was that children in the something condition had an initial tendency to look towards the negated noun, and only 3 -year-olds were able to eventually override this preference and look to the correct target. There is some evidence that a similar pattern occurs in adult processing of negative sentences. Several priming studies have found that the representation of a negative sentence changes in the moments after the sentence unfolds (Kaup \& Zwaan, 2003; Kaup, 2001; Kaup, Ludtke, \& Zwaan, 2006; Hasson \& Glucksberg, 2006). In addition, ERP studies have shown N400 activation, associated with the processing of a semantically unexpected word, in sentences where the unexpected noun is negated (Fischler, Bloom, Childers, Roucos, \& Perry Jr, 1983; Lüdtke, Friedrich, De Filippis, \& Kaup, 2008). That is, sentences such as "A robin is a truck" and "A robin is not a truck" show greater negativity at the N400 than sentences such as "A robin is/is not a bird" (Fischler et al., 1983). This work has been interpreted as suggesting that adults do not immediately integrate negative elements into sentence meaning. Our findings here suggest that this may be true for children as well.

In our sample, both 2- and 3-year-olds found looking to the correct referent difficult when the target was holding nothing, i.e. nonexistence negation. It seems incorrect to attribute this to a lack of understanding of nonexistence, due to children's early production of negation. A more likely explanation is that orienting to the target in these trials required greater inhibitory control because the target character is less interesting to children. Identifying the specific kinds of negation that children hear in naturalistic contexts can help us under-
stand what kinds of contexts might facilitate comprehension of negation.

Overall, this study of children's comprehension of negation provides a complement to previous work on the acquisition of negation, which has primarily focused on production. Our ultimate goal is to examine young children's understanding of different negative concepts, and how this conceptual structure is influenced by the acquisition of linguistic negation. This goal speaks to a broader question about the extent to which linguistic development influences conceptual development and vice versa. Negation is an important case study for examining this question, because linguistic negation emerges early in childhood and can therefore be studied in conjunction with children's understanding of negative concepts. By exploring this relationship, we hope to shed light not only on the acquisition of negation, but also on the ways that language and concepts influence each other throughout development.

\begin{abstract}
Recent studies show controversial results on the trainability of working memory (WM) capacity being a limiting factor of human cognition. In order to contribute to this open question we investigated if participants improve in trained tasks and whether gains generalize to untrained WM tasks, mathematical problem solving and intelligence tests.
83 adults trained over a three week period ( 7.5 hours total) in one of the following conditions: A high, a medium or a low WM load group. The present findings show that task specific characteristics could be learned but that there was no transfer between trained and untrained tasks which had no common elements. Positive transfer occurred between two tasks focusing on inhibitory processes. It might be possible to enhance this specific component of WM but not WM capacity as such. A possible enhancement in a learning test is of high educational interest and worthwhile to be investigated further.
\end{abstract}

Keywords: working memory; training; intelligence; inhibition

\section*{Theoretical Background}

The concept of WM has received much attention lately by various psychological disciplines for its importance as a basis of human intelligence and as a limiting factor of human cognition. WM can be seen as a cognitive system for simultaneously storing and manipulating information, and hence strongly relates to reasoning abilities and the handling of novel information (Baddeley \& Hitch, 1974). Also the attention to goal-relevant information and inhibition of irrelevant information are important functions of WM.

High correlations between WM capacity and intelligence (Oberauer, Süss, Wilhelm, \& Wittmann, 2008), notably when measured by Matrices Tests (e.g. Advanced Progressive Matrices Test; Raven, 1990) as well as high correlations between WM capacity and applied fields, e.g. mathematical problem solving tasks leave the following open question: What happens to intelligence and
mathematical problem solving skills when WM capacity potentially gets enhanced? One possibility could be a likewise enhancement of WM and intelligence (and mathematical problem solving skills). The similarity of the two concepts would make far transfer plausible. But as stated earlier, results are controversial and more evidence is needed.

Early studies were positive in judging the possibility of a WM training being able to enhance WM capacity and performance in related fields. These early studies were also more explorative in nature. Later studies took criticism (Moody, 2009; Sternberg, 2008) into consideration and the complexity of study designs has been raised (for example by Redick et al. (2012) a non-replication of the study by Jaeggi, Buschkuehl, Jonides, \& Perrig, (2008)). In the current study the following criticisms of the past studies are taken into consideration and examined: a) inclusion of an active control group, b) administering a wide variety of transfer tasks and c) examining long term effects.

The trainability of WM capacity would mean that we are able to broaden an important limiting factor of human cognition and this would be of highly practical as well as of seminal educational relevance. There is a growing body of WM training literature (Chein \& Morrison, 2010; Klingberg, 2010; Shipstead, Redick, \& Engle, 2012). Melby-Lervåg and Hulme (2012) conducted a meta-analytic study and compared effects: Across training studies, effects vary in whether WM training paradigms are effective in improving cognitive abilities.

We included three training groups: a high, a medium and a high WM load group. Their training differed in the amount as well as in the type of WM load included. The first two groups focused on resolution of proactive interference - an ability tapping the WM subcomponent of inhibition, which is regarded as critical subcomponent of WM (Friedman \& Miyake, 2004). The third group was an active control group (low to zero WM load) solving a control reaction time task. The further manipulations
referred to whether the task was adaptive and whether the task was dual. If WM load during training is the crucial factor for transfer effects to occur there should of course be no training gains for control groups and gains should be more pronounced for a high than for a medium WM load group. The advantage of a graded design lies in being able to differentiate whether a transfer gain can be attributed to enhanced WM capacity or not.

The inclusion of a wide variety of transfer tasks is necessary to decide whether changes can be attributed to an enhancement of WM capacity or merely to task specific learning because an enhancement of WM capacity can only be demonstrated if transfer occurs generally and is not limited to single tasks (Shipstead et al., 2012). In the present study transfer to an untrained WM task is referred to as near transfer and transfer to tasks with another cognitive demand than WM is categorized as far transfer. Far transfer is typically measured using intelligence tests as well as other reasoning tests. In addition to intelligence tests, in the present study mathematical tasks are administered to assess possible far transfer to school-related abilities. According to a literature review by Raghubar, Barnes, and Hecht (2010), WM and skills in mathematical problem solving are highly correlated, in particular mental arithmetic, and are therefore suitable as transfer tasks.

In sum, the main goal of the current study is to test a) whether a WM training yields near transfer, an enhancement of performance in untrained WM tasks, and b) to systematically test whether such a potential WM enhancement can provoke far transfer in the domain of intelligence and mathematical problem solving and whether such an enhancement is depending on the amount of WM load during training. Further we investigate to what extent training gains are found in an active control group, to what extent enhancement of performance is dependent on to the level of WM load during training and how stable these effects are.

\section*{Method}

\section*{Participants}

A total of 83 healthy students of science- and humanitiesrelated fields from three Swiss universities completed the study ( \(M_{\text {age }}=23.7, S D=3.3\) ). Eight participants dropped out due to installation problems of the training software on their home computer ( 5 participants) or due to non-adherence to the training paradigms or sessions at the institute (3 participants).

\section*{Procedure}

Participants were randomly designed to one of three groups: A high, a medium or a low WM load group. All groups trained during a three week period five days a week for half an hour on their home computer, resulting in a total training time of 7.5 hours. The first and the last training session were completed at the institute in order to ensure understanding of the tasks and to control for the correct
handling of the training software. Solution rates and times as well as other parameters were logged by the training software for all sessions. Before and after training, two assessment sessions took place at the first author's institute: An individual and a group session where participants had to solve WM tasks and a mental arithmetic task, mathematical problem solving tasks and intelligence tests. The sessions before training served to assess baseline performance and the sessions after training aimed to assess possible transfer from the WM training. In order to make an intervention and a possible enhancement meaningful it should show an impact over a certain time. Long term training effects were assessed by a follow-up testing session after a three months period. Participants again solved trained tasks as well as paralleled versions of untrained tasks.
The three groups did not differ significantly in their initial intelligence level, in demographical factors (age, sex, field of study) and in personality factors (measured by the NEOFFI (Costa \& McCrae 1992)). Their initial performance of training and transfer tasks was also in the same range and didn't differ significantly between groups.

\section*{Material}

\section*{Training}

A high WM load group trained a dual version of the nback task, similar to Jaeggi et al. (2008). Simultaneously, letters were presented orally and squares visually at different positions on the screen. Participants had to indicate whether the letter and the position \(n\) trials back was the same or not. This adaptive and dual version of the n-back task placed high WM load because a large amount of interference trials was incorporated. Also the duality of the task adds to the high WM load level. Through the dual nature of the task participants trained the visual and oral domain simultaneously. Participants worked on the task for 30 minutes per day with the size of \(n\) adapted to the actual level of performance. In this group the average n-back level was assessed.

The medium WM load group trained with three nonadaptive WM tasks: A three-back task with letters and the following two recognition tasks. In the face recognition task participants had to decide whether a single face was part of a previously presented set of four faces or not. In the letter recognition task participants had to decide whether a letter was part of the previously presented set of four letters or not. The tasks were characterized by moderate WM load with a focus on resolution of proactive interference in WM. Solution times and rates were measured and each task was performed for 10 minutes. In all three tasks, a high level of interference was produced by incorporating a large amount of lure trials, i.e., trials in which the objects were shown in another trial than the one actually referred to.
The low WM load group trained similar tasks as the medium WM load group, but with a very low WM load. Participants had to solve a 1-back task and for the recognition tasks participants had to compare one face/letter
with a previously presented single face/letter. Solution time and rates were measured.

The amount of WM load is not the only variation between the three groups but all other differences as for example duality vs. singularity of the task can also be seen as a variation of the level of WM load.

\section*{Tasks to assess near transfer}

The four WM transfer tasks each represented a different subcomponent of WM and showed varying similarities to the trained tasks. In the complex span task participants solved simple equations while keeping single letters in mind. At task switching participants had to either decide whether the value of a three digit number was below or above 500 , or whether the number was even or odd. In a monitoring task participants had to detect changes in a grid of nine three-digit-numbers and react on certain constellations of same final digits. A forth WM transfer task was kept very similar to a trained task of the medium WM load group. In this so called 'pseudowords'-task, participants of the medium WM load group had to accomplish the same task requirements as in their trained letter recognition task and also the trained face recognition task was very similar. The mentioned transfer and training tasks showed the same surface structure but other content material than the trained task: Recognition of pseudowords, nonsense syllables obeying phonetic rules, in the transfer situation instead of the trained recognition of single letters or faces. For the control group the same was true except that they trained task versions with minimal WM load. The high WM load group on contrary had no correspondent training.

\section*{Tasks to assess far transfer}

As fluid intelligence tests the Advanced Progressive Matrices Test (APM, Set II) by Raven (1990) and the 'Intelligenz-Struktur-Test' (I-S-T 2000 R) by Amthauer, Brocke, Liepmann, and Beauducel (2001) were administered.

The three transfer tasks of the mathematical domain consisted of different levels of reasoning requirements and complexity. A mental arithmetic task with subtractions of two digit numbers with carries was conducted without participants taking any notes. A so-called mathematics test (Mathematik-Test, Ibrahimovic \& Bulheller, 2005) was exhibited to test participants’ ability to solve mathematical word problems. In a last mathematical task with high WM load participants had to keep in mind three simple but interlinked equations as well as the value of the three unknowns.

\section*{Learning of novel material}

We further investigated whether WM training can enhance the learning of novel material. In this task participants learned to calculate in the septimal system (base 7 system) while inhibiting their usual counting routines of the decimal system. This learning task was presented immediately after the last training session and in order to assess the learning of new principles and the establishing of new routines while overcoming well-trained ones the task comprised of a 40 min problem solving period with a total
of 150 trials of additions in the septimal system. This design enables us to investigate the possibility of not only having WM training enhance certain untrained WM tasks, but also enhance the chance of grasping and administering new principles and rules. This would be new and very tempting for educational purposes.

\section*{Results}

In the medium and high WM load groups the implementation check was positive in that through training participants enhanced their performance significantly in trained tasks. The medium WM load group showed significant increases in solution time and solution rate in the three trained tasks. The high WM load group showed significant increase in the average n-back-level. Participants of the low WM load group also significantly increased their solution times, but not solution rates (see Appendix, Table 1).

Enhancements specific to groups occurred in two of nine untrained tasks. First, group specific enhancements occurred in the 'pseudowords' task. An ANOVA for reaction time measures with the between subject factor group and the within subject factor time was conducted. A significant interaction between time and group \((F(2.99,118.09)=\) 22.92, \(p<.001, \eta^{2}{ }_{p}=.37\); see also Figure 1 and Appendix Table 2) and pairwise comparisons revealed that the medium and low WM load groups likewise accelerated more than the high WM load group, which showed only slight enhancement. This analysis also showed a significant main effect time as all participants got faster ( \(F(1.50\), \(\left.118.09)=136.18, p<.001, \eta_{p}^{2}=.63\right)\).

Figure 1: Course of solution times in the transfer task 'pseudowords' during and after training. *** indicate time periods with group specific significant main effects, \(p<\) .001. Please note, that there is also a significant interaction between time (pre-, post and follow-up-test) and the three groups.

The second differential transfer gain occurred in the one learning task. In the 'Base7' task groups varied in their
amount of gain manifesting in a significant interaction between groups and beginning versus end of the test \(\left(F(11.19,447.74)=2.15, p<.05, \eta_{p}^{2}=.05\right)\). Post hoc tests showed that the high WM load group showed a higher degree of progress than the low WM load group over the course of the 150 trials (see Figure 2). In this task all groups enhanced their performance significantly over the 150 trials \(\left(F(5.60,447.74)=32.67, p<.001, \eta_{p}^{2}=.29\right)\).

No differential transfer occurred in any of the mathematical problem solving tasks or in the intelligence tests, therefore in none of the untrained WM tasks such interactions were found. However, there was a significant temporary enhancement of solution times and rates for all transfer tasks, but with no difference between the three groups, as no interaction was detected (see table 2 for changes from pre- to post-measure).

Long term gains over a three month period were found in some tasks, but no differences between the three groups were found. The only exception is the aforementioned recognition task 'pseudowords', where differential changes between pre- and post-tests could be held throughout the three months.

Figure 2: Course of solution rates in the learning task 'Base7'. The y -axis represents solution rate ( \(1.0=\) maximum, \(0.5=50 \%\) right). The \(x\)-axis marks the 15 parts of the test, 10 trials are summarized into one part. Please note, that there is a significant interaction between part (1-

15 ) and group (low, medium and high WM load).

\section*{Discussion}

The actual focus of the present study are the questions to what extent training gains are found in an active control group, to what extent enhancement of performance is dependent on to the level of WM load during training, what near and far transfer effects can be observed and how stable these effects are. Only in two out of nine cases were such differential enhancements found. In all other untrained WM tasks no such interactions were found so that no positive transfer specific to medium or high WM load during training occurred in any of the mathematical problem
solving tasks or in any intelligence tests. According to Shipstead et al. (2012) it is crucial to compare a wide variety of tasks to decide where the reason of changes may lie. Generally occurring transfer effects could be attributed to an enhancement of WM capacity whereas rare transfer should be explained by only task specific learning. For the present study it can therefore be concluded that no enhancement of WM capacity as such is found.
The two cases of group specific enhancement are discussed separately. First, differential enhancement occurred in one untrained task with a similar surface structure but different content material than in the trained tasks of the medium WM load group (recognition of 'pseudowords' instead of recognition of letters). Also the low WM load group trained a recognition task with the same surface structure but minimal WM load. Both the medium and low WM load group developed similarly, this suggests that high WM load was not essential for the development, but rather the similarity of the trained and untrained task. This explains why the development of the low WM load group was likewise the one of the medium WM load group and why the high WM load group training with a very different paradigm but being exposed to high WM load during training - developed in a different way. In conclusion, training gains can transfer to very similar tasks only. The similarity of the tasks or in other words the common elements of trained and untrained tasks are crucial for transfer.
Second, in the 'Base7' learning task all groups enhanced their performance significantly over the 150 trials, but the high WM load group showed a higher progress than the low WM load group. The trained dual n-back task of the high WM load group and the 'Base7' task at their surface show no similarity but both tasks particularly focused on inhibitory processes. It can therefore be concluded, that inhibitory processes could possibly be enhanced through a specific training focusing on inhibition. In order to exclusively answer this assumption more evidence would be needed to exclude the possibility of just task specific characteristics being responsible for this result. Moreover, this gain was measured in a novel task type: A learning task - to our knowledge not administered in any other WM training study and the only learning task included in the present WM training study. The possible enhancement in a learning test is of high educational interest and also has to be verified by further testing.
There was significant general enhancement of solution times and solution rates for all transfer tasks, but no difference between the three groups for seven of nine tasks. As also the low WM load group with virtually zero WM load during training got significantly better from pre- to post-test, enhancement cannot be explained by expanded WM capacity. It can therefore be stated that participants perform significantly better after WM training but not due the characteristics of the training and not due to an enhancement of WM capacity.

Numerous authors (Chein \& Morrison, 2010; Moody, 2009; Shipstead, Redick, \& Engle, 2010; Shipstead et al., 2012; Sternberg, 2008) judge the selection of an appropriate control group as essential in interpreting data. In the present study the low WM load group served as an active control group and also increased their performance. Through an active control group effects due to a different degree of study involvement can be ruled out.

Long term gains over a three month period were found in some tasks, but no differences between the three groups were found. The only exception is the aforementioned recognition task where the differential changes between pre and post testing could be held throughout the three months.

In summary, the theoretical and educational significance of the present results are threefold. First, our results suggest that WM training is of limited use to enhance human cognition in general. The present findings show that task specific characteristics could be learned but that there was no transfer between trained and untrained tasks which had no common elements. Second, as positive transfer occurred between two tasks focusing on inhibitory processes, it might be possible to enhance this specific component of WM. Third, the possible enhancement in a learning test is of high educational interest and is worthwhile to be further investigated.

\title{
The synergy of top-down and bottom-up attention in complex task: going beyond saliency models.
}

\author{

}

\begin{abstract}
This paper studies how visual perception of a scene is affected by cognitive processes beyond the scene's bottom-up saliency. The game of SET is taken as an example where contrast-based salient parts of a scene are ignored in favor of a larger group of similar elements. Using results from a laboratory experiment and a model simulation we explain how three cognitive mechanisms, differential acuity, visual iconic memory and declarative retrieval, considered together help to explain player's visual perception in SET.
\end{abstract}

\section*{Introduction}

Many studies describe how perception of a visual scene is governed by visual bottom-up mechanisms (Rayner, 1998). The conclusions derived in those studies are often based on results from relatively simple tasks involving free scanning or target search. It is widely accepted that visual attention is drawn toward a scene's salient parts (Egeth \& Yantis, 1997). This bottom-up saliency is commonly used to explain popout effect of items that are increasingly different from its surroundings (Theeuwes, 1992). However, these findings alone may lead to incorrect conclusions if used within a context of more complex problem-solving tasks. It is important to consider a relationship between salience and other cognitive mechanisms to properly understand the inner workings of human mind in such tasks. We use the game of \(\mathrm{SET}^{1}\) as an example of a problem-solving task that gives results that can be interpreted initially as contradictory to the visual pop-out effect. Next, we describe how the same results can be explained within a framework that combines bottom-up saliency with top-down goal-directed attention.

The deck in SET consists of 81 cards. Each card is uniquely defined by a combination of four attributes: color, shape, shading and number of shapes. Each attribute can have one of three distinct values: red, green, and blue for the color; open, solid and textured for the shading; one, two and three for the number; oval, rectangle and squiggle for the shape. At any moment in the game, 12 cards are dealt face up (Figure 1). From 12 cards, players should find any combination of three cards, referred to as a set, satisfying a rule stating that in the three cards the values for each particular attribute should be all the same or all different.

Jacob and Hochstein (2008) studied how bottom-up components of the game, such as attribute value distribution among cards, influences player's strategy. They concluded

\footnotetext{
\({ }^{1}\) SET is a game by Set Enterprises (www.setgame.com)
}
that players prefer to search for a set inside the largest group of cards that share at least one common value. They referred to a common value as the Most Abundant Value (MAV) and the group of cards that contained it as a MAV group. Sets that were inside MAV group were found sooner than sets outside of the group with an observed probability being significantly higher than a chance probability.

According to the bottom-up saliency mechanism it is expected that players should start a search with visually unique, hence most salient, cards. However, Jacob and Hochstein's finding suggests that player's visual attention is drawn toward larger group of cards that are visually similar. From a perspective of a bottom-up saliency, this is a highly counterintuitive result. Furthermore, another study by Nyamsuren and Taatgen (2013b) revealed that a similarity along particular attribute dimension plays more important role in players' strategy than the saliency of any individual card. Players are more likely to search for a set among larger group of cards with the same color than to attend a card, for example, with a unique shape.

Figure 1: An example array of 12 cards. The cards with solid and dashed borders represent two valid sets.

In this paper, we describe a more controlled experiment with set cards with an aim of more in-depth exploration of underlying cognitive processes. In order to use the MAV strategy, subjects must be able to recognize very quickly, which attribute values are most common. The goal of the study is to focus on this particular aspect of SET: to answer the question what cognitive processes facilitate such quick recognition in players. Based on experimental results and model simulations, we describe how three cognitive mechanisms that include visual acuity, visual memory and declarative memory retrieval help to explain MAV effect and bias toward similarity in color attribute.

\section*{Experiment}

\section*{Design and Procedure}

14 subjects participated in the experiment. All subjects were students of University of Groningen. Subjects' age ranged from 18 to 27 ( \(M=22\) ). Subjects started each trial by looking at the center of a computer screen. Next, they were shown a \(3 \times 4\) array of SET cards for a predetermined duration of time. After image of cards disappeared, subject was prompted to select one of 12 possible attribute values subject perceived as being the most abundant. The experiment consisted of 336 unique trials generated semirandomly. Trials were divided into a short and a long condition block. The array of cards was shown to subjects for 600 and 2000 ms in the short and long conditions respectively. For half of the subjects, blocks were presented in a reverse order. Within a block, trials were presented in a random sequence. In each block, the MAV group size varied from 6 to 12. There were six trials in each combination of MAV group size and attribute type. Prior to experiment, subjects were asked to do eight, four from each block, trials to let them get familiar with an experiment setup. Results from those trials were not included in the analysis. In addition, subjects' eye movements were recorded. We used the EyeLink 1000, a desktop-mounted remote eye tracker with monocular sampling rate of 500 Hz and spatial resolution of \(<0.01^{\circ}\) RMS. Exactly the same experiment setup and stimulus sizes as in Nyamsuren and Taatgen (2013b) were used in this study.

\section*{Experiment Results}

Scanpaths The difference in trial durations also results in quite clear difference in scanpaths. Subjects on average make 8.8 ( \(S E=0.38\) ) fixations in the long condition compared to 2.9 ( \(S E=0.17\) ) fixations in the short condition. Figure 2 provides a more detailed look on the trials' fixation counts. There is an \(87 \%\) probability that subject will make from seven to 11 fixations in the long condition. In contrast, subjects are likely to make only 2 to 4 fixations in \(94 \%\) of all trials in the short condition.

Figure 3a shows mean durations of fixations in a trial. All durations are measured in milliseconds. The last fixations are excluded from the calculation of these means since it is likely that those fixations were interrupted when the time limit was reached. The first two fixations do not show much difference between the short and long conditions. The durations for consecutive fixations in the long condition does not change much. In contrast, durations of third and fourth fixations in the short condition gradually become lower. There can two explanations to this. It may be an artifact of averaging. Smaller number of trials with three or four fixations may be resulting in lower mean. On the other hand, it is possible that shorter durations are deliberate. To test this hypothesis we have also calculated the average duration of fixations in the short condition trials with exactly four fixations. As we have expected, fixations in these trials have much shorter durations than respective
fixations in the long condition trials. Therefore, it is indeed possible that subjects were deliberately making shorter fixations in the short condition.

Figure 2: Frequencies of fixation counts subjects made during a trial. Frequencies are calculated separately for the (a) long and (b) short conditions.

Figure 3: (a) Changes in mean fixation durations over course of a trial in the short and long conditions. (b)
Changes in saccade amplitude over the course of a trial in the short and long condition.

Figure 3b shows how saccade amplitude changes over the course of a trial in both long and short conditions. Amplitude is measured in number of pixels that the saccade covers. There is not much difference between the two duration conditions. However, there is an obvious gradual rise in saccade amplitude as trial progresses. It suggests that there is a specific pattern in subjects' scanpaths.

Accuracy As Figure 4 shows, the overall accuracy increases as MAV group size increases. This is true for both short and long conditions. A test of proportions on pooled data indicate that subjects were more accurate in the long condition than in the short condition, \(\chi^{2}(1, N=4704)=\) \(35.63, p<0.001\). However, as Figure 4 shows, there are remarkably small differences in accuracies with respect to group sizes in two duration conditions.

Figure 5 shows a boxplot of accuracy variations based on attribute type and duration. We did logistic mixed-effect regression analysis using the duration condition, attribute type and the interaction between the two as predictors. The intercept in the regression model reflects expected accuracy in a short condition trial where the MAV belongs to shading. Relative accuracy increased when MAV belonged to color ( \(z=3.19, p=0.001\) ) and decreased when MAV
belonged to either number ( \(z=-4.142, p<0.001\) ) or shape ( \(z=-2.577, p=0.01\) ). Overall performance in the long condition increased significantly ( \(z=2.093, p<0.036\) ). However, there were no significant interactions between duration conditions and attribute types.

Chi-square tests confirmed that subjects were significantly better at identifying the MAV with a color attribute than any other attribute type. Subjects showed little difference in accuracies in the short and long conditions with respect to color \(\left(\chi^{2}(1, N=1176)=2.91, p=0.088\right)\). It is surprising that, despite the significant difference in average number of fixations made, subjects are equally good at identifying color value in both duration conditions. In contrast, accuracies in the long condition were significantly higher for number \(\left(\chi^{2}(1, N=1176)=15.283, p<0.001\right)\), shape \(\left(\chi^{2}(1, N=1176)=16.94, p<0.001\right)\) and shading \(\left(\chi^{2}(1, N=1176)=4.12, p=0.04\right)\) than in the short condition.

Figure 4: Mean accuracies averaged over all combinations of MAV group sizes and duration conditions.

Figure 5: Mean accuracies averaged over all combinations of attribute types and duration conditions.

\section*{Experiment Discussion}

Effect of MAV Group Size on Accuracy This effect can be explained by the priming of declarative memory by the visual system. There are several studies indicating that the human visual system has some form of iconic memory (Kieras, 2009). It is a low-resolution high-capacity memory where visual information is stored pre-attentively for a short duration of time. The process of gathering information is massively parallel and almost instantaneous. However, information about a visual object is stored as a collection of separate feature channels (such as color or shape) rather than single coherent object (Treisman \& Gelade, 1980).

Therefore, iconic memory has just enough resolution to guide further attention shifts and encoding.

There is evidence that visual perception can influence processes of memory retrieval (Wais, Rubens, Boccanfuso, \& Gazzaley, 2010). It is reasonable to assume that visual stimuli can facilitate memory retrieval of items that are in some form related to the stimuli. Furthermore, we assume the same process applies to iconic and declarative memories. Items in iconic memory facilitate retrieval of similar or related items in declarative memory. In other words, items in declarative memory get activated by items in iconic memory. The strength of such activation depends on the number of items in iconic memory that are related to the item in declarative memory.

This interaction between iconic and declarative memories can explain why subjects find it easier to identify the MAV among larger group of cards. Subjects need to do two tasks: (1) gather visual information through attention shifts and (2) retrieve the MAV from memory when prompted. The second retrieval step is influenced by the content of iconic memory that was gathered during the first step. When MAV group size is large, more values enter iconic memory, and corresponding MAV value in declarative memory receives a higher activation during the retrieval.

Effect of Attribute Type and Duration on Accuracy The exchange of activations from iconic to declarative memories also helps to explain why subjects are better at identifying color values than values from any other attribute type.
However, there are studies showing that an ability to capture finer details of a visual scene becomes worse as the distance from a foveal region increases (Nelson \& Loftus, 1998). This introduces limitations on what visual features can be gathered into iconic memory. As an object is further away from the foveal region it becomes more likely that some of its features will not enter iconic memory due to limitations of peripheral vision. A feature's acuity threshold defines the maximum distance from a foveal point at which the feature is still recognizable (Kieras, 2009). Compared to other features, color has a higher threshold making it easier to recognize in the peripherals. Thus, color values have a higher chance of entering iconic memory thereby spreading more activation to the same values in declarative memory.

When features, such as shape and shading, have a limited acuity, subjects need to fixate closer to respective visual objects to bring them within threshold distance. This explains why subjects perform better in the long condition trials. Subjects can make more fixations and gather a more complete gist of the visual scene in iconic memory, which then facilitates a more accurate declarative retrieval.

Scanpaths There are two interesting effects in subjects' scanpaths. Firstly, subjects seem to react to time pressure in the short condition by having shorter fixation durations. This behavior also supports our assumption that iconic memory and peripheral vision play an important role. It is possible that subjects compensate for a shorter duration by
making as many fixations as possible and accumulating in iconic memory as much visual information as possible. The pattern of increasing saccade amplitudes provides a clue about preferences of possible fixation locations. Subjects start by fixating on the cards closest to the center of the screen and gradually switch to the cards on the peripherals. These fixations from inwards toward outwards should result in increasing saccade amplitudes shown in Figure 3b. In addition to providing more clues about subjects' behavior, scanpaths provide additional measurements besides accuracy against which model fit can be evaluated.

\section*{Cognitive Model}

\section*{Cognitive Architecture}

We have used ACT-R cognitive architecture (Anderson, 2007) to develop the model. An additional module called Pre-attentive and Attentive Vision (Nyamsuren \& Taatgen, 2013a) was used instead of ACT-R's default vision module. The PAAV module provides several extra functionalities that are otherwise not supported by ACT-R.

PAAV can pre-attentively capture the gist of a visual scene and store it in iconic memory. The content of iconic memory is updated before and after each saccade and before each time the memory is accessed. The update process is instantaneous from a perspective of model's timeframe. Iconic memory may contain complete information for some visual objects, such as an object's color, shape, shading and size. However, for most visual objects the iconic memory will contain incomplete information (e.g. color only) due to limited acuity. PAAV recognizes that not everything in a visual scene can be resolved by model's peripheral vision at any given moment. In PAAV two parameters, \(a\) and \(b\), define differential acuities of color, shape, size and shading with color having the highest acuity. Fitness of these parameters was tested on models of three different visual search tasks and the updated model of game of SET (Nyamsuren \& Taatgen, 2013a). An object's feature in iconic memory, although persisting through saccades, decays after a short period of time (currently 4 sec ) if not recognizable in peripheral vision anymore.

The content of iconic memory is used to guide the model's visual attention. Visual objects with the highest saliency values are prioritized for visual attention and further encoding. In PAAV, the bottom-up saliency is a sum of saliency values calculated for each feature dimension as a function of contrast to its surrounding. For example, a single red card among green, otherwise similar, cards will be the most salient one and draw the model's attention. PAAV uses a binary measure of similarity: 1 for exact match and 0 otherwise. No adjustable parameters are used in calculation of bottom-up saliency (Nyamsuren \& Taatgen, 2013a). It is a simplified version of Wolfe's (2007) saliency function.

In ACT-R knowledge chunks are stored in declarative memory. Each chunk has an activation value that usually reflects chunk's recency and frequency of use by a model. A chunk with the highest activation has the highest probability
of retrieval. Besides frequency and recency, a chunk's activation can be increased by the content of iconic memory. Each visual object in iconic memory spreads activation to every declarative chunk with the same features. So depending on the content of iconic memory at the time the results of two same retrievals can differ. The model uses exactly the same set of parameters for declarative retrieval as in the original model of game of SET. Details of those parameters are described in Nyamsuren \& Taatgen (2013b).

\section*{Model of MAV Task}

Model Strategy Model performed 50 times the same two blocks of trials subjects did. Model starts each trial while fixating at the center of the screen. When cards are shown, models need some time to create a working memory before the first saccade is made. At the same time, model updates its iconic memory with representations of cards. Then model follows with free scanning using bottom-up saliency values to calculate consecutive fixation points. Each fixation is followed by encoding of an attended card. Free scanning stops when time limit is reached and representations of cards disappear. At this point model retrieves any one of 12 possible attribute values from declarative memory. Result of this retrieval depends on content of iconic memory the model has built up during the free scanning. The retrieved value is recorded as model's response for the trial.

Model Accuracy Model is quite good at replicating subjects' accuracy. Figure 6 shows that model's accuracy increases linearly as the MAV group size increases. This effect is present in both the short and long condition. However, just like subjects, the model shows a better performance in the long condition.

Figure 6: Mean accuracies averaged over all combinations of MAV group sizes and duration conditions.

The model is also good at reflecting subjects' accuracy depending on combination of attribute types and duration conditions. Firstly, as Figure 7, there is a general increase in model's accuracy in the long condition. Except in color, the model clearly benefits from additional time in all other three attributes. Next, Figure 7 shows that model is much better at identifying MAV belonging to color attribute than to any other attribute type. Similar to human performance, model's accuracy for color in the short condition is higher than the accuracies for other three attribute types in the longer trials.

Figure 7: Mean accuracies averaged over all combinations of attribute types and duration conditions.

Model Scanpaths Comparison of model's scanpaths to that of subjects should give additional measure of how well the model fits human data at the level of raw eye movements. Figure 8 shows distributions of fixation counts the model made in the long and short conditions. In \(99 \%\) of all long condition trials, the model made 9-10 fixations. It is within a range of 7-11 fixations subjects made. In the short condition, the model made either two or three fixations. It is also within a range of 2-4 fixations subjects made. As Figure 9a shows, model's fixation durations do not differ in the long and short conditions. The lower duration for the third fixation in the short condition is a result of interruption due to duration limit.

Figure 8: Frequencies of fixation counts model made during a trial. Frequencies are calculated separately for (a) long and (b) short conditions.

The model was able to reproduce a pattern of increasing saccade amplitudes in long condition trials, as it is shown in Figure 9b. It was not completely expected since we have not incorporated into the model any deliberate mechanisms to promote this behavior. Because the model makes only one or two saccades in a short condition trial, it is hard to make any conclusive statements about the pattern of amplitude changes. The same model is used in both duration conditions. Hence, there is no reason to expect the model to show different scanpath pattern in the short condition. The lower amplitude for the second saccade in the short condition is most likely due to smaller number of observations from which the mean is calculated. For exactly the same reason, amplitudes for the 9th and 10th saccades drop in the long condition since there are fewer trials that have more than 10 fixations.

Figure 9: (a) Changes in model's mean fixation durations over course of the trial in the short and long conditions. (b) Changes in model's saccade amplitude over the course of the trial in the short and long condition.

\section*{Discussion on Model Results}

The point at which model has to decide on a choice of MAV is the retrieval from a declarative memory. As model shows, the spreading activation from iconic memory is a major factor deciding the result of this retrieval. However, it is possible to counter-argue that spreading activation from iconic memory is not necessary, and items in declarative memory are activated directly through visual encoding of similar items. Such mechanism is possible and used in our model. Cards with the MAV have a higher chance probability of getting visual attention and being encoded. As a result, the MAV in declarative memory receives more activation and is retrieved. Although this argument would explain subjects' behavior in the long condition, it does not explain why there is a similar effect of MAV group size in the short condition. Neither subjects nor model can encode more than two cards in the short condition, and it is not enough to influence the retrieval. Instead, it is likely that subjects rely on visual information in peripheral regions for choosing MAV. Furthermore, the fact that subjects are quite good at identifying the MAV even within 600 ms implies that process of gathering information from peripherals is very efficient. The model simulation suggests that it may be massively parallel and instantaneous.

In the other side, acuity limitations of visual features in peripheral vision can result in incomplete and inaccurate iconic memory. This imperfect internal representation may explain why subjects fail to reach \(100 \%\) accuracy. It also explains why subjects get better given opportunity to do more fixations in the long condition. More fixations negate the effect of low acuity and result in a more complete representation of the scene inside iconic memory. Furthermore, giving a higher acuity to color in model simulation increases model's accuracy in identifying the most abundant color values in both conditions. This result is similar to the result from the experiment, and, therefore, supports the assumption that human vision is affected significantly by different acuity properties of visual features.

The model produces the same pattern of increasing saccade durations in the long condition without any deliberate mechanisms. It suggests that spatial arrangement
and the bottom-up salient parts of the visual scene define the topology of fixation points, more specifically the characteristic fixations from inwards to outwards. In the model, cards around the edges of the screen are not fully visible due to limited acuity. Those cards have reduced bottom-up activation compared to cards around the center of the screen. As a result, the model prefers to fixate on cards closer to the screen center at the early stages of the trial. We were not able to simulate the deliberate reduction in fixation durations subjects have shown in the short condition. Visual processes currently implemented in ACT-R do not provide appropriate mechanisms to simulate this effect.

\section*{Discussion and Conclusion}

The model fits subjects' accuracies and scanpaths well supporting the hypothesis that the same cognitive processes simulated in the model may also be used by human subjects. More specifically, a combined effect of differential acuity, pre-attentive visual iconic memory and implicit communication with declarative memory can influence our visual perception of the world.

The results from this study can explain player's behavior in game of SET. Player has to decide on a group of cards to be searched for a set. This choice is made through a declarative retrieval of an attribute value that is common among group cards. Similar to the experiment's task, this retrieval is influenced by a content of iconic memory introducing a bias toward a larger group of cards and cards with same color. The retrieved value is used to target attention to specific cards with that value. This top-down control over eye movements overrides the bottom-up saliency of the scene. It explains both why players are better at finding set within a group with many similar cards (Jacob \& Hochstein, 2008) and the general preference toward cards with a similar color (Nyamsuren \& Taatgen, 2013b). The model of SET player implemented on the same principles described here was able to simulate player's behavior (Nyamsuren \& Taatgen, 2013a, 2013b). It is a good example of a case where cognitive mechanisms beyond bottom-up saliency can influence the behavior in a reasonably complex problem-solving task. It implies that not every eye movement pattern can be attributed to bottomup salient components of the scene.

Subjects are far better in identifying the MAV even in the most difficult conditions. In 600 ms condition with smallest MAV group size, subjects show much higher accuracy than \(8 \%\) chance probability of success. This result indicates that capabilities of human visual system may be higher than previously expected. The ability to capture a gist of a visual scene from first few fixations is known for a long time (Loftus \& Mackworth, 1978). However, it is commonly viewed that functionality of such gist is limited to attentional guidance and providing early structural information for encoding, a preview effect (Rayner, 1998). On the other hand, our study suggests that gist, in form of iconic memory, may be involved in decision-making. It is possible through connections between memories in human
brain. In this study, we talked about similarity-based crossmemory activations between iconic and declarative memories. However, it may be possible that similar cross activations exist between other forms of memory.

The model code and the data can be downloaded via following link: http://www.ai.rug.nl/~n_egii/models/.

\begin{abstract}
Most studies examine holistic processing with respect to facial identity, but at least one study has also looked at holistic processing of facial expressions (Calder, Young, Keane, \& Dean, 2000). However, this work used the partial composite paradigm, which is known to exhibit bias effects (Richler, Cheung, \& Gauthier, 2011). The complete composite paradigm (Gauthier \& Bukach, 2007) provides a bias-proof way to quantitatively measure holistic processing. In this paper, we perform the corresponding experiment in our face processing model (EMPATH, (Dailey, Cottrell, Padgett, \& Adolphs, 2002)) to predict whether holistic processing of facial expressions will be found if the corresponding human experiments are performed, and our prediction is that it will. We also compared our model's performance to the participants in recent experiments in facial expression recognition in humans (Tanaka, Kaiser, Butler, \& Le Grand, 2012). Tanaka et al. (2012) concluded that expression recognition is not always holistic, but our results suggest that it is.
\end{abstract}

Keywords: holistic processing

\section*{Introduction}

Is all facial processing holistic? For example, when we are judging whether a person is trustworthy, tired, middle-aged, or happy, is our decision based on a global percept of the face rather than constituent parts? One might suspect that the answer is no, at least in some cases. Holistic processing might depend upon the task. The evidence from face inversion, composite, and parts-wholes experiments weighs in favor of holistic over parts-based processing for face identity (Yin, 1969; Tanaka \& Farah, 1993; Cheung, Richler, Palmeri, \& Gauthier, 2008; Richler, Tanaka, Brown, \& Gauthier, 2008). Less research has focused on understanding the nature of facial expression recognition. One reason to suspect that expression recognition is different is the categorization of expressions into just seven categories - happy, sad, surprised, angry, disgusted, fearful, and neutral - in line with the "six basic expressions" theory (Ekman \& Friesen, 1976), at least as practiced in most psychology experiments. Previous work in our lab has shown that the basic level processing of objects (e.g., into an overall category, such as chairs or lamps), does not behave in the same manner as subordinate level processing in our models, and does not engage our model's equivalent of the Fusiform Face Area. One consideration is that the holistic processing of faces may be induced if there is any variation in identity, regardless of the task being performed. In our modeling work, we tested the hypothesis that without any variation in identity, the processing of facial expressions is holistic.

Holistic processing of facial stimuli is generally measured with composite face paradigms, where chimeric faces are constructed from the top and bottom halves of different "source" faces. Subjects are asked to identify face halves of chimeric faces or to judge whether two halves of a pair of chimeric faces are the same or different. Misalignment of the top and bottom halves generally leads to an increase in the subjects' accuracy and/or a decrease in reaction time relative to the aligned condition, demonstrating that faces are processed holistically. We test our model with simulations based on the complete composite paradigm (Gauthier \& Bukach, 2007), an improvement upon what Gauthier \& Bukach call the partial design, which is what is classically used (Young, Hellawell, \& Hay, 1987). The complete composite paradigm eliminates the effects of response bias (for example, a preference towards answering "same" for misaligned stimuli). our results predict that a facial expression recognition experiment with humans based on the complete composite paradigm will indicate holistic processing.

We then use our model to account for experimental results in Tanaka et al. (2012). Tanaka et al. used their own nonstandard composite paradigm in one of their experiments that we simulated and a variation on the partial design in another that we also simulated. They inferred from their experimental results that facial expression processing is holistic when there is a clash between parts of a facial expression (e.g. angry-happy composite) but analytic or parts-based when there is little or no conflict between the parts (e.g. normal happy face). They posit an earlier stage where a stimulus is rapidly assessed for parts that clash to determine the processing pathway to be used. However, we achieved similar results with our model which (1) has one processing pathway for all stimuli, (2) does not have an earlier stage for quick appraisals, and (3) is not trained to combine decisions on parts of a stimulus into an overall decision. Our results suggest that one holistic processing pathway is sufficient to account for their data.

\section*{Complete Composite Paradigm (CCP)}

In composite paradigms, participants in experiments are presented with two composite faces, and asked to make samedifferent judgments about the cued face halves (top or bottom) while ignoring the other face halves. The complete composite paradigm (CCP) (Gauthier \& Bukach, 2007) provides a bias-proof way to quantitatively measure the interaction between a subject's decision and the presence or ab-

Figure 1: Schematic showing the complete composite paradigm. The subject must decide whether the top face halves are the same or different. In the congruent condition, the top and bottom face halves would generate the same answer, while in the incongruent condition, they would not. Holistic processing is measured as a congruency effect.
sence of a change in the unattended face halves (see Fig. 1). If the answer is the same for the top and bottom halves, it is a congruent trial, otherwise, it is incongruent. A congruency effect, difference in sensitivity, \(d^{\prime}\), between congruent and incongruent trials, is indicative of holistic processing: the unattended face half is obligatorily processed. The partial design only has trials where the unattended halves are different, and holistic processing is measured as a difference in performance between aligned and misaligned trials. This is a flawed measure; using it, researchers concluded holistic processing was unrelated to performance on the Cambridge Face Memory Test (CFMT). The relationship is found to be strong using the complete design (Richler et al., 2011).

\section*{Methods}

\section*{The Model}

Each input image goes through a two-step preprocessing stage: Gabor filtering and Principal Component Analysis (PCA). The biologically motivated 2-D Gabor filter is constructed by using a two-dimensional sinusoid localized by a Gaussian envelope (Daugman, 1985). By tuning to particular spatial frequency and orientations, the Gabor filter magnitudes can be used to simulate the responses of complex cells in primary visual cortex (V1). Following Gabor filtering, PCA reduces the dimensionality of the information, simulating the information extraction mechanism beyond V1. After these preprocessing steps, each image is represented by a vector with relatively low dimension to be input to the perceptron.

We computed each Gabor filter using the following equation:
\[
\begin{aligned}
& G(x, y, S, F, W)= \\
& \quad k \cdot e^{-\pi S^{2}\left(x^{2}+y^{2}\right)} \cdot\left(e^{j(2 \pi F(x \cos W+y \sin W))}-e^{-\pi\left(\frac{F}{S}\right)^{2}}\right)
\end{aligned}
\]
where \(S\) is a scaling parameter, \((F, W)\) is the polar frequency of the complex sinusoid, \((x, y)\) are the spatial coordinates and \(k\) is a constant (Dias, 2007; Movellan, 2002). There were five spatial frequencies \(\left(F=1 / 2^{i}\right.\) for \(\left.i=2, \ldots, 6\right)\) and eight spatial
orientations \((W=j \pi / 8\) for \(j=0, \ldots, 7)\) for a total of 40 different Gabor filters. \(S\) was related to \(F\) as follows: \(S=3 F / \sqrt{2 \pi}\). \(S\) was chosen such that each filter had the characteristic form of biological two-dimensional receptive field profiles (Hubel, 1988; Daugman, 1988). The filters were centered and applied at the 1080 points in a 36 by 30 grid on each image.

We then use PCA to map the Gabor filter features from a 43200-dimensional space to a space with many fewer dimensions. In forming the PCA projection matrix, we retained enough eigenvectors to account for \(90 \%\) of the variance. For classification, a single-layer perceptron was trained with gradient descent using a cross-entropy error function.

\section*{Network Training and Testing}

70 gray-scale images were selected from the Pictures of Facial Affect (POFA) (Ekman \& Friesen, 1976). These were cropped to \(240 \times 292\) pixels and adjusted to ensure that there was uniformity in the upright frontal face views; to allow for shifting, the input images were 1.5 times as wide as the face images (i.e. images of size \(360 \times 292\) ) with the faces flush against the left or right edge, as shown in Fig. 3a. Misaligned face halves are shown in Fig. 3b.

The POFA dataset includes seven facial expressions (Happy, Sad, Surprised, Angry, Disgusted, Fearful, and Neutral) for each of 14 actors. We selected 10 of these for our experiments (em, gs, jj, mf, mo, nr, pe, pf, sw, wf). We trained on 9 and tested on 1 , repeating this 10 times with each actor getting a chance to be tested. For the remaining 9 actors, we trained on 8 and used the 9th as a hold-out to stop training. This was repeated 9 times with each of the 9 actors having a turn as the hold-out; so we ended up with 9 networks predicting the expression on each stimulus. The consensus of the 9 instances was taken as the model's decision for an experimental run. We averaged the results of the 10 runs.

Experimental tasks in our simulations involving the identification of top and bottom face halves necessitated training the model to classify vectors of Gabor features corresponding to images with only half of a face. We modeled attention to half a face by using a transformation of the Gabor features that reduced the contribution of the top or bottom of a face to the total training set covariance. The transformation that we used for this and a proof that the contribution of transformed Gabor features to the total covariance is reduced is beyond the scope of this paper. In modeling the process of identifying top and bottom face halves in testing and in the experiments, we simulated giving more attention to half of a face using this transformation.

The PCA projection matrix was generated from the Gabor feature vectors designated for training the model. Both before and after the projection of the training stimuli by the matrix, the projections were z -scored in order to put each input to the perceptron on the same scale (LeCun, Bottou, Orr, \& Mueller, 1998). The stimuli for cross-validation were rescaled as one set of vectors, and the stimuli for testing and the experiments were rescaled as another set; with the new sample variances for these sets equal to the ratio of the set sizes to the size of

Figure 2: The real components of Gabor filters are shown relative to the size of an image at five scales and orientations.

Figure 3: (a) left- and right-shifted images and (b) top-left-bottom-right (TLBR) and TRBL images
the training set. This was done to ensure that the rescaling was as uniform as possible across all the feature vectors.

All composites were constructed from the same individual (ten times, once for each test individual, as described above), which ensured that expression and identity recognition were not confounded. The networks were trained as described above, to classify each (whole, unaltered) face into one of seven expression categories. In order to obtain a same/different judgment from a network that only processed one face at a time, we presented the network with the two stimuli (with attention on the queried half, as described above), one at a time. Since there were actually nine networks for each test face (as described above), we compared the consensus of the networks on one stimulus with the consensus on the other. If they match, the overall response is "same"; otherwise the response is "different".

To obtain reaction times, we appeal to the well-established inverse relationship between reaction time and confidence ratings (Audley, 1960; Baranski \& Petrusic, 1998) in mind, we computed a measure of confidence for our model which was the ratio of the number of network instances in agreement with the consensus to the total number of instances for each decision made (when the consensus was the correct decision). To model reaction time, we subtracted these values from one.

For the experiments by Tanaka et al. (2012) (described shortly), since there are no comparisons between two images (all the subjects had to do was decide if the cued half of the stimulus was happy or angry), we simply use a consensus of the nine networks.

\section*{Simulations}

Simulation 1: The CCP on expression recognition The first simulation used the CCP (Fig. 1) to test whether our model predicts that facial expression recognition is holistic. Samedifferent judgments were obtained (as described above), and
holistic processing was then measured as the difference in sensitivity, \(d^{\prime}\), between congruent and incongruent trials.

Simulation 2: Experiment 1 of Tanaka et al. (2012) In experiments performed by (Tanaka et al., 2012), subjects were asked to decide if the cued half of the stimulus was happy or angry. Tanaka et al. (2012) measured the subjects' percentage accuracies and reaction times (in milliseconds). They based their experimental design on the observation that happy expressions are bottom biased (meaning it is easier to recognize a happy expression from the bottom of a happy face than it is from the top half) and angry expressions are top biased (Calder et al., 2000); they only counted trials in which the correct responses for the cued lower halves were happy, and those for the cued upper halves were angry. In their first experiment, Tanaka et al. (2012) compared subjects' performance for a happy lower half face in four pairings: (1) with a happy top half face (normal), (2) with an angry top half face (angry-happy), (3) without a top half face (isolated), and (4) with a neutral top half face (neutral). \({ }^{1}\) There were four corresponding pairings for an angry top half face (see Fig. 4). Their reasoning was that if happy expressions in the lower face half and/or angry expressions in the top face half of normal, neutral, and isolated stimuli were recognized equally easily, then this was evidence for parts-based processing (since this would suggest that the other face half is being "ignored"); and if recognition of angry-happy stimuli was worse than that of neutral and isolated stimuli, then this was evidence for holistic processing. To assess whether our model could account for their observations (some of which were interpreted as indicating parts-based processing), we simulated their experiment with POFA (Ekman \& Friesen, 1976) (Figure \(7 \mathrm{~b}-\mathrm{c}\) ).

Simulation 3: Experiment 3 of Tanaka et al. (2012) Tanaka et al. (2012) looked at the performance of subjects in identifying happy and angry expressions in the lower and upper face halves respectively with two different stimuli types: (1) normal (happy + happy, angry + angry), and (2) angryhappy (happy lower half + angry top half), under two different conditions of alignment: aligned and misaligned (see Fig. 5). We note that their third experiment was based on the partial design which we explained previously has drawbacks. Their reasoning was that equal performance in the aligned

\footnotetext{
\({ }^{1}\) We have chosen to label as normal and angry-happy the stimuli types that they called congruent and incongruent to avoid confusion in this paper.
}

Figure 4: Stimuli types from Exp. 1(Tanaka et al., 2012).

Figure 5: Stimuli types from Exp. 3 (Tanaka et al., 2012).
and misaligned conditions for the normal stimuli would indicate parts-based processing and better performance in the misaligned condition relative to the aligned condition for the angry-happy stimuli would indicate holistic processing. Once again, to assess whether our model could account for their observations (some of which they attributed to parts-based processing), we simulated their experiment with POFA (Ekman \& Friesen, 1976).

\section*{Results and Discussion}

In Simulation 1, the sensitivity, \(d^{\prime}\), for the incongruent trials was less than the sensitivity for the congruent trials (Fig. 6). This observation of the congruency effect confirmed that the model processes facial expressions holistically. It is now left for an experiment in expression recognition with humans based on the CCP to be conducted; we expect that a congruency effect will be observed.

In their first experiment, Tanaka et al. (2012) found that, for happy expressions, the percent accuracy on angry-happy stimuli was reliably less than the accuracy on the other stimuli types. In the case of the model, while there were no statistically significant differences between the four stimuli types, we observed a very similar trend. The reaction time for the angry-happy stimuli was reliably greater than the reaction time for the other three stimuli types in the experiment. In modeling, the difference in reaction time for angry-happy and normal stimuli approached statistical significance, and was reliable for angry-happy and isolated stimuli. Notably, there were no significant differences between the percent accuracy

Figure 6: sensitivity \(\left(d^{\prime}\right)\) in aligned and two misaligned conditions for congruent and incongruent trials of the complete composite paradigm. Error bars indicate standard error of the mean.
or reaction time for the normal, isolated and neutral stimuli in the experiments and in modeling. From their observations, Tanaka et al. (2012) concluded that the recognition of lower half face happy expressions is analytic when there is little or no conflict between the face halves (e.g. normal, isolated and neutral stimuli) but holistic when their is a clash between the face halves (e.g. angry-happy stimuli). However, we made similar observations in the model which possesses a single pathway of holistic processing.

For angry expressions, Tanaka et al. (2012) found that the percent accuracy on isolated stimuli was less than the accuracy on normal and neutral stimuli, and that the accuracy on angry-happy stimuli was less than the accuracy on the other three stimuli types; no other differences were observed for accuracy or reaction time. They concluded from their observations that the recognition of top half face angry expressions was not purely analytic and in fact benefited from the presence of whole-face information. While we did not observe any statistically significant differences between accuracy or reaction time for the four stimuli types in the model, we once again - observed a similar trend with the model (Fig. 78).

In their third experiment, Tanaka et al. (2012) found a lower percent accuracy and greater reaction time for angryhappy stimuli in the aligned condition relative to the misaligned condition, and attributed this to holistic processing. In contrast, for normal stimuli, there was no difference between the accuracy in the aligned and misaligned conditions. They expressed surprise at seeing a shorter reaction time in the misaligned relative to the aligned condition. They attributed the absence of a holistic facililation for aligned normal stimuli to analytic processing. Yet once again, we observed very similar trends in the model, suggesting that holistic processing suffices for explaining the experimental results (Fig. 9-10).

Our modeling work emphasizes the importance of modeling in cognitive science. Without a model, inferences from experimental results can be misleading. While we cannot

Figure 7: percent accuracy in simulation 2 with our model (a) and experiment 1 in Tanaka et al. (2012) (b).

Figure 8: "reaction time" in simulation 2 with our model (a) and reaction time in experiment 1 of (Tanaka et al., 2012) (b).
claim - based on our model - that facial expression processing in humans is purely holistic, we can conclude that Tanaka et al.'s experiments do not show that it has analytic attributes.

\begin{abstract}
Interpretation of a pronoun is driven by properties of syntactic distribution. Consequently, acquiring the meaning and the distribution are intertwined. In order to learn that a pronoun is reflexive, learners need to know which entity the pronoun refers to in a sentence, but in order to infer its referent they need to know that the pronoun is reflexive. This study examines whether discourse information is the information source that the learner might use to acquire grammatical categories of pronouns. Experimental results demonstrate that adults can use discourse information to accurately guess the referents of pronouns. Simulations show that a Bayesian model using guesses from the experiment as an estimate of the discourse information successfully categorizes English pronouns into categories corresponding to reflexives and non-reflexives. Together, these results suggest that knowing which entities are likely to be referred to in the discourse can help learners acquire grammatical categories of pronouns.
\end{abstract}

Keywords: language acquisition; Bayesian modeling
English speakers know that the sentence in (1) means that Alice saw Alice in the mirror and the sentence in (2) means that Alice saw someone else in the mirror.
(1) Alice saw herself in the mirror.
(2) Alice saw her in the mirror.

These interpretations reflect adults' knowledge that reflexives like herself require different syntactic relations with their antecedents than non-reflexives like her. Evidence shows that children acquiring various languages have knowledge of the grammatical distributions of pronouns (Jakubowicz, 1984; Crain \& McKee, 1985, among many). However, it is not yet known how children acquire this knowledge.

In English, the distribution of pronouns is governed by two constraints on the pronoun-antecedent relation: locality and c-command. Locality refers to the domain of the syntactic relation between the pronoun and its antecedent. Reflexive pronouns must have their antecedents in the local domain, corresponding approximately the same clause in English (Chomsky, 1973). The second constraint is that reflexive pronouns must be c-commanded by their antecedent (Reinhart, 1976). In the sentence 'Alice's sister saw herself', English speakers know that the antecedent of herself is not Alice, but Alice's sister. That is, when the hierarchical structure of the sentence is represented as a tree in Figure 1, the reflexive herself is contained in the sister node of its antecedent Alice's sister. Non-reflexive pronouns appear in exactly those

Figure 1: Syntactic tree showing a c-command relationship between the antecedent Alice's sister and the pronoun herself.
contexts where reflexives do not appear: approximately contexts in which the antecedent is either non-local, not in a ccommanding position, or both (Chomsky, 1973). This means that the relationship between the grammatical positions of antecedents and pronouns, as characterized by locality and ccommand, defines the distribution of grammatical categories of pronouns in English.

Critically, these grammatical constraints concern the relationship between a pronoun and its antecedent. This means that syntactic knowledge alone is insufficient for acquiring pronouns, because it cannot be applied without knowing the intended antecedent of a pronoun. In order to learn that herself is reflexive, learners need to interpret the sentence in (1) as 'Alice saw Alice', recognizing that Alice and herself corefer to the same entity. However, in order to interpret the meaning of the sentence, they need to use the knowledge that herself is a reflexive pronoun, whereas her is a non-reflexive pronoun. This circularity poses a potentially difficult problem for children acquiring language.

In this paper we show that discourse information can help learners categorize pronouns into appropriate distributional classes. If learners use discourse information to predict that the pronoun herself in (1) is likely to refer to Alice and the pronoun her in (2) is likely to refer to someone else, this provides information that can help them categorize these pronouns into different classes. We examine (i) to what extent discourse context is informative for determining the referent of a pronoun and (ii) whether this estimate of a pronoun's reference is sufficient for learning to classify pronouns.

The paper is organized as follows. Our next section describes a behavioral experiment that measures the discourse information available to listeners. The following section
presents Bayesian modeling results showing that this discourse information can help bootstrap grammatical knowledge of pronoun categories. Finally, the last section addresses open questions and implications.

\section*{Experiment 1: Human Simulation}

To test to what extent language contexts are informative about the referents of pronouns, we used a variant of the human simulation paradigm (Gillette, Gleitman, Gleitman, \& Lederer, 1999). In this paradigm, adult participants guess the identity of a missing word on the basis of linguistic and/or situational data. Because participants know there is a word, but not what it is, they are simulating what it is like to be a language learner who hears a word but does not know its meaning. A goal of the human simulation paradigm is to see what can be inferred about the meaning of a word based on information present either in the linguistic input or in the scene. Past experiments using the human simulation paradigm have examined the degree to which adults (Gillette et al., 1999; Kako, 2005) or older children (Piccin \& Waxman, 2007) can guess identities of common nouns and/or verbs.

In our experiment, adult participants were shown text excerpts of conversations between adults and children. Their task was to guess the identity of a word or phrase that had been blanked out, which was either a reflexive pronoun, a non-reflexive pronoun or a lexical noun phrase. The goal was to determine whether conversational context provides sufficient information for adults to guess what is being referred to. If so, this would provide evidence in favor of the idea that language learners can determine the referents of pronouns they do not yet know based on conversational context.

\section*{Methods}

Participants Participants were 40 undergraduates at the University of Maryland, College Park ( 11 men, 29 women). All were native English speakers and all were at least 18 years old. Participants were enrolled in introductory linguistics courses and received course credit for their participation.
Materials Text excerpts of real recorded conversations between adults and young children were taken from the ENG-USA section of the CHILDES database (MacWhinney, 2000). In each excerpt, one line was bolded. This bolded line had a noun phrase (NP) that had been deleted and replaced with a blank. The deleted noun phrase always came from an adult utterance. There were 12 lines of dialogue before the bolded line and six lines afterwards. Every deleted noun phrase was the object of one of five verbs: hurt, see, help, dry, and cover. Using the same verbs in all contexts allowed us to factor out any possible contribution of verb knowledge to determining which pronoun was intended. The deleted noun phrases belonged to one of three categories: 25 were reflexive pronouns ( 4 tokens of myself, 1 token of ourselves, 7 tokens of himself, 10 tokens of yourself, and 3 tokens of themselves), 25 were non-reflexive pronouns ( 4 tokens of \(m e, 1\) token of us, 7 tokens of him, 10 tokens of you, 3 tokens of them), and

25 were lexical NPs (names - including Mommy or Daddy - and definite descriptions). This led to a total of 75 test items. Within the test items, frequencies of corresponding non-reflexive and reflexive pronouns were matched (e.g., me was matched in frequency with myself, etc).

The dialogues were chosen randomly from all adult utterances in CHILDES that used the relevant verbs with the relevant type of NP object, with the exception that we threw out utterances that were direct repetitions of a previous line or that were well-known quotations. Finally, the materials were chosen to balance, as much as possible, the person of the pronoun object of the verb (though due to an imbalance in the available CHILDES data we were still left with more secondperson objects than first or third person). In addition to the lines of dialogue, each item in the experiment provided a list of participants in the conversation and the age of the child in the conversation. No information was given about the situation or context in which the conversation took place.

After each excerpt, participants were given a list of 15 choices for what NP could have gone in the blank. The choices always included the same five reflexive pronouns (yourself, myself, ourselves, himself, themselves) and nonreflexive pronouns (you, me, us, him, them). They also included five lexical NPs which would have been prominent in the conversation: e.g., the names of the participants (including Mommy or Daddy) and prominent people or objects mentioned in the conversational excerpts. If the actual sentence contained a lexical NP then this lexical NP was one of the five lexical NPs provided. The NPs were presented in alphabetical order.
Procedure Participants were given an hour in a quiet room to complete the experiment. Test items were presented on paper, one per page. Participants were instructed to read the dialogues, which were real conversations between adults and children, and pick the word or phrase (from the list of 15 choices) they thought belonged in the blank. Participants wrote answers on a separate answer sheet. The test items were presented in random order. Twenty participants received the first 38 test items, and the remaining twenty participants received the remaining 37 test items.

\section*{Results and Discussion}

Overall, participants were highly accurate at guessing the correct word from a list of 15 choices. The first row in Table 1 breaks up guesses of the correct word by syntactic category of the NP (reflexive pronouns, non-reflexive pronouns, or lexical NPs). Individual participants chose the correct NP out of 15 choices an average of \(63.8 \%\) of the time. This ranged from \(32.4 \%\) for the least accurate participant to \(84.2 \%\) for the most accurate participant, with a standard deviation of \(10.6 \%\), and was significantly better than chance \((t(39)=34.19, p<0.0001)\). These results show that adults can usually guess the identity of a missing NP given only a small amount of linguistic context.

However, these results underestimate participants' ability
\begin{tabular}{|c|c|c|c|}

\end{tabular}

Table 2: Confusion matrix obtained in Experiment 1
to guess what is being referred to. The second row in Table 1 shows guesses of a plausibly correct word, a word that plausibly had the same intended referent as the correct word (for instance, a pronoun with the same gender/number features as the name that had actually been used, or vice versa). These results show that adults are good at guessing which entity is referred to given a context, irrespective of grammatical knowledge relevant to pronouns.

Table 2 breaks up the results by syntactic category of the NP. Participants' guesses were usually of the same category that the actual word had been. Importantly, adults usually guessed correctly whether the missing word had been a reflexive pronoun-when the word actually had been reflexive, participants guessed a reflexive \(68.2 \%\) of the time. When the word had been a lexical NP or a non-reflexive pronoun, they almost never guessed that it had been a reflexive.

This task parallels that of a child identifying an unfamiliar word. Of course, the parallel is not complete. In some ways, adult participants were provided with less information than the children they were meant to simulate: they only received a small excerpt of the conversation and did not receive any visual information. In other ways, the participants had more data: they already knew the meanings of all of the other words in the conversation, they had full syntactic and discourse knowledge where children might only have partial knowledge (e.g., Arnold, Brown-Schmidt, \& Trueswell, 2007), and they were limited to 15 choices of possible meaning. Furthermore, choosing an answer in this experiment was not subject to any time pressures, whereas in actual acquisition processing speed could potentially impact the learner's ability to use the discourse context as an information source. However, to the extent that the adult simulation reflects the prior information presented in the discourse, it provides an estimate of the information that children might have access to. Where adults (who already know the distribution of reflexives) can guess that a missing word is reflexive, a child might be able to guess that a missing word co-refers with a specific NP. Together with syntactic knowledge of locality and c-command, this should provide learners with useful in-
formation for acquiring grammatical categories of pronouns. To explore this possibility, we formalize a Bayesian model that learns to categorize pronouns.

\section*{Experiment 2: Bayesian Model}

In this section, we develop a Bayesian model that integrates the discourse information measured in Experiment 1. This model investigates whether the information in discourse could be sufficient to learn the grammatical categories of English pronouns in principle (a computational-level model; Marr, 1982). The model discovers:
1. how many pronoun categories there are in a language
2. the distribution of pronouns in each category
3. which syntactic position of an antecedent is associated with each pronoun category

This ideal learner is assumed to have (a) discourse knowledge that helps define the distribution of the potential antecedents, (b) syntactic knowledge relevant to pronoun categories (details follow), and (c) lexical knowledge that is sufficient for distinguishing pronouns from lexical noun phrases. Other linguistic information relevant to pronouns, such as gender and number, is not represented in our model; we ask simply whether our ideal learner can acquire two categories corresponding to reflexive and non-reflexive pronouns.

Regarding (b) above, this ideal learner is assumed to already know locality and c-command before learning pronoun categories, and is further assumed to know that these are relevant for categorizing pronouns. Thus, the learner is able to identify the syntactic position of each potential antecedent. The model distinguishes four syntactic positions based on the knowledge of locality and c-command; [+local,+c-command], [+local,-c-command], [-local,+c-command], and [-local,-c-command]. In English, if an antecedent is in a syntactic position described by [+local,+c-command], that pronoun must be a reflexive pronoun. If the potential antecedent is elsewhere, that pronoun must be a non-reflexive pronoun. However, the learner does not know in advance which syntactic position is associated with which pronoun category, and needs to acquire this knowledge from the input. We return to this issue of prior syntactic knowledge in the Discussion.

\section*{Generative Model}

Our model assumes the following generative process. For each pronoun, an antecedent in one of the four syntactic positions described above is chosen given prior discourse knowledge \((\mathcal{D})\). Then a pronoun category is chosen based on the syntactic position of the antecedent, and a pronoun is generated from the chosen pronoun category.

Figure 2 illustrates this process with a graphical model. \({ }^{1}\) Each antecedent category distribution \(\theta_{j}\) is a random variable

\footnotetext{
\({ }^{1}\) This model is a nonparametric extension to the author-topic model (Rosen-Zvi, Griffiths, Steyvers, \& Smyth, 2004) that allows for an infinite number of categories (called topics in their model).
}

Figure 2: Graphical Model
that encodes the distribution over pronoun categories favored by an antecedent in syntactic position \(j\). For example, the category reflexive would have high probability in the distribution \(\theta_{[+ \text {local },+\mathrm{c}-\text { command }]}\). (Here we use the category name reflexive for exposition, but the model does not associate any labels with the pronoun categories it recovers.) Each category word distribution \(\phi_{k}\) is a distribution over words that encodes the probability distribution over pronouns in pronoun category \(k\). For example, pronouns such as herself and myself would have high probabilities in the distribution \(\phi_{\text {reflexive }}\). In addition to learning this distribution, our model learns the number of pronoun categories needed to describe the data. For each pronoun in the corpus, an antecedent in a syntactic position \(x\) is assumed to be sampled from a distribution we refer to as discourse knowledge \(\mathcal{D}\) (see the next section for the details). A pronoun category \(z\) is then sampled from the multinomial distribution with parameter \(\theta\) associated with the syntactic position \(x\) of the antecedent and a pronoun \(w\) is sampled from a multinomial distribution with parameter \(\phi\) associated with pronoun category \(z\).

To learn the number of pronoun categories based on the observed data, we use the hierarchical Dirichlet process (Teh, Jordan, Beal, \& Blei, 2006). The advantage of this model is that it allows the model to flexibly learn how many categories are present in the data, while still allowing categories to appear across multiple grammatical contexts. The summary of the generative process follows.
1. Draw a distribution over pronoun categories \(\theta_{0} \sim \operatorname{GEM}(\gamma)\), where GEM is the Griffiths, Engen, McCosky distribution (Pitman, 2002).
2. For each antecedent syntactic position \(j=1 \ldots 4\), draw a pronoun category distribution \(\theta_{j} \sim \operatorname{DP}\left(\alpha, \theta_{0}\right)\).
3. For each pronoun category \(k=1 \ldots \infty\), draw a distribution over tokens \(\phi_{k} \sim \operatorname{Dir}(\beta)\).
4. For each pronoun in the corpus \(n=1 \ldots N\)
(a) Draw an antecedent syntactic position from the discourse knowledge \(x_{n} \sim \mathcal{D}\)
(b) Draw a pronoun category \(z_{n} \sim \operatorname{Mult}\left(\theta_{x_{n}}\right)\).
(c) Draw a word \(w_{n} \sim \operatorname{Mult}\left(\phi_{z_{n}}\right)\).

\section*{Prior Knowledge}

The observed discourse knowledge \(\mathcal{D}\) defines a prior distribution over potential antecedents in the discourse. Recall that our ideal learner maps each antecedent in the discourse deterministically to its syntactic position (defined in terms of locality and c-command), and in this way \(\mathcal{D}\) defines a distribution over syntactic positions \(x\) for each pronoun's antecedent.

Rather than specify a parametric form for this prior distribution, we estimate it directly from participants' responses from Experiment 1. In one experimental item, for example, participants guessed the identity of the missing word in the sentence "You drying _- off?". Nine out of 20 participants guessed that the missing word is yourself, six out of 20 guessed him, three out of 20 guessed me, and two out of 20 guessed Seth. Under the assumption that experimental participants have sampled their responses from a shared prior distribution over entities in the discourse, these guesses provide an estimate of participants' beliefs about how likely each entity is to be referred to in the discourse.

Where participants chose yourself, the antecedent of this pronoun is you, which is a local and c-commanding antecedent. Where participants chose him and me, the antecedents could be in any of the remaining three syntactic positions, but in this particular dialogue the only potential antecedents for non-reflexives are neither local nor ccommanding. \({ }^{2}\) We ignored responses in which participants chose lexical NPs (here Seth) based on the assumption that learners distinguish pronouns from lexical NPs. We then normalized each count by the total number of pronoun guesses. The resulting prior distribution over syntactic positions for antecedents in this example is \(p\left(x_{[+ \text {local },+c \text {-command }]} \mid \mathcal{D}\right)=0.5\) and \(p\left(x_{[- \text {local },-c \text {-command }]} \mid \mathcal{D}\right)=0.5\). In this way the results from Experiment 1 provide us with an informative prior distribution regarding which entities are likely to be referred to in the discourse, and through simulations we can test whether this prior knowledge helps an ideal learner acquire pronoun categories \({ }^{3}\).

\section*{Inference}

Given this generative process, we can use Bayesian inference to recover the learner's beliefs about pronoun categories. We use the Gibbs sampling algorithm from Rosen-Zvi et al. (2004) to estimate latent variables: the antecedent-category parameter \(\theta\), the category-word parameter \(\phi\), the antecedent's syntactic position \(x\), and the pronoun category \(z\). The assignments of \(x\) and \(z\) for a particular token are sampled as a block, conditioned on everything else, so that in each iteration we compute the conditional distribution \(p\left(x_{i}, z_{i} \mid w_{i}, \mathbf{x}_{-i}, \mathbf{z}_{-i}\right)\) where \(\mathbf{x}_{-i}\) and \(\mathbf{z}_{-i}\) denote all syntactic position and category

\footnotetext{
\({ }^{2}\) In cases of non-reflexive guesses where potential antecedents appeared in multiple syntactic positions, we assumed the prior probability for each syntactic position to be proportional to the number of potential antecedents in that position.
\({ }^{3}\) This prior distribution differs from the distribution seen in Tables 1 and 2 because it is based on individual experimental items rather than on aggregated data.
}
assignments not including the \(i\) th pronoun. This is proportional to
\[
p\left(w_{i} \mid x_{i}, z_{i}, \mathbf{x}_{-i}, \mathbf{z}_{-i}\right) \cdot p\left(z_{i} \mid x_{i}, \mathbf{x}_{-i}, \mathbf{z}_{-i}\right) \cdot p\left(x_{i} \mid \mathcal{D}\right)
\]
where the first term is the likelihood function from RosenZvi et al. (2004), the second is defined by the hierarchical Dirichlet process (Teh et al., 2006), and the third is estimated directly from participants' responses in Experiment 1.

\section*{Simulations}

In order to test the effectiveness of discourse information for the categorization of pronouns, our simulations compare three models: a Baseline model, a Discourse model, and a Strong syntax model. The Baseline model has information about locality and c-command, but it lacks information about which entities are likely to be referred to in the discourse. It assumes that potential antecedents are sampled uniformly, so that \(p\left(x_{i} \mid \mathcal{D}\right)\) is defined by counting the number of discourse entities that appear in each syntactic position. The Discourse model is identical to the Baseline model, but it contains the adult-like discourse knowledge estimated in Experiment 1, as described above. Comparing the performance of the Discourse model to the Baseline model allows us to quantify the degree to which discourse information helps an ideal learner acquire pronoun categories.

The Strong syntax model is similar to the Baseline model in that it assumes that potential antecedents are sampled uniformly, but it additionally incorporates built-in knowledge of the grammatical constraints on reflexive and non-reflexive pronouns in English. This model knows there are two grammatical categories of pronouns. Furthermore, it knows that pronouns that have local c-commanding antecedents are reflexive pronouns and that pronouns that do not have local c-commanding antecedents are non-reflexive pronouns (i.e., the antecedent-category parameter \(\theta\) is observed). Thus, the model only needs to learn the distribution of each category over pronouns. Comparing this Strong syntax model to the Baseline model allows us to examine whether this type of strong prior syntactic knowledge is sufficient to help learners categorize pronouns.

Each model was trained on 50 dialogues from Experiment 1, 25 with reflexive and 25 with non-reflexive pronouns. For each dialogue, the model was provided with the pronoun, a prior distribution over possible antecedents for that pronoun, and the syntactic positions of those antecedents relative to the pronoun. Through the unsupervised learning procedure described above, the models recovered a distribution over categories associated with each syntactic position and a distribution over pronouns for each category.

Results For each model, we ran 10 independent Gibbs chains for 2000 iterations each. Hyperparameters \(\alpha, \beta\), and \(\gamma\) were fixed at 1.0, 0.01, and 0.001 , respectively \({ }^{4}\). We com-

\footnotetext{
\({ }^{4}\) We chose the best parameter values based on multiple runs, but results were qualitatively consistent across a range of parameter values. The same parameter values were used for all three models.

\hline
\end{tabular}

Table 3: Baseline model results
puted pairwise F-scores using the final samples from each chain. The Baseline model consistently failed to learn the correct categories, achieving a mean pairwise F-score of 0.55 across the 10 sampling chains. In all 10 chains, the model learned 3-4 categories, where the correct number of categories is two. Table 3 shows the distribution over pronouns belonging to each category obtained at the 2000th iteration of the sampling run with the highest likelihood. The maximum likelihood estimate \(p\) (word \(\mid\) category) gives the proportion of times each pronoun occurs in a category, based on a single sample from the posterior distribution over \(z\) and \(x\).

The Discourse model performed much better than the Baseline model, achieving a mean pairwise F-score of 0.97 across the 10 sampling runs. In seven of the 10 runs, the model perfectly categorized English pronouns into two classes. In two additional runs, the model learned two categories, but the membership was not consistent. In the final run, the model learned three categories. Table 4 shows the pronouns belonging to each category, obtained at the 2000th iteration of the Gibbs sampling run which had the highest likelihood. The pronouns associated with each category are reflexive pronouns and non-reflexive pronouns, respectively. This model also learned that there are exactly two categories, as expected. These results indicate that discourse information can help an ideal learner categorize pronouns.

Although the Baseline model has prior knowledge of ccommand and locality, it is still possible that the low performance in this model might result from insufficient syntactic knowledge. For this reason, we compare the Strong syntax model with the Baseline model to see whether even stronger prior syntactic knowledge is sufficient for categorizing pronouns. The mean F-score was 0.56 for this model. Table 5 shows the pronouns in each category, obtained at the 2000th iteration of a Gibbs sampling run which had the highest likelihood. The lack of improvement of the Strong syntax model over the Baseline model suggests that simply having strong prior syntactic knowledge is not sufficient for acquiring grammatical categories of pronouns.

Table 4: Discourse model results

These simulation results suggest that knowing which entities are likely to be referred to in the discourse can help learners acquire grammatical categories of pronouns. On the other hand, simply having strong prior knowledge about the grammatical distribution of pronouns is not sufficient to support the acquisition of pronoun categories.

\section*{Discussion}

This study examined the potential utility of discourse information as a cue to the acquisition of pronoun categories. We showed that discourse information can help adults accurately guess the identities of missing pronouns, and that a Bayesian model with prior knowledge of discourse information can accurately recover grammatical categories of pronouns without knowing in advance how many categories are present in a language. This supports a role for discourse information in helping learners acquire grammatical knowledge of pronoun categories and shows one way in which they can overcome the circularity problem inherent to language acquisition at the syntax-semantics interface.

While it is possible that hearing a few unambiguous sentences could also be sufficient for acquiring pronoun categories, our analysis shows that this type of unambiguous data may not be required. Instead, an ideal learner can achieve the same outcome by relying on the discourse information that is actually present in child-directed speech. The data used in our analysis were taken from CHILDES, and therefore provide a good characterization of input a child receives. However, one limitation of our work is that distributions of verbs and pronouns were balanced in our experimental stimuli, whereas they may not be balanced in the input. To ensure that the true distributions of verbs and pronouns support learning, it will be important to replicate our modeling results on more extensive corpora.

Our model assumed that learners have prior knowledge of the relevance of syntactic locality and c-command relations to the acquisition of pronouns, but we do not know the degree to which this parallels children's acquisition. Children appear to have acquired relevant locality constraints on pronouns by age five at the latest (Zukowski, McKeown, \& Larsen, 2008), though we do not know when knowledge of the domains themselves becomes available to learners. Knowledge of c-command also appears to be available to children at this age or even earlier (Lidz \& Musolino, 2002; Sutton, Fetters, \& Lidz, 2012). However, cross-linguistically, locality and c-

command are neither necessary nor sufficient for defining the distributions of grammatical categories of pronouns. Future modeling work will explore the potential role of discourse as an evidentiary source not only in discovering categories of pronouns, but also in determining which grammatical features are relevant for anaphoric dependencies.

Constraints on Theories of Serial Order Memory Revisited: The Cases of the Fill-In and Protrusion Effects
}

\begin{abstract}
In his seminal dissertation, Henson (1996) identified a number of constraints on theories of serial order memory. Two constraints, the fill-in constraint, in which an item that is erroneously recalled early is likely to be followed by its predecessor rather than its successor (recall of ACB is more likely than ACD), and the protrusion constraint, in which prior list intrusions are likely to be recalled in the same output position as their previous serial position, were considered evidence against chaining theories. We present results from two experiments which investigate the extent to which these effects are dependent on experimental methodology. When participants are given an open set of items, an equal ratio of fill-in and infill errors was observed and a protrusion effect was obtained. However, when a reconstruction of order task was used, a fillin effect was observed. Implications for theories of serial order memory are discussed.
\end{abstract}

Keywords: serial recall; serial order memory; episodic memory; short term memory; working memory; chaining models; positional models; memory models

The problem of understanding serial order memory is possibly the oldest problem in the field of memory studies. Over a century of work has produced theories that can be broadly placed into two camps: positional theories, which claim that items in a sequence are coded with respect to their position in the sequence, and chaining theories, which claim that order is implicit in the associations among the items in a sequence; retrieval consists of using retrieval retrieved items as cues for their successors.

A watershed moment in theorization of serial order memory came with the seminal dissertation of Henson (1996). Through a series of experiments and meta-analyses, Henson outlined the regularities of the serial recall paradigm and dubbed them the constraints on serial order memory. The discussed regularities were diverse and ranged from effects of serial position to repetition errors and omissions. Of interest to the present investigation were regularities in error patterns that were particularly problematic for chaining models of serial order memory. One such regularity was the fill-in effect, which states that when an item is recalled one position too early, it is more likely to be followed by its predecessor than its successor. As an example, consider when a sequence \(A B C D E\) is studied and a subject erroneously recalls \(A C\), skipping over the \(B\) item. Henson found that participants are more likely to recall \(A C B\) than \(A C D\), as if they are "filling in" the missing response. The latter, the \(A C D\) case, is considered an in-fill error, and any chaining model with asymmetric associations is predicted to produce a greater incidence of in-fill errors than fill-in errors. The fill-in effect was replicated by

Surprenant, Kelley, Farley, and Neath (2005) using a reconstruction of order paradigm.

Another such constraint was the protrusion constraint, which states that intrusions from prior lists tend to share the same position in both the current and prior lists. That is, if a subject is attempting to recall to item 3 on the current list and makes an intrusion from the prior list, the intrusion is most likely to be the third item on the previous list. Henson (1996) dubbed such in-position intrusions protrusions. The protrusion effect was initially discovered by Conrad (1960) and has been cited as evidence for positional coding.

Both the protrusion and fill-in constraints along with several other regularities that Henson (1996) discovered became canonical in the serial recall literature. Virtually every model that has been published since has no role of inter-item associations. The majority of the recent models are positional models; these include the the model of Burgess and Hitch (1999, 2006), Henson's own Start-End Model (Henson, 1998), the recurrent model of Botvinick and Plaut (2006), and the grouping model (Farrell, 2012). The constraints outlined by Henson (1996) were benchmark phenmonena for each of these models, as several of these models demonstrated how both fill-in and protrusion effects could be explained by positional representations.

The role of chaining in memory for serial order was revisited by Solway, Murdock, and Kahana (2012), who conducted a re-analysis of three serial recall studies and found a robust in-fill effect, contrary to the analyses of Henson (1996) and in agreement with the predictions of chaining models. They proposed a compound chaining model which yielded a good fit to the data, whereas the positional model of Burgess and Hitch (2006) did not yield an adequate fit. An open question remains as to why the analysis of Solway et al. yielded an in-fill effect whereas the analyses of Henson yielded the opposite pattern. In response to Solway et al., Farrell, Hurlstone, and Lewandowsky (2013) presented a re-analysis of over a dozen datasets, the vast majority of which yielded a fill-in effect. Farrell et al. posited that the datasets used by Solway et al. used longer list lengths than most serial recall experiments (minimum of ten items), which might be beyond the capacity of short-term memory and thus utilize different representations.

However, another difference between the studies analyzed by Solway et la. and Farrell et al. is that in the former, items were not re-used across trials (this is referred to as an open
set of items). The studies considered by Henson and Farrell et al. often used small sets of stimuli such that items were frequently re-used across trials (referred to as a closed set of items). This is often standard practice in serial recall experiments, as it is believed that when a large set of stimuli is used the participant has to remember both the items and the order in which they occurred. If a closed set of stimuli is employed, item memory quickly reaches ceiling and only the order among the items has to be remembered on a given trial (Healy, 1974). Another similar approach to obtaining a relatively "pure" measure of order memory is to employ a reconstruction of order task, wherein the participant studies a list of items but at retrieval they are provided with the items and asked to place them in the correct order (Healy, Fendrich, Cunningham, \& Till, 1987); this task was used in the experiments of Surprenant et al. (2005) that demonstrated a fill-in effect.

Closed sets and reconstruction of order tasks may yield different results than serial recall experiments with open sets in that the former tasks are susceptible to guessing strategies and the latter has a high incidence of omissions. When a closet set or a reconstruction task is used, item memory is at ceiling, which may cause participants to guess as to the locations of the items without having any knowledge of their positions. Under some circumstances, this can lead to an artificially high degree of fill-in errors. Consider a case in which a participant studied a list \(A B C D\) and knows the locations of \(A\) and \(B\), but cannot recall the positions of \(C\) and \(D\) and guesses on the third and fourth responses. In this circumstance, the participant can either a.) get the sequence correct ( \(A B C D\) ) or b.) produce a sequence with a fill-in error \((A B D C)\). Under this circumstance, only fill-in errors can be produced and there is no possibility for making an in-fill error.

However, when an open set is used in a serial recall task, item memory is imperfect and there is a high incidence of omissions, which can disguise a fill-in effect as an in-fill effect. Consider if sequence \(A B C D\) is represented in memory as \(A C B D\). This would yield a fill-in effect if all of the represented items were output, but if \(B\) is omitted at retrieval, sequence \(A C D\) is produced. This may be especially likely in the studies of Solway et al. since the lists in the experiments they analzyed were quite long and the performance of the participants was relatively poor.

Even if guessing strategies are responsible for the finding of the fill-in effect, the compound chaining model of Solway et al. has no recourse for producing protrusion errors. Nonetheless, a number of traditional studies of serial recall collect responses on a series of lined response grids in which participants can see the previous responses. A simple explanation for the protrusion effect is that when participants are not able to recall a given item, they glance at the output position from the previous trial and use that response in their answer.

The present study attempt to control for both of these possibilites using simple means. In Experiment 1, we conducted
a serial recall experiment that used a large open set of words, such that items are not repeated from trial to trial making it unlikely that participants should be able to guess from a pool of possible responses. Additionally, participants entered their responses on a keyboard rather than on lined response grids and were not given access to their previous responses. In Experiment 2, we used the same procedure as Experiment 1 but employed a reconstruction task by showing the participants the list items at retrieval in a new randomized order.

Serial recall experiments using open sets have been conducted, but to date there have been no analyses of whether the data collected from these experiments exhibit a predominance of fill-in or in-fill errors or whether they exhibit the protrusion effect. Investigations of set size effects have instead been concerend with other issues, such as word frequency effects (Roodenrys \& Quinlan, 2000) or the phonological similarity effect (Coltheart, 1993; Conrad, 1963). We found that the open set did affect the fill-in to in-fill ratio, as we observed equivalent levels of fill-in and in-fill errors in Experiment 1. In Experiment 2, we conducted a reconstruction of order task and replicated the fill-in effect found by Surprenant et al. (2005).

\section*{Experiment 1: Serial Recall}

Experiment 1 was an immediate serial recall task using a large set of words such that every list a participant received was composed entirely of unique items. To capture different levels of performance, we employed lists of five and six items and list length was manipulated between subjects.

\section*{Method}

Participants A total of 204 undergraduate psychology students (105 participants for the list length five condition, 99 for the list length six condition) from The Ohio-State University participated in this experiment in exchange for course credit in an introductory psychology course.
Materials Participants studied words that were randomly selected from a word pool of 625 words from the Google search counts. Words ranged from 4 to 7 letters in length and from 30 to 250 counts per million in word frequency.

Procedure To familiarize participants with the nature of the task, all participants began each session with four unscored practice lists of three, four, five, and six items in order. Participants were given feedback upon completion of each of the practice lists. If any errors were made, participants were reminded that they have to recall the items in the order in which they were presented. No feedback was given at any point in the experiment after the practice session was completed.

Upon completion of the practice session, participants were given 62 trials with lists of either five or six items. During the study phase, participants were presented with each word for one second followed by a blank screen for 250 ms . Following completion of the study list, participants were presented with a recall prompt that was a series of three question marks ("???") on the center of the screen. Participants were
instructed to begin recalling the items upon seeing the prompt by typing their respones on a keyboard and were given \(20 \mathrm{sec}-\) onds to recall the sequence. After the first key was pressed, the question marks disappeared and replaced with the letters typed by the participant. Participants signaled completion of a word by hitting the "ENTER" key on the keyboard. Upon completing a response, the response disappeared from view on the computer screen and was replaced by the question marks. Participants signaled completion of the recalled sequence by typing the word "done" and hitting "ENTER." Upon completion of each trial, participants signified readiness to begin the next trial by hitting the "ENTER" key.

Halfway through the experiment, participants were given a break in which they played a digital card game for 180 sec onds. Stimulus presentation and response collection was handled using the Python experimental library (Geller, Schleifer, Sederberg, Jacobs, \& Kahana, 2007).

\section*{Results}

Serial Position Effects The proportion of correctly items recalled in their correct serial position are shown in Figure 1. Performance was significantly worse in the length six condition than in the length five condition, \(t(201.37)^{1}=8.26, p<\) .001. A mixed analysis of variance (ANOVA) using serial position as a within subjects factor and list length as a between subjects factor revealed that performance varied as a function of serial position, \(F(5,906)=850.40\), and there was a serial position by length interaction, \(F(4,906)=34.99\), both \(p \mathrm{~s}<\) .001. Post hoc comparisons revealed a negative recency effect (poorer performance for the last item than the second to last item) in both the length five, \(t(104)=-10.99\), and length six, \(t(98)=-14.12\), conditions, both \(p \mathrm{~s}<.001\).

Fill-In and In-Fill Errors Henson (1996) classified fill-in errors by focusing on all responses following the first item that was recalled one position too early. If the following item was from one serial position earlier than the just recalled item, this was considered a fill-in error. If the following item was from one serial position later than the just recalled item, this was considered an in-fill error. However, one need not just consider transitions that only traverse one serial position. Rather, the initial error could be more than one position too early and the subsequent fill-in or in-fill could be more than one position earlier or later, respectively. We will henceforth refer to the one position restriction as the lag 1 analysis and the latter case which considers longer transition as the any lag case; both will be considered in the present analysis.

The analyses of Solway et al. (2012) and Farrell et al. (2013) both used a strict scoring procedure in which fill-in errors and in-fill errors are only considered for cases where the initial skip was the first error in the trial. We follow their example here and use strict scoring in our analyses.

The mean number of fill-in and in-fill errors for each classification style can be seen in Figure 2. Separate mixed

\footnotetext{
\({ }^{1} t\) test degrees of freedom (df) are corrected df from the WelchSatterwaithe equation.
}

Figure 1: Serial position curves for Experiment 1 (A), which used a traditional serial recall procedure, and Experiment 2(B), which used a reconstruction task. Error bars indicate \(95 \%\) within subjects confidence intervals.

ANOVAs with error type (fill-in or in-fill) as a within subjects factor and list length as a between subjects factor for both the any lag and lag 1 transition analyses. Results indicated there was neither a fill-in effect or an in-fill effect when transitions of any lag were analyzed, \(F(1,202)=.246\), or when analyses were restricted to lag 1 transitions, \(F=1.291\), both \(p \mathrm{~s}>.05\).
Protrusion Errors All analyses on intrusion rates were restricted to immediate intrusions (intrusions from only one list prior to the current study list). A visualization of the intrusion rates for the serial position of each intruding item at each output position can be seen in Figure 3. As can be seen by the spiked nature of the graph, intrusions tend to appear in the same output position as their serial position in the prior list.

A statistical analysis was performed by calculating the proportion of immediate intrusions that were protrusions for each participant. Because there were some participants that exhibited no prior list intrusions, this analysis was restricted to participants that made at least one immediate intrusion error. The proportion of immediate intrusions that were protrusions (in-position) was above chance for both the list length five, \(t(69)=4.49\), and list length six conditions, \(t(82)=3.50\), both \(p \mathrm{~s}<.001\), which is consistent with the findings of Henson (1996) and Conrad (1960).

\section*{Discussion}

We conducted a serial recall experiment that used experimental parameters that were highly similar to previous experiments with the exception that stimuli were not reused from trial to trial in an effort to gauge the the generality of the constraints on serial recall established by Henson (1996). In contrast to Henson's data and the analyses of Solway et al., we observed roughly equivalent numbers of fill-in and in-fill er-

Figure 2: Mean number of fill-in and in-fill errors for each classification type for list length 5 (top) and list length 6 (middle) conditions of Experiment 1, along with the reconstruction task used in Experiment 2 (bottom). Error bars indicate \(95 \%\) within subjects confidence intervals.
rors. In other words, when an item was recalled too early, participants were equally likely to continue in a forward order or to return to the skipped item. The protrusion effect, in contrast, was robust in our experiment. The spiked, positional nature of immediate intrusions strongly resembled the data displayed by Henson \((1996,1998)\).

Nonetheless, it was still somewhat surprising that we did not observe a fill-in effect in our experiment because Surprenant et al. (2005) found a robust fill-in effect with both a small and large set of items. Nonetheless, their experiments used a reconstruction of order paradigm, and as previously discussed, such a task might introduce guessing strategies in the same manner as a small set size would in a standard serial recall paradigm. Thus, we repeated our experiment using the same parameters but employed a reconstruction of order task at retrieval and hypothesized that the results would favor a fill-in effect.

\section*{Experiment 2: Reconstruction of Order}

Experiment 2 was identical to that of Experiment 1 with the exception that a reconstruction of order task was used at retrieval. During the test phase, participants were presented with all of the study list items in a randomized order and told to recall the words in the order in which they were presented. Because performance was far superior to that of the serial recall task in Experiment 1, we only collected data with a list length of six items.

\section*{Method}

Participants A total of 95 undergraduate psychology students from The Ohio-State University participated in this ex-

Figure 3: Proportions of immediate intrusions from each serial position in the prior list for each output position of the current trial for both the list length five (top) and list length six (bottom) conditions. The serial position of the prior list intrusion is indicated by the numbers on the lines.
periment in exchange for course credit in an introductory psychology course.

Procedure The procedure was identical to that of Experiment 1 with the exception that at retrieval, participants were presented with all of the studied words at the top of the screen in a randomized order. The words remained fixed on the screen through the test and did not disappear as participants entered the corresponding words. Participants were instructed in advance of the experiment that they would be presented with the words and were told that they should type out the words in the order in which they had appeared in the study list.

\section*{Results}

Due to the severe rarity of prior list intrusions in Experiment 2, analyses were restricted to serial position effects and fill-in and in-fill errors.

Serial Position Effects A one way repeated measures ANOVA revealed a main effect of serial position, \(F(5,470)\) \(=225.6, p<.001\). Post hoc inspection of the serial position data revealed a positive recency effect for the last item in the list, \(t(94)=6.45, p<.001\).
Fill-in and In-Fill Errors Mean number of fill-in and infill errors were calculated for each participant and can be seen in the bottom panel of Figure 2. Fill-in errors outnumbered in-fill errors when any lag transitions were considered, \(t(94)\) \(=14.02\), and when only lag 1 transitions were considered, \(t\) \(=9.80\), both \(p \mathrm{~s}<.001\). Thus, in contrast to Experiment 1, a fill-in effect was observed.

\section*{Discussion}

Consistent with our hypothesis, usage of a reconstruction of order task at retrieval produced a robust fill-in effect. Our results are consistent with the findings of Surprenant et al. (2005), who found a fill-in effect with a large set size using a reconstruction task.

\section*{General Discussion}

The two experiments we conducted found that a previously established regularity of serial order memory, the fill-in effect, depended on the type of task used to gauge serial order memory. In Experiment 1, we used a traditional serial recall paradigm with the exception that items were not repeated across trials and found equivalent levels of fill-in and in-fill errors. In Experiment 2, we employed a reconstruction of order task and found the traditional fill-in effect. These results are theoretically relevant because the fill-in effect has been used to argue against chaining models of memory, and while an in-fill effect was observed in the analyses of Solway et al., our results using shorter lists of words do not show a preponderance of in-fill errors over fill-in errors.

This begs the question as to what class of models the results in these experiments support. While an in-fill effect is predicted by chaining models with asymmetric associations (stronger associations in the forward than in the backward direction), chaining models with symmetric associations (equal strength associations in the forward and backward direction, such as in the TODAM model of Lewandowsky \& Murdock, 1989) would be perfectly compatible with the equal ratios of fill-in and in-fill errors observed in Experiment 1 and a guessing response strategy could be appended to such models to produce fill-in effects as observed in the reconstruction task in Experiment 2. However, one should be reminded of the fact that the protrusion effect applied in both conditions of Experiment 1 and any simple chaining model with either symmetric or asymmetric associations has no recourse for predicting in-position prior list intrusions without positional representations.

\section*{Is there a role of inter-item associations in serial recall?}

We reject the central claim made by Solway et al. (2012) that participants' recall sequences are indicative of a chaining model with asymmetric associations, as we were unable to replicate their finding of an in-fill effect using shorter lists of words. Nonetheless, a number of other studies in the literature have exhibited findings that are in accordance with the predictions of chaining models. During retrieval, when participants are given study list items in the same order as they were presented at study, participants perform better than when they're given unordered list items as cues, suggesting that they're using the cues to retrieve neighboring items from the list (Serra \& Nairne, 2000; Basden, Basden, \& Stephens, 2002). Similarly, when participants are given the same list of words from trial to trial but the starting point of the list differs
(the spin list paradigm: Sequence \(A B C D E\) might be repeated as \(C D E A B\) ), participants are only slightly worse than when the same list is repeated with all of the items in the same positions (Kahana, Mollison, \& Addis, 2010). Positional models, in contrast, would predict a more dramatic impairment to performance in the spin lists than in the repeating lists. While positional models might be extended to produce both of these sets of results, these results follow intuitively from the predictions of chaining models.

While one might be inclined to suggest a hybrid model that incorporates inter-item associations to account for the above findings and positional representations to account for the protrusion effect \({ }^{2}\), such a framework is not only inelegant but is an ad hoc solution to the problem. A more elegant approach is the constraint satisfaction (CS) model proposed by Dennis (2009). In the CS model, asymmetric associations in the forward direction are stored among all of the list items. The model differs from the aforementioned chaining models because at retrieval, the stored representation of the list is compared to all possible ordered list constructions; the distances between the possibilities and the list representation determine the probability of outputting a given sequence.

The basic principle behind the model is that the more differences there are between a candidate sequence and the studied sequence, the less likely it will be that the candidate sequence will be output. Dennis demonstrated that fill-in errors are more frequent than in-fill errors for this reason because a sequence with a fill-in such as \(A C B D E F\) only misses the \(B-C\) connection and erroneously introduces a \(C-B\) connection (two differences from the original sequence), whereas a sequence such as \(A C D E F\) misses all of the connections between \(B\) and its subsequent items (four differences from the original sequence). The model might be able to produce a lower incidence of fill-in errors if it's assumed that list items from the retrieved sequence are only output if they're sufficiently strong, producing more omissions when item memory is poor and lowering the fill-in to in-fill ratio. Dennis also demonstrated that introducing a component of similarity that is common to all of the items allows the model to capture key phenomena that have used to argue for positional representations, such as the protrusion effect as well as the mixed-list phonological similarity effect (e.g.: Baddeley, 1968).

\section*{Conclusion}

Our work evaluating two of the constraints on theories of serial order memory established by Henson (1996) uncovered a generality of one (the protrusion constraint) and a limitation of the other (the fill-in constraint). These results may indicate a need to re-evalute whether inter-item associations are sufficient to support memory for serial order.

\footnotetext{
\({ }^{2}\) The model of Burgess and Hitch (1992) incorporated both interitem and positional associations. However, later versions of the model did not include inter-item associations.
}

\begin{abstract}
A robust empirical regularity in decision making is that the negative consequences of an option (i.e., losses) often have a stronger impact on people's behavior than the positive consequences (i.e., gains). One common explanation for such a gain-loss asymmetry is loss aversion. To model loss aversion in risky decisions, prospect theory (Kahneman \& Tversky, 1979) assumes a kinked value function (which translates objective consequences into subjective utilities), with a steeper curvature for losses than for gains. We highlight, however, that the prospect theory framework offers many alternative ways to model gain-loss asymmetries (e.g., via the weighting function, which translates objective probabilities into subjective decision weights; or via the choice rule). Our goal is to systematically test these alternative models against each other. In a reanalysis of data by Glöckner and Pachur (2012), we show that people's risky decisions are best accounted for by a version of prospect theory that has a more elevated weighting function for losses than for gains but the same value function for both domains. These results contradict the common assumption that a kinked value function is necessary to model risky choices and point to the neglected role of people's differential probability weighting in the gain and loss domains.
\end{abstract}

Keywords: cognitive modeling; loss aversion; risky choice; prospect theory; probability weighting

\section*{Introduction}

For many of our decisions we are unable to tell with certainty what consequence the decision will have-for instance, when deciding between different medications that potentially lead to some side effects. Ideally, we have knowledge of the nature of the possible consequences as well as some inkling of the chances that the consequences will occur, but our decisions must necessarily remain in the "twilight of probability" (Locke, 1690/2004). Elaborating how such risky decisions are made (and how they should be made) has engaged decision scientists at least since Bernoulli's (1738/1954) seminal work on subjective utility.
One of the most influential and successful modeling frameworks of risky decision making is prospect theory (Kahneman \& Tversky, 1979; Tversky \& Kahneman, 1992). A prominent feature of prospect theory is the assumption that the subjective disutility of a negative outcome is higher than the subjective utility of a positive outcome of the same size. In other words, prospect theory assumes an asymmetry between gains and losses in its value function, which
translates objective outcomes into subjective magnitudes. This assumption of loss aversion can explain, for instance, that people dislike gambles in which one has a \(50 \%\) chance to win a particular amount of money and a \(50 \%\) can to lose the same amount. Similarly, loss aversion is invoked to account for the endowment effect-the phenomenon that people evaluate an object higher in a buyer perspective than in a seller perspective (e.g., Pachur \& Scheibehenne, 2012; for a general overview of gain-loss asymmetries, see Peeters \& Czapinski, 1990).

However, the way prospect theory-more specifically, its mathematical formulation in cumulative prospect theory (CPT; Tversky \& Kahneman, 1992)—is usually implemented allows for asymmetries in the evaluation of positive and negative prospects to be represented also in other ways than via the value function. For instance, the parameters of CPT's weighting function, which translates objective probabilities into subjective decision weights, are typically estimated separately for the gain and the loss domain (e.g., Gonzalez \& Wu, 1999). Furthermore, it has been argued that choice sensitivity (i.e., how accurately choices between two alternatives reflect their subjective valuations) differs between options involving losses and those involving gains only (Yechiam \& Hochman, 2013a).

Crucially, these possible representations of gain-loss asymmetries within CPT have never been directly pitted against each other in a model-comparison analysis (Linhart \& Zucchini, 1986), where the descriptive power of a model is evaluated in light of its complexity (but see Harless \& Camerer, 1994; Stott, 2006). Conducting such a model comparison is our goal in this paper. To that end, we use CPT to model data collected by Glöckner and Pachur (2012), where 64 participants were asked to make choices between 138 two-outcome monetary gamble problems. \({ }^{1}\) Fitting different implementations of CPT to this data also allows us to test specific predictions of how a gain-loss asymmetry should be reflected in specific parameter patterns, such as choice sensitivity (Yechiam \& Hochman, 2013a) or probability sensitivity (Wu \& Markle, 2008). Next we provide a detailed description of CPT's parameter

\footnotetext{
\({ }^{1}\) In Glöckner and Pachur (2012) each participant made choices between 138 gamble problems at two separate sessions (separated by one week). Here we analyze the data from the first session.
}
framework, which we then use to formalize different ways to represent gain-loss asymmetries in risky decision making.

\section*{Cumulative Prospect Theory}

According to CPT, the possible consequences of a risky option are perceived as gains or losses relative to a reference point. The overall subjective value \(V\) of an option with outcomes \(x_{\mathrm{m}}>\ldots \geq x_{1}>0>y_{1}>\ldots>y_{\mathrm{n}}\) and corresponding probabilities \(p_{m} \ldots p_{l}\) and \(q_{1} \ldots q_{n}\) is given by:
\[
\begin{equation*}
V(A)=\sum_{i=1}^{m} v\left(x_{i}\right) \pi_{i}^{+}+\sum_{j=1}^{n} v\left(y_{j}\right) \pi_{j}^{-}, \tag{1}
\end{equation*}
\]
where \(v\) is a value function satisfying \(v(0)=0 ; \pi^{+}\)and \(\pi^{-}\)are decision weights for gains and losses, respectively, which result from a rank-dependent transformation of the outcomes' probabilities. The decision weights are defined as:
\[
\begin{align*}
\pi_{m}^{+} & =w^{+}\left(p_{m}\right) \\
\pi_{n}^{-} & =w^{-}\left(q_{n}\right) \\
\pi_{i}^{+} & =w^{+}\left(p_{i}+\ldots+p_{m}\right)-w^{-}\left(p_{i+1}+\ldots+p_{m}\right) \quad \text { for } 1 \leq i<\mathrm{m} \\
\pi_{j}^{-} & =w^{-}\left(q_{j}+\ldots+q_{n}\right)-w^{+}\left(q_{j+1}+\ldots+q_{n}\right) \quad \text { for } 1 \leq j<\mathrm{n} \tag{2}
\end{align*}
\]
with \(w^{+}\)and \(w^{-}\)being the probability weighting function for gains and losses, respectively (see below). The weight for each positive outcome represents the marginal contribution of the outcome's probability to the total probability of obtaining a better outcome; the weight for each negative outcome represents the marginal contribution of the outcome's probability of obtaining a worse outcome.

Several functional forms of the value and weighting functions have been proposed (see Stott, 2006, for an overview). In our analyses, we use the power value function suggested by Tversky and Kahneman (1992), which is defined as
\[
\begin{gather*}
v(x)=x^{\alpha}  \tag{3}\\
v(y)=-\lambda(-y)^{\beta}
\end{gather*}
\]

For \(\alpha\) and \(\beta\) usually values smaller than 1 are found, yielding a concave value function for gains and a convex value function for losses. The parameter \(\lambda\) reflects the relative sensitivity to losses versus gains and is often found to be larger than 1 , indicating loss aversion.

The weighting function has an inverse \(S\)-shaped curvature, indicating overweighting of unlikely events (i.e., those with a small probability) and underweighting of likely events (i.e., those with a moderate to high probability). Here we use a two-parameter weighting function originally proposed by Goldstein and Einhorn (1987), which separates the curvature of the function from its elevation (cf. Gonzalez \& Wu, 1999):
\[
\begin{array}{ll}
w^{+}(p)=\frac{\delta^{+} p^{\gamma^{+}}}{\delta^{+} p^{\gamma^{+}}+(1-p)^{\gamma^{\gamma}}} & \text { for } x  \tag{4}\\
w^{-}(q)=\frac{\delta^{-} q^{\gamma}}{\delta^{-} q^{\gamma-}+(1-q)^{\gamma}} & \text { for } y
\end{array}
\]
\(\gamma^{+}\)and \(\gamma^{-}\)(both \(<1\) ) govern the curvature of the weighting function in the gain and loss domains, respectively, and
indicate the sensitivity to probabilities. The parameters \(\delta^{+}\) and \(\delta^{-}\)(both \(>0\) ) govern the elevation of the weighting function for gains and losses, respectively, and can be interpreted as the attractiveness of gambling. In other words, \(\delta^{+}\)and \(\delta^{-}\)also indicate a person's risk attitude, with higher (lower) values on \(\delta^{+}\left(\delta^{-}\right)\)for higher risk aversion in gains (losses).

In addition to these core components of CPT, a choice rule is required when applying CPT to model binary choice. To derive the predicted probability of CPT that a gamble A is preferred over a gamble B we used an exponential version of Luce's choice rule:
\[
\begin{equation*}
p(A, B)=\frac{e^{\phi V(A)}}{e^{\phi V(A)}+e^{\phi V(B)}}, \tag{5}
\end{equation*}
\]
where \(\phi\) is a choice sensitivity parameter, indicating how sensitively the predicted choice probability reacts to differences in the valuation of gambles A and B. A higher \(\phi\) indicates more deterministic behavior; with \(\phi=0\), choices are random.

\section*{Modeling Gain-Loss Asymmetries}

As described in the previous section, the common approach to accommodate an asymmetric evaluation of positive and negative prospects is to assume a kinked utility function, for instance produced by \(\lambda>1\) (see also Usher \& McClelland, 2004; Ahn, Busemeyer, Wagenmakers, \& Stout, 2008). Note, however, that observed choices are modeled based on three intertwined components, a value function, a weighting function, and a choice rule, all of which could, in principle, represent an asymmetry between gains and losses. In the following, we describe how gain-loss asymmetries could be modeled within each these components.

\section*{Utility Accounts}

The formalization of CPT's value function allows for two ways to represent a gain-loss asymmetry.
Differential weighting of losses and gains Tversky and Kahneman's (1992) original version of CPT accommodates a gain-loss asymmetry using the loss aversion parameter \(\lambda\), with \(\lambda>1\) leading to a stronger impact of losses (relative to gains). As can be seen from Equation 3, the effect of \(\lambda\) is to multiplicatively magnify the utility of losses relative to the utility of gains, implying greater sensitivity to losses.
Differences in outcome sensitivity In many applications of CPT the exponent of the value function is estimated separately for gains and losses (cf. Fox \& Poldrack, 2008). If the latter (i.e., \(\beta\) in Equation 3) is higher than the former (i.e., \(\alpha\) in Equation 3), this could also lead to a kinked utility function, and thus a gain-loss asymmetry. Note that this pattern has been observed in studies that included pure gain and pure loss gambles (e.g., Abdellaoui, Vossmann, \& Weber, 2005).

\section*{Probability Weighting Accounts}

Equation 1 shows that according to CPT-as in other models in the expectation tradition-the evaluation of an
option closely ties the outcomes to their probabilities, as both are combined multiplicatively. Therefore, an apparent gain-loss asymmetry in the choices might also be represented by assuming differences between gains and losses in probability weighting (Zank, 2010; see also Birnbaum, 2008). Existing studies that have estimated the weighting function separately for gains and losses show that doing so indeed partly absorbs a gain-loss asymmetry (and might decrease the estimated value of \(\lambda\) ). In particular, the elevation is commonly found to be higher for losses than for gains (for an overview, see Fox \& Poldrack, 2008). Nevertheless, it is currently unclear to what extent estimating different weighting functions for losses and gains interacts with the estimation of the \(\lambda\) parameter and whether the increased model flexibility gained by adding more parameters actually leads to better predictive performance.
Differences in probability sensitivity Wu and Markle (2008) highlighted that an asymmetry might not necessarily exist between gains and losses, but between problems with mixed gambles and problems with single-domain gambles (i.e., those that offer either only gains or only losses). They found support for a version of CPT that allows probability sensitivity to differ between mixed and single-domain problems, with a lower probability sensitivity for mixed gambles than for single-domain problems. Moreover, Wu and Markle showed that this version of CPT can account for violations of gain-loss separability (that the evaluation of outcomes and their respective probabilities is done separately for the gain and the loss domains, as shown in Equation 1), which is a fundamental assumption in Tversky and Kahneman's (1992) original description of CPT.

\section*{Choice Sensitivity Account}

A radically different explanation for an asymmetry between the gain and the loss domain was proposed by Yechiam and Hochman (2013a). They argued that the somewhat inconsistent manifestation of loss aversion in risky choice studies might be due to the fact that processing information about potential losses increases the amount of attention allocated to the task at hand. According to Yechiam and Hochman, this should be reflected in a higher choicesensitivity parameter in problems involving losses (i.e., pure-loss gambles and mixed gambles) as compared to problems involving gains only. In a task in which participants responded to sequentially learned risks and using a reinforcement model, Yechiam and Hochman (2013b) found support for this hypothesis; to our knowledge, it has not been tested in the context of description-based tasks and using CPT as modeling framework.

\section*{Which Model Provides The Best Account?}

Several investigations have challenged the utility account of gain-loss asymmetries (e.g., Schmidt \& Traub, 2002; Yechiam \& Hochman, 2013a). However, one problem of these studies is that they focused on specific items and are thus silent with regard to the importance of the elements of
utility accounts (e.g., the loss aversion parameter) for CPT's ability to describe risky choices more generally.

For a more general test, one needs to compare different CPT implementations (representing alternative accounts of gain-loss asymmetries) and to determine which fares best in trading off model fit and model complexity (Myung, 2000).

Such a modeling analysis also allows us to test hypotheses concerning specific parameter patterns predicted by some of these accounts. For instance, according to the choice-sensitivity account by Yechiam and Hochman (2013a) choice sensitivity should be higher in tasks involving losses than in tasks involving gains only. This hypothesis has not been tested directly in the context of description-based tasks.

A second hypothesized parameter pattern follows from the probability weighting account proposed by Wu and Markle (2008), according to which the probability sensitivity (i.e. the curvature of the weighting function) is lower for mixed gambles than for single-domain gambles. Wu and Markle found support for this pattern using Tversky and Kahneman's (1992) one-parameter weighting function; one limitation of this function is, however, that curvature and elevation are confounded. Whether the hypothesized parameter pattern also emerges when using a function that allows to disentangle curvature and elevation (e.g., using the two-parameter weighting function described in Equation 4) has not yet been tested.

\section*{Modeling Approach}

To evaluate the different accounts of gain-loss asymmetries described above, we tested a total of 10 different implementations of CPT in their ability to describe people's risky choices. The implementations, which are summarized in Table 1, differ in terms of whether a gain-loss asymmetry is represented in the value function, the weighting function, or the choice rule.

Table 1: Versions of CPT tested.
\begin{tabular}{|c|c|c|c|c|c|c|c|c|}

& 0 \\
& 0
\end{aligned}
\] & &  \\
\hline \(\mathrm{CPT}_{\text {nola }}\) & \(\alpha\) & \(\gamma\) & \(\delta\) & & \(\lambda=1\) & \(\phi\) & & 4 \\
\hline \(\mathrm{CPT}_{1}\) & \(\alpha\) & \(\gamma\) & \(\delta\) & & \(\lambda\) & \(\phi\) & & 5 \\
\hline \(\mathrm{CPT}_{\text {ab }}\) & \(\alpha \quad \beta\) & \(\gamma\) & \(\delta\) & & \(\lambda=1\) & \(\phi\) & & 5 \\
\hline \(\mathrm{CPT}_{\mathrm{gd}}\) & \(\alpha\) & \(\gamma^{+} \gamma^{-}\) & \(\delta^{+}\) & \(\delta^{-}\) & \(\lambda\) & \(\phi\) & & 7 \\
\hline \(\mathrm{CPT}_{\text {d }}\) & \(\alpha\) & \(\gamma\) & \(\delta^{+}\) & \(\delta\) & \(\lambda\) & \(\phi\) & & 6 \\
\hline \(\mathrm{CPT}_{\text {dixi }}\) & \(\alpha\) & \(\gamma\) & \(\delta^{+}\) & \(\delta^{-}\) & \(\lambda=1\) & \(\phi\) & & 5 \\
\hline \(\mathrm{CPT}_{\mathrm{g}}\) & \(\alpha\) & \(\gamma^{+} \gamma^{-}\) & \(\delta\) & & \(\lambda\) & \(\phi\) & & 6 \\
\hline \(\mathrm{CPT}_{\text {gfixl }}\) & \(\alpha\) & \(\gamma^{+} \gamma^{-}\) & \(\delta\) & & \(\lambda=1\) & \(\phi\) & & 5 \\
\hline \(\mathrm{CPT}_{\text {phila }}\) & \(\alpha\) & \(\gamma\) & \(\delta\) & & \(\lambda=1\) & & \(\phi^{ \pm /-}\) & 5 \\
\hline \(\mathrm{CPT}_{\mathrm{gsm}}\) & \(\alpha\) & \(\gamma^{+V-} \gamma^{ \pm}\) & \(\delta\) & & \(\lambda\) & \(\phi\) & & 5 \\
\hline
\end{tabular}
\(\mathrm{CPT}_{1}\) can be considered as the standard implementation of CPT. It assumes the same exponent in the value function
(Equation 3) for gains and losses (i.e., \(\alpha=\beta\) ), but allows for a gain-loss asymmetry by having \(\lambda\) as a free parameter. \(\mathrm{CPT}_{1}\) uses one common set of curvature ( \(\gamma\) ) and ( \(\delta\) ) elevation parameters across the gain and loss domains. In a restricted version of \(\mathrm{CPT}_{1}, \mathrm{CPT}_{\text {nola }}, \lambda\) is set to 1 and thus assumes no gain-loss asymmetry. \(\mathrm{CPT}_{\text {nola }}\) will serve as a benchmark model. \(\mathrm{CPT}_{\mathrm{ab}}\) also sets \(\lambda\) to 1 but allows the exponents of the value function to differ between gains ( \(\alpha\) ) and losses ( \(\beta\) ).
\(\mathrm{CPT}_{\mathrm{gd}}\) is the model with the largest number of free parameters: it allows for differences between gains and losses both in curvature ( \(\gamma^{+}\)and \(\gamma^{-}\)) and elevation ( \(\delta^{+}\)and \(\delta^{-}\)) of the weighting function. The restricted versions \(\mathrm{CPT}_{\mathrm{d}}\) and \(\mathrm{CPT}_{\text {dixi }}\) allow a gain-loss asymmetry in the elevation only, thus assuming a single curvature parameter for gains and losses \(\left(\gamma^{+}=\gamma^{-}\right)\); in \(\mathrm{CPT}_{\text {dixi }} \lambda\) is set to \(1 . \mathrm{CPT}_{\mathrm{g}}\) and \(\mathrm{CPT}_{\text {gfixl }}\) allow a gain-loss asymmetry in the curvature of the weighting function only, thus assuming a single elevation parameter \(\left(\delta^{+}=\delta\right)\); for \(\mathrm{CPT}_{\text {gixix }} \lambda\) is set to 1 .
The two remaining models, \(\mathrm{CPT}_{\text {phila }}\) and \(\mathrm{CPT}_{\text {gsm }}\) implement the proposals by Yechiam and Hochman (2013a) and Wu and Markle (2008), respectively. \(\mathrm{CPT}_{\text {phila }}\) assumes a gain-loss asymmetry neither in the value function (i.e., \(\lambda=\) 1) nor in the weighting function ( \(\gamma^{+}=\gamma^{-}\)and \(\delta^{+}=\delta^{-}\)); instead, it allows for separate choice sensitivity parameters in gambles involving losses ( \(\phi^{ \pm-}\)) and gambles involving gains only \(\left(\phi^{+}\right)\). \(\mathrm{CPT}_{\text {gsm }}\) assumes no gain-loss asymmetry in the value function, but allows for different curvatures of the weighting function for single-domain gambles ( \(\gamma^{+\vee-}\) ) than for mixed gambles ( \(\gamma^{ \pm}\)).

The models were fitted to individual participants using the maximum-likelihood method. In order to avoid local minima, the optimization algorithm was supplemented with an initial grid search (considering up to 80,000 value combinations of the entire parameter space, with all parameters partitioned similarly).

To evaluate the models, we relied on the Bayesian Information Criterion (BIC), which penalizes a model as a function of its number of free parameters (Schwarz, 1978). The BIC of a given model is given by:
\[
\begin{equation*}
B I C=-2 \log (f(d \mid \hat{\theta}))+\log (N) k \tag{6}
\end{equation*}
\]
with \(d\) denoting the data, \(N\) the number of data points (i.e., the number of gamble problems), and \(k\) the number of free parameters in the model. BIC is an approximation of the Bayes Factor (Kass \& Raftery, 1995), providing a theoretically-principled framework for model comparison that takes into account goodness of fit as well as model complexity (e.g., Myung, 2000). A lower BIC indicates a better model fit.
Data We applied the different CPT implementations to model individual data in Glöckner and Pachur (2012). \({ }^{2}\) In

\footnotetext{
\({ }^{2}\) Note that while Glöckner and Pachur also compared some implementations of CPT, they neither tested Wu and Markle's (2008) sensitivity account, nor Yechiam and Hochman's (2013a) choice sensitivity account. More importantly, they also neither considered implementations of CPT in which only some of the
}
this study, 63 participants ( 25 male, mean age 24.7 years) indicated their preferences between 138 two-outcome monetary gamble problems that contained 70 pure gain, 30 pure loss, and 38 mixed gambles, all drawn from sets of gamble problems used in previously published studies (see Glöckner \& Pachur for details). The outcomes of the gambles ranged from \(-1000 €\) to \(1200 €\). At the completion of each session, one of the chosen gambles was picked randomly, played out and the participant received an additional payment proportional to the resulting outcome.

\section*{Results}

\section*{Is there a Gain-Loss Asymmetry in the Value Function?}

For the standard version of \(\mathrm{CPT}, \mathrm{CPT}_{1}\), which allows for a gain-loss asymmetry only through the loss aversion parameter, the median (across participants) best-fitting value of the \(\lambda\) parameter was substantially larger than \(1, \lambda=1.40\). \(71.9 \%\) of the participants had a \(\lambda\) larger than 1 . Moreover, \(\mathrm{CPT}_{1}\) showed a considerably better fit than \(\mathrm{CPT}_{\text {nola }}\), which does not allow for an asymmetry between gains and losses (median BIC: 158.34 vs. 160.23). These results thus provide evidence for a gain-loss asymmetry in the data.
Is choice sensitivity higher in gambles involving losses? As previously stated, Yechiam and Hochman (2013a) argue that due to differences in attention, choice sensitivity should be higher when the gambles include a potential loss. We tested this prediction by modeling the data with \(\mathrm{CPT}_{\text {phila }}\), which allows for a gain-loss asymmetry in choice sensitivity only. As it turned out, there was no evidence for Yechiam and Hochman's hypothesis; in fact, we find the opposite pattern, with a higher choice-sensitivity parameter for gains than for losses, median values \(\phi^{+}=0.18\) and \(\phi^{ \pm-}=0.09\), Wilcoxon test: \(W=2,609, p=.0008\) (two-tailed). This pattern of results was found for 58 of the 64 participants (91\%).
Is probability sensitivity lower in mixed gambles? Consistent with Wu and Markle's (2008) hypothesis, the estimates for \(\gamma\) obtained with \(\mathrm{CPT}_{\text {gsm }}\) indicated a lower probability sensitivity for mixed gambles than for singledomain gambles, median values \(\gamma^{+\mathrm{V-}}=0.58\) and \(\gamma^{ \pm}=0.86\), Wilcoxon test: \(W=2,928, p=.0001\) (two-tailed). Fortyeight out of 64 participants ( \(75 \%\) ) showed this pattern.

To summarize, these analyses indicate that people's choices reflect an asymmetry between gains and losses. Of two proposals concerning the specific nature of such asymmetries, we found support for only one, namely Wu and Markle's (2008) hypothesis that probability sensitivity is reduced in mixed as compared to single-domain gamble problems. Yechiam and Hochman's (2013a) proposal of a higher choice sensitivity for gambles involving losses was not supported (in fact, we found the opposite pattern). Next, we turn to the question of how well the different
parameters of the weighting function were estimated separately for gains and losses, nor implementations with a fixed \(\lambda\) parameter.
implementations of CPT summarized in Table 1 can account for people's choices. For instance, even if there is support for Wu and Markle's (2008) hypothesis of a lower probability sensitivity in mixed (as compared to singledomain) gambles, does an implementation of CPT allowing for this pattern (i.e., \(\mathrm{CPT}_{\mathrm{gsm}}\) ) also perform well in terms of BIC?

\section*{Model Comparison}

Figure 1 shows the median (across participants) BICs for each of the CPT implementations. As can be seen, the bestperforming model is \(\mathrm{CPT}_{\text {dfixl }}\), which allows for gain-loss asymmetries in the elevation of the probability weighting function but sets \(\lambda=1\). Figure 2 shows the probability weighting function of \(\mathrm{CPT}_{\text {dfixl }}\), based on the median bestfitting parameter values. The figure shows that this model represents a gain-loss asymmetry by having a more elevated weighting function for losses than for gains, \(\delta^{-}=1.69, \delta^{+}=\) 0.63 . Like models implementing the utility account, \(\mathrm{CPT}_{\text {dfixl }}\) gives more weight to losses than to gains, but does this via the decision weights resulting from the weighting function rather than via the value function. \(\mathrm{CPT}_{\text {dfixl }}\) not only achieved the best performance in terms of the median BIC, but also the overwhelming majority of individual participants ( \(54.7 \%\) ) were best accounted for by this model. \({ }^{3}\)

Figure 1: Performance of the different versions of CPT, as indicated by the median BIC (across participants)

\section*{Discussion}

One of the fundamental assumptions in prospect theory is that negative prospects receive more weight in people's evaluations of risky alternatives than positive prospects. In general, our analyses provide support for this assumption by

\footnotetext{
\({ }^{3}\) The second-best model in terms of selection frequency was \(\mathrm{CPT}_{\text {nola }}\), which best accounted for \(17.2 \%\) of the individual participants. Interestingly, the second-best performing model in terms of the median BIC, \(\mathrm{CPT}_{\mathrm{d}}\), best accounted for only \(4.7 \%\) of the participants.
}
finding evidence for a gain-loss asymmetry. However, we pointed out that the parametric menagerie of CPT can, in principle, represent gain-loss asymmetries in many different ways, such as via outcome sensitivity, probability sensitivity, the elevation of the weighting function, and choice sensitivity. Crucially, our analyses showed that a model that assumes a gain-loss difference in the elevation of the weighting function and a symmetric value function provided the best account of people's choices. The common assumption of a kinked utility function thus does not seem to be necessary. Other proposed implementations of CPT, such as one that attributes gain-loss asymmetries to differences in the choice rule (Yechiam \& Hochman, 2013a) or one that replaces the assumption of strict gain-loss separability by allowing for differences in probability sensitivity between single-domain and mixed gambles ( Wu \& Markle, 2008), were also clearly outperformed.

Figure 2: Shapes of the separate probability weighting functions for gains and losses of \(\mathrm{CPT}_{\text {dfixl }}\), the best performing model, when using the median best-fitting parameter estimates. The weighting functions differ only in terms of their elevation, which is higher for losses than for gains.

Our results seem to challenge the approach taken in previous tests of prospect theory that have focused on specific and individual gamble problems. For instance, using problems specifically designed to test gain-loss separability, Wu and Markle (2008) found evidence for a superiority of a version of CPT that allowed for different probability sensitivity in single-domain than in mixed gamble problems. By contrast, in the data set used here, where the gamble problems were not constructed to test specific assumptions of CPT (instead many of the gambles had been randomly generated; see Glöckner \& Pachur, 2012, for details), Wu and Markle's modified version of CPT performed rather poorly (Figure 1). The results of our model comparison thus suggest that model developments based on focused tests may sometimes sacrifice a model's
ability to account for choices more generally for its ability to account for idiosyncratic cases.

What does the superiority of the version of CPT with a more elevated probability weighting for losses than for gains (Figure 2) mean psychologically? The cognitive underpinnings of probability weighting are still rather little understood. This has led some researchers (e.g., Brooks \& Zank, 2005; Zank, 2010) to focus more on what can be called "behavioral gain-loss asymmetries", that is, specific choice patterns that follow from gain-loss asymmetries on the value and/or probability weighting functions.
These open questions notwithstanding, our results suggest that if one's goal is to predict how people will decide between risky alternatives, modeling gain-loss asymmetries in terms of differences in probability weighting rather than utility weighting promises to be a more successful approach. Our conclusions thus resonate well with Prelec's (2000) assessment that "probability nonlinearity will eventually be recognized as a more important determinant of risk attitudes than money nonlinearity." (p. 89)

\begin{abstract}
Previous studies of semantic implicit learning in language have only examined learning grammatical form-meaning connections where learning could have been supported by prior linguistic knowledge. Also, these studies assessed awareness by verbal report, which is arguably not the most reliable measure. Here we target the domain of verb meaning, specifically semantic preferences of novel verbs (e.g. a novel verb takes abstract objects). Using a reaction time methodology we show that after exposure to correct verb-noun combinations, reaction times to incorrect combinations are slowed down even for participants who are unaware of the semantic regularity. This effect was also obtained even when the semantic regularity was irrelevant to the tasks being performed, suggesting that the semantic generalisation is learned and exerts its influence automatically, hence satisfying one criterion for implicitness. Combined with a lack of verbalisable knowledge in any participant these experiments provide strong evidence for semantic implicit learning in language.
\end{abstract}

Keywords: implicit learning; consciousness; formmeaning connections; vocabulary learning; verb learning, second language acquisition; automaticity.

\section*{Introduction}

Most research on implicit learning has examined regularities at the level of form, be they in sequences of letters generated by artificial grammars, screen positions in repeating sequences, and in the domain of language, phonological (Dell et al., 2001) and orthographic (Pacton et al., 2001) patterns. This limits generalizability to other aspects of language learning where regularities might be conditioned by distinctions at the level of meaning, as opposed to form. Some research in visual perception has exposed semantic-based implicit learning, notably using the contextual cuing paradigm, where target locations are predicted from semantic properties of contexts, (Goujon, 2007). But can semantic implicit learning effects be obtained in the domain of language, especially in the adult language learner? Given arguments that even in children vocabulary acquisition requires declarative, explicit, memory
(Ellis, 1994) and shared attention (Bloom, 2000) one might suspect not. However, these arguments relate to learning referential meaning. Others have hypothesised that other aspects of word meaning, such as connotation and collocational behaviour, might be learned implicitly by the non-declarative system (Paradis, 2004). Here we test this proposal in the context of semantic preferences of verbs.

Previous research on semantic implicit learning in language has focused exclusively on article-noun agreement regularities (e.g. Williams, 2005; Leung \& Williams, 2012). This work has demonstrated sensitivity to the semantic properties of nouns in learning about the distribution of articles in miniature semi-artificial languages, and has provided evidence of implicitness of knowledge through postexperiment verbal report. The present experiments extend this work in terms of generalizability to other aspects of language, and in terms of methodology. We will discuss methodology in Experiment 2, but with regard to generalizability, there was evidence in these earlier experiments that implicit learning was dependent upon prior knowledge of article agreement systems in other languages (Williams, 2005). There was also evidence that learning depended on the semantic regularity in question, since effects were obtained for agreement based on animacy, but not on relative size (Leung \& Williams, 2012). Putting these two together one might argue that learning was dependent both on prior knowledge of the potential for article noun agreement, and on dispositions based on the "potentially encodable distinctions" that can be grammaticised in language (Bickerton, 1999). The question arises, therefore, whether similar effects could be obtained for an aspect of language that falls outside the realm of grammar, and is not so potentially affected by prior dispositions. This motivated the current investigation of learning the collocational behaviour, specifically semantic preferences, of novel verbs.

A semantic preference can be understood as a particular type of collocation, where collocation refers to higher than chance co-occurrence of two or more words. Collocates sound natural together and substituting one of them with a near-synonym results
in a loss of naturalness for native speakers. For example in English it is better to say fast car and fast food, rather than *quick car or *quick food. Conversely, it is more natural to say quick glance and quick meal instead of *fast glance or *fast meal. It has been traditionally proposed that collocations reflect syntagmatic relations between words, and are related to surface form, rather than paradigmatic relations regarding meaning (Firth, 1957). However, syntagmatic regularities may not be the optimal, or the sole way of accounting for the existence and acquisition of semantic preferences. After all, new collocates can be freely generated, as long as they follow implicit assumptions regarding applicable semantic sets. For example, knowing that pack collocates with dog, hounds, wolves etc. while swarm with bees, mosquitoes, bats, naturally suggests other animals which would be appropriate in either set. It makes sense therefore, to predict that the existence of such semantically preferred sets of collocates involves generalisations at a level higher than form. The question is, can such semantic generalisations be learned implicitly?

The present experiments used four novel verbs, powter, mouten, gouble, and conell. The participants were exposed to these verbs in verb phrases containing a direct object noun. Their task required them to think about whether the verb conveyed an 'increase' or 'decrease' meaning, either as inferred from the context (Experiment 1) or as they had learned before the experiment (Experiment 2). What they were not told was that powter and gouble took abstract collocates, whereas mouten and conell took concrete collocates (Table 1). For example, correct verb phrases would be powter the significance, gouble the power, mouten the calcium, conell the chocolate. We tested whether participants would learn the semantic preferences of these novel verbs implicitly using two techniques. Experiment 1 embedded the verb phrases in sentence contexts, and required participants to make an explicit concreteness decision on the nouns, and indicate whether the verb meant increase or decrease at the end of the sentence. The prediction was that after exposure to many correctly formed trials concreteness decision times and/or increase/decrease response times would be faster to new verb-noun combinations that respect the rule than to combinations that do not (e.g. powter with a concrete collocate such as compost). These will be referred to as the New Grammatical (NG) and New Ungrammatical (NU) conditions respectively. If learning is implicit then this effect would be obtained even for participants who evinced no awareness of the relevance of concreteness to the collocational behavior of the verbs, as assessed by a post-test.

In Experiment 2 participants saw only the verb phrases, but this time they had to decide whether the noun conveyed positive or negative connotations (a decision that is subjective and irrelevant to the hidden regularity). This was followed by the increase/decrease decision, as before. Any effect here would arguably provide stronger evidence for implicit learning, and would speak to the automaticity of the semantic activation underlying the effect.

\cline { 3 - 4 } & decrease & gouble & conell \\
\hline
\end{tabular}

\section*{Experiment 1}

\section*{Participants}

40 students of the University of Cambridge participated in the experiment. 17 were native speakers of English. All of the nonnative participants had achieved at least IELTS 7.5.

\section*{Materials and Procedure}

A total of 80 sentences were created, 20 for each novel verb, in which the verb conveyed either an 'increase' or 'decrease' meaning with respect to the object. For procedural reasons the word order was scrambled so that the verb phrase occurred at the beginning of the sentence. Examples are shown in Table 2.

Table 2. Example sentences from Experiment 1
\begin{tabular}{|l|}
\hline \begin{tabular}{l} 
POWTER the prestige of wealthy families, artists \\
can.
\end{tabular} \\
\hline \begin{tabular}{l} 
GOUBLE the role of nuclear weapons, Obama \\
stresses the need to.
\end{tabular} \\
\hline MOUTEN the nutrients you need, make sure you. \\
\hline CONELL the histamine stores, the sweating helps to. \\
\hline
\end{tabular}

The experiment comprised two blocks of trials, although the participants were not aware of any division between them. In the first block there were 44 training trials in which each novel verb occurred equally often. The collocates occurred with both increase and decrease verbs (e.g. POWTER the
prestige and GOUBLE the prestige occurred, but in different sentence contexts). Block 2 contained 32 critical trials in which the novel verbs occurred in new sentences and with new collocates not encountered in Block 1. Half of these items respected the semantic preference rule ("new grammatical", NG, condition), and half violated it, for example by pairing a concrete noun with POWTER ("new ungrammatical", NU, condition). The new collocates in the critical test items were chosen so as to be roughly synonymous with an object noun that occurred in the training phase (e.g. POWTER the importance occurred in training, and POWTER the significance occurred in test). Each object noun appeared only once in the critical trials. Assignment of items to conditions was rotated around two presentation lists so as to control for item effects. Block 2 also contained an additional 44 grammatical sentences so as to provide more reinforcement for the rule. These were sentences repeated from Block 1. The order of trials in Blocks 1 and 2 was independently randomized for each subject.

The sentences were presented word by word in the centre of the screen. First the noun, e.g. POWTER, was presented in capital letters for 600 msecs followed by the article the for 600 msecs . This was followed by a noun, e.g. prestige, in red lower case letters. The participants were instructed to indicate as quickly as possible whether this noun referred to an abstract or a concrete object by pressing the left or right buttons on a response box. If they made an error the word remained on the screen until they pressed the correct button. Upon a correct response the display changed to a recall prompt '__ the ___' and they had to recall the noun phrase aloud, i.e. say "powter the prestige". They then pressed a response button and the remainder of the sentence appeared at a rate of 600 msecs per word, e.g. of wealthy families artists can. At the end of the sentence the prompt +/appeared on the screen and the participants had to indicate as quickly as possible whether they thought the verb conveyed a broadly increase or decrease meaning by pressing the right or left buttons on the response box.

In order to assess awareness, at the end of the experiment the participants were presented with 8 new sentences from which the verb had been removed. They were asked to indicate which of the four novel verbs they thought should be used in that context and to think aloud as they made their decision. Any participant who referred to the abstract/concrete distinction, or similar, was classified as 'aware', regardless of their actual performance on the post-test.

The experiment was run using Superlab software and a Cedrus response box.

\section*{Results and Discussion}

Out of 40 participants, 13 revealed at least fragmentary explicit knowledge in the postexperiment debriefing, and were classified as 'aware'. The remaining 27 participants were classified as 'unaware'. For each participant, response times that were more than 2.5 standard deviations above the mean response time over the 32 critical trials were winsorized (i.e. replaced with the next highest value). Additionally, in cases where an error was made on the first (abstract/concrete) decision, the response on the second decision was removed from the analysis. This was because participants were likely to have been distracted on the subsequent increase/decrease decision by just having had to correct themselves.

An initial analysis of the data revealed that for both the aware and unaware groups there were no differences in either reaction time or error rate between the NG and NU conditions on the first, concrete/abstract, decision. This was rather surprising because we expected that if the regularity had been learned the verb would set up an expectation of a certain type of collocate. However, a significant NUNG reaction time difference was obtained on the second, increase/decrease, decision. After excluding two unaware participants with excessively long response times (of 3231 msecs and 3359 msecs ) the remaining 25 unaware participants had a mean response time of 1101 msecs in the NG condition and 1332 msecs in the NU condition, \(\mathrm{F}(1,23)=5.11, \mathrm{p}<\) \(0.05, \eta 2=0.20\). There was no difference in error rates ( \(25.2 \%\) and \(23.4 \%\) respectively). As for the aware participants, despite showing a large numerical difference between the NG and NU conditions on the increase/decrease decision (1478 msecs and 1611 msecs respectively) this difference was not significant, \(\mathrm{F}(1,11)=1.70, \mathrm{p}=0.23\). Neither was there an effect in errors ( \(22.5 \%\) and \(23.9 \%\) respectively).

A post hoc analysis was carried out to check for potential differences in performance between the native and non-native English-speaking participants. An ANOVA revealed no interaction between grammaticality and native/non-native speaker status, F \(<1.0\).

This experiment provides evidence of implicit learning of a semantic preference rule. The fact that learning effects are apparent on the decisions involving purely the indication of whether a
particular verb meant to 'increase' or 'decrease' is particularly compelling, since the decision was being made with reference to the meaning of the verb, not the collocate, and knowledge of the semantic preference rule does not directly inform this decision. This effect actually provides stronger evidence of the use of implicit knowledge than if it had occurred on the concreteness decision (a point which we will elaborate below).

Having said this, it is not clear how the effect of grammaticality on the increase/decrease decision arises. One possibility is that the mismatch between the verb and noun in the NU condition somehow disturbed the process of deriving the increase/decrease meaning from the verb and its context. It may also have caused confusion about the identity of the verb (since the collocate would have suggested other verb possibilities than the one that occurred). However, there is an alternative explanation that cannot be ruled out at this stage. The effect may not reflect learning of a semantic regularity at all, but rather associations between novel verbs and patterns of button presses (e.g. POWTER was associated with successive responses on the right-hand button). Experiment 2 was designed to rule out this possibility, as well as creating conditions under which awareness of the hidden regularity was much less likely to occur, and under which any effect of knowledge on behavior was more likely to reflect automatic, as opposed to controlled, behavior.

Even if we suppose that the effect obtained in Experiment 1 was semantic in origin, the question remains as to the nature of the generalization that was formed. Although the noun collocates in the critical test items were different from those that occurred in training they were in fact roughly synonymous with a noun that had occurred in the training phase. This means that it is hard to defend the claim that what was learned was a correlation between verbs and the abstract/concrete distinction as such. Rather the effect could have reflected the similarity between individual nouns in training and test. In order to address this issue, the noun collocates in Experiment 2 were changed so as to represent a more heterogeneous set of abstract and concrete nouns, and no noun in the test phase was a synonym of a noun in the training phase. Learning over these items would be more likely to reflect abstraction of a broad concreteness distinction.

\section*{Experiment 2}

This experiment employed a reaction time methodology similar to Experiment 1. Two main changes were made. First, a simplified procedure was employed in which only verb phrases were presented. Participants were informed about the increase/decrease meanings of the verbs prior to the experiment. The second change was that instead of making a concreteness decision on the collocates participants now had to indicate whether the collocate had positive, negative, or neutral connotation. For example, chocolate and holidays would be expected to receive positive judgments, whereas horror would be expected to receive a negative judgment. Participants were informed that the choices were subjective and that there was no correct answer. Crucially, the semantic preference rule was exactly the same as in Experiment 1; powter and gouble went with abstract nouns and conell and mouten with concrete nouns. Given that no systematic alignment between connotative meaning judgments and concreteness is expected this means that there will be no systematic relationship between the button pressed on the first decision and the second increase/decrease decision. Thus, learning is unlikely to be based on associations between nonsense verbs and patterns of button presses. This also means that any influence of noun concreteness on the second decision must reflect automatic activation of this aspect of meaning, rather than explicit retrieval as part of the task (as was the case in Experiment 1).

\section*{Participants}

46 students of the University of Cambridge participated in the experiment. Three participants were excluded due to problems with the task. Of the remaining group of 43 participants, 22 were native speakers of English. All of the nonnative participants had achieved at least IELTS 7.5.

\section*{Materials and Procedure}

The experimental design was identical to Experiment 1. The nouns for the training and test items were changed so as to comprise a more heterogeneous set of abstract and concrete nouns. The broadened category of abstract nouns included ones as different as happiness, wisdom, impact, understanding. The category of concrete nouns was similarly broadened to include, for example, chocolate, luggage, metal and paper. Only verb phrases were presented.

Participants were first informed about the increase/decrease meanings of the novel verbs. The
simplified procedure in Experiment 2 comprised the following sequence of events. First the verb was presented in capital letters for 600 msecs . This was followed by the word the for 600 msecs , followed by the noun in red. The participants made their decision about the connotation of the noun within an allocated time of 3 secs. Responses were entered on a millisecond accurate keyboard where \(M\) indicated 'positive', Z 'negative', and space bar 'neutral'. Upon making any response the noun was replaced by the 'inc/dec' prompt and the participant indicated whether the verb meant increase or decrease by pressing M and Z respectively. After every two stimuli participants received prompts that required them to recall out loud one of the phrases they had just seen. The prompt revealed either the first part of the phrase, for example "MOUTEN the \(\qquad\) ", or the second part: " the prestige", and participants were asked to pronounce the complete phrase. The memory task was to encourage full attention to the materials and the data were not analysed. All stimuli were presented in the centre of the screen. The experiment was followed by a posttest similar to that in Experiment 1.

\section*{Results and Discussion}

None of the participants appeared to have any awareness of the correlation between the novel verbs and the concreteness of the noun (whereas in Experiment \(132.5 \%\) of the participants were classed as aware). The data were treated in the same way as in Experiment 1. Two of the native participants were excluded on the basis of excessively long second decision response times. As before there were no reaction time effects on the first decision. This time there were no effects on the second, increase/decrease, decision either. Response times in the NG and NU conditions were 616 msecs and 627 msecs respectively, and error rates were \(6.1 \%\) and 6.7\% (note that reaction times were much faster than in Experiment 1, presumably because the decision was made immediately after the noun, rather than being delayed until the end of a sentence). When the data for the native English-speaking and non-native groups were compared an interesting pattern emerged. For the natives, reaction times in the NG and NU conditions were 556 msecs and 612 msecs , with error rates of \(7.2 \%\) and \(5.9 \%\). In contrast for the nonnatives the reaction times in the NG and NU conditions were 690 msecs and 655 msecs , with error rates of \(5.1 \%\) and \(7.4 \%\). An ANOVA was performed on the reaction time data with Group (native or nonnative) and Presentation List as between-subjects factors, and Condition (NG vs NU) as a withinsubjects factor. The interaction between Group and

Condition was significant, \(\mathrm{F}(1,37)=8.74, \mathrm{p}<0.01\), \(\eta 2=0.19\). Follow-up ANOVAs showed that the learning effect was only significant for the native speaker group \(\mathrm{F}(1,17)=9.13, \mathrm{p}<0.01, \eta 2=0.34\). There were no significant effects on errors.

Experiment 2 provides stronger evidence for semantic implicit learning than Experiment 1 because the learned generalisation was unrelated to the tasks being performed. Knowledge of the correlation between verbs and noun concreteness was unrelated both to the decision being made on the noun (connotative meaning) and to the increase/decrease decision. It has been argued that implicit knowledge should exert its influence on behaviour in an automatic rather than controlled way (Cleeremans \& Jimenez, 2002), and that the strongest test of implicit knowledge is to be obtained in situations where knowledge has an effect on performance even though it is irrelevant to the task at hand (Tzelgov, 1997; Vinter \& Perruchet, 1999). The present experiment seems to satisfy those criteria. Furthermore, on this occasion none of the participants demonstrated awareness of the semantic regularity in the post-test, which in itself suggests that the relevant knowledge was well below the level of awareness.

Experiment 2 also shows that the effects obtained in Experiment 1 were not due to learning associations between the novel verbs and patterns of keystrokes. This was because the nouns in the abstract and concrete categories would have elicited a range of 'positive' (M), 'negative' (Z) and 'neutral' (space bar) responses. Thus the effects must have had a semantic origin. Furthermore the learning effect in natives was obtained over sets of nouns that were more heterogeneous than in Experiment 1, and the critical test nouns were not synonyms of any nouns in training. Therefore the learning effect must have been supported by a broad generalisation, which we assume is essentially based on the abstract versus concrete distinction.

The fact that in this experiment learning was not obtained for non-native speakers is perhaps not surprising. There is a wealth of evidence that the mapping from second language words to meaning is less automatic than from first language words. For example, automatic semantic priming from second language words can only be obtained at very high levels of proficiency (Basnight-Brown \& Altarriba, 2007). Thus, in a situation in which a decision is made about one aspect of meaning it is not surprising that the non-natives in Experiment 2 did not activate other aspects of meaning with sufficient strength to produce a learning effect.

\section*{Conclusion}

The present experiments demonstrate that semantic implicit learning of linguistic regularities can be obtained outside of the realm of grammar, and can extend into learning about verb meaning. However, this is not to say that all aspects of word meaning have the potential to be learned implicitly. Paradis (2004) has proposed that learning referential meaning requires the declarative system, and hence presumably depends upon awareness of the connection between form and meaning. But other aspects of meaning, such as semantic preferences, could be acquired implicitly. Although it is not clear whether the kind of learning demonstrated here actually depends on the operation of the procedural system, as hypothesised by Paradis, the present results do show that this aspect of verb meaning is amenable to implicit learning.

It should also be stressed that the present experiments demonstrate learning semantic preferences in a situation in which some aspect of the meaning of the verbs (i.e., their increase or decrease meaning) is already explicitly known (as in Experiment 2) or being intentionally inferred from context (Experiment 1). Thus, we regard these learning effects as essentially reflecting the process of 'tuning' an already-established meaning of which the participants are aware. Whilst this tuning process undoubtedly forms an important part of word learning through usage, it has to be distinguished from the process of actually forming new form-meaning connections from scratch.

Finally, the fact that there was no semantic implicit learning effect in Experiment 2 for non-native speakers provides a cautionary note in relation to the role this process may play in second language acquisition. The implication is that semantic regularities will be most effectively learned when attention is drawn to the relevant aspects of meaning by the task. Otherwise semantic implicit learning effects may be limited unless semantic access from known words in the context is highly automatic. This does not mean, though, that learners have to be aware of the actual underlying regularities. Even if in some cases it may be necessary to be aware of both form and meaning, it is not necessary to be aware of the semantic generalisations that they license.

\title{
The role of verbal labels in attention to dimensional similarity
}

\begin{abstract}
In general, young children focus on holistic similarity and older children focus on dimensional similarity (selectively attending to one property, such as brightness, to the exclusion of others, such as size). Research on early word learning, however, suggests the process of learning words trains attention to category-relevant dimensions. We ask: does word learning scaffold dimensional attention more generally? By showing labels support dimensional attention, these results clarify the processes involved in similarity perception and unify our understanding of attentional processes in word learning with those in a broader context.
\end{abstract}

Keywords: Labels; categorization; selective attention.
Over the course of development, we become increasingly skilled at attending to one thing to the exclusion of others (see Hanania \& Smith, 2010 for review). For example, adults can easily focus on the color of a lime, rather than its exact shape or size, in order to distinguish it from a lemon. Evidence that older children and adults are generally much better than younger children at selectively attending to one dimension to the exclusion of others comes from a variety of domains, but we still do not know the process by which such changes occur. The goal of this paper is to explore the processes driving changes in selective attention with respect to their effects on similarity perception.

Of particular relevance to the current study is the holistic-to-dimensional shift, or the tendency for young children to focus on holistic similarity and older children and adults to focus on dimensional similarity relationships (Smith \& Kemler, 1977). Imagine you are presented with an orange, a yellowish-orange ball, and a yellowish-orange toy car. If you are an adult, you would be more likely to group the ball with the car because they match exactly along one dimension (i.e. identical in color). A young child, however, would group the orange with the ball because they are similar along multiple dimensions (i.e. shape and color)they are holistically similar. This shift in similarity perception occurs during the early school-age years, such that younger children ( \(<8\)-years-old) tend to be holistic classifiers and older children dimensional classifiers. Free classification, such as the triad classification task pictured in Figure 1, is the standard task used to examine this shift. As can be seen, two stimuli (A and B) match on one dimension (e.g. size) but vary greatly along another dimension (e.g. brightness). The third stimulus, C , is highly similar to A along both dimensions, but not identical to it on either. If a
participant were using holistic similarity, she would classify A and C together. If a participant were using dimensional similarity, she would classify A and B together. Smith and Kemler (1977) found that 5-6 year-olds made mostly AC matches and 10-11 year-olds made mostly AB matches.

Figure 1: Schematic representation of stimuli used in Smith and Kemler's 1977 triad classification task.

One explanation for this change comes from what we know about the role of word learning in the development of dimensional attention and categorization. For example, Landau \& Shipley (2001) demonstrated that when two objects are given the same label, participants generalize it to all intermediate morphs between the objects. If the two objects are given different names, participants divide the intermediates into two distinct categories. Lupyan and colleagues (2007) demonstrated that labels facilitated adults' category learning. Importantly, in this example, the labels were task irrelevant, providing information redundant with category structure. Other researchers have argued that redundant associations between cues strengthen the associations between other perceptual cues and category structure and that the facilitative effect of labels is fundamentally developmental (Yoshida \& Smith, 2005). By this view, over the course of word learning, the frequent redundancy between labels and other cues such as solidity, syntax, and category organization helps children use labels to facilitate learning. The more experience children have learning regularities in these overlapping cues, the better they can attend to relevant dimensions of similarity, at least in the context of further word learning.

This is most clearly seen in the development of wordlearning biases. For example, children acquire a shape bias, or the tendency to generalize names of novel objects by similarity in shape (Landau et al., 1988). This bias emerges from regularities present in the linguistic environment: a majority of the early words children learn name categories of solid objects organized by similarity in shape, e.g., ball.

As children learn more words, their attention is trained such that they automatically attend shape when learning names for solid objects. Smith and colleagues (2002) therefore describe word learning as "on-the-job training for attention," and have shown teaching children names of categories organized by similarity in shape leads them to precociously attend to shape when learning new words. As they learn words that name categories organized in other ways, e.g., names for nonsolids in categories organized by similarity in material or adjectives that name properties of objects, they acquire other biases and learn to flexibly attend to context-appropriate dimensions.

Over development, learning words directs children's attention to dimensional similarity in future word learning Thus, the critical unanswered question, however, is whether learning words also directs children's attention in nonlinguistic contexts. We propose word learning provides on-the-job training for attention more globally: in particular that labels scaffold dimensional attention in similarity perception. The regularity between words and attending to dimensional similarity leads to a higher-order association between labels and attending to dimensional similarity. According to our hypothesis, then, the tight links between labels, categorization, and dimensional similarity should gradually lead to a bias for dimensional similarity even outside of a labeling/word learning context. In 2 experiments we asked: 1) if there are developmental differences in category learning related to dimensional attention in similarity classification, and 2) if labels can support dimensional attention and facilitate categorization.

\section*{Experiment 1}

Experiment 1 examines if developmental differences in attention to dimensional similarity affect category learning.

\section*{Methods}

Participants 33 5- to 8 -year-old children participated. One child did not complete the experiment, thus there were 32 children in the final group.
Stimuli The stimuli were squares varying metrically in size and brightness (see Goldstone, 1994) and were presented on a pc with a touch screen monitor using Eprime 2.0.
Procedure Children completed a triad pretest and were divided into classifier groups based on performance on this task (Smith \& Kemler, 1977). There were 16 holistic classifiers (chose primarily holistic matches) and 16 dimensional classifiers (primarily dimensional matches).

Children next completed the category-learning task and category test. In the category-learning task children were presented with a square (a "rock") and asked to decide to which of two categories it came from (the ocean or jungle) by touching a picture on the computer screen. During the learning task, children received auditory feedback regarding accuracy of each decision (bell or buzzer sound). Learning blocks were made up of 8 trials, 4 trials for each category. Half of the children in each classification group were trained with categories organized by similarity in size (size
learners), half with brightness (brightness learners). The learning criterion was getting 7 out of 8 trials per block correct, 2 blocks in a row. If a child did not reach criterion after 30 blocks, the learning phase ended. The learning task was followed by the category test, where no feedback was given after each trial. Stimuli used at test included exemplars from training and 6 novel exemplars from each category. The test consisted of 4 blocks of 20 trials.

It was expected that dimensional classifiers would be able to learn the categories and generalize to novel category exemplars, but that holistic children should have more difficulty. For both groups, correct categorization of novel exemplars should require learning something about category organization rather than something about specific stimuli.

Next, children completed the discrimination task that measured their ability to distinguish between close values on test dimensions. Children were presented with a target and two test stimuli and asked to indicate which of the test stimuli matched the target by touching it. All three stimuli were present until the children responded. The target matched one of the test stimuli on every trial. Discrimination was tested both within and across category boundaries. All pairs were presented four times-each stimulus within a pair was presented twice as target and matching test item, and twice as foil-for a total of 96 trials. All children were presented with the same pairs, such that any given trial forced children to discriminate along a dimension that was only relevant for one group's learned category: e.g., a pair that differed only in size would test discrimination along the relevant dimension for the sizelearners and the irrelevant for brightness-learners. This allowed examination of changes in children's ability to make discriminations along category-relevant and irrelevant dimensions and within and between categories.

Finally, children completed a posttest triad task that was identical to the pretest version. Children who were dimensional classifiers on the triad pretest should still classify dimensionally as learning categories should not decrease their ability to selectively attend to dimensional similarity. Similarly, children who were holistic classifiers on the triad pretest should still classify holistically.

\section*{Results and Discussion}

Category learning It was expected that dimensional classifiers would be able to learn the categories but that holistic children would have more difficulty. To examine this, we measured the number of blocks to criterion for each child in the category-learning task (see Figure 2). A linear mixed regression model of the interaction between classifier type (holistic v. dimensional) and category structure (brightness v . size organization) on the number of blocks it took children to reach criterion, revealed a significant effect of classifier type such that dimensional classifiers were faster to reach criterion than holistic classifiers, \(t=21.88\), \(p<.0001\). (Because of the difficulty in determining degrees of freedom in linear mixed models, we conducted MCMC sampling to find p -values). This model also showed an
effect of category structure such that children were faster to reach criterion when learning categories organized by brightness, \(t=-23.00, p<.0001\). This brightness advantage replicates Goldstone's (1994b) finding with adults. There was also an interaction between classifier type and category structure such that holistic classifiers showed less of a difference in speed of learning brightness and size categories than dimensional classifiers, \(t=2.66, p<.01\). Thus, children who were able to selectively attend to a single dimension learned a novel category distinction based on one dimension faster than children who were holistic attenders. However, because dimensional classifiers were generally older than holistic classifiers, it is possible age could be the basis for these results. However, a model with both classifier type and age was significantly better than one with only age, \(X^{2}(1)=12659, p<.0001\), but no different from one with only classifier type. Thus classifier type, but not age, was necessary to account for findings.

We next examined performance in the other tasks using logistic mixed regression. These analyses included only data from children who reached learning criterion. We report results of classification groups separately because we are interested in whether dimensional and holistic classifiers both show, for example, enhanced between-category discrimination, than whether dimensional classifiers are more accurate than holistic classifiers. Because other researchers have found differences in learning brightness and size categories (e.g. Goldstone 1994), we examined performance of these groups separately. Results of regression models ( z and p values) are reported in Table 1.

Experiment 1: No Label
Experiment 2: Label
Figure 2: Number of blocks to criterion in category learning.
Category test We expected dimensional classifiers to generalize to new exemplars but that this should require learning something about category organization rather than about specific stimuli. Overall, children were very accurate in the categorization test. Dimensional classifiers who learned brightness categories, \(M=.87, t(7)=41.61, p<.0001\), dimensional classifiers who learned size categories, \(M=.77\), \(t(6)=4.98, p<.01\), holistic classifiers who learned brightness categories, \(M=.83, t(6)=6.33, p<.001\), and holistic classifiers who learned size categories, \(M=.70, t(4)=3.01, p<.05\), were all significantly better than chance.

Logistic mixed regression reveals that both dimensional classifiers who learned brightness and who learned size categories categorized familiar and novel stimuli equally well. Similarly, both holistic classifiers who learned brightness and who learned size categories categorized familiar and novel stimuli equally well. These results suggest both groups might have learned about the categoryrelevant dimension rather than specific stimuli.
Discrimination Goldstone (1994) found an advantage for relevant discriminations over irrelevant discriminations only for adults who learned brightness categories. Thus, while we expected dimensional classifiers would show worse withincategory discrimination along the irrelevant dimension and enhanced between-category discrimination, overall, we expected these results to be strongest for the brightness learners. Because it was predicted holistic classifiers would not be selectively attending to category-relevant dimensions, they should not demonstrate differences in discrimination on relevant versus irrelevant dimensions.

To examine changes in selective attention to categoryrelevant and irrelevant dimensions, we measured accuracy for each type of discrimination: between-category, withincategory along the relevant dimension and within-category along the irrelevant dimension. Overall, children were quite accurate in discriminating stimuli: dimensional classifiers who learned brightness categories, \(M=.82, t(7)=15.71\), \(p<.0001\), dimensional classifiers who learned size categories, \(M=.81, t(6)=6.27, p<.001\), holistic classifiers who learned brightness categories, \(M=.74, t(6)=5.96\), \(p<.001\), and holistic classifiers who learned size categories, \(M=.73, t(4)=5.04, p<.01\), were all significantly better than chance (.50) at discriminating stimuli.

A logistic mixed regression model of effect of discrimination comparison type (between, within relevant, within irrelevant) on accuracy revealed dimensional classifiers in the brightness learning group had significantly increased accuracy for between category compared to within category discriminations on either irrelevant, or relevant dimension. They were also more accurate at within-category discriminations along relevant than irrelevant dimensions, demonstrating, overall, they were more accurate at relevant than irrelevant discriminations. However, dimensional classifiers who learned size categories were no more accurate at between-category than within-category discriminations on either irrelevant, or relevant dimensions.

Holistic classifiers are thought not to selectively attend to category relevant dimensions. Therefore, they should not show the same pattern as dimensional classifiers. However, a logistic mixed regression model showed that holistic classifiers who learned brightness categories were more accurate at between category than within category discriminations along both the irrelevant, and relevant dimension. Additionally, these children were significantly more accurate at within-category discriminations along the relevant than the irrelevant dimension, demonstrating that overall, they were more accurate at discriminating across the relevant than the irrelevant dimension. Holistic classifiers

Table 1: Results of logistic mixed regression for Category Test, Discrimination (comparing between versus withincategory discriminations on the irrelevant and relevant dimensions and within-category discriminations on the relevant versus the irrelevant dimensions) and Triad Classification. z and p values/significance are reported for each model.

\hline
\end{tabular}
learning size categories had no accuracy differences. Thus, both groups' category learning affected their discrimination abilities-but only if they learned brightness categories.
Posttest triad We next examined results of the posttest triad task. The primary question of interest is whether there was a change in the number of dimensional matches children choose from pre- to posttest. Such a change indicates learning dimensional categories-which require the learner to selectively attend to one dimension to the exclusion of another-increased children's selective dimensional attention in similarity classification. It was predicted that the dimensional classifiers would not show an increase in dimensional responding from pre to post test because they were already attending dimensionally. A logistic mixed regression model showed neither dimensional classifiers who learned brightness nor size categories were more likely to choose dimensional matches during posttest than pretest.

Holistic classifiers were also predicted to not show an increase in dimensional responding, because they were not expected to be attending dimensionally in the categorylearning task. A logistic mixed regression model showed holistic classifiers who learned brightness categories had no increase in dimensional responding. However, those who learned size categories were marginally more likely to select dimensional matches during posttest. This suggests that perhaps these children did learn to selectively attend to size. Conclusions Learning to categorize stimuli along a dimension increases attention to that dimension and leads to changes in discrimination. We predicted that for this to happen, the learner has to be able to attend to the relevant dimension in the first place-which holistic classifiers were not expected to do. The results of the category-learning task support this idea, demonstrating holistic classifiers were slower to learn categories organized by a single dimension.

However the results of the discrimination and posttest triad tasks paint a more complicated picture. For example, holistic classifiers who learned brightness categories showed similar changes in their discrimination as the dimensional classifiers did, and holistic classifiers showed increases in dimensional responding in the posttest triad task. These results suggest that category learning on its own can facilitate dimensional attention. The critical question, then, is do labels work with category learning to boost it even more?

\section*{Experiment 2}

Results of E1 suggest holistic classifiers are slower to learn categories than dimensional classifiers, but they show some increases in dimensional attention following category learning. Research shows that young children can do this in the context of novel noun generalization (Smith et al., 2002). Furthermore, we know labels facilitate category learning in adults (Lupyan et al., 2007). If labels support the development of dimensional attention more generally, then we should see a facilitative effect of labels on holistic classifiers' category learning and perhaps an even greater facilitation of their dimensional attention. In E2, we examined category learning in the context of redundant labels and assess subsequent changes in attention.

\section*{Methods}

Participants 35 5-8-year-olds participated. 3 children did not complete the experiment ( 2 quit and 1 for equipment error), thus there were 32 children in the final group.
Procedure Methods were identical to E1, except during category learning, novel auditory category labels (leebish and grecious) were presented after feedback (the bell or buzzer) on each trial. These labels were redundant with category structure such that, for example, after each trial
where a rock belonging from the ocean was presented (regardless of correct categorization) the child would hear the "leebish" Results were analyzed as in E1.

\section*{Results and discussion}

Category learning As can be seen in Figure 2, a linear mixed regression model of the interaction between classifier type (holistic \(v\). dimensional) and category structure (brightness v . size organization) on the number of blocks it took children to reach criterion revealed no effect of classifier type, \(t=.04, N S\), nor of category structure, \(t=-.30\), NS. Thus, labels facilitate learning of dimensional categories, such that holistic classifiers were now as quick to reach criterion as dimensional classifiers.
Category test Both groups were very accurate: dimensional classifiers who learned brightness categories, \(\mathrm{M}=.84\), \(\mathrm{t}(6)=11.11, \mathrm{p}<.0001\), dimensional classifiers who learned size categories, \(\mathrm{M}=.86, \mathrm{t}(6)=15.16, \mathrm{p}<.0001\), holistic classifiers who learned brightness categories, \(\mathrm{M}=.85\), \(\mathrm{t}(6)=13.32, \mathrm{p}<.0001\), and holistic classifiers who learned size categories, \(\mathrm{M}=.69, \mathrm{t}(7)=4.30\), \(\mathrm{p}<.01\), were all significantly better than chance at categorization.

A logistic mixed regression model of trial type on categorization accuracy showed neither dimensional classifiers who learned brightness nor size categories were different in accuracy for familiar and novel stimuli. Similarly, neither holistic classifiers who learned brightness nor size categories were different in accuracy for familiar and novel stimuli. This suggests that all children may have learned something about category organization rather than about specific stimuli.
Discrimination Children were accurate in discriminating stimuli: dimensional classifiers who learned brightness categories, \(M=.83, \quad t(\sigma)=16.40, \quad p<.0001\), dimensional classifiers who learned size categories, \(M=.80, t(6)=10.90\), \(p<.0001\), holistic classifiers who learned brightness categories, \(\quad M=.76, \quad t(6)=7.42, \quad p<.001, \quad\) and holistic classifiers who learned size categories, \(M=.77, t(7)=6.27\), \(p<.001\), were all significantly better than chance.

A logistic mixed regression model of effect of discrimination type (between, within relevant, within irrelevant) on accuracy showed that dimensional classifiers in the brightness-learning group were more accurate at between category than within category discriminations for both irrelevant, and relevant dimensions. These children were also significantly more accurate at within-category discriminations along relevant than irrelevant dimensions. Dimensional classifiers who learned size categories were no more accurate at between category discriminations than at within category discriminations on either the irrelevant, or relevant dimension, nor were they more accurate at withincategory discriminations along either dimension.
A logistic mixed regression model showed that holistic classifiers who learned brightness categories were more accurate at between category, compared to within category, discriminations along both the irrelevant, and relevant dimensions. However, those in size learners did not show any differences in discrimination. Thus, all children showed
an effect of category learning on discrimination-but only if they learned brightness.
Posttest triad It was predicted that dimensional classifiers would not increase in dimensional responding from pre- to posttest. A logistic mixed regression model showed dimensional classifiers who learned brightness were no more likely to choose dimensional matches during the post test than on pretest. Interestingly, however, dimensional classifiers who learned size were more likely to choose dimensional matches during post test.

If labels drive attention to dimensions, holistic classifiers should show an increase in attention dimensional similarity. In fact, a logistic mixed regression model showed both holistic classifiers who learned brightness and size categories increased in dimensional responding.
Conclusions Incidental labels in a category-learning task scaffolded selective attention to dimensional similarity. Unlike in E1, holistic and dimensional classifiers are equally quick to learn the categories. Holistic classifiers have relatively weak selective attention and take longer to learn dimensional categories. Once they learn the categories, however, they show slight increases in dimensional attention-as evidenced by discrimination accuracy and increases in dimensional classification. Labels support even weak selective attention, thus when holistic classifiers learn dimensional categories in the context of labels, they learn the categories more quickly. This increase in selective attention cascades forward to both their discrimination abilities and classification biases. So, as Lupyan suggested in his 2008 study of category grouping on visual processing, "categories matter; named categories matter more." A direct comparison of holistic classifiers from the two experiments should clarify the extent to which performance of those in E2 is, in fact, significantly better than those in E1.

\section*{Between-experiment comparison}

Category learning A linear mixed regression model of the interaction between experiment (label v. no label) and category structure (size v. brightness) on the number of blocks to reach learning criterion revealed holistic classifiers were significantly faster to reach criterion in the label than in the no label experiment, \(\mathrm{t}=-26.57, \mathrm{p}<.0001\). There was an overall effect of category structure, such that children were faster to learn brightness than size categories, \(\mathrm{t}=-23.66\), \(\mathrm{p}<.0001\), however, there was also an interaction such that children in the label experiment showed less difference in speed of learning the two category types than those in the no label experiment, \(\mathrm{t}=7.47, \mathrm{p}<.0001\). This is direct evidence that labels facilitate category learning in children who have difficulty attending to dimensional similarity.
Category test A mixed logistic regression model of the interaction between experiment (label versus no label) and trial type (familiar or novel) on children's categorization revealed that neither holistic classifiers who learned brightness nor size categories showed an effect of experiment. Thus, children were equally accurate at categorizing familiar and novel stimuli.

Discrimination If labels facilitate category learning because they increase children's selective attention to categoryrelevant dimensions, then children in the label experiment should show the biggest enhancement in accuracy for relevant over irrelevant discriminations. A logistic mixed regression model of the interaction between experiment (label v. no label) and discrimination type (between, withinrelevant, or within-irrelevant) revealed that children in the label experiment showed a larger difference in accuracy in between-category discriminations relative to withincategory discriminations on the relevant dimension, and relative to within-category discriminations on the irrelevant dimension. However, size learners did not show an effects of experiment. This demonstrates (for brightness learners) the presence of a label made effects of categorization on discrimination stronger. Labels increase selective attention to dimensions above and beyond category learning.
Posttest triad If word learning drives the emergence of selective attention to dimensions over development, then when labels are presented during category learning we may also see indices of these changes in attention over the course of an experiment. Therefore holistic classifiers in the label experiment should show the largest increases in dimensional responding from pre- to posttest triad task. This was supported by logistic mixed regression models of the effect of experiment (label v. no label) on change in dimensional responses from pre- to posttest triad revealing that both holistic classifiers who learned brightness and size categories had a larger increase in dimensional responding from pre- to posttest in the label experiment. The presence of a label not only immediately facilitated category learning, but also led to cascading changes in similarity classification.

\section*{Conclusions}

Results of the comparison analyses demonstrate the extent to which labels support selective attention above and beyond category learning by demonstrating that holistic classifiers were significantly faster to learn in the presence of labels. Similarly, while the qualitative assessment of E1 and 2 demonstrated both groups of holistic classifiers who learned brightness categories showed the "adult" pattern found by Goldstone (1994), the comparison analysis shows that those in the label experiment demonstrate a more extreme pattern. This suggests category learning affects attention to dimensions, but labeled category learning affects it more. Finally, comparison of changes in dimensional responding in the triad task offers additional evidence that labels scaffold attention to dimensional similarity above and beyond category learning. The only difference between the two experiments was the presence of incidental, redundant, labels during category learning. Yet this was enough to change children's pattern of responding in an unrelated similarity classification task.

Overall, these analyses generally demonstrate that while category learning supports selective dimensional attention even in children who preferentially attend to holistic similarity, labeled category learning exaggerates
this process, facilitating both category learning and attention to dimensional similarity. However, one important remaining question that needs to be addressed by future research is why category learning and labeled category learning only have these effects when the categories are organized by brightness and not size. While our results replicate Goldstone's 1994 findings with adults, it is still unclear why brightness is easier to learn and why learning brightness, but not size, should lead to differences in discrimination abilities.

Our results clearly demonstrate that labels can scaffold this attention in similarity classification, suggesting that, as in the case of early word learning biases, regularities between labels, categories, and similarity lead to selective attention to dimensions. Future research will be needed to further explore how children can eventually do this without any external linguistic support. Nevertheless, these experiments are an important first step in unifying our understanding of the attentional processes involved in early word with those in a broader context.

\begin{abstract}
A remarkable property of human cognition is the systematic co-occurrence of certain cognitive abilities. One challenge for cognitive science is to determine the (computational) principles that derive this property as part of a broader goal of establishing the foundations of cognitive architecture (i.e. the basic processes and modes of combination affording cognitive capacity) for a science of cognition. This paper continues a category theory approach to compositionality and cognitive capacity that posits universal construction (e.g., products) as a fundamental cognitive architectural component. As shown here, products can be modeled in other frameworks, thereby providing a link between an abstract computational principle and a concrete cognitive resource needed for particular capacities. For example, a network of weighted connections implementing a categorical product uses fewer resources when the number of task instances sharing a common product structure is greater than two; otherwise it is more economic to realize each instance independently. This cross-over may explain why human cognition is not always systematic: the cost of universal construction may not outweigh its expected gain.
\end{abstract}

Keywords: category theory; cognitive capacity; compositionality; systematicity, similarity; product; universal construction

\section*{Introduction}

A remarkable property of human cognition is the systematic co-occurrence of certain cognitive abilities. For example, if one has the ability to infer square as the first shape in the pair (square, triangle), then one also has the ability to infer triangle as the first shape in the pair (triangle, square), assuming that squares and triangles are recognizable. This property is called systematicity (Fodor \& Pylyshyn, 1988), and is characterized as having capacity \(c_{1}\) if and only if \(c_{2}\) (McLaughlin, 2009), i.e., as an equivalence class of cognitive capacities.

For cognitive science, a major challenge has been to explain why cognitive capacity is systematically distributed in a particular (non-arbitrary) way. The main theoretical frameworks propose some form of compositionality to explain systematic cognitive capacity. The classical (symbol system) explanation is that cognitive processes are sensitive to grammatical structure (Fodor \& Pylyshyn, 1988). Thus, the two shape capacities (above) are inseparable because they involve a common process: say, \((p, q) \rightarrow p\), where \(p\) and \(q\) are symbols for squares and triangles, on the assumption of having component processes \(\square, \triangle \rightarrow p, q\) for recognizing squares and triangles. \({ }^{1}\) Similarly, a connectionist (neural network) account of capacity can make use of common processes in

\footnotetext{
\({ }^{1}\) Systematicity pertains to "molecular" not "atomic" capacities, hence that an architecture permits the recognition of squares, but not triangles, is not a counterexample to having the systematicity property (Fodor \& Pylyshyn, 1988).
}
the form of activation units and weighted connections modeling cognitive processes that are sensitive to spatial structure (Phillips \& Wilson, to appear). In this case, the two shape capacities factor through a common (sub)network of weighted connections that map (neuronal) vector representations of shape pairs to first shapes. Although classical and connectionist models can be constructed such that capacity \(c_{1}\) if and only if \(c_{2}\), systematicity doesn't necessarily follow from classical, or connectionist principles: one can also devise models from those principles such that \(c_{1}\), but not \(c_{2}\). Additional, ad hoc (i.e. arbitrary) assumptions are needed to exclude models that lack systematicity. So, classical and connectionist theories (principles) fail to fully explain systematicity (Aizawa, 2003).

Another approach to the systematicity problem (Phillips \& Wilson, 2010, 2011, 2012) used a mathematical theory of structure, called category theory (Mac Lane, 2000). In category theory, a universal construction relates a collection of arrows (interpreted as cognitive processes) via a common mediating arrow (cognitive process) in a unique way. Hence, all capacities are indivisibly linked to this mediating arrow as the common component. The mediating arrow is associated with an equivalence class of systematically related cognitive capacities (Phillips \& Wilson, 2011, Text S4).

This paper further explores a categorical approach to compositionality and cognitive capacity by looking at the relationship between universality and cognitive resources. First, our category theory approach to the systematicity problem, and related models, are recalled to motivate its continued use here. Then, the relationship between a specific universal construction (product) and the resources needed for implementation are examined: fewer resources are needed when the number of task instances sharing a product is greater than two; otherwise, it is cheaper to realize each task instance independently. The implications of this relationship for development (learning) are discussed in the final section.

\section*{Compositionality and universal constructions}

Definitions of category and product are provided in this section. Other definitions are provided in Appendix A. Deeper introductions to category theory can be found in many books on the subject (see, e.g., Mac Lane, 2000; Simmons, 2011).

\section*{Category theory and cognition}

Category theory starts with a definition of a category, which is a collection of objects and relations between objects, called arrows (or morphisms, or maps). The category theory approach to cognition presented here regards a cognitive archi-
tecture (i.e., the basic component processes and the ways in which those processes are combined) as a category (of possibly other categories), where objects are interpreted as components of the architecture and arrows are relations between those components. For instance, an object may be a set of cognitive representational states and an arrow may be a function between two sets of states (objects) that transforms cognitive representations (states).
Definition (Category). A category \(\mathbf{C}\) consists of:
- a class of objects \(|\mathbf{C}|=(A, B, \ldots)\);
- for each pair of objects \(A\) and \(B\) in \(\mathbf{C}\), a set \(\mathbf{C}(A, B)\) of morphisms (also called arrows, or maps) from \(A\) to \(B\), where each morphism \(f: A \rightarrow B\) has \(A\) as its domain and \(B\) as its codomain, including the identity morphism \(1_{A}: A \rightarrow A\) for each object \(A\); and
- a composition operation, denoted " \(\circ\) ", of morphisms \(f\) : \(A \rightarrow B\) and \(g: B \rightarrow C\), written \(g \circ f: A \rightarrow C\) that satisfies the laws of:
- identity, where \(f \circ 1_{A}=f=1_{B} \circ f, \forall f: A \rightarrow B\); and
- associativity, where \(h \circ(g \circ f)=(h \circ g) \circ f, \forall f: A \rightarrow\) \(B, g: B \rightarrow C, h: C \rightarrow D\).

An example of a category is Set, which has sets for objects and total functions for arrows, where the identities are the identity functions and composition is function composition. Set is used here to model cognitive architecture as a collection of sets of representational states and cognitive processes as functions sending states to states, where identities are "do nothing" functions.

Most models of cognition support some kind of compositionality that affords the representation of a pair of entities from which the constituent entity representations are recoverable. In category theory, a basic kind of (universal) construction of a pair of objects from which the component objects are recoverable is called a product. \({ }^{2}\)
Definition (Product). In a category \(\mathbf{C}\), a product of two objects \(A\) and \(B\) is an object \(P\) (also denoted \(A \times B\) ) together with two morphisms \(p_{1}: P \rightarrow A\) and \(p_{2}: P \rightarrow B\), such that for every object \(Z \in|\mathbf{C}|\) and every pair of morphisms \(f: Z \rightarrow A\) and \(g: Z \rightarrow B\), there is a unique morphism \(u: Z \rightarrow P\) (also denoted \(\langle f, g\rangle\), since it is determined by \(f\) and \(g\) ), such that \(f=p_{1} \circ u\) and \(g=p_{2} \circ u\), as indicated in commutative diagram \({ }^{3}\)

\footnotetext{
\({ }^{2} \mathrm{~A}\) closely related construction involving pairs of objects is called coproduct, which is obtained by reversing the directions of the arrows in the definition of product (Mac Lane, 2000).
\({ }^{3}\) I.e. where all pairs of paths (one or both having more than one arrow) from the same start object to the same finish object are equal.
}

In Set, the Cartesian product of sets \(A\) and \(B\) is the set \(A \times B=\{(a, b) \mid a \in A, b \in B\}\) together with functions \(p_{1}\) : \((a, b) \mapsto a\) and \(p_{2}:(a, b) \mapsto b\) recovering the first and second elements of each pair is a product. Accordingly, for any set \(Z\) and functions \(f\) and \(g\) there is a unique function, called the product function, \(\langle f, g\rangle: z \mapsto(f(z), g(z))\), that maps each element \(z \in Z\) to the pair of elements \((f(z), g(z))\) with the desired elements \(f(z) \in A\) and \(g(z) \in Z\) recoverable via \(p_{1}\) and \(p_{2}\). Projections \(p_{1}\) and \(p_{2}\) are part of this universal construction; they are the same functions employed for every \(Z, f\) and \(g\). Cartesian product is an instance of categorical compositionality, and a concrete example of deriving systematicity with regard to the shape-pairs example (see next).

\section*{Categorical compositionality and systematicity}

A challenge for cognitive science is to explain why cognitive capacity is organized in a particular way: e.g., why is it that if one can infer square as the first shape in the pair (square, triangle), then one can infer triangle as the first shape in the pair (triangle, square), given that they can recognize squares and triangles; yet, the capacity to infer squares and triangles is independent of the capacity to count? The general, categorytheoretic claim is that underlying every collection of systematically related cognitive capacities is a universal construction of some kind. Each member of a collection of systematically related capacities is realized by two cognitive components: a common component and a unique capacity-specific component. \({ }^{4}\) The presence or absence of the common arrow implies the presence or absence of the entire collection of capacities. For the shapes example, the common arrow(s) corresponds to a capacity to retrieve the first and second elements of a pair, and the unique arrow corresponds to recognition of specific shape instances. By contrast, the capacity to count involves a different kind of universal construction (Phillips \& Wilson, 2012), and hence a different mediating arrow.

\section*{Models of categorical compositionality}

The relationship to the above categorical theory of compositionality and systematicity to specific (classical, or connectionist) models is analogous to a relationship in categorical algebra, where a model of (say) a theory of groups is a functor (a structure-preserving map, see Appendix A) from a category representing the theory and a category capturing the semantics of the model, e.g., Set, where the group is based on elements of a set (Lawvere, 1963). A (classical or connectionist) model of categorical compositionality and therefore systematicity is a functor from a universal construction (as a category) to a particular concrete category of cognitive representations and processes. \({ }^{5}\)

Returning to the shape example, suppose we model cognitive architecture in the category Set where objects are sets of cognitive representations and arrows are cognitive processes

\footnotetext{
\({ }^{4}\) See Appendix A for the general form of universal construction.
\({ }^{5}\) Functors compose, so a model at one level may be construed as a theory (functor image as a category) relative to a model of that theory at another level (functor from it into another category).
}
mapping representations. Consider the collection of objects and arrows (identities not shown) in Diagram 1 as a category (theory). A functor (model) of this category into Set is indicated by commutative diagram

where \(S=\) \{square, triangle \(\}\) is a set of elements representing square and triangle, \(S \times S=\{(\) square, triangle \(), \ldots\}\) is the set of all pairwise combinations of square and triangle, \(Z=\{\square \triangle\}\) is a singleton set containing the image of a square to the left of a triangle, \(Z^{\prime}=\{\triangle \square\}\) is a singleton set containing the image of a triangle to the left of a square, \(f\) st \(: \square \triangle \mapsto\) square maps the image of a square and triangle to square, snd \(: \square \triangle \mapsto\) triangle maps the image of a square and triangle to triangle, and \(u=\langle f s t, s n d\rangle: \square \triangle \mapsto\) (square, triangle). Functions \(f s t^{\prime}\) and \(s n d^{\prime}\) are defined similarly. Systematicity is realized by common mediating functions (projections) \(p_{1}\) : (square, triangle) \(\mapsto\) square, \(\ldots\) and \(p_{2}\) : (square, triangle) \(\mapsto\) triangle, \(\ldots\). This model can be regarded as classical where each element is a symbol, and the constituents of the complex symbols for each pair are tokened whenever each pair is tokened-classical compositionality.

Another model is obtained from the category Vec of vector spaces for objects and linear functions for arrows. In the case of the objects and arrows in Diagram 2, suppose \(S\) is a vector space over the field of real numbers containing vectors \(\vec{s}\) and \(\vec{t}\) representing square and triangle, respectively. Likewise, suppose \(Z\) and \(Z^{\prime}\) are vector spaces containing vectors \(\overrightarrow{s t}\) and \(\vec{t} s\) representing the images \(\square \triangle\) and \(\triangle \square\), respectively. A product object in Vec is a product vector space. Hence, \(S \times S\) is a product vector space of vector space \(S\) with itself containing all pairwise products of vectors \(\vec{s}\) and \(\vec{t}\), e.g., \(\vec{s} \vec{t}\) and \(\vec{t} \vec{s}\), etc. In this model, the arrows are linear functions mapping vectors in one space to vectors in another space. Specifically, \(f s t: \overrightarrow{s t} \mapsto \vec{s},\langle f s t, s n d\rangle: \overrightarrow{s t} \mapsto \vec{s} \vec{t}, p_{1}: \vec{s} \vec{t} \mapsto \vec{s}\) and \(p_{2}: \vec{s} \vec{t} \mapsto \vec{t}\) (similarly for the other arrows). If we choose particular bases for these vector spaces, then we have a category of coordinate spaces, and the linear functions are realized as matrices, where the identities are identity matrices and composition is matrix multiplication. Further, if we identify each basis vector with a neuron, hence each object is a collection of real-valued neurons, and each matrix as a matrix of weighted connections between neurons in different objects, then we have a connectionist network realizing this model. Systematicity is realized by common linear functions \(p_{1}\) and \(p_{2}\). Note that there is no requirement that constituent vectors be tokened whenever their host product vectors are tokened (e.g., the coordinates specifying \(\vec{s}\) are not necessarily a subset of the coordinates specifying \(\vec{s} \vec{t}\) )—connectionist (functional) compositionality.
The vector spaces and linear functions in this Vec-based model of compositionality contain many more vectors and
mappings than may be needed as a model of cognitive capacity. A further connectionist refinement of the model may be to add connections between neurons within an object, e.g., as in a Hopfield network (Hopfield, 1982), so as to restrict the number of representational states to just those needed (in the shape example, two vectors representing square and triangle for the object \(S\), and four vectors representing each pairwise combination of square and triangle for the product object \(S \times S\) ). In this case, we have networks (not just collections of neurons) for objects, whence we need some kind of structurepreserving map for arrows satisfying the usual axioms to be a category. However, not just any combination of objects and arrows constitutes a product (see next). One possibility, for further work, is to extend the category \(\mathbf{G p h}\) of graphs and graph homomorphisms, which has products, \({ }^{6}\) by considering a connectionist network as a graph with additional structure. \({ }^{7}\)

\section*{(Non-)Universality and cognitive capacity}

Understanding the relationship between universal constructions, systematic cognitive capacity and cognitive resources requires a specific model of categorical compositionality that gives meaning to a concept of cognitive resource. An example of compositionality that does not involve a universal construction follows. Suppose a Set-based model of the shape-related capacities, shown in Diagram 3, that consists of an object \(T=\left\{t_{1}, t_{2}\right\}\) and arrows \(g_{1}: Z \rightarrow T ; \square \triangle \mapsto t_{1}\), \(h_{1}: T \rightarrow S ; t_{1} \mapsto\) square, \(t_{2} \mapsto\) triangle and \(h_{2}: T \rightarrow S ; t_{1} \mapsto\) triangle, \(t_{2} \mapsto\) square, where composition \(h_{1} \circ g_{1}\) correctly infers square as the first object from image \(\square \triangle\) and \(h_{2} \circ g_{1}\) correctly infers triangle as the second object from image \(\square \triangle\). Likewise, suppose arrow \(g_{2}: Z^{\prime} \rightarrow T ; \triangle \square \mapsto t_{2}\), where composition \(h_{1} \circ g_{2}\) correctly infers triangle as the first object from image \(\triangle \square\) and \(h_{2} \circ g_{2}\) correctly infers square as the second object from image \(\triangle \square\). The object \(T\) together with arrows \(h_{1}\) and \(h_{2}\) do not constitute a product, because for object \(Z^{\prime \prime}=\{\square \square\}\) and arrows \(f s t^{\prime \prime}: Z^{\prime \prime} \rightarrow S ; \square \square \mapsto\) square and snd \(d^{\prime \prime}: Z^{\prime \prime} \rightarrow S ; \square \square \mapsto\) square there does not exist an arrow \(u^{\prime \prime}: Z^{\prime \prime} \rightarrow T\) such that \(h_{1} \circ u^{\prime \prime}=f s t^{\prime \prime}\) and \(h_{2} \circ u^{\prime \prime}=s n d^{\prime \prime}\). This arrangement does not support the systematically related capacities of inferring square as the first and second shapes from the image \(\square \square\). (A similar lack of systematicity also applies for image \(\triangle \triangle\), etc.)

In general, for a network that dedicates one unit for each element of each set, the number of units required to represent

\footnotetext{
\({ }^{6}\) A categorical product of two unlabeled graphs \(G\) and \(H\) is the Cartesian product of their nodes with edges between pairs of nodes just in case their is an edge between the first node of each pair in \(G\) and an edge between the second node of each pair in \(H\).
\({ }^{7}\) See Ehresmann and Vanbremeersch (2007) for a category theory description of neurons and systems, and Healy et al. (2009) for an application to neural network modeling.
}
a categorical product of sets \(A\) and \(B\) is the size of set \(A\) times the size of set \(B\). This additional cost in resources to represent a universal construction raises the question of why a cognitive system would incur such an expense. As shown in the next section, implementing a categorical product becomes cheaper when the number of task instances sharing a common product structure exceeds a certain number. That number depends on the relative costs of representing the task-common and taskspecific components.

\section*{Resources and (non-)universal constructions}

A simple calculation for the resources needed to realize a sequence of task instances with a common product structure using non-universal versus universal constructions reveals a cross-over point. Suppose a sequence of tasks such that each task \(i \in\{1,2,3, \ldots, n\}\) consists of two maps \(f_{i}: Z_{i} \rightarrow A\) and \(g_{i}: Z_{i} \rightarrow B\). Consider a cognitive system without the capacity for constructing products. To realize \(n\) such tasks, a cognitive system must implement \(2 n\) functions (i.e. two functions for each task instance). Consider a second architecture with the capacity to construct a product \(\left(A \times B, p_{1}, p_{2}\right)\). In this case, the \(n\) tasks are realized by the two projections \(p_{1}: A \times B \rightarrow A\) and \(p_{2}: A \times B \rightarrow B\), and the \(n\) unique functions \(u_{i}: Z_{i} \rightarrow A \times B\), totalling \(n+2\) functions. Thus, the advantage of constructing products is obtained when \(n>2\), i.e. when the cognitive system must have a capacity for three or more task instances sharing the same product structure.

The precise relationship between cognitive resource and systematic cognitive capacity will depend on the underlying model and the kind of universal construction. The general form of a universal construction (given in Appendix A) with respect to a functor \(F\) is a pair \((A, \phi)\) such that each capacity \(f: F(Z) \rightarrow Y\) is composed of a common component \(\phi: F(A) \rightarrow Y\) and a unique component \(F(u): F(Z) \rightarrow F(A)\) such that \(f=\phi \circ F(u)\). Hence, the number of task instances \((n)\) at which fewer resources are deployed to realize capacity via a universal construction will depend on the relative costs of realizing components \(\phi, F(u)\) and \(f\). The benefit of universal constructions is more pronounced when the most expensive part of realizing \(f\) is with \(\phi\), since the \(\phi\) construction is only required once, whereas one \(F(u)\) component is required for each task instance. In general, computing with universal constructions over \(n\) tasks becomes cheaper when
\[
\begin{equation*}
n>\frac{\operatorname{cost}(\phi)}{\operatorname{cost}(f)-\cos t(F(u))} \tag{4}
\end{equation*}
\]

Hence, the benefit of universal construction will be obtained from fewer task instances when the cost of constructing each unique component \(F(u)\) is low compared to each \(f\). Otherwise, the benefits will only start to accrue after realizing many task instances.

\section*{Discussion}

Category theory generalizes the classical and connectionist notions of compositionality. Classical compositionality is the
idea that representations of the constituents of complex entities are tokened, in a consistent way, whenever the representations of their complex host entities are tokened (Fodor \& Pylyshyn, 1988). Symbol systems are the paradigmatic classical cognitive architecture, e.g., where the symbols representing constituents John, Mary, and loves appear in the symbolic representation of complex entity John loves Mary. Categorical compositionality generalizes this idea from symbols to arrows, and from tokening to arrow composition, while specializing the kinds of compositions to those that constitute universal constructions. This specialization is crucial to avoid otherwise arbitrary assumptions over which modes of tokening capture systematicity.

Connectionist compositionality is the idea that representations of complex entities are a function of the representations of their constituent entities without necessarily being tokened whenever the complex host representation is tokened (van Gelder, 1990). Category theory generalizes this idea from functions between sets to arrows between objects with additional internal structure beyond set membership and spatial structure (e.g., a graph, or a group), while specializing to functors (which appear in the definition of universal construction) that preserve that internal structure. This specialization is crucial, since although a functor is a kind of generalized function mapping objects and arrows, not all generalized functions are functors (i.e., preserve identity and associativity). Again, specialization is crucial to avoid arbitrary assumptions over which generalized functions capture systematicity.

\section*{Systematic capacity and cognitive development}

Models of universal constructions provide a functorial link from an abstract computational principle to a concrete cognitive resource. A connectionist example illustrated this point as a capacity-resource tradeoff. This non-universal situation may arise during cognitive development when the cognitive system does not have sufficient cognitive/neural resources to compute products, as suggested by the example in Set. Consistent with this idea, a category theory approach to the analysis of reasoning in young children explained developmental differences in terms of the capacity to compute (co)products (Phillips, Wilson, \& Halford, 2009). The analysis was based on empirical evidence from multi-paradigm studies where children from different age groups were tested on various reasoning tasks under easy and hard conditions (see Halford, 1993): a repeatedly observed result (see, e.g., Andrews \& Halford, 2002; Andrews, Halford, Bunch, Bowden, \& Jones, 2003; Andrews, Halford, Murphy, \& Knox, 2009) was that if a child (typically older than five years) was significantly above chance for both easy and hard conditions on one reasoning task (e.g., transitive inference), then that child was significantly above chance for easy and hard conditions on another reasoning task (e.g., class inclusion); conversely, if a child (typically younger than five years) was significantly above chance for the easy, but not the hard condition on one task, then they were significantly above chance for the easy,
but not the hard condition on another task. Analysis of the easy and hard conditions for seven reasoning tasks used to test children in such multi-paradigm studies showed that all hard conditions involved some kind of binary (co)product, in contrast to the easy conditions that did not, or what could also be called a unary (co) product \({ }^{8}\) (Phillips et al., 2009). \({ }^{9}\)

This relationship between universality and cognitive resource may shed light on why human cognition is not always systematic: the initial (short-term) cost of realizing a universal construction does not outweigh the expected (longterm) gain. Put in more familiar terms, when faced with a problem one often has two choices: devise a quick and simple solution that works for the current situation only, or a general-purpose solution that takes more time to develop. This choice will depend on how likely the same problem will reappear in other contexts, and whether the cost of developing a general-purpose solution will be repaid in subsequent savings. From a developmental perspective, this choice may be forced: the necessity of having a solution that works at least for the currently presented cases may preclude development of a general-purpose alternative. Hence, children may first go through a period of non-systematicity before attaining some forms of systematic cognitive capacity.

If non-systematicity is forced by the immediate demands on having a functioning system, then how do universal constructions (systematic capacity) eventually develop? The development of universal constructions may be driven (in part) by limited cognitive resources and the subsequent need to simultaneously realize multiple instances of tasks sharing a common component.
Further work is needed to explore the implications of the relationship between compositionality, systematic cognitive capacity and cognitive resource. The category-theoretic analysis presented here identified the essence of this relationship.

\section*{Appendix A}

Definition (Functor). A functor \(F: \mathbf{C} \rightarrow \mathbf{D}\) is a map from category \(\mathbf{C}\) to category \(\mathbf{D}\) that associates each object \(A\) in \(\mathbf{C}\) an object \(F(A)\) in \(\mathbf{D}\); and each map \(f: A \rightarrow B\) in \(\mathbf{C}\) a map \(F(f): F(A) \rightarrow F(B)\) in \(\mathbf{D}\), such that \(F\left(1_{A}\right)=1_{F(A)}\) for each object \(A\) in \(\mathbf{C}\); and \(F\left(g{ }^{\circ} \mathbf{C} f\right)=F(g) \circ_{\mathbf{D}} F(f)\) for all maps \(f: A \rightarrow B\) and \(g: B \rightarrow C\), where \({ }^{\circ} \mathbf{C}\) and \(\circ_{\mathbf{D}}\) are compositions in categories \(\mathbf{C}\) and \(\mathbf{D}\).

Two examples of functors, used in the construction of products, are the diagonal and product functors. The diagonal functor \(\Delta: \mathbf{C} \rightarrow \mathbf{C} \times \mathbf{C} ; A \mapsto(A, A), f \mapsto(f, f)\) sends objects and arrows to pairs of objects and arrows. The product functor \(\Pi: \mathbf{C} \times \mathbf{C} \rightarrow \mathbf{C} ;(A, B) \mapsto A \times B,(f, g) \mapsto f \times g\) send pairs of objects and arrows to their respective products.
Definition (Universal morphism/construction). Given a functor \(F: \mathbf{A} \rightarrow \mathbf{C}\) and an object \(Y \in|\mathbf{C}|\), a universal morphism from \(F\) to \(Y\) is a pair \((A, \phi)\) where \(A\) is an object in \(\mathbf{A}\), and \(\phi\) is a morphism in \(\mathbf{C}\), such that for every object \(Z \in|\mathbf{A}|\) and every morphism \(f: F(Z) \rightarrow Y\), there exists a unique morphism \(u: Z \rightarrow A\), such that \(\phi \circ F(u)=f\), as indicated in commutative diagram

A universal construction is a universal morphism, or its dual a couniversal morphism, obtained by reversing the directions of the arrows in the definition of universal morphism.

A product \(\left(A \times B,\left(p_{1}, p_{2}\right)\right)\) is an instance of a universal morphism, hence a universal construction, and indicated in commutative diagram

where functor \(F: \mathbf{A} \rightarrow \mathbf{C}\) in the definition of universal morphism is the diagonal functor, and product object \(A \times B\) is obtained by application of the product functor to object \((A, B)\). Compare Diagram 6 with Diagram 1.

\begin{abstract}
Most computational models of analogy assume they are given a delineated source domain and often a specified target domain. These systems do not address how analogs can be isolated from large domains and spontaneously retrieved from long-term memory, a process we call spontaneous analogy. We present a system that represents relational structures as feature bags. Using this representation, our system leverages perceptual algorithms to automatically create an ontology of relational structures and to efficiently retrieve analogs for new relational structures from long-term memory. We provide a demonstration of our approach that takes a set of unsegmented stories, constructs an ontology of analogical schemas (corresponding to plot devices), and uses this ontology to efficiently find analogs within new stories, yielding significant time-savings over linear analog retrieval at a small accuracy cost.
\end{abstract}

\section*{1 Spontaneous Analogy}

In our day-to-day experience, we often generate analogies spontaneously (Wharton, Holyoak, \& Lange, 1996; Clement, 1987). That is, with no explicit prodding, we conjure up analogs to aspects of our current situation. For example, while reading a story, we may recognize a plot device that is analogous to one used in another story that we read long ago. The shared plot device may be a small part of each story, it is usually not explicitly delineated for us or presented in isolation from the rest of the story, and we may recognize the analogy of the plot device even if the general plots of the two stories are not analogous. Somehow, we segment out the plot device and retrieve the analog \({ }^{1}\) from another story in longdormant memory. Spontaneous analogy is the process of efficiently retrieving an analog from long-term memory given an unsegmented source domain such that part of the source shares structural similarity with the analog, though they might not share surface similarity. This process differs from standard models of analogy, which are given a delineated source concept, and often a target concept. Given a pair of analogs, analogical mapping is relatively straightforward. The more difficult problem is finding the analogs to begin with. As Chalmers, French, and Hofstadter (1992) argue "when the program's discovery of the correspondences between the two situations is a direct result of its being explicitly given the appropriate structures to work with, its victory in finding the analogy becomes somewhat hollow".

\footnotetext{
\({ }^{1}\) In our terminology, an analog is substructure of a domain that is structurally similar to a substructure of another domain, and an analogical schema is a generalization of an analog. For example, an input domain might be the entire story of Romeo \& Juliet, an analog would be the part of the story where Romeo kills Tybalt, who killed Romeo's friend, Mercutio (like in Hamlet where Hamlet kills Claudius, who killed Hamlet's father), and an analogical schema would be the generalized plot device of a "revenge killing".
}

Figure 1: An analog of Analogical Mapping vs. Spontaneous Analogy. In Analogical Mapping (a), we are given an explicit source and target, free from interfering context. In spontaneous analogy (b), the analogs are spontaneously retrieved from long-term memory.

The process of spontaneous analogy shares some properties with low-level perception, as exemplified in Figure 1. Within seconds of being presented with a visual image of a pterodactyl flying over a canyon, one can typically describe the image using the word "pterodactyl", even if one has had no special explicit recent priming for this concept, indeed even if one has not consciously thought about pterodactyls for several years. For us to produce the word "pterodactyl", we must segment the pterodactyl from the canyon and retrieve the "pterodactyl" concept from the thousands of concepts stored in memory. We must have learned the "pterodactyl" concept to begin with from unsegmented images. This perceptual process is robust to noise: The pterodactyl in the image could be partially occluded, ill-lit, oddly colored, or even drawn as a cartoon, and we are still able to correctly identify this shape (to a certain point). Likewise, many details of the plot devices from the above story example could be altered or obfuscated, but this analogy would degrade gracefully.

Our primary technical contribution in this paper is an algorithm called Spontol \({ }^{2}\) that solves the problem of spontaneous analogy: efficient parsing, storage, and retrieval of analogs from long-term memory. That is, given a corpus of many large unsegmented relational structures, Spontol discovers analogical schemas that are useful for characterizing the corpus and efficiently retrieves analogs given a new structure. E.g., given a set of narratives in predicate form, Spontol discovers plot

\footnotetext{
\({ }^{2}\) Spontol is short for "spontaneous analogy using the Ontol ontology learning and inference algorithm".
}
devices and analogs between the stories. We know of no prior work that scales to this task when the number of narratives and statements per narrative are both in the hundreds.

In the remainder of this paper, we describe related work (Section 2), give background on perceptual systems (Section 3), describe the Spontol algorithm, which transforms the problem of spontaneous analogy into a "perceptual" problem (Section 4), demonstrate Spontol's performance on a story database (Section 5), discuss implications and shortcomings of Spontol, and conclude (Section 6).

\section*{2 Related Work}

There has been earlier work on the problem of analogy in the absence of explicitly segmented domains. The COWARD system (Baldwin \& Goldstone, 2007) addresses this problem by searching for mappings within a large graph, essentially searching for isomorphic subgraphs. SUBDUE (Holder, Cook, \& Djoko, 1994) compresses large graphs by breaking them into repeated subgraphs, but is limited in that its output must be a strict hierarchy, and would be unable to discover the lattice structure of the concepts in Figure 2. Nauty (McKay, 1981) uses a number of heuristics to efficiently determine whether one graph is a subgraph of another, but this must be given source and target graphs to begin with. We can also apply The Chunker (described in Section 3) to feature bag graphlet kernels (Shervashidze, Vishwanathan, Petri, Mehlhorn, \& Borgwardt, 2009), which are related to Spontol's transform \(T\) in that both represent partial graphs, but this earlier work applies only for cases where there is one kind of entity, one kind of relation, and only binary relations, while Spontol works for multiple kinds of entities and relations, including relations of large arity.

The MAC phase of MAC/FAC (Forbus, Gentner, \& Law, 1995) bears some relation to our spontaneous analog retrieval. MAC uses vectors of content, such as the number of nodes and edges in a graph, as a heuristic for analog retrieval. However, in cases where the subgraph in question is a part of a much larger graph, the heuristics that MAC uses are drowned out by the larger graph. Likewise, ARCS (Thagard, Holyoak, Nelson, \& Gochfeld, 1990) also assumes that analogs have been delineated (i.e., it matches an entire source domain, rather than a substructure). SEQL (Kuehne, Forbus, Gentner, \& Quinn, 2000) generalizes relational concepts, but doesn't build a hierarchical ontology of analogical schemas.

There has been some work on representing structures as feature vectors. For example, Holographic Reduced Representations have been used to implement Vector Symbolic Architectures in which there is a correlation between vector overlap and structural similarity (Gayler, Levy, \& Bod, 2009). This work is limited in that it requires vectors of length 10,000 to represent very small graphs ( \(\leq 10\) nodes), and only represents binary relations of a single type, so this approach is not directly extendable to relational structures such as the stories in our demonstration. This is also a limitation for the system proposed by Rachkovskij, Kussul, and Baidyk (2012).

Both these systems are also limited in that they are unable to exploit partial analogical schemas. That is, a partial overlap in these systems' vectors does not correspond to a common subgraph in the corresponding structures. These systems stand in contrast to Spontol, which is able to represent larger structures and efficiently find common substructures.

\section*{3 Background: Perceptual Systems}

Spontol transforms relational structures into feature bags so that their surface similarity corresponds to the structural similarity of the relational structures. After Spontol has made this transformation, the problem of spontaneous analogy is reduced to the problem of feature overlap, and any of several existing "perceptual" systems can be used to find and exploit patterns in feature vectors. Our implementation of Spontol uses a model inspired by the human sensory cortices (auditory, visual, tactile) called Ontol (Pickett, 2011). Ontol is a pair of algorithms, both of which are given "sensor" inputs (fixed-length, real-valued non-negative vectors). The first algorithm constructs an ontology that concisely encodes the inputs. For example, given a set of vectors representing visual windows from natural images, Ontol produces a feature hierarchy loosely modeled on that seen in the visual cortex. The second algorithm takes as input an ontology (produced by the first algorithm) and a new vector, and parses the vector. That is, it produces as output the new vector encoded in the higher-level features of the ontology. In addition to "bottomup" parsing, the second algorithm also makes "top-down" predictions about any unspecified values in the vector.

Ontol is ignorant of the modality of its input. That is, Ontol is given no information about what sensory organ is producing its inputs. Because of this ignorance, we are able to leverage Ontol to find patterns in abstract "sensory" inputs that are actually encodings of relational structures.

\section*{Ontology Learning}

Ontol's ontology formation algorithm, called The Chunker, seeks to find concepts (or chunks) that allow for concise characterization of vectors. Since chunks themselves are vectors, The Chunker is applied recursively to create an ontology. In essence, this algorithm is similar to the recursive block pursuit algorithm described by Si and Zhu (2011) in that both search for large frequently occurring sets of features. The Chunker differs in that it allows for multiple inheritance, while recursive block pursuit creates only strict tree structures. In Section 4, we show the importance of this property for finding multiple analogical schemas within a single relational structure. For simplicity, we describe the discrete binary version of The Chunker algorithm (chunk \((B)\), which takes as input a set \(B\) of feature bags and produces an ontology \(\Omega\) ) provided by Pickett (2011), but this can be modified for continuous vectors. In this version, each vector is treated as a set, with a value of 1 for feature \(f\) signifying inclusion of \(f\) in the set, and a value of 0 signifying exclusion.

The Chunker searches for intersections among existing feature bags and proposes these as candidates for new concepts.

Each candidate is evaluated by how much it would compress the ontology, then the best candidate is selected and added to the set of feature bags, and the process is repeated until no candidates are found that further reduce the description length of the ontology. Figure 2 shows the ontology constructed by this algorithm when applied to an animal dataset, where the "sensory percepts" are features for each animal".

Figure 2: The Zoo Ontology with some instances. Instances are individual animals shown on the left, and base features are on the right. Black nodes in the middle correspond to higher-level features. The concept that corresponds to "fish" is marked. Inhibitory links are shown as dark circles.

\section*{Parsing and Prediction}

Given an ontology and a new instance, Ontol's parse \((b, \Omega)\) algorithm characterizes the feature bag instance \(b\) using the higher-level features in the ontology \(\Omega\). For example, given a new animal (a goldfish) that doesn't breathe, has fins, has no feathers, and is domestic, Ontol will parse the animal as an instance of the fish concept, with the exception that it is domestic. If Ontol is given no other information about the animal, it will also perform top-down inference, and unfold the fish concept to predict that the new instance has eggs, no hair, has a tail, etc.. This latter step is called "top-down prediction". Ontol searches for the parse that minimizes the description length of the instance. In our goldfish example, the "raw" description of the goldfish consists of 4 elements, while the "compressed" description has only 2 elements.

\footnotetext{
\({ }^{3}\) A full description and implementation of The Chunker, as well as source code for our demonstration of Spontol can be downloaded at http://marcpickett.com/src/analogyDemo.tgz.
}

Although the parsing problem is NP-complete, a single bottom-up pass can be performed in logarithmic time (Pickett, 2011). Importantly, Ontol examines only a small subset of the concepts and instances while parsing. This means that, when judging concept similarity, Ontol does not need to compare each of its \(n\) nodes. This property is important for spontaneous analog retrieval (described below).

\section*{4 Analogy as Perception}

We now describe a method for transforming relational structures into sparse feature vectors (or feature bags) such that the problem of analog retrieval is reduced to the problem of percept parsing. An example of this process is shown for the Sour Grapes fable in Figure 5. For this process, we rely on a transform \(T\) (described below) that takes a small relational structure and converts it into a feature bag (exemplified in Figure 5(c)). The size of relational structure is limited for \(T\) because \(T\) 's runtime is quadratic in the size of the structure. We view this limitation as acceptable because people generally cannot keep all the details of an entire lengthy novel (or all the workings of a car engine) in working memory. Generally, people focus on some aspect of the novel, or some abstracted summary of the novel (or engine). Therefore, we break each large relational structure into multiple overlapping windows. A window is a small set of connected statements, where two statements are connected if they share at least one argument. Spontol exploits a principle akin to one used by the HMax model of the visual cortex (Riesenhuber \& Poggio, 1999): as the number of windows for a relational structure increases, the probability decreases that another structure has the same windows without being isomorphic to the first.

The process for building an ontology of analogical schemas from large relational structures, called Spontol-Build, is described in Figure 3. This algorithm extracts numWindows windows from each large relational structure and transforms them into feature bags (exemplified in Figure 5(d)) and chunks these feature bags to create an ontology of windows called windowOntology. Spontol-Build then re-encodes the windows by parsing them using this ontology, and re-encodes the larger structures (from which the windows came) as a feature bag of the parsed windows. Finally, Spontol-Build runs another pass of chunking on the re-encoded structures to generate the schema ontology.

The process of spontaneous analog retrieval, called Spontol-Retrieve, is given in Figure 4. When given a new relational structure \(s\), we encode \(s\) by extracting windows from it, parsing these using the windowOntology, then parsing the feature bag representation using the schemaOntology. This yields a set of schemas that are contained in \(s\).

\section*{Transforming Small Relational Structures}

Here, we describe an operation \(T\), which transforms a (small) relational structure into a feature bag. In our demonstration, we assume that the relational structure is described in predicate logic, but our approach is not limited to this representation. We consider a relational structure to be a

Figure 3: Spontol's Ontology Learning Algorithm
// Creates an ontology of schemas given a set of structures \(S\). // numWindows is the number of windows to grab per structure. // windowSize is the number of statements per window.
define Spontol-Build (S, numWindows, windowSize)
// Randomly grab windows from each structure,
// and transform them into feature bag form.
foreach \(s \in S\); for \(i=1, \cdots\), numWindows let \(w_{s, i}=\) grabConnectedStatements ( \(s\), windowSize) add \(T\left(w_{s, i}\right)\) to allWindows
// Run The Chunker to generate the window ontology windowOntology \(=\) chunk (allWindows)
// Re-encode each structure using the reduced-size windows.
foreach \(s \in S\); for \(i=1, \cdots\), numWindows
add parse ( \(T\left(w_{s, i}\right)\), windowOntology) to bigWindows
// Run The Chunker to generate the schema ontology.
schemaOntology \(=\) chunk (bigWindows)
return schemaOntology, windowOntology

return relevantSchemas

```
set of relational statements, where each statement is either a relation (of fixed arity) with its arguments, or the special relation sameAs, which uses the syntax sameAs <name> (<relation> <arg1> <arg2> ...). The sameAs relation allows for statements about statements. E.g., the statements in Figure 5(b) encode (among other things) that "a fox \(d e\) cides that the grapes are sour".

Given a small relational structure \(s(\lesssim 10\) statements), \(T\) transforms \(s\) into a feature bag using a variant of conjunctive coding. That is, \(T\) breaks each statement into a set of roles and fillers. For example, the statement want Of3Fox Of3Grapes has two roles and fillers, namely the two arguments of the want relation. So \(T\) breaks this statement into want1=0f3Fox and want2=0f3Grapes, where want 2 means the 2 nd argument of want (i.e., the "wanted"). \(T\) then creates one large set of all the roles and their fillers. If there are multiple instances of a relation, it gives them an arbitrary lettering (e.g., wantB1=Of3Fox). \(T\) makes a special case for the sameAs relation. In this case, \(T\) uses a dot operator to replace the intermediate variable. For example, the statements sameAs \(f 35\) (decide Of3Fox f36) and sameAs f36 (sour Of3Grapes) would yield decide2.sour1=0f3Grapes. The dot operator allows \(T\) to encode nested statements (i.e., statements about state-
"A fox wanted some grapes, but could not get them. This caused him to decide that the grapes were sour, though the grapes weren't. Likewise, men often blame their failures on their circumstances, when the real reason is that they are incapable."

\hline
\end{tabular}
(b) Predicate Form (Spontol's actual input)

(c) Transforming a Window

(d) Many Transformed Windows

Figure 5: Transforming the Sour Grapes Story. We show the transformation of Sour Grapes from predicate form to feature bag form. For clarity, we show an English paraphrase of the story (a), though the input to Spontol has already been encoded in the predicate form shown in (b), which shows the story as a set of 18 statements. In (c), we show a window \(w\) from the story and its feature bag transform \(T(w)\). Finally, the story is represented as many transformed windows (d).
ments). Given a set of roles and fillers, \(T\) then chains the fillers to get filler equalities. For example, if we have that decide1=0f3Fox and want1=0f3Fox, then chaining gives us decide1=want1. Chaining is essential for recognizing structural similarity between relational structures, and allows us to side-step a criticism of conjunctive coding and tensor products: that the code for wantB1=Of3Fox may have no overlap with the code for want1=0f3Fox (Hummel et al., 2004). Chaining introduces the code for want \(\mathrm{B} 1=\) want 1 , which makes the similarity apparent when searching for analogs (these "chained" features are a core difference between MAC's content vectors and our feature bags). After
chaining the roles and fillers, \(T\) treats each of these role-filler bindings as an atomic feature. Note that, when we treat roles and fillers as atomic features, Ontol doesn't recognize overlap among feature bags unless they share exactly the same feature. For example, the atomic feature wantB1=0f3Fox has no more resemblance to want \(1=0 f 3\) Fox for Ontol than it does for any other feature. Also note that the ordering of the roles in each feature is arbitrary but consistent ( \(T\) uses reverse alphabetical order), so there is a men \(1=\) incapable1 feature, but not an incapable1=men1 feature. The left side of Figure 5(c) shows a window taken from the sour grapes story from Figure 5(b). On the right side is the feature bag transform of this set of 6 statements, consisting of 11 atoms.

\section*{5 Demonstration}

We applied Spontol to a database of 126 stories provided by Thagard et al. (1990). These include 100 fables and 26 plays all encoded in a predicate format, where each story is a set of unsorted statements. An example story in predicate form is shown in Figure 5(b). Note that although the predicates and arguments have English names, our algorithm treats all these as gensyms except for the special sameAs relation. In this encoding, the smallest story had 5 statements, while the largest had 124 statements, with an average of 39.5 statements.

We ran Spontol-Build on these stories using numWindows \(=\) 100 and windowSize \(=20\) which produced an ontology of stories, part of which is shown in Figure 6. In this figure we see a "Double Suicide" analogical schema found in both Romeo \& Juliet and in Julius Caesar. In the former, Romeo thinks that Juliet is dead, which causes him to kill himself. Juliet, who is actually alive, finds that Romeo has died, which causes her to kill herself. Likewise, in Julius Caesar, Cassius kills himself after hearing of Titinius's death. Titinius, who is actually alive, sees Cassius's corpse, and kills himself. The largest schema found (in terms of number of outgoing edges) was that shared by Romeo \& Juliet and West Side Story, which are both stories about lovers from rival groups. The latter doesn't inherit from the Double Suicide schema because Maria (the analog of Juliet), doesn't die in the story, and, Tony (Romeo's analog) meets his death by murder, not suicide. Some of the schemas found were quite general. For example, the oval on the lower right with 6 incoming edges and 3 outgoing edges corresponds to the schema of "a single event has two significant effects". And the oval above the Double Suicide oval corresponds to the schema of "killing to avenge another killing".

Spontol-Retrieve uses this schema ontology to efficiently retrieve schemas for a new story, which can be used to make inferences about the new story in a manner analogous to the "goldfish" example from Section 3. To evaluate the efficiency of Spontol-Retrieve, we randomly split our story dataset into 100 training stories and 26 testing stories. We then used an ontology learned from the training set, and measured the number of comparisons needed to retrieve schemas (during parse) for the testing set. We compare this approach to MAC/FAC, which, during the MAC phase, visits each of

Figure 6: Part of the ontology Spontol learned from the story dataset. As in the Zoo Ontology in Figure 2, black ovals represent higher level concepts. The "raw" features (corresponding to the white ovals in Figure 2) are omitted due to space limitations. Instead, we show the outgoing edges from each black oval. While in the Zoo Ontology, the higher level concepts correspond to shared surface features, in this figure, high level concepts correspond to shared structural features, or analogical schemas. For example, the highlighted oval on the right represents a Double Suicide schema, which happens in both Romeo \& Juliet and in Julius Caesar.
the 100 training stories. Whereas MAC/FAC returns entire stories, Spontol-Retrieve returns analogical schemas (just as a visual system would return a generic "pterodactyl" concept rather than specific instances of pterodactyls). For comparison, we modify Spontol-Retrieve to return the set of instances that inherit from relevantSchemas, rather than just the schemas.

Table 1: Speed/Accuracy Comparison of Spontol
\begin{tabular}{|lcc|}
\hline & Accuracy & Average \# Comparisons \\
MAC/FAC & \(100.00 \% \pm .00 \%\) & \(100.00 \pm .00\) \\
Spontol & \(95.45 \% \pm .62 \%\) & \(15.43 \pm .20\) \\
\hline
\end{tabular}

Results are shown in Table 1, averaged over 100 trials. We show accuracy (and standard error) for both systems mea-
sured as the percentage of stories correctly retrieved, where a story was determined to be correct if it was retrieved by MAC/FAC. Spontol effectively improves on a linear (in the number of structures) case-by-case comparison to an "indexed" logarithmic-time look-up at a slight cost of accuracy. Therefore, Spontol requires orders of magnitude fewer comparisons than MAC/FAC, or any linear look-up algorithm (for a survey, see (Rachkovskij et al., 2012)). For larger datasets, we hypothesize that these differences will be even more pronounced. Although each comparison by both MAC and Spontol-Retrieve is a fast vector operation, for very large datasets (e.g., \(10^{9}\) relational structures), even a linear number of vector operations becomes impractical. In future work, we will test these systems on a broader range of relational datasets to help elucidate the conditions under which Spontol yields high accuracy and very-low retrieval cost.

\section*{6 Conclusion}

The chief contribution of this paper is a demonstration of a system, Spontol, that is able to solve the problem of spontaneous analogy. That is, we have demonstrated how Spontol can efficiently store and retrieve analogs without the need of human delineation of schemas.

Our representation also offers a new solution for the binding problem for long-term (static) memory that allows for efficient analog retrieval in the absence of explicitly segmented domains. The binding problem asks how we can meaningfully represent bindings between roles and fillers. Most solutions to the binding problem in connectionism do so in terms of temporal synchronicity (e.g., LISA (Hummel \& Holyoak, 2005)). Temporal synchronicity only works for knowledge in working memory, and these models typically address storage in long-term memory by relying on some form of conjunctive coding or tensor products. Though these systems fail to address how relational structures can be efficiently retrieved from long-term memory, we hypothesize that a workingmemory system, such as LISA, is necessary for the "chaining" process on which our system relies.

Spontol may offer evidence in support of a uniform "substrate" of intelligence (Mountcastle, 1978). In particular, we've shown how a system that was designed to process perceptual data (Ontol) can be leveraged to process "symbolic" data (i.e., relational structures). This may provide insight into how species capable of higher-order cognition might have evolved from species capable of only low-level perception.

Although Spontol addresses some outstanding problems in Computational Analogy, there is still ample room for future work. Our implementation for characterizing a relational structure as a set of windows might not scale well to very large structures without some modifications. An open problem is how windows might be managed in a sensible way. Spontol currently uses "bags of windows" for medium-sized structures. We propose extending Spontol by allowing hierarchies of progressively higher-order bags to represent larger structures (e.g., bags of bags of bags of windows).

\title{
Type-token representations in conceptual representation
}

\author{

}

\begin{abstract}
Concepts of kinds of things (e.g. DOG), have the dual function of specifying how to think about indefinitely many things as well as providing the means for thinking about a single abstract kind which is constituted by indefinitely many instances. In this talk, I sketch a theory of conceptual representation that places this dual function of concepts at its core. The theory is shown to provide a natural way of capturing four key characteristics of the ways in which we think about kinds and instances of kinds. These characteristics are not accounted for by standard approaches to conceptual representation. In the final section of the paper, I consider how the phenomena discussed in this paper may be accommodated by current approaches to conceptual representation.
\end{abstract}

Keywords: concepts; type-token representations; kind representations; generic knowledge.

Concepts are the mechanisms by which we think about things. For example, the concept DOG provides the means for thinking about indefinitely many distinct things as being a given kind of thing (e.g. dogs). Furthermore, it also provides the means for thinking about the kind dog itself. This dual function of specifying how to think about indefinitely many things as well as providing the means for thinking about a single abstract kind which is constituted by indefinitely many instances has generally escaped the focus of most research on conceptual representation. In this paper, I sketch a theory of conceptual representation that places this dual function of concepts at its core. The theory is shown to provide a natural way of capturing four key characteristics of the ways in which we think about kinds and instances of kinds. These characteristics are not currently accounted for by standard approaches to conceptual representation, however, they constitute empirical phenomena that any adequate theory of conceptual representations would have to handle. In the final section of the paper, I consider how the phenomena discussed in this paper may be accommodated by current approaches to conceptual representation.

\section*{Mechanism for thinking about instances of kinds and kinds.}

Following Prasada \& Dillingham (2009) and Prasada (2012), the theory developed here proposes that concepts for kinds of things are represented via a generative type-token mechanism such as (1) which is capable of generating
indefinitely many representations (2) each of which provide the means for thinking about distinct instances of that kind.
(1)
(2) \(\mathrm{K}_{1} \quad \mathrm{~K}_{2} \quad \mathrm{~K}_{3} \quad \ldots\)

The mechanisms in (1) and (2) highlight the close connection between the mechanisms needed to make generic and non-generic reference. The mechanisms needed for thinking about instances of kinds (2) are generated by the mechanism needed for thinking about kinds (1) which makes implicit reference to instances of kinds. As such, the mechanisms that underlie generic and non-generic reference are intrinsically related and thus one may expect the ability to make generic and non-generic reference to be closely tied in development. This is, in fact, the case. Recent research suggests that children appear to use noun phrases generically and non-generically from a very early age (Pappas \& Gelman, 1998; Gelman \& Tardif, 1998; Goldin-Meadow, Mylander \& Gelman, 2005; Gelman, Goetz, Sarnecka \& Flukes, 2008).

\section*{Instances of kinds may be qualitatively identical.}

The mechanisms in (1) and (2) also highlight a fundamental characteristic of the manner in which we think about instances of kinds. Instances of a given kind need not be qualitatively distinct in any way. They need only be numerically distinct. Thus we are perfectly capable of thinking about qualitatively identical instances of kinds. This is, of course, easier to do for some kinds (e.g. paperclips) than others (e.g. dogs), nevertheless, it is possible for any kind of thing and our conceptual mechanisms must support such thoughts. This characteristic of how we think about instances of kinds is captured by the fact that the representations in (2) differ only in their indicies which have a purely indexical function and have no intrinsic descriptive content.

\section*{Distinct kinds cannot be qualitatively identical.}

Turning our attention to the representation of kinds (1), a natural question is whether kind representations may also be distinguished merely by an index (e.g. \(\mathrm{K}_{\mathrm{i}}^{1} \& \mathrm{~K}_{\mathrm{i}}{ }_{\mathrm{i}}\) ). A moment's reflection makes it clear that it makes no sense to speak of qualitatively identical and merely numerically distinct kinds. Kinds, unlike instances of kinds, must be qualitatively distinct. This means that the representation of kinds in (1) must be augmented with a component that has
descriptive content that characterizes the kind and provides the basis for individuating kinds.

Given that kinds are constituted by indefinitely many instances, characterizing a kind must involve representing a connection between the kind and properties that is understood to be non-accidental and thus extendible to indefinitely many instances that have yet to be encountered (Goodman, 1955). Prasada, Khemlani, Leslie \& Gucksberg (2013) provide evidence that our conceptual systems distinguish at least three types of non-accidental connections between kinds and properties (principled connections, statistical connections, and causal connections) that provide at least three ways of characterizing kinds. Nevertheless, kinds cannot be generally be individuated in terms of properties that involve merely statistical connections to the kind because such properties are extrinsic to the kind. Furthermore, kinds cannot be generally be individuated in terms of properties that involve causal connections to kinds because such connections are only possible for material kinds.

Principled connections, on the other hand, involve properties that instances of kinds are understood to have by virtue of their being the kinds of things they are (e.g. having four legs for dogs) (Prasada \& Dillingham, 2006). As such, it is possible to identify properties that have a principled connection to a kind for any kind of thing. Properties that have a principled connection to a kind ( \(k\)-properties in Prasada \& Dillingham's (2006) terminology) are (i) properties whose presence in instances of a kind receive formal explanations -- explanations by reference to the kind of thing something is (e.g. Fido has four legs because he is a dog), (ii) properties for which we have normative expectations such that instances of the kind that lack kproperties are judged to be defective or incomplete, and (iii) properties that are generally expected to be present in instances of the kind (Prasada \& Dillingham, 2006, 2009). Kproperties differ from definitional properties in important ways. Unlike definitional properties which are necessarily present in all instances of a kind, k-properties need not be present in all instances of the kind (e.g. there are many dogs that do not have four legs). Relatedly, the representation of definitional properties are understood as specifying necessary conditions for the use of the kind concept of which they are a part whereas k-property representations do not specify conditions for the use of the kind concept with which they are connected. Instead, k-property representations specify properties that are understood to be lawfully related to being that kind of thing such that the presence of k-properties in instances of a kind is understood to be due the things being the kinds of things they are. In fact, k-properties are understood to be aspects of being the given kind of thing (e.g. having four legs is one aspect of being a dog) and thus are represented via a formal part-whole relation between the kind and property (Prasada \& Dillingham, 2009). These findings lead Prasada \& Dillingham (2009) to revise the mechanism for representing kinds in the following manner.
(3) \(K_{i} \sim<a 1, a 2 \ldots\)

In this representation (3), the mechanism for representing a kind projects \({ }^{1}\) an aspect structure by means of which the properties that have a principled connection to the kind (kproperties) can be represented as aspects of being that kind of thing. \({ }^{2}\)

The mechanism for representing kinds (3) is now seen to have a descriptive component in terms of which kinds are (qualitatively) individuated via distinct sets of \(k\)-properties. It should be noted that though kinds cannot be merely numerically distinct and thus kind representations cannot be distinguished merely by indexical representations devoid of any descriptive content (e.g. \(\mathrm{K}_{\mathrm{i}}^{1} \& \mathrm{~K}_{\mathrm{i}}^{2}\) ), it is possible that kinds may be distinguished indexically in addition to being distinguished qualitatively via their k-properties. In fact, it is possible that developmentally it is sometimes the case that two kinds may initially be distinguished only indexically via their names with the expectation that they will additionally differ in yet to be discovered ways (Xu, 2012). The theory being developed here suggests that in such cases, the expectation is that the kinds also differ in their k-properties.

\section*{Modes of existence of instances of kinds and kinds.}

The mechanisms in (3) and (2) also highlight an important difference between the ways in which we think about instances of kinds and kinds. At any given time, there are some definite number of instances of a kind that actually exist or have actually existed. In addition, there are indefinitely many instances of the kind that do not actually exist, but exist only potentially. Potentially existing instances of a kind differ from actually existing instances of a kind only in their mode of existence. No qualitative differences distinguish actually existing and potentially existing instances of a kind. Given that this is the case, it should be immediately evident that there cannot be potentially existing kinds as this would require that the putatively potentially existing kinds be qualitatively identical to actually existing kinds, but as we saw above, distinct kinds cannot be qualitatively identical.

\section*{Relation to existing theories of conceptual representation.}

The phenomena pertaining to the manner in which we think about kinds and instances of kinds discussed in this paper are generally not addressed by standard approaches to conceptual representation. How might standard approaches to conceptual representation respond to these phenomena? To answer this question, it will be helpful to summarize the

\footnotetext{
\({ }^{1}\) I use the \(\sim<\) symbol to mean "projects". Prasada \& Dillingham (2009) and Prasada (2012) use -> for the same notion, however, that is easily confused with implication.
\({ }^{2}\) As the details of how principled connections are represented via such a mechanism are not pertinent here, I skip over them. See Prasada \& Dillingham (2009) for details.
}
generative type-token mechanism theory proposed in the present paper and situate standard approaches with respect to it. As illustrated in Figure 1, a kind concept such as DOG is, at its core, a generative mechanism which has the capacity to generate indefinitely many representations each of which represent an instance of the kind and which are distinguished from one another numerically via an index devoid of any intrinsic descriptive content. The generative mechanism itself implicitly contains the indefinitely many instances and thus provides the means for thinking about the kind itself. Finally, the kind projects an aspect structure which provides the means for representing the properties that have a principled connection to the kind (k-properties) as aspects of being that kind of thing. This component of the mechanism serves to qualitatively distinguish the kind from other kinds.

Figure 1. Schematic summary of the generative type-token mechanism that provides the means for thinking about kinds and instances of kinds.

Given this characterization, it becomes evident that the definitional, prototype and theory approaches to conceptual representation can best be understood as corresponding to the aspect structure component of the approach developed here in that they provide different accounts of how kinds are qualitatively individuated from one another. As such, these approaches, as currently formulated, lack the mechanisms for thinking and reasoning about kinds and instances of kinds. The exemplar approach to conceptual representation, on the other hand, involves representations that correspond most closely to those that represent instances of kinds. The exemplar approach lacks any mechanisms for representing kinds or information for individuating kinds, by design.

We are now in a position to consider how standard approaches may accommodate the phenomena discussed in the present paper which are handled naturally by the generative type-token mechanism approach. One possibility is that each approach may use the tools within their framework to incorporate these phenomena. While this may be possible, it is hard to see what relevant resources exist within the definitional, prototype, exemplar, or theory theories to form representation of instances of kinds and kinds such that they have the characteristics discussed here. A second possibility which would be available to the
definitional, prototype and theory approaches would be to graft the formal mechanisms developed here onto one's favorite approach. This avenue would be in line with suggestions in the philosophical and psychological favoring hybrid theories of conceptual representation (e.g. Genone \& Lombrozo, 2012; Keil, 1989; McNorgan, Kotack, Meehan, \& McRae, 2007; Sloman, Love \& Ahn, 1998). This option is presumably not available to the exemplar approach which eschews summary representations and thus kind representations and components of kind representations that individuate kinds could presumably not be grafted onto exemplar representations. A third response may be to see the present work as potentially increasing the diversity of conceptual representations available thus providing further fuel to theories favoring conceptual pluralism and heterogeneity (Dove, 2009; Machery, 2009; Weiskopf, 2009).

The final possibility I'd like to consider and endorse is that the present theory contains key elements from each of the standard approaches and thus it may be possible to develop a theory of conceptual representation that has many of the advantages of hybrid theories, but in a manner that is more principled and organic. The present theory involves the generation of representations of instances of kinds (2) and thus provides a natural way of accounting for phenomena that are best handled by exemplar theories of concepts.
Furthermore, the k-properties that individuate kinds do not specify conditions for the application of the kind concept. Instead, they specify properties that instances of the kind are expected to have in virtue of their being the kinds of things they are but may be lacking in instances for reasons other than their being the kinds of things they are (Prasada \& Dillingham, 2006, 2009). As such, the k-properties that characterize a kind are like properties in prototype representations in that they are typically present in members of the kind, but need not be.

The link to the explanation-based theory approach to concepts is evident in the fact that the k-properties are represented as involving a lawful (non-accidental) link between the kind and properties. The mechanism in (3) represents principled connections between kinds and properties by representing the property as an aspect of being that kind of thing. As such, it supports a formal mode of explanation whereby the presence of k-properties in instances of kinds may be explained by reference to the kind of thing something is (Prasada \& Dillingham, 2009). The mechanism in (3) also provides the basis for psychological essentialism by identifying the properties that are understood to be caused by the essence. As the essence is typically not known (Medin \& Ortony, 1989; Gelman, 2003), the properties caused by the essence cannot be identified by the essence and must be identified in another manner. The k-properties represented in (3) thus potentially provide the basis for psychological essentialism.

Furthermore, as mentioned above, kinds may also be characterized via the causal and statistical connections they have to properties (Prasada, Khemlani, Leslie \& Gucksberg,
2013). Though the addition of causal and statistical connections between kinds and properties to the mechanism in (3) is not required by our ability to think about kinds and instances of kinds (as is the addition of principled connections), their addition is necessary for capturing the range of ways in which we can characterize kinds. As such, their addition is principled and motivated within the present approach and allows the theory to capture further phenomena that are typically accounted for within the prototype and theory views of concepts.

Though much more needs to be said, I hope it is already evident that a theory which is centered on the generative type-token mechanisms needed for thinking about kinds and instances of kinds can not only capture the phenomena discussed in the present paper, but potentially provides a principled and organic way of capturing the key characteristics of current approaches to conceptual representation.

\title{
Category Change in the Absence of Falsifying Feedback
}

\begin{abstract}
Many conceptual change theories posit that change occurs when the learner becomes dissatisfied with the current conception (Ohlsson, 2011; Strike \& Posner, 1992). A necessary component of dissatisfaction is falsifying feedback. The present experiments investigate whether participants exposed to a novel method for eliminating the ability to directly falsify a misconception will still be able to recategorize compared to participants that can directly falsify. The results suggest that direct falsification of a misconception is not necessary for recategorization, and that direct falsification may slow the learning process. Implications are discussed.
\end{abstract}

Keywords: Learning, recategorization, feedback, nonmonotonic change.

\section*{Introduction}

Both common sense and past research have assumed that conceptual change in particular and non-monotonic cognitive change in general is driven by a person's dissatisfaction with his or her current conception (Ohlsson, 2011). Dissatisfaction is in turn caused by falsifying information and experiences that are inconsistent with the current conception. Without falsification a person would presumably lack motivation to change (Chi, 2005; Chi, 2008; Chi \& Brem, 2009; Gopnik \& Wellman, 2012; Slotta \& Chi, 2006; Strike \& Posner, 1982, 1992). But once dissatisfaction has set in, the learner is ready to search for an alternative conception (Elio \& Pelletier, 1997; Strike \& Posner, 1982, 1992; Chi \& Ohlsson, 2005; Ozdemir \& Clark, 2007). The theme of falsification first became dominant in the history of science via the works of Karl Popper and Thomas Kuhn, but it has since spread to all aspects of knowledge change.

For example, Strike and Posner's (1982) claimed that students in a science classroom must be dissatisfied with their current conception before they are ready to learn a new conception. Moreover, dissatisfaction must surpass the threshold at which accommodation supersedes assimilation. The threshold is surpassed by the accretion of falsifying pieces of information that accumulate until the discrepancy cannot be ignored.

Similarly, the Theory-Theory posits that the knowledge revision process takes place when dissatisfaction with the current conception reaches an individual's threshold for
conceptual change in the course of cognitive development (Gopnik \& Wellman, 2012).
As a final example, the Categorical Shift Theory describes conceptual change as a process that requires one to abandon or reject prior misconceptions via the recognition of differences between two or more general categories (Chi, 2005; Chi \& Brem, 2009). Failure to filter information through an existing knowledge base leads to dissatisfaction with the current conception. Dissatisfaction leads to a search for an alternative knowledge structure capable of accommodating the new information.
In short, these and other theories of cognitive change assume that dissatisfaction is a necessary prerequisite for cognitive change in children, students, and both lay adults and scientists. However, both common sense and psychological research agree that although people respond to falsifying information by trying to reduce the cognitive dissonance it causes, they tend to process the falsifying information in such a way as to minimize its impact on current knowledge (Ohlsson, 2011). If so, why should we believe that falsifying information is a necessary component of conceptual change?
In contrast to the theories mentioned above, the Resubsumption Theory claims that conceptual change can occur even in the absence of falsification of a person's current conception. This is possible when the learner possesses two alternative theories that apply to the same case or phenomenon. Change from one theory to the other occurs through competitive evaluation on the basis of cognitive utility rather than truth or falsity (Ohlsson, 2009). Competitive evaluation triggers a change by revealing that the alternative theory is more applicable in a given instance.

In the current study, we used the re-categorization paradigm (Cosejo, Oesterreich \& Ohlsson, 2009) to create a situation in which the participants needed to change a newly learned definition a category into a different definition of the same category in the absence of information that falsified the latter. Specifically, the participants learned how to categorize a novel set of stimuli through the standard procedure used in countless categorization experiments (Ashby \& Maddox, 2005): view a potential category member, judge whether it is a member, receive feedback on the judgment, and go to the next trial. Once the participants showed that they had mastered the category, the category was changed without warning. To succeed, the learner had
to re-learn the category, i.e., learn a new definition of it, and consequently, a different way of categorizing the relevant stimuli. The particular version of recategorization that we used in this study presented stimuli that mimicked a science-learning scenario. Images of fictitious alien bacteria were categorized with respect to their resistance to atmospheric oxygen; see details in the Method section.

The present study used the recategorization paradigm to investigate whether falsification is necessary for a learner to recategorize. All participants were given both supportive and falsifying feedback on their categorization judgments during the initial phase of the study. We refer to this as initial learning, and the category definition learned as the initial category or the 'misconception'. After learning the initial category, the participants were exposed to one of two feedback conditions during the second phase of the experiment. We refer to the second phase as the target learning, and the new category definition acquired in this phase as the target category.

The participants in the complete feedback condition received both confirmatory and falsifying feedback (the complete condition). The participants in the second feedback condition were presented with stimulus items that had been altered in such way that the initial category, once acquired, could not be directly falsified (the confirmation only condition). This was accomplished by deleting crucial features from the stimuli; see Method section for details. However, they received the same information required to learn the target category as the participants in the complete condition. In short, the purpose was to compare recategorization in the presence and absence of falsifying feedback.

\section*{Predictions}

There are three potential outcomes of this experiment. We could find that having complete feedback (i.e., both confirmation and falsification) yields the most efficient categorical change. Alternatively, we could find that the absence of falsification has no effect on recategorization, that is, learners need confirmation to learn, not falsification. Finally, we could find that falsification is not necessary, but harmful. That is, the presence of falsification might hinder recategorization, perhaps by creating cognitive conflicts that trigger defensive processing mechanisms (Ohlsson, 2011). The latter might use up cognitive resources that are needed for learning.

We have specific quantitative predictions regarding these outcomes. The predictions relate to different measures of performance. The first measure examines overall success, that is, do the groups learn the target when compared to chance. Specifically, it is hypothesized that the complete condition (i.e., those with both types of feedback) will perform better than chance because the combination of confirmatory feedback and falsifying feedback will allow the learner to adopt the target category. The confirmatory condition is hypothesized to perform better than chance because of the availability of confirmatory feedback.

The first measure (i.e., overall success) is examined between groups. That is, are there differences between groups in their ability to learn the target category? It is hypothesized that there will be no difference in target learning between the confirmatory and complete condition. This is expected because the use of confirmatory feedback will allow learners to adopt the target category (for both confirmatory and complete conditions). No differences between the confirmation and complete conditions will demonstrate that falsification is not necessary for recategorization to occur.

The second measure examines how quickly the groups can recategorize. There are three different scenarios that could occur for speed of categorization that will answer the question regarding what type of feedback appears to be the most effective for increasing speed of categorization. The first scenario would have complete learning faster than confirmatory. This would demonstrate that having both confirmation and falsification could result in faster learning compared to confirmation without falsification. That is, falsification is beneficial for increasing the speed of categorical change compared to not having the ability to directly falsify the misconception.
The second scenario would be that no difference exists between complete and confirmatory only conditions. This would suggest that the presence or absence of falsification has no effect on categorical change so long as confirmatory feedback is available.
The third scenario would show that speed of learning is faster for confirmatory compared to complete. This type of outcome would demonstrate that falsification might not be necessary for categorical change, but that it might hinder categorical change as evidenced by the complete condition underperforming compared to the confirmatory condition.

\section*{Method}

\section*{Participants}

One hundred twenty introductory psychology students participated in the study for course credit. Random assignment yielded 66 participants in the complete condition and 54 participants in the confirmatory condition.

\section*{Design}

The study was a between-participants design with two conditions (Complete and Confirmatory).

\section*{Materials}

The materials consisted of 128 fictional bacteria images including some that were incomplete, i.e., some features were deleted (see Figure 1). The bacteria have six different parts that have different binary attributes resulting in 64 complete variants: Nuclei (grey or black), Headbulbs (three or none), Ribosomes (bent or straight), Tail Cilia (present or absent), Cell Membrane (singular or double), and Cytoplasm (white or grey).

Figure 1. Example bacterium with parts labeled.
Additionally, some images were incomplete, that is, some images would not show the nuclei and some would not show the tail (see Figure 2). The images were presented on a computer screen via E-Prime software; see (www.pstnet.com/products/E-Prime/default/).

Figure 2. Bacteria with and without nuclei shown.

\section*{Procedure}

Phase 1: Misconception Learning. Participants first learned to categorize whether an alien bacteria was oxygen resistant based on feedback that supported the misconception feature (i.e., black nuclei) over the course of five training blocks of 16 trials each. Each training block was balanced to include in randomized order six images that contained the misconception, six images that contained the target, two images that contained neither, and two images that contained both the misconception and the target. After five training blocks, unbeknownst to the participants the feature that determines oxygen resistance changed to bent ribosomes (i.e., the target).

Phase 2: Target Learning. Participants had five target training blocks of 16 randomized trials to learn that bent ribosomes determined oxygen resistance. The target training had two different experimental conditions.

Condition 1: Complete Stimuli. This condition consisted of stimuli that were similar to what participants had already used for classification. Each training block was balanced to include in randomized order six images that contained the misconception, six images that contained the target, two images that contained neither, and two images that contained both the misconception and the target. All parts of the bacteria were visible on the screen allowing participants to falsify their prior categorization in favor of a new categorization supported by the computers feedback. For example, in phase 1, the participant learned that black nuclei are responsible for oxygen resistance. In phase 2, the participant was then confronted with an image containing black nuclei with feedback stating that the bacteria was not oxygen resistant. This feedback should allow the learner to negate the prior conception. Moreover, when the learner is confronted with an image that does not have a black
nucleus, but is shown to be oxygen resistant the learner should logically conclude that another part of the bacteria is responsible for oxygen resistance.

Condition 2: Incomplete Stimuli. This condition contained no stimuli that could be used to directly falsify the misconception. Specifically, bacteria images containing the dark nuclei with straight ribosomes were not shown for any trial. However, there were stimuli that did not show the nuclei, resulting in an inability of the learner to directly falsify the initial category. Each training block was balanced to include in randomized order six images that did not display the misconception, six images that fit the target category, two images that fit neither category, and two images that fit both the misconception and the target categories. The purpose of the latter was to make the learning situation somewhat more challenging by introducing a small amount of noise into the information the participants received.

\section*{Procedure}

Participants were seated in separate cubicles. Each participant was instructed to first participate in a training session, which consisted of a series of PowerPoint slides outlining how one can sort a variety of objects into different categories. The training session ended with participants categorizing stick figures based on their features. When participants finished with the initial training activity, they were instructed to participate in the more challenging bacteria paradigm.

Participants read the instructions for the task on the computer screen and asked questions if needed. Participants were given a script stating that alien bacteria was recently discovered on a distant planet and that scientists needed to determine whether there were oxygen resistant variants of the bacteria. Participants were then asked to rate how important each feature was in determining oxygen resistance on a 7-point Likert scale from 1 (Not at all) to 7 (Extremely). After rating the features, participants went through a prompt that described the importance of determining which bacteria were oxygen resistant. Each participant was tasked with determining whether the pictured bacterium was oxygen resistant. Participants indicated their response via the keyboard. The following responses were acceptable: \(\mathrm{y}=\mathrm{yes}, \mathrm{n}=\mathrm{no}, \mathrm{d}=\) don't know. Participants would then receive immediate feedback from the computer either stating that the bacterium was or was not oxygen resistant. Participants were instructed to make as few errors as possible.

After completing all trials, participants were again asked how motivated they were to perform the task well and to rate the importance of different features in determining oxygen resistance on the same 7-point Likert scale as before. The participants keyed in an open-ended response about which features they thought determined oxygen resistance. They then went to the next screen which asked whether oxygen resistance was always determined the same way. Finally, participants answered demographic questions.

\section*{Results}

Thirty-eight participants in the complete condition and 36 participants in the incomplete condition met the criterion for inclusion in analyses (i.e., correctly classifying 14 of 16 alien bacteria in any of the initial five training blocks). The inclusion criterion was chosen as a way to insure that we tested participants who were successful in learning the misconception. We wanted to examine whether falsification is necessary for adopting a new method of categorization for the participants who succeeded in learning the initial misconception feature, not whether falsification is necessary to learn the target category from scratch.

\section*{Learning Misconception}

Our first analysis determined whether random assignment was effective at producing equivalent groups. In order to determine whether participants might differ in their ability to learn the misconception, we examined their performance on the first five blocks via a repeated measures analysis of variance (ANOVA) with Greenhouse-Geisser correction found a main effect for blocks, that is, regardless of condition, participants improved in performance from blocks 1 thru 5, \(F(2.32,166.84)=66.76, p<.001, \eta_{\text {partial }}^{2}=\) .653. There was no main effect of condition, \(F<1, \eta_{\text {partial }}^{2}=\) .008 nor did groups differ at rate of learning, \(F(2.32\), \(166.84)=1.09, n s ., \eta_{\text {partial }}^{2}=.307\). These results suggest that the groups were equivalent in their ability to learn the misconception.

\section*{Learning the Target}

Our next step was to assess whether the confirmatory condition learned the target in blocks 6 through 10. Performance of 14 out of 16 or greater on any of the blocks 6 through 10 was rated as successful learning of the target; we found that 29 of 36 (80.55\%) participants correctly learned the target category. Whereas, if participants maintained the misconception for all trials they would have resulted in 0 of 36 participants demonstrating that they learned the target.

Using a chi-squared goodness-of-fit test we measured overall target acquisition (i.e., in general did learning occur yes or no) against a more stringent probability (i.e., chance at 50\%). Specifically, the results revealed that the confirmatory condition's target acquisition was better than chance, \(\chi^{2}(36)=13.44, p<.001\). Similar results were found for the complete condition where 29 of 38 (76.31\%) participants learned the target, \(\chi^{2}(36)=9.00, p<.01\).

\section*{Differences between Groups for Target Learning}

We examined whether conditions differed in target acquisition via a chi-squared test-of-independence that showed that the groups did not differ in target acquisition, \(\chi^{2}\) (36) \(=2.90, p=.09\). This suggests that removing the ability to directly falsify the misconception does not hinder a learner's ability to adopt a new method of categorization.

Additionally, we examined potential differences in learning rate based on condition following the switch. That
is, we wanted see whether one group learned faster than the other. A repeated measure ANOVA with GreenhouseGeisser correction was used to determine whether there would be a difference in performance following the switch from the misconception to the target for blocks 6 through 10. The analysis revealed a main effect for blocks showing that participants improved with training, \(F(2.646,190.477)\) \(=75.01, p<.001, \eta_{\text {partial }}^{2}=.671\), and a main effect for condition showing that the confirmatory condition performed better than the direct condition, \(F(1,72)=7.60\), \(p<.01, \eta_{\text {partial }}^{2}=.096\). The interaction was significant, rate of learning was faster for the confirmatory condition than the complete condition, \(F(2.646,190.477)=5.21, p<.01\), \(\eta_{\text {partial }}^{2}=.146\). These results suggest that the confirmatory condition may result in faster learning of a new conception (see Table 1).

\end{tabular}

\section*{Overview of Response Type by Condition}

In Figure 3, responses that are misconception consistent (MCR) or target consistent (TCR) separated by condition are shown by training block. MCRs were responding no on target bacteria and TCRs were responding yes on target bacteria. These response types are independent from each other because of the don't know response option. The figure shows how response tendencies changed when the feedback was altered to support the target within and between conditions.

Figure 3. Percentage consistent with response type by condition.

\section*{Discussion of Experiment 1}

The results of Experiment 1 suggest that the incomplete, confirmatory feedback only condition might initially speed
up learning of a new conception in comparison to the complete condition. We investigated whether participants would adopt a new conception after the switch and whether rate of learning would vary based on condition. We found that the participants in both conditions adopted the new conception. However, participants in the complete condition learned at a slower rate than those in the confirmatory condition. We propose that this difference was due to the need for participants in the complete condition to make sense of conflicting information. The sense making absorbed cognitive resources that otherwise would have been available for learning the target category, slowing down the re-categorization process.

\section*{Experiment 2}

In Experiment 2, we attempted to replicate the findings of Experiment 1 with the addition of two learning aids. Learning aids were included in an effort to reduce the number of participants that are eliminated from analysis for failing to learn the misconception. The first learning aid was included in the prompt that participants read before engaging in the categorization process. The learning aid suggested that parts within the cell body may be influential in determining oxygen resistance (This statement is true as both misconception and target features are within the cell body). We assumed that the inclusion of this statement might focus search for what promotes oxygen resistance to the interior of the bacteria. The second learning aid was a handout that showed an image of the bacteria with parts labeled (see figure 1) as well as a list of the possible variants of each feature. This was meant to serve as a working memory aid.

Finally, the handout included a statement that "some of the images of the bacteria that you will see may be INCOMPLETE, that is, all bacteria have the 6 parts described, but some parts may not be visible." This aspect of the handout was included in an effort to refute claims that participants may be viewing bacteria that do not show the dark nuclei as being bacteria without nuclei, which could result in a different interpretation of the stimuli by the participants.

\section*{Method}

\section*{Participants}

Sixty-one introductory psychology students participated in the study for course credit. Random assignment yielded 30 participants in the complete condition and 31 participants in the confirmatory condition.

\section*{Design \& Procedure}

The same procedure as in Experiment 1 was used in Experiment 2, with the addition of the two learning aids (i.e., the hint in the prompt and the handout).

\section*{Results}

Twenty-one participants in the complete condition and 21 participants in the confirmatory condition met the criterion
for inclusion in analyses (i.e., correctly classifying 14 of 16 alien bacteria in any of the first five blocks).

\section*{Learning Misconception}

Our first analysis sought to determine whether participants might differ in their ability to learn the misconception via a repeated-measures ANOVA where we examined percentage correct per block for the first five blocks. We found a main effect for blocks, that is, regardless of condition, participants improved in performance from blocks 1 thru 5, \(F(4,160)=\) 55.60, \(p<.001, \eta_{\text {partial }}^{2}=.582\). There was no main effect of condition, \(F(1,40)=1.69, p=.201, \eta_{\text {partial }}^{2}=.041\) nor did groups differ at rate of learning, \(F(4,160)=1.19, p=.319\), \(\eta_{\text {partial }}^{2}=.029\). These results suggest that the groups were equivalent in ability to learn the misconception.

\section*{Learning the Target}

Our next step was to assess whether the confirmatory condition learned the target in blocks 6 through 10. Performance of 14 out of 16 or greater on any of the blocks 6 through 10 was rated as successful learning of the target. We found that 15 of 21 ( \(71.43 \%\) ) participants correctly learned the target category. Using a chi-squared goodness-of-fit test the results revealed that the confirmatory condition's target acquisition was better than chance, \(\chi^{2}(21)\) \(=3.86, p=.05\). Alternatively, results for the complete condition where 14 of 21 (66.67\%) participants learned the target, their target acquisition was not better than chance, \(\chi^{2}\) (21) \(=2.33, p=.127\).

\section*{Differences between Groups for Target Learning}

We examined whether conditions differed in learning the target via a chi-squared test-of-independence that showed that the groups did not differ in learning the target, \(\chi^{2}(42)=\) \(.11, p=.739\). This replicates the finding from experiment 1 that the ability to directly falsify a misconception is not necessary for learning the new conception.

Given the relatively small sample size for Experiment 2 and the likelihood of differences occurring in earlier blocks we opted to conduct a series of t-tests on target learning blocks 6 through 10 instead of a repeated measure ANOVA, which might fail to differentiate the effect. The results of the t-tests revealed that participants in the confirmation condition performed better than the complete condition for block \(6, t(40)=4.56, p<.001\) and marginally better on block 7 for a one-tailed t-test, \(t(40)=1.67, p=.051\). There were no differences between the groups for blocks 8,9 , and 10, \(t<1\) (see Table 2).

Table 2: The means and (standard deviations) for percentage correct for blocks 6-10.

& \((12.66)\) & \((19.89)\) & \((16.11)\) & \((19.8)\) & \((23.67)\)
\end{tabular}

\section*{Discussion}

In the present study, we examined whether participants randomly assigned to receive one of two types of stimuli differed in their ability to falsify an initially acquired category. The present findings provide modest support that there may be instances in which falsification is not only unnecessary for overriding a prior conception, but might actually be harmful. In both Experiments 1 and 2 we found that participants who could not directly falsify the misconception adopted the target conception in fewer trials compared to those participants who could falsify the misconception directly.

If replicated, our demonstrating that falsification is not necessary for categorical change could have multiple implications. For instance, theories of conceptual change that posit the necessity of dissatisfaction might themselves need revision. In addition, instruction in the classroom for scientific topics known to require knowledge revision has found that direct refutation is not necessarily effective at promoting change (Vosniadou, 1994; Vosniadou \& Verschaffel, 2004), but perhaps novel development of another ontological structure could without refutation be developed and then integrated into the learning environment. Further investigation would be required in order to determine the most effective ways to improve conceptual change processing amongst students.

The present work should be viewed in consideration to its experimental controls, which might limit external validity. Specifically, the use of novel stimuli may not promote the same types of recategorical processes as stimuli that hold some greater individual meaning. Additionally, the population used in the study (university students) cannot be expected to adequately represent all types of learners. Furthermore, the learning processes observed in this experiment were of short duration. In many situations that require non-monotonic cognitive change, a direct verbal statement of the target concept is available but it was not part of our experimental procedure. Finally, we point out that conceptual change in real life usually involves a system of interrelated concepts rather than a single concept.

Future research might explore how different types of stimuli might influence recategorical change. Moreover, studies that mimic a classroom environment might also offer insights into what processes might bring about conceptual change. Additionally, studies that are able to use multiple daily training sessions and then attempt to recategorize might help in the understanding of temporal exposure and its influences on recategorization.

\title{
The 'universal' structure of name grammars \\ And the impact of social engineering on the evolution of natural information systems
}

\begin{abstract}
Proper name systems provide individuals with personal identifiers, and convey social and hereditary information. We identify a common information structure in the name grammars of the world's languages, which makes this complex information processing task manageable, and evaluate the impact that the re-engineering of naming practices for legal and political purposes has had on the communicative and psychological properties of these socially evolved systems. While East-Asian naming systems have been largely unaffected by state legislation, legal interference has transformed Western naming practices, making individual names harder to process and remember. Further, the structural collapse of Western naming systems has not affected all parts of society equally: In the US, it has had a disproportionate impact on those sections of society that are least successful in economic and social terms. We consider the implications of these changes for name memory across the lifespan, and for future naming practices.
\end{abstract}

Keywords: Names; Learning; Memory; Information Theory

\section*{What's in a name?}

Naming is unique to our species and central to our lives. Names are the primary linguistic means by which we discriminate individuals from their peers, and they are an integral part of our identities. Names also play an important social role: they carry hereditary information that helps regulate marriage between relatives and the transference and distribution of property, as well as fostering group identities that bring cohesion to the conduct of social enterprises such as agriculture, industry, statecraft, and war.

While names for individuals appear to be as old as civilization itself, some functions of names are recent developments (Scott, 1998). Henry VIII decreed that English marital births be recorded under the surname of the father in the 14th Century, but children could, and regularly did adopt different surnames. Hereditary family names only became universal in the UK with the establishment of Her Majesty's Register Office in 1836 (Matthews, 1967). Naming conventions in the Netherlands were formalized by statute in 1811 (Van Poppel, Bloothooft, Gerritzen \& Verduin, 1999); in Korea, naming practices were regulated in 1812 (Nahm, 1988), the same year that a Prussian edict granted citizenship to Jews in return for the adoption of fixed patronyms (Scott, Tehranian \& Mathias, 2002).

Despite their personal and social importance, names are uniquely difficult to learn and remember (Cohen, \& Burke, 1993; Valentine, Brennen \& Bredart, 1996). Names produce most naturally occurring tip of the tongue states (TOTswhere one cannot produce a word one is sure one knows) (Rastle \& Burke, 1996; Griffin, 2010); patients with cognitive impairments show greater decrements in name
retrieval than for other knowledge (Yasuda, Nakamura \& Beckman, 2010); and the recall of names appears to be disproportionately impaired in old age. Indeed, many older adults consider deteriorating name memory to be the most disturbing cognitive problem they face (Lovelace \& Twohig, 1990).

Here, we identify a common information structure in the name grammars of the world's languages, and reveal the impact that regulating names for legal and political purposes has had on their memorability as populations have grown in the wake of industrialization: while some name systems survive intact, legislation has had a detrimental effect on many name grammars, dramatically undermining their communicative efficiency.

\section*{Why names are different-and difficult}

While most nouns are generic-spoon, dog, ideapersonal names are sui generis: ideally, they uniquely discriminate individuals from their peers. While this could easily be achieved by giving each individual a unique label, this approach would massively increase linguistic complexity. By now, it would have generated a billion extra English words. At points in speech where a name could occur in this kind of a system, entropy-a formal, information theoretic measure of uncertainty (Shannon, 1948)-would vastly exceed anything heretofore encountered. Because entropy peaks accurately predict difficulties in the production and comprehension of speech (McDonald \& Shillcock, 2001; Clark \& Wasow, 1998), this would cause far more processing problems than actual English names, which are already far more taxing than other vocabulary items.

Thus, while 'one-name-per-person' would eliminate residual uncertainty about the identity of named individuals, it would maximize processing demands in doing so. Realistically, the psychological cost of such a system is too high: Given the highly social, interconnected nature of human life, and our finite information processing capacities, one-name-per-person would prove unworkable as societies developed beyond small groups. Unsurprisingly, no major language has a naming system remotely close to it (Alford, 1987).

\section*{A "Universal" Grammar for Names}

Although some fine-grained details differ, all the world's major languages have evolved the same solution to the challenges names pose: instead of using unique labels, individual identifiers are formed from hierarchically structured naming tokens. Name grammars enable large sets of identifiers to be constructed out of much smaller sets of
naming words, assigning individuals relatively unique identifiers, while avoiding the outrageous peaks in entropy that would result from a one-name-per-person system.
\begin{tabular}{lll} 
Family Name & Clan / Generation Name & Given Name \\
Least Uncertain & More Uncertain & Most Uncertain \\
Baek & Seung & Ki
\end{tabular}

For example, in the traditional Sinosphere (Matisoff, 1990) naming system used in Chinese-speaking countries and Korea (Kwang-Sook, 2003), names comprise 3 elements: 1) a small number of family names, 2) a clan or generation name (Martin, 2006), and 3) a given name, fairly specific to the individual. (Here, the first parts of physicist Seung Baek Ki’s name mean, "a Baek from Suwon." (Kiet, Baek, Jeong \& Kim, 2003)). Elements are distributed in these sets in a highly efficient, Zipfian manner (Baek, Kiet \& Kim, 2007)2: there are only around 250 Korean family names, three of which are common to around \(50 \%\) of the population ( \(20 \%\) of all Koreans are called Kim). Because of this, names act as efficient hierarchical decision trees: each name element increases the degree to which an individual is identified, while minimizing the entropy at the point each element is encountered (Figure 1).

These distributions have been stable for centuries. As Korea's population grew post-industrialization (Zipf, 1965), the peak entropy of Korean names barely changed. Name grammars in Chinese-speaking countries have developed along similar trajectories.

Figure 1. Hierarchical branching minimizes entropy (which quantifies the uncertainty produced when a number alternatives that need to be processed at any point) as a Korean name unfolds in time.

This efficient information structure is not unique to Sinosphere names: it is common to the native name grammars of all the world's major languages. For instance, traditionally, English names comprised a given name drawn from a relatively small set, optional middle name(s), and an identifier (in Modern English, a family name), drawn from a large set of personal characteristics, topographic and toponomic features, occupations and patronyms: e.g., John the Farmer, or John White Head. English names rarely contained a specific, unique identifier. Instead, individual identities were the sum of a name's parts: the 11th Century English name in (3) means, "Adam, a farmer from Ramscar" (Ramskir, 1973).
\begin{tabular}{lll} 
Given Name & Other Name & Identifier \\
Least Uncertain & More Uncertain & Most Uncertain \\
Adam & Hegger & de Romeskerre
\end{tabular}

What may be surprising from a modern perspective is that the distributional pattern of names in modern Korea would have been familiar to pre-industrial Europeans: In every 50year period from 1550 to 1799 , around \(50 \%\) of boys born in England were named William, John or Thomas, and 50\% of girls Elizabeth, Mary or Anne (Smith-Bannister, 1997), mirroring the distribution of Korean family names. Given names in other Western and Northern European languages were also distributed this way (Galbi, 2002; Lieberson \& Lynn, 2003; Bourin, 1994) even when patronymic conventions were employed (Williams, 1961). Historically, compact, stable Zipfian first name distributions were the norm: prior to industrialization, one-in-five English girls had the first name Mary, just as around one-in-five Korean girls today has the first name Kim. What caused some distributions to change, while others have remained as they were?

Figure 2. The hierarchical organization of modern English names. The proportion of surnames to given names reflects the fact that given names-which occur before surnames in Englishcontribute less to individual identities than surnames. The surnames depicted here represent over \(95 \%\) of the US population in the 2000 census, and the given names over \(95 \%\) of social security applications in the US in 2000.

\section*{The rise of nation states, and their impact on Western name grammars}

Ordinarily, nobody knows everybody. However, the development of centralized states created entities that actually did want to know everyone: for the purpose of taxation, conscription, etc. To facilitate this, states regulated names. In the Sinosphere, the burden of coding heredity fell on the first (least diverse) name element. However, in other parts of the world, the final, most diverse element was targeted. In English, idiosyncratic features specific to individuals - such as John the farmer, John with the white head - became fixed hereditary markers, such that bakers might be called Farmer, or redheads Whitehead. English name grammar retained its hierarchical structure (Figure 2). Consequently, as population growth accelerated in the 19th and 20th centuries (Figure 3), two changes occurred:
1. A larger, more diverse set of first names began to be used, increasing the peak signal entropy of names, making them harder to process and recall.
2. More people shared last names, increasing the likelihood of two people having the same name, increasing residual entropy about the individual identified by a name.

Both these changes had an impact on the efficiency of English names.

In the UK in 1801, 3 male names accounted for \(52 \%\) of male births and 3 female names 53\% of female births (the traditional distribution). By 1994, this had dropped to \(11 \%\) and \(9 \%\), respectively. In both instances, the relationship to population growth is strong: \(\mathrm{r} 2=.99 \& .97\). Similarly, while in \(1801,85 \%\) of males and \(82 \%\) of females received 1 of 10 names, by 1994 , this had dropped to \(28 \%\) and \(24 \%\); related to population growth, \(\mathrm{r} 2=.99\) and .97 . In \(1801,22 \%\) of males and \(24 \%\) of females in the UK received the most common first name for their sex; in 1994, it was \(4 \%\) and \(3 \%\) (both \(\mathrm{r} 2=.98\) ). Social Security card applications in the US between 1900-1999 show the same patterns of change in naming: a big decline in the number of babies being given the most frequent names, and an increase in the diversity of given names. (For all reported correlations, \(\mathrm{p}<0.001\) )
*The sample for this survey was taken from the U.S. Social Security Administration (http://www.ssa.gov/oact/babynames/).

Figure 3. The top panel illustrates the distribution by rank frequency of Korean family names in 2000. The bottom panel shows the change in the written frequencies of the 500 most common US male names as the United States population grew in the \(19^{\text {th }}\) and \(20^{\text {th }}\) Centuries \((1810-1990)\). The greater similarity in the distribution of Korean family names and American male names at the beginning of the \(19^{\text {th }}\) Century is apparent, as is the change thereafter.

An analysis of the 500 most common male names from 1810-1990 in the Corpus of Historical American English (400,000,000 words) indicates that at the beginning of the 19th century, US given name distributions were similar to Korean family names (Figure 3). While the distribution of Korean family names remained stable, the distribution of

American and British given names changed dramatically as populations grew.

\section*{Measuring the Effects of Change: A Tale of Two Congresses}

Mainland China has experienced massive population growth in the past two centuries, but its traditional Sinosphere naming system has changed little as a result (Yuan, 2002; Mountain, Wang, Du, Yuan, 1992). To illustrate how the changes to the distribution of American names have affected name efficiency, we compared two similarly-sized, naturally-occurring samples of names from each of these two countries: the Senators and Representatives of the 112th United States Congress ( \(\mathrm{n}=440\) ), and the members of several subcommittees of the National Committee of the Chinese People's Political Consultative Conference ( \(\mathrm{n}=431\) ).
*The samples for this survey were taken from the website of the United States Congress (http://www.house.gov/representatives/) and the website of the Chinese People's Political Consultative Conference (http://www.cppcc.gov.cn/)

Figure 4. The information challenge posed by names as their numbers grow. The y-axis plots perplexity, which describes the entropy ( x -axis) in a complex distribution in terms of a number of equally likely alternatives. The perplexity of US names is more than twice that of Chinese names in this sample.

The total entropy of both samples is almost identical (US Congress \(=8.78\) bits; CPPCC \(=8.75\) bits), because in each case, no members share names; accordingly, there is no residual entropy in either sample. There is, however, a marked disparity in the way information is distributed in the samples: the first elements in the CPPCC names contain only 5.84 bits of information (in information processing terms, this is equivalent to differentiating between around 60 equally likely name labels; Figure 4). By contrast, the given (first) names of US Congress members contain 7.39 bits (equivalent to processing around 170 equally likely labels). Both sets of names convey the same amount of overall information, but this information is more evenly distributed in Chinese names: US first name elements impose far greater information processing demands than their Chinese equivalents, and later US name elements are far more redundant (full form analysis-treating Mike / Mick as forms of Michael-reduced US name perplexity to 120 ,
suggesting that Congressional names would more memorable if nicknames were avoided).

\section*{Winners and Losers in the Decline of the US Naming System}

Although the efficiency of English names has declined in the past 200 years, the effect of these changes has not been felt in the same way across society. Traditionally, the perplexity of US female names was slightly greater than male names (Figure 5A), but the difference in perplexity between male and female names was relatively constant. However after 1950 this difference began to rise sharply (Figure 5B), increasing the difference in the amount of information that had to be processed in recalling, producing and comprehending female names as compared to male names.
\[
\begin{aligned}
& \text { The Perplexity Gap 1880-2010 }
\end{aligned}
\]

Figure 5. Top: The perplexity of male and female names with a count \(\geq 5\) in US social security applications at 5 year intervals from 1880 to 2010. Bottom: The difference in the perplexity of female names as compared to male names (female perplexity - male perplexity) across this period.

Given that the period since 1950 saw an increase in economic and social equality between males and females in the US (Fullerton, 1999), the close relationship (Figure 6A) between the growth in the perplexity difference between male and female names and the increasing percentage of females in the workforce is surprising, as is the fact that increases in the number of women working outside the home have coincided with an exponential increase in the degree to which female names are harder to process than male names. Figure 6B offers one possible explanation for this: the strong correlation between population size and female name diversity may indicate that parents actually take great care in naming their daughters, but that the
constraints that have been imposed on Western naming practices are distorting the intended effect of name choices.
Figure 6. Top: The proportion of men and women over age 16 in the US workforce (male - female percentage) plotted against the different perplexity of female and male names (female perplexity male perplexity) in the period 1950-1998 (data from the US Bureau of Labor Statistics \& US Social Security Administration).
Bottom: The increase in the US population at five-year intervals from 1880-2010 and the increase in the number of male and female names with a count \(\geq 5\) in US social security applications.

\section*{Nobody Knows My Name}

Women are not the only group in the US to have experienced a disproportionate decline in name efficiency. As has often been noted, African American parents systematically choose distinctive given names for their children (Lieberson \& Mikelson, 1995). The pattern of this trend is puzzling: although Black parents living in predominantly White communities choose distinctive names for their children, Black parents living in predominantly Black communities choose even more distinctive names. (If it were simply the case that parents choose distinctive names to signal affinity with the wider Black community, the opposite pattern might be expected; Fryer \& Levitt, 2004).

The question is: why? As we noted earlier, when surnames are fixed and a population expands, the residual entropy of names invariably rises. In such circumstances, parents may be more likely select diverse first names for their children to increase their name's overall uniqueness. Given the legacy of slavery (Dunaway, 2003), residual entropy is a particular problem for the Black community, where a smaller (less diverse) pool of surnames places more of the burden of providing uniquely identifying information
on first name elements. The residual entropy of Black surnames is considerably higher than for White surnames: the most frequent 500 US surnames convey just 2.5 bits of information about the White community, but over 4 bits of information about the Black community \((\mathrm{t}(499)=8.00\), \(\mathrm{p}<0.001\); Figure 7), meaning that surnames convey far less information about individuals within Black communities. Residual perplexity-which increases when more people share a surname-is twice as high for these names in Black communities than in White communities. Since people called Smith will be likely to give their children distinctive first names (because the surname Smith has high residual entropy), and since this likelihood will increase if a high proportion of their neighbors are also called Smith, the tendency of Black parents to choose more distinctive names for their children when their neighbors are Black than when they are White is not really puzzling at all: it simply reflects the desire of parents to provide each child with a unique identifier.

Figure 7. Top: The residual entropy of the 500 most common American surnames in the White- and African-American communities ( 2000 US Census). Bottom: The 500 most common White surnames and 500 most common Black surnames (high residual entropy \(=\) less information about individuals).

\section*{Names, age and memory}

Problems with remembering names represent the most disturbing aspect of aging for many people. The analyses reported here raise a question: does memory for names really decline, or are older adults confusing social change with personal change? After all, the changes to the distribution of Western names guarantees that name processing must have grown increasingly difficult over the last century. To provide an estimate of the effect this could have had on name memory, we examined the effect of
changing name distributions in a model that simulates human performance in lexical decision tasks.

The naive discriminative reading model (NDR; Baayen, Milin, Durdevic, Hendrix \& Marelli, 2011) is a two-layer network that takes letter unigrams and bigrams as cues, and learns to discriminate lexical targets as outcomes (e.g., 'hand', 'John') using the equilibrium equations (Danks, 2003) of the Rescorla-Wagner (Rescorla \& Wagner, 1972) learning rule. The model's output is entirely determined by its training corpus-it has no free parameters-and it captures a wide variety of empirical effects in reading (Baayen, 2010; Baayen, Hendrix \& Ramscar, in press), and successfully predicts patterns of age-related reading time differences (Ramscar, Hendrix \& Baayen, 2012).

To simulate the cross-generational effects of changing name distributions, three versions of the NDR were trained on an identical set of naturalistic linguistic training data ( \(1,500,000\) tokens from the Google Unigrams Corpus were used to simulate the experience of reading to age 20). Names from the distribution of US social security applications for a given year (1910, 1960 and 2010) were interpolated into this sample, based on the frequency with which names appear in the corpus, and the distribution givens name in each year. Recognition latencies were calculated for the set of names common to the 1910, 1960 and 2010 name distributions, and for the total set of names learned by each model: Figure 8A shows the cost the distribution of names imposes at each point in time, and Figure 8B shows the average effect this had on precisely the same set of names. The simulations suggest that the simple task of recognizing a name grew harder in the 20th Century, especially in its latter half: the change in simulated reaction time from 1960 to 2010 is three times greater than 1910 to 1960.

Not only did the number of names increase dramatically (the 1960 model learned \(60 \%\) more names than the 1910 model, and the 2010 model \(83 \%\) more), but the number of non-name words that were learned declined over time, by \(2.5 \%\) in 1960 , and \(5 \%\) in 2010 . Given that the models were trained on exactly the same number of name tokens, this reflects the degree to which the boundary between English names and non-names has become blurred over time, increasing the memory problem that names pose.

Figure 8. A plots the average simulated recognition times for the set of names learned by a " 20 year old" model trained on 1.5 million unigrams when sampling from the name distribution in 1910 (left bars), 1960 (center bars) and 2010 (right bars). B plots the average simulated reading times in each model for the set of names that are common to the 1910, 1960 and 2010 US social
security applications: i.e., each model's predictions for the same set of names.

Finally, to simulate the effect of these changes within a single lifespan, we compared the predictions of a " 20 year old" reading model, trained on \(1,500,000\) unigram tokens, with names sampled from the summed distribution of social security applications from 1950-1960 (the age at which current septuagenarians were 20), to a model trained on \(9,000,000\) unigram tokens, sampling from the summed name distribution from 1950-2010 (extending the "experience" of the younger model to age 70).

Figure 9. A plots the average simulated recognition times for the set of names learned by a "20 year old" model (trained on 1.5 million unigrams, including names from the 1950-1960 distributions; left bars), and a " 70 year old" model (trained on 9 million unigrams, including names from the 1950-2010 distributions; right bars). B plots the average simulated reading times in each model for the set of names that are common to 1960 and 2010 US social security applications. The area below the dashed line represents a 320 ms response constant (button pressing) added to both models in simulating reaction times.

Names and other proper nouns comprise a very large proportion of natural language: whereas the younger model learned 34,480 word types and 4,540 names, the older model learned 61,839 word types and 19,976 names. Although total vocabulary doubled, name lexicon grew fourfold. Figure 9A shows the predicted impact of experience on average name recognition for someone aged 70 in 2010 as compared to fifty years earlier. Figure 9B shows the projected effect of these processing costs on the same set of names in the same individual. After a response constant is removed from the simulated latencies, the model predicts that on average, simply recognizing a name will take today's septuagenarian nearly half a second longer than when she was 20 . Although older adults have hard time remembering names in comparison to their younger selves, a large part of this difference is likely due to the increasing complexity of social name distributions, and the increasing number of names that individuals encounter over the course of their lives.

\section*{The Name Game}

We identified a common information structure in the world's name grammars that helps satisfy the complex demands of communicating about individuals, and described some of the consequences of recent changes in Western naming practices. Two things are worth noting
about these findings: First, the data we report are not inferred from samples of populations, but are instead calculated from records representing the actual populations themselves; and second, the information theoretic methods we used to analyze this data describe and govern all of the physical devices that have come to define our information age. Accordingly, our finding that American female names have twice the perplexity of male names is a statistical fact about the population, which entails that female names in this country must exert considerably higher information processing costs than male names.

These findings may help shed light on many social issues that are far less clear-cut: for example, an often cited reason for the under-representation of women in many professional bodies is that when appointments are made, women's names often don't "come up" (Donald, 2012). It is highly likely that the different processing costs associated with male and female names contribute to this. In a similar vein, these findings offer food for thought for parents choosing names for children in the West, as well as for people with names formed using different grammars as they traverse our increasingly multicultural world. In particular, these findings suggest that the tendency to simply reverse the order of Asian names in Western languages should be viewed with caution.

Finally, these results have implications for our understanding of memory and aging. The belief that memory processes decline as we age rests, in large part, on apparent selective deficits for names in the elderly (Shafto et al., 2007). However, the problem of remembering a name has been getting exponentially harder since before anyone now alive was born (Figure 7). Because current measures of name memory 'deficits' fail to take into account changes to name distributions, it is unclear whether name memory really does decline, or whether these measures simply reflect the overwhelming increases in name information we have documented (see also Dahlgren, 1998; JuncosRabadán, Facal, Soledad Rodríguez \& Pereiro, 2010). It may be that older adults troubled by their "declining" name memories are presently falling into the trap of taking personal responsibility for a broader social problem.

At the height of the information age, in a world where population growth is inexorably increasing the amount of name information societies must shoulder, the social practices that evolved to maximize the efficiency of name processing are, in many cases, in a state of collapse. Although names are the hardest vocabulary items people have to learn and remember, the problems they pose are currently far harder than they should be. Understanding the information structure of names, as well as how name efficiency can vary and be quantified, can help individuals and societies make more informed choices about names and naming practices. It may even make the names of future generations easier to recall.

\title{
The Cross-Domain Re-interpretation of Artistic Ideas
}

\author{

\begin{abstract}
The goal of this study was to investigate the translate-ability of creative works into other domains. We tested whether people were able to recognize which works of art were inspired by which pieces of music. Three expert painters created four paintings, each of which was the artist's interpretation of one of four different pieces of instrumental music. Participants were able to identify which paintings were inspired by which pieces of music at statistically significant above-chance levels. The findings support the hypothesis that creative ideas can exist in an at least somewhat domainindependent state of potentiality and become more welldefined as they are actualized in accordance with the constraints of a particular domain.
\end{abstract}

Keywords: art; artifacts; common coding; creativity; domain generality; ekphrastic expression; individual differences; interpretation; music; self-expression; style; potentiality; synesthesia; translation.

\section*{Introduction}

Although much social interaction occurs directly through words or actions, a great deal of what humans attempt to communicate, such as ideas for works of art, science, or technology, are not readily expressed through these channels. Complex ideas are therefore often communicated indirectly by way of artifacts. There is evidence that artists leave something of themselves-their own personal signatures or creative styles-in their artifacts, and that creators' identities are recognizably present in their creative works. For example, creative writing students familiar with each other's writing identified significantly above chance, not just which of their creative writing classmates had written each particular piece of writing but which of their creative writing classmates had created each artwork (Gabora, 2010; Gabora, O’Connor, \& Ranjan, 2012). Thus, at least in some cases, if a viewer is familiar with the works of creators in a particular domain (such as creative writing), it is possible for the viewer to recognize which creator generated which work, and this is even the case if the works are in a different domain (such as art).

This does not, however, imply that creative artifacts are just the external expression of individual style. We suggest that artifacts constitute a beehive of hidden social interaction, and that their forms reflect, in part, the attempt to transcend one's individuality, i.e., to relinquish oneself to the essence of an idea. We suggest that when personal style is recognizably evident in a work, this is not necessarily due to an attempt to express this style, but a side effect of
participating in the human enterprise of interactively evolving cultural outputs by adapting them to different personal styles, perspectives, and modalities. The creative process involves not just accessing and combining knowledge, experiences, and ideas, but also inspiration, translation, and re-interpretation (Cropley, 1999; Feldhusen, 1995, 2002; Munford \& Gustafson, 1988; Sternberg \& Lubart, 1995). Components of a creative work may originate from oneself, others with whom one has communicated directly or indirectly by way of others, or even multiple individuals through the course of history who each put their own spin on it. Inspiration may come from a work in same domain as the work it inspires (as when one poem inspires an idea for another poem). Alternatively, an idea may first be expressed by one individual in one domain, and subsequently translated by someone else into another domain (as when a piece of music gets re-cast in another musical genre, or even inspires a poem). With the advent of new technologies and social media, the distinction between social interaction and individual creative expression becomes increasingly blurred. For example, as one moves from face-to-face communication, to avatarmediated communication, to music inspired by and intended for someone else, to background music to accompany the activities of a particular cartoon character, to music composed with no obvious inspirational source, it is difficult to draw the line between social interaction and individual self-expression, and cross-modal perception.

The goal of this research was to test the hypothesis that it is possible to recognize the source of inspiration for a creative work when that source of inspiration comes from a different medium. There are several phenomena that suggest that a creative work need not be in the same domain as the inspirational source for the work.

\section*{Related Phenomena}

We now review phenomena that point to cross-domain interpretation of ideas as a source of the character of creative works: synesthesia, ekphrastic expression, and cross-domain style.

Synesthesia Individuals referred to as synesthetes naturally and spontaneously translate stimuli into another sensory domain. For example, they may see particular letters or numbers in particular colors. Ramachandran (2003) proposed that synesthesia occurs as a result of hyperconnectivity in the brain due to partial collapse of the barrier between sensory domains. Artists, poets, and novelists, are
more likely than average to be synesthetes, which suggests that synesthetically driven re-interpretation of inputs from one modality to another can play a role in these creative domains (Ramachandran, 2003).

Ekphrastic Expression There is a tradition in the arts of interpreting art from one medium (e.g., oil paint) into another (e.g., watercolor) and thereby coming to know its underlying essence. This practice is referred to as ekphrastic expression. The idea behind ekphrastic expression is that an artist may have a more direct impact on an audience by translating art from one medium into another medium because this involves capturing, and thereby becoming intimate with, its underlying form or essence. Ekphrasis may be related to the late nineteenth Century practice of associating particular kinds of music with particular colors. There is anecdotal evidence that music of this time frequently served as a direct inspiration for paintings, and musical terminology was used as titles for paintings. Ekphrastic expression is not just a phenomenon of the past. Modern day film composers attempt to compose music that conveys the emotional tone of the events portrayed in the film, thereby heightening the viewer's experience of these events. Thus film scoring can be seen as a form of ekphrasis. The application of ekphrastic methods in the arts supports the idea that creative individuals extract patterns of information from the constraints of the domains in which they were originally expressed and transform them into other domains.

Cross-Media Style Another reason to suspect that the character of creative works arises through cross-domain reinterpretations of ideas is the widespread phenomenon of cross-media style. This refers to artistic style that is demonstrated by works of art in more than one medium. For example, the term rococo is applied to a style of painting, sculpture, literature, and music of the \(18^{\text {th }}\) Century. Works in a given style are thought to derive from abstract archetypal forms or potentialities that make the artistic mind want to explore different arrangements or manifestations (Burke, 1957).

Cross-modal Perception The phenomenon of crossmedia style provides evidence that creative works in different media may be similar in terms of psychophysical, collative, and ecological properties (Hasenfus, 1978). Aesthetic perceptions stimulated by creative works may generate emotional, cognitive, behavioral, and/or physiological responses that are amenable to re-expression in another form. This may arise in part due to regularities with respect to the choice of elements (i.e., colors, shapes, words) and/or how they are used (e.g., in an orderly or chaotic manner) (Berlyne, 1971). Studies indicate that there are non-arbitrary mapping between properties of vision and sound (Griscom \& Palmer, 2012; Mark 1975, Melara, 1989; Melara, \& Marks, 1990; Melara \& O’Brien, 1987; Palmer, Langlois, Tsang, Schloss, \& Levitin, 2011; Ward et al. 2006). For example, the processing of some visual features, such as spatial frequency and lightness, can be affected by auditory features such as pitch and timbre (Mark, 1987).

In the study that perhaps comes closest in spirit to this one, composers were asked to write music inspired by four simple line-drawn shapes: a square, a lightning bold, a curvy shape, and a jagged shape (Willmann, 1944). Music inspired by the same shape was more similar than music inspired by another shape with respect to tempo, melodic pattern, mood, and other characteristics, and listeners could match above chance the music to the shape that inspired it. However, the music could not be said to be reinterpretations of creative works, for the impoverished nature of the stimuli undoubtedly limited the scope for creative expression. The study reported here is the inverse of Willmann's; it investigates not music inspired by art but art inspired by music. Moreover, the goal was to go beyond simple crossmodal mappings to convey in another domain the rich emotionality of genuinely creative works.

\section*{Methods}

This study examined whether people were able to correctly recognize which works of art were inspired by which pieces of music. The study was divided into two phases. In the first phase, expert artists created four paintings, each of which was the artist's interpretation of one of four different pieces of instrumental music. In the second phase, naïve participants attempted to determine which piece of music was used as the source of inspiration for each artwork.

\section*{Phase One}

Participants Two local expert artists, each with approximately 25 years of experience in the field of painting, were recruited for this study. They each received \(50 \$\) for their participation.

Musical Stimuli Four pieces of piano music from commercially produced sound track CDs with no vocal tract and no other instrumentation were used as stimuli to inspire art. They were selected from a pool of 45 pieces chosen as exemplary of different musical styles: baroque classical, romantic, jazz, and contemporary. Each of these original 45 pieces of music was cropped to three minutes duration, and then rated by three raters on 64 descriptive adjectives on five point Likert scales. The adjectives were derived from previous research on the collative properties of stimulus patterns, specifically, measures of affective reactions to artwork (Berlyne, 1974), and the affective circumplex (Russel, 1980; Watson \& Tellegen, 1985). The raters had no previous musical training.

Factor analysis and multidimensional scaling were used to compute the basic dimensions of aesthetic experience in the ratings, and to reveal how the 45 pieces of music were dispersed in the dimensional spaces. The Euclidean distances between the pieces of music across the spaces were used to select four pieces of music from different regions that were clearly dissimilar from each other. The four selected pieces of music were:
(1) 'Love is a Mystery' by Ludovico Einaudi
(2) Number 29 B Flat Major', by Ludwig van Beethoven
(3) 'Circus Gallop' by Marc-André Hamelin

\section*{(4) 'All of Me' by Jon Schmidt}

Creation of Artworks Each of the two artists created one painting for each of the four pieces of piano music, for a total of 8 paintings. On days that paintings were to be created, each artist was provided with a single piece of music and asked to reinterpret it as a painting, i.e., to paint what the music would look like if it were a painting. They were instructed to paint while listening to the music, and encouraged to listen to it as many times as they wished while they painted. They were allowed to use whatever painting supplies they thought could most effectively express the music (e.g., watercolors, oils, and acrylics were all acceptable). They were instructed to complete their paintings in one sitting without interruption. They were instructed to take up to a maximum of 120 minutes to listen to the music and complete the painting. The paintings were created in the artists' personal studios. In order to limit the influence of the previous pieces of music on the new painting, the artists were instructed not to re-listen to the piece of music after the painting was finished, and there was a gap of four days between each painting session.

Representative examples of the music-inspired paintings obtained in Phase One of the study are provided in Figures 1,2 and 3 . These paintings constituted the stimuli that were used in Phase Two. Figures 1 and 2, painted by the same artist in response to different pieces of music, provide the reader with a qualitative sense of the extent to which an artist's personal style comes through in different paintings.

Figure 1. A painting generated by first of the artists as an interpretation of the piece Number 29 B Flat Major', by Ludwig van Beethoven.

Figure 2. A painting generated by first artist as an interpretation of the piece 'All of Me' by Jon Schmidt.

By comparing figures 2 and 3, painted by different artists in response to the same piece of music, the reader can obtain a qualitative sense of how a common musical source of inspiration manifests in different paintings.

Figure 3. A painting generated by the second artist as an interpretation of the piece 'All of Me' by Jon Schmidt.

\section*{Phase Two}

In the second phase of the study we tested whether it was possible to recognize which pieces of music were interpreted as which paintings.

Participants The participants were two groups of undergraduates enrolled in psychology courses at the

University of British Columbia, consisting of 107 and 89 students respectively, for a total of 196 students. They received partial course credit for their participation.

Analytic Methods Two statistics, \(H\) and \(H u\), were computed to assess the accuracies of the participants' paintings-to-music matches. \(H\) is the simple hit rate, or the proportion of correct guesses. Hu comes from signal detection theory (Wagner, 1993). It corrects for chance guessing and for response bias, such as the tendency to use particular response categories more or less than other response categories. For each set of paintings (i.e., for paintings by artist one and artist two), two hit rate statistics were computed for each participant. One-sample t-tests and a data randomization procedure (Manly, 2007) were then used to assess the statistical significance of the mean \(H\) and \(H u\) values. The tests indicated whether the mean \(H\) and \(H u\) values were significantly different from the \(H\) and \(H u\) values that would have been obtained had participants provided random guesses.

Procedure and Materials This part of the study was set up online. There were two sets of the study, one for each artist. In each set, there were the four pieces of music and the four paintings created in phase one by each artist. Each painting was displayed on a web page. Next to each painting were links to the four pieces of music. Two groups of participants consisting of 89 and 107 students were asked to look at the painting and to listen to the four pieces of music respectively. They were asked to identify which piece of music inspired each painting.

\section*{Results}

The results are summarized in Table 1.
Table 1: Mean hit rates, \(t\)-test values, and \(r\) effect size for identification of paintings inspired by pieces of music. All hit rates and t values were statistically significant.
\begin{tabular}{lllll}
\hline & \begin{tabular}{c} 
Mean \\
Hit Rate
\end{tabular} & \begin{tabular}{c} 
Chance \\
Hit Rate
\end{tabular} & \(t(d f)\) & \begin{tabular}{r}
\(r\) \\
Effect \\
Size
\end{tabular} \\
\hline \begin{tabular}{lllll} 
Artist One \\
Hit Rate \((H)\)
\end{tabular} & .35 & .24 & \(4.0(88)\) & .39 \\
\begin{tabular}{l} 
Artist One \\
Unbiased
\end{tabular} & .36 & .24 & \(4.0(88)\) & .40 \\
\begin{tabular}{l} 
Hit Rate \\
\((H u)\)
\end{tabular} & & & & \\
\begin{tabular}{l} 
Artist Two \\
Hit Rate \((H)\)
\end{tabular} & .44 & .25 & \(6.3(106)\) & .52 \\
\begin{tabular}{l} 
Artist Two \\
Unbiased \\
Hit Rate \\
\((H u)\)
\end{tabular} & .46 & .25 & \(6.3(106)\) & .52 \\
\end{tabular}

For the first artist, the mean hit rates were \(H=.35\) and \(H u=\) .36. The mean hit rates that would have been obtained on the basis of random guesses for these questions were .25 and .25 , respectively. Both hit rates are statistically significant according to both conventional and data randomization t-tests \((\mathrm{t}(88)=4.0, \mathrm{t}(88)=4.0, \mathrm{p}<.001)\), and the \(r\) effect sizes were large, .39 and .40 . For the second artist, the mean hit rates were high, \(H=.44\) and \(H u=.46\), statistically significant according to both conventional and data randomization t -tests \((\mathrm{t}(106)=6.3, \mathrm{t}(106)=6.3, \mathrm{p}<\) .001 ), and the effect sizes were large, \(r=.52\) and \(r=.52\). Thus participants identified at above-chance levels which paintings were inspired by which pieces of music for both artist one and artist two.

\section*{Discussion}

There is a longstanding debate concerning the extent to which the semantic complexity of artistic works is amenable to scientific methods (Becker, 1982). We tested the hypothesis that the core idea behind a creative work is recognizable when it is translated from one domain to another. To our knowledge, the only other previous study to test this hypothesis (Willmann, 1944) used highly artificial stimuli that most would not consider creative works in and of themselves. The hypothesis was supported by our finding that when pieces of music were re-interpreted as paintings, naïve participants were able to guess significantly above chance which piece of music inspired which painting. Although the medium of expression is different, something of its essence remains sufficiently intact for an observer to detect a resemblance between the new work and the source that inspired it. The results are consistent with a number of phenomena familiar to artists, mentioned in the Introduction, namely synesthesia, ekphrastic expression, cross-media style, and cross-modal perception.

The research reported on here may be a step toward distinguishing between domain-specific and domain-general aspects of creative works. We suggest that at their core, creative ideas may be much less domain-dependent than they are generally assumed to be. Our results support the view that the uniqueness of a creative work derives at least in part from, not just the personal style of the creator, but from encounters with works in domains that differ from the domain of the creative output, or even different kinds of experiences altogether. In other words, it is possible for the domain-specific aspects to be stripped away such that the creative work exists in an abstracted state of potentiality at which point they are amenable to re-expression in another form. A creative idea may exist in form that is freed of the constraints of a particular domain, and that the creator's job may be in part to, to simply allow that domain-independent entity to take a particular form, using domain-specific expertise and the tools of his or her trade. Over time they may become more fully actualized, and well-defined, as they are considered from different perspectives in accordance with the constraints of the domain in which they are expressed.

The capacity for cross-domain translation of creative ideas supports the hypothesis that an individual's creative outputs are expressions of a particular underlying uniquely structured self-organizing internal model of the world, or worldview. Our creative abilities may be a reflection of the tendency of a worldview to transform in such a way as to find connections, reduce dissonance, and achieve a more stable structure (Gabora \& Merrifield, 2012). This view of creativity is consistent with previous research showing that midway through a creative process, an idea may exist in a 'half-baked' state of potentiality, in which one or more elements are ill-defined (Gabora, 2005, Gabora \& Saab, 2011). When a work is translated from one domain (e.g., music) into another (e.g., painting), the two works may be recognizably related because the process by which the worldview assimilates or comes to terms with the works is at a structural level deeply analogous.

Although that idea that at least some creative tasks involve the abstraction and re-expression of 'raw' potentialities or forms seems obvious to many artists we have spoken with, it stands in contrast with most academic theories of creativity. Creativity is typically portrayed as a process of searching and selecting amongst candidate ideas that exist in discrete, well-defined states. This can be traced back to early views arising in the artificial intelligence community, wherein creativity was thought to proceed by heuristically guided search through a space of possible solutions (Newell, Shaw \& Simon, 1957; Newell \& Simon, 1972; Simon, 1973, 1986) or possible problem representations (e.g., Kaplan \& Simon, 1990, Ohlsson, 1992). The view that creativity proceeds through a process of search and selection is also assumed in more contemporary theories, such as the theory that creativity is a Darwinian process; i.e., new ideas are obtained by generating variations more or less at random and selecting the best (e.g., Campbell, 1965; Simonton 1999a,b, 2005).

Our results bring up the question of what it was about the paintings that made it possible to trace them to the artworks that had inspired them. We are currently investigating to what extent people assign similar experience variable ratings and similarity ratings to paintings and the music that inspired them and whether these ratings correspond even when participants cannot identify which piece of music inspired the painting. A possible clue to the mechanisms underlying cross-domain interpretation of creative ideas comes from research by Feedberg and Gallese (2007) on perceiving action in artwork. They propose that art observers implicitly imitate the creative actions undertaken by the artist in the making of the work. In our study it is possible that observers were not just perceiving action in art but were also able to match qualities of the art with qualities such as the rhythm and tempo of the music that inspired it. The phenomenon of action perception in paintings could also at least partially account for the ability to recognize the essence of ideas interpreted across domains. In order to recognize the inspiration of an artwork or a cross-media style, expertise in a domain might stimulate the action
system while the observer imagines how the artwork was created. Thus, future research will also investigate the role of expertise in the recognition of a connection between works in different domains. We hypothesis that expertise in a domain might increase the activation of the action system while the observer imagines how the artwork got created, thereby enhancing the capacity for recognition of crossdomain re-interpretation in a task such as this.

The effect of inspirational source on creative output may be weaker than the effect of personal style reported earlier (Gabora, 2010; Gabora, O’Connor \& Ranjan, 2012), given that paintings by different artists inspired by the same piece of music could be quite different, as seen by comparing Figures 2 and 3. This could however reflect individual differences with respect to which elements of the source had sufficient personal relevance to serve as departure points for the artists' own creative works. This interpretation is consistent with the finding that when pictures were used as stimuli for poetry, poets focused on particular portions of the pictures to serve as the basis for their poems, and different poets focused on different portions (Patrick, 1935). We are currently investigating how these two factors interact, i.e., whether artists' individual styles influence the ease of identifying which music inspired their paintings. Our aim is not to partition out how much creative works owe their distinctive character to their creators and how much they owe to other sources. We suspect that such a partitioning is not possible, that in the most successful creative works there is a fusion of the two, and that the ability to fuse ones' personal style with the inspirational source for a work plays a role in artistic genius. Though commonly portrayed as introverted and withdrawn, the creative genius may, through the assimilation and generation of creative artifacts, be deeply immersed in a form of social interaction that connects all of humanity to the deepest and most influential thinkers our world has known. We suggest that the extent to which the arts feed on the cross-domain adaptation and reinterpretation of ideas has been underappreciated, and that it may in fact play a pivotal role in the evolution of human culture.

\title{
A neural reinforcement learning model for tasks with unknown time delays
}

\begin{abstract}
We present a biologically based neural model capable of performing reinforcement learning in complex tasks. The model is unique in its ability to solve tasks that require the agent to make a sequence of unrewarded actions in order to reach the goal, in an environment where there are unknown and variable time delays between actions, state transitions, and rewards. Specifically, this is the first neural model of reinforcement learning able to function within a Semi-Markov Decision Process (SMDP) framework. We believe that this extension of current modelling efforts lays the groundwork for increasingly sophisticated models of human decision making.
\end{abstract}

Keywords: reinforcement learning; neural model; SMDP

\section*{Introduction}

One of the most successful areas of cross-fertilization between computational modelling and the study of the brain has been the domain of reinforcement learning (RL). This began with the work of Schultz (1998), who demonstrated that the well-defined computational mechanisms of models (e.g., TD reinforcement learning) could provide insight into some of the more opaque mechanisms of the brain (e.g., dopamine signalling).

The models used in that early work were purely algorithmic, with little relation to the biological properties of the brain. However, since that first demonstration many new models have been developed, allowing novel or more detailed comparisons to neural mechanisms-models that more closely reflect the structures of the brain (Frank \& Badre, 2012; Stewart et al., 2012), the behaviour of individual neurons (Seung, 2003; Potjans et al., 2009), or synaptic learning mechanisms (Florian, 2007; Baras \& Meir, 2007).

In our work we seek to retain the neuroanatomical detail of these models, but expand their functionality; that is, to build models capable of more powerful learning and decision making, enabling them to solve more complex problems. Here we present some first steps in that direction. Specifically, we will discuss the implementation and show early results from a model that is able to solve tasks requiring extended sequences of actions, in environments where there may be unknown and variable time delays between actions and rewards.

\section*{Background}

Sutton \& Barto's seminal introduction to reinforcement learning illustrates the important challenge for expanding the function of neural RL models: "Reinforcement learning is learning what to do-how to map situations to actions-so as to maximize a numerical reward signal...In the most interesting and challenging cases, actions may affect not only the imme-
diate reward but also the next situation and, through that, all subsequent rewards (Sutton \& Barto, 1998)."

Most existing neural models have performed only associative reinforcement learning, where there is no consideration of future reward (Niv et al., 2002; Seung, 2003; Baras \& Meir, 2007; Florian, 2007; Izhikevich, 2007; Frank \& Badre, 2012; Stewart et al., 2012). An example of this type of task is bandit learning, where the agent selects one of \(n\) available options, receives reward, then is reset back to the choice point. Each trial is independent, so the agent only needs to learn the immediate reward associated with each option, and then pick the best one. This can be expressed in the RL notation as
\[
\begin{equation*}
Q(s, a)=r(s, a) \tag{1}
\end{equation*}
\]
where \(Q(s, a)\) is the agent's estimate of the value of taking action \(a\) in state \(s\), and \(r(s, a)\) is the immediate reward received for performing that action in that state. These \(Q\) values can be learned by observing \(r(s, a)\) and then updating \(Q(s, a)\) to bring it closer to the observation. The challenge addressed by many of the models above is how to do that update in a neurally plausible manner.

An example of a more complex reinforcement learning task is a navigation problem, where an agent seeking to reach a goal must choose a direction to move. The agent may receive no immediate reward for making a choice, but there are still good and bad choices (bringing it closer to or farther from the goal). In order to make correct decisions, the agent needs to be able to learn not only the immediate rewards, but the rewards to be expected in the future after taking a given action. This can be expressed as
\[
\begin{equation*}
Q(s, a)=r(s, a)+\gamma Q\left(s^{\prime}, a^{\prime}\right) \tag{2}
\end{equation*}
\]

In other words, the value of taking action \(a\) is equivalent to the immediate reward (as in the previous case), plus the expected value of the action taken in the resulting state (indicating the future reward expected from that state). The future value is discounted by \(\gamma<1\) to indicate that future rewards are valued less than immediate rewards. The \(Q\) values can be learned by comparing the predicted value of action \(a\) to the observed values upon arriving in state \(s^{\prime}\). This is the temporal difference (TD) learning formula \({ }^{1}\) :
\[
\begin{equation*}
\Delta Q(s, a)=\kappa\left[r(s, a)+\gamma Q\left(s^{\prime}, a^{\prime}\right)-Q(s, a)\right] \tag{3}
\end{equation*}
\]

Most complex problems of the type faced by the brain require the consideration of the future impact of a given action; thus

\footnotetext{
\({ }^{1}\) More specifically, this is the SARSA learning update (Rummery \& Niranjan, 1994).
}
building models capable of this type of learning is an important step in understanding the decision making processes in the brain.

There have been models built that solve these types of tasks, but often they take the TD error signal (Equation 3) as given, or it is computed outside the model (Foster et al., 2000; Strösslin \& Gerstner, 2003). This reduces to a problem very similar to Equation 1, where the agent has a signal coming in and only needs to worry about the current value of that signal. The challenging aspect of TD learning is how to learn with only immediate rewards as input to the model.

Potjans et al. (2009) presented one of the most complete neural models of reinforcement learning. In order to compute the TD error they use two activity traces, one fast and one slow, on the output of the neurons representing the \(Q\) values. For a brief window in time after the system transitions from state \(s\) to state \(s^{\prime}\), the slow trace will still be representing \(Q(s, a)\) while the fast trace will be representing \(Q\left(s^{\prime}, a^{\prime}\right)\); combining that information with the incoming reward enables the neurons to calculate the equivalent of Equation 3.

The downside of this approach is that the necessary information is only present immediately after the state transition, within that window of time before the slow activity trace catches up to the fast; if action selection occurs earlier than the state transition, or if the rewards are not delivered within that window, the system will not be able to learn. This is true of all systems that rely on some type of activity/eligibility trace to preserve the action values (e.g., Izhikevich, 2007; Florian, 2007). These models rely on an environment that follows a reliable clock-like sequence of action selection, state transition, and reward.

In some cases that may be a reasonable assumption, but in our work we seek a more general mechanism that can learn when there is an unknown and potentially variable delay between action selection and state transition or reward. This can be expressed as a Semi-Markov Decision Process (SMDP; Howard, 1971). Whereas in basic MDPs (the standard model for RL tasks) states, actions, and rewards all occur instantaneously, SMDPs introduce the concept of a time delay between action selection and state transition, and rewards that can be delivered at different points in time.

One way to address the problem of time delays in the MDP environment (without resorting to SMDPs) is to imagine the delay period as a series of state transitions. That is, the states/actions/rewards continue to proceed in a regular clocklike manner, and time delays are represented by multiple cycles through that loop. However, this requires the learning to propagate back through all the "decisions" made during the delay period. This greatly complicates the learning process, and for lengthy delay periods with many different decisions it can render successful learning practically impossible. An important advantage of the SMDP framework is that it encapsulates all the activity of the delay period within a single learning update. This is particularly useful in situations such as hierarchical decision making, discussed more in the con-

Figure 1: Overall architecture of the model, see text for details. The interior of the \(E\) component is shown in Figure 2.
clusion.
The learning update from Equation 3 can be reformulated for an SMDP environment (Bradtke \& Duff, 1994; Sutton et al., 1999) as
\[
\begin{equation*}
\Delta Q(s, a)=\kappa\left[\sum_{t=0}^{\tau-1} \gamma^{t} r(s, a, t)+\gamma^{\tau} Q\left(s^{\prime}, a^{\prime}\right)-Q(s, a)\right] \tag{4}
\end{equation*}
\]
where \(t\) is the time elapsed since action \(a\) was selected, \(r(s, a, t)\) is the reward received at time \(t\), and the transition to state \(s^{\prime}\) occurs at time \(\tau\). The obvious changes are that a) the rewards received are summed over time, and b) the discount is applied across the delay period. However, the more subtle change is that the agent does not know \(\tau\). That is, it cannot rely on the rewards or discount being limited to some specific time window, or the update being applied at a particular time; it must simply wait, and be able to calculate Equation 4 whenever the state change occurs. For the sake of simplicity we have expressed time here as consisting of discrete time steps, but it can be expressed in the continuous case by taking the integral over the incoming reward signal (this is the approach used in our model).

With the SMDP framework, an agent can learn to select actions in a more general environment, incorporating arbitrary time delays into the reinforcement learning process. By taking this theory and implementing it in a neural model, we will develop a more powerful and flexible model of reinforcement learning in the brain.

\section*{Methods}

\section*{Model architecture}

The overall structure of the model is shown in Figure 1. At the top is a population of neurons representing the current state (we will discuss how the environmental state is translated into neural activities in the next section). Beneath are populations associated with each available action (four in this
case, but the model can work with any number). The state population is connected to each action population, and it is in the synaptic weights of these connections that the \(Q\) values are calculated. Assuming that correct weights have been learned, the output of the state neurons will cause each action population to represent the value of taking its associated action in that state (i.e., \(Q\left(s, a_{n}\right)\) ).

In order to act, the model needs to make a decision based on those \(Q\) values; this is the purpose of the selection component. In our model the agent follows a simple greedy policy of always selecting the highest value action. We compute the max operation using the basal ganglia model described in Stewart et al. (2010). That output is used to activate inhibitory gates within the network of the selection component, so that neural populations corresponding to the non-selected actions will not be active. The output of the selection component is both the value of the selected action, which is sent to the error calculation network (to be discussed later), and the actual output of the agent (i.e., the action it sends to the environment).

The operation of the agent is independent of the details of the environment; this model is designed to function in any task that can be described in the SMDP framework. All that is required is that the environment somehow takes the output of the agent (e.g., an action such as "move left"), calculates an updated state (e.g., the new position of the agent), and sends the new state and any reward received back to the agent. As per the SMDP framework, the state transition can occur at any time, and the rewards can be delivered at any time. When the new state is sent to the agent, it will modify the activities in the state population, a learning update will be performed as in Equation 4, and the agent will decide on a new action.

\section*{Representing and computing with neural activities}

The model operates entirely in neural activities, but it needs to interact with environments and perform computations that are defined in terms of abstract mathematical variables. To translate back and forth between these two domains we use the Neural Engineering Framework (NEF; Eliasmith \& Anderson, 2003).

The first component of the translation is encoding. For example, the abstract state output by the environment needs to be encoded into the activities of the state population. Suppose the state is represented by a vector \(x\) (perhaps describing the position of the agent). The model operates in continuous time, so the changing state over time can be represented by \(x(t)\). That input signal is encoded into the activities of the state population as
\[
\begin{equation*}
s_{i}(x(t))=G_{i}\left[\alpha_{i} e_{i} x(t)+J_{i}^{b i a s}\right] \tag{5}
\end{equation*}
\]
\(s_{i}(x(t))\) represents the activity of neuron \(i\) in the state population. \(G_{i}\) is the neuron model; in our case we use leaky integrate and fire (LIF) neurons. The components within the braces represent the current that is input into the neuron model. \(\alpha\) and \(J_{i}^{\text {bias }}\) are parameters of the neuron, randomly
chosen from within biologically plausible ranges, representing the gain and background activity, respectively. The vector \(e_{i}\) identifies the neuron's preferred stimulus, the area of the input space to which this neuron is most sensitive (these are also randomly chosen). Thus each neuron will respond to the input according to its internal parameters and how close the input is to the neuron's preferred stimulus. The combined activity of the whole population then comprises a distributed representation of where the current input is in the input space. Note that while for demonstration purposes we have described this here in terms of encoding the state, this is a general purpose mechanism for encoding any input into the activities of a population of neurons.

The second aspect of the translation is decoding, translating the activities of a population of neurons back into an abstract value. For example, this allows the activities of neurons in the selection network to be interpreted as an action for the environment, or the activities of the action populations to be interpreted as \(Q\) values. This is accomplished by a weighted summation of the neural activities:
\[
\begin{equation*}
\hat{x}(t)=\sum_{i} s_{i}(x(t)) d_{i} \tag{6}
\end{equation*}
\]

The weights, or decoders, \(d_{i}\), can be calculated by
\[
\begin{align*}
d & =\Gamma^{-1} \Upsilon \\
\text { where } & \\
\Gamma_{i j} & =\int s_{i}(x) s_{j}(x) d x \\
\Upsilon_{j} & =\int s_{j}(x) f(x) d x \tag{7}
\end{align*}
\]
\(f(x)\) gives the option of decoding a (possibly nonlinear) function of the encoded value. However, in most cases all that is desired is the identity of the represented value, in which case \(f(x)=x\). With these two tools, encoding and decoding, we can translate back and forth between the neural activities of the model and the variables and computations of the RL framework.

\section*{Learning}

The basic process of TD reinforcement learning involves updating the agent's estimation of the value of each action, the \(Q\) values. In the architecture of the model, this means modifying the synaptic weights on the connections between the state and action populations. To perform these updates we use an error modulated neural learning rule developed by MacNeil \& Eliasmith (2011):
\[
\begin{equation*}
\Delta \omega_{i j}=\kappa \alpha_{j} e_{j} E s_{i}(x) \tag{8}
\end{equation*}
\]
\(\Delta \omega_{i j}\) is the change in the connection weight between neuron \(i\) (in the state population) and neuron \(j\) (in an action population). \(\kappa\) is the learning rate, \(\alpha_{j}\) and \(e_{j}\) are properties of neuron \(j\) (as shown in Equation 5), \(s_{i}(x)\) is the activity of neuron \(i\), and \(E\) is the error. For this model, the error is the desired change in the \(Q\) value, i.e., \(\Delta Q(s, a)\) from Equation 4. This is

Figure 2: Network to calculate the SMDP learning error (the interior processing of the \(E\) component shown in Figure 1). See text for details.
a neurally plausible weight update in that it only makes use of information available locally at neuron \(j\) (assuming all neurons also receive the error signal \(E\) ). MacNeil \& Eliasmith (2011) show that this learning rule will cause the weights to be adjusted so as to minimize \(E\), meaning that over time the weights will come to calculate the desired \(Q\) values.

\section*{Error calculation}

The previous section raises the question of where the error, \(E\), comes from. That is, how is Equation 4 computed? The network that performs this calculation is shown in Figure 2. Note that this is the \(E\) component shown in Figure 1, and receives the inputs shown there (the \(Q\) value of the selected action, and the reward from the environment).

One challenge is the integration of the incoming reward (the summation in Equation 4). This is accomplished by the top-right component in the network. The central feature of the integration population is the recurrent connection, which allows it to maintain its activity in the absence of input. This means that as new rewards enter the population they will be added to the previous rewards already being represented, so that the population represents the sum of the given rewards. The details of how to set up a recurrent network to perform these kinds of computations are described in Eliasmith (2005).

The "current value" population represents the value of the currently selected action. When the action is first selected, this value is transferred into the "stored value" population in the bottom left. Again, this is a population that will maintain its represented value via its recurrent connections. When a state transition occurs, the bottom population will then be representing the value of the selected action in the new state, \(Q\left(s^{\prime}, a^{\prime}\right)\), while the "stored value" population maintains \(Q(s, a)\).

The discount is calculated by integrating the value repre-

Figure 3: Example of policy learned by the agent. The arrows represent the weighted sum of the four possible movement directions, where each direction is weighted by the learned \(Q\) value of that action. Contours indicate the state value (the value of the highest-valued action).
sented in the "stored value" population, using the same recurrent setup as is used to integrate the incoming reward. This value is then subtracted from the current \(Q\) input to calculate a discounted action value. This is not identical to the discount expressed in Equation 4, but it has a similar computational effect: it reduces the value of future states proportional to the time elapsed and the value of the state.

The final "error" population thus has all the pieces it needs to compute the SMDP learning update. It adds the accumulated reward and the discounted \(Q\left(s^{\prime}, a^{\prime}\right)\) value, and subtracts the stored \(Q(s, a)\) value, resulting in the error signal required by the neural learning rule (Equation 8).

\section*{Results}

We tested the model on a spatial navigation task (the same task used in Potjans et al. 2009). The agent is randomly placed in a \(5 \times 5\) grid, surrounded by walls. The agent's state is its \(x, y\) location in the grid, and the available actions are movement in the four cardinal directions. Selecting any of those actions will cause the agent to move one square in that direction, unless it is attempting to move into a wall in which case it remains in the same position. The agent's time in each state is randomly determined, ranging between 600 and 900 ms . The task is to move to some fixed target location. This is equivalent to a water-maze type task, where the agent has no idea where the goal might be, and must find it by exploring the environment. When the agent finds the goal state it receives a constant reward of 1 as long as it remains in the state. After a brief period of time the agent is then moved to a random location, and must find the target again.

Figure 3 shows an example of a policy learned by the model after spending approximately 2 hrs of simulated time

Figure 4: Comparison of learning times between a) an algorithmic implementation of RL (basic table-based Q-learning), b) the neural MDP reinforcement learning model of Potjans et al. (2009), and c) the model presented here. Latency is measured as the difference between the Manhattan distance from start to goal and the number of steps taken by the model. Data for b) from Potjans et al. (2009).
in the task. The arrows display the weighted sum of the four movement directions, where the weights are the learned \(Q\) values associated with each action. Since the agent picks the highest valued action, it will move in whichever cardinal direction is closest to the direction of the arrow. The contours indicate the value of the highest valued action (i.e., the state value function). It can be seen that the agent has successfully learned a policy that will take it to the goal state from any position, despite the random time delays.

Figure 4 shows a comparison between the learning times of our model and that of Potjans et al. (2009), with a purely computational RL implementation as a baseline. Each trial begins when the agent is placed at a random location in the grid, and ends when it reaches the goal (at which point it is placed in a new location for the next trial). We have followed Potjans et al. in using latency as a measure of how well the agent has learned the task. Latency is defined as the difference between the Manhattan distance between the start and goal \(\left(\operatorname{start}_{x}-\operatorname{goal}_{x}+\operatorname{start}_{y}-\right.\) goal \(\left._{y}\right)\), which is the shortest possible path length, and the number of steps taken by the model. It can be seen that our model performs better than that of Potjans et al., and roughly equivalently to the purely computational solution. It is also worth noting that our model is operating in the more challenging SMDP framework, with random time delays; it is unlikely that the Potjans et al. model would be able to perform this task at all.

SMDPs also provide a more powerful language with which to describe problem domains, by allowing for the incorporation of time directly into the task description. For example, Figure 5 shows a task similar to that in Figure 3, but certain states (shown in grey) take a longer period of time for the agent to move through (simulated by adding three seconds

Figure 5: Policy learned by the system in a task where certain states take longer periods of time to move through (shown in grey). The agent has learned to avoid the slow areas even though it requires taking a less direct route.
to the usual randomly determined state transition time). This means that the most efficient route to the goal is no longer a direct path; the agent has learned to trade off the cost of a detour with the cost of moving through the slow areas. Time is often an important part of real world tasks, thus the ability to incorporate time directly into the agent's learning is another advantage of the SMDP framework.

\section*{Discussion}

We have presented a novel neural model capable of autonomous reinforcement learning. The model is able to solve complex tasks that require an extended sequence of actions in order to achieve the reward, rare for biologically based neural models. In addition, it is able to solve these tasks in a realistic SMDP environment, where there are potentially random and unknown delays between action selection, state transition, and reward. We believe this is currently the only neural model capable of this type of performance.

This model is still only an early step on the path of expanding the functional capabilities of neural RL models, and there are a number of ways in which it can be improved. First, more neural detail could be incorporated into the model. For instance, incorporating more realistic spiking neurons would allow for more detailed comparisons to neural recordings. Another improvement to the model would be a more principled approach to exploration. At the moment exploration is accomplished by injecting random noise into the action values as they enter the selection component (a neural approximation of the standard \(\varepsilon\)-greedy approach). However, in the future it would be desirable to have more control over the exploration process, so that, for example, the agent could make decisions about how much exploration to pursue based on its current knowledge.

Another avenue for future work is to incorporate the learning components of this system into a more complete agent model. The inputs and outputs of this model are abstract, thus it ignores the complexity of sensory processing and motor output. However, recent work in our lab has developed an integrated brain model that is able to perceive visual input, process it internally, and control motor outputs (Eliasmith et al., 2012). That model was able to perform associative reinforcement learning, but not the more complex learning displayed here. Adding the abilities of this model into that detailed neural agent would allow for the study of the full reinforcement learning process, from input through to output.

One of the most interesting possibilities opened up by this model is the construction of a neural model capable of hierarchical reinforcement learning (Barto \& Mahadevan, 2003). In hierarchical RL the "actions" that an agent chooses between can be augmented with subroutines that define whole new behaviours. For example, instead of the agent just choosing between "go left", "go right", and so on, one of its options could be "go to the doorway", which would then lead to a sequence of decisions designed to take the agent to that location. What all of the hierarchical approaches have in common is that they use the SMDP framework as their underlying structure. The unknown time delay between action and state transition can be used to encapsulate the time when the high-level action is executing. The SMDP framework allows the agent to incorporate those time delays and rewards, and learn how to correctly select between its complex set of actions. A model such as the one we present here is a step toward a functional neural model capable of hierarchical learning and decision making.

\begin{abstract}
Difficulty with social interactions is a hallmark characteristic of autism spectrum disorders. While many studies have investigated the neural mechanisms underlying atypical social cognition, the methods used have rarely involved social interaction, relying instead on offline reasoning about a character. In the current study, we examined whether and which brain systems are sensitive to online social interactions in individuals with autism. We compared functional MRI data collected from 15 neurotypical (NT) and 15 autism spectrum disorder (ASD) participants during live real-time interactions (Live) and during a video replay of the same interaction (Recorded-Same) and a novel interaction (Recorded-Novel). Whole brain analyses demonstrated a significantly greater response to Live than Recorded conditions, in NT vs ASD, within left posterior superior temporal sulcus (pSTS) and regions of the cerebellum bilaterally. Region of interest analyses revealed that right posterior temporal regions were differentially recruited during online social interactions in the ASD and NT groups. Also, regions commonly associated with personal salience (i.e., dorsal anterior cingulate and bilateral insula) were sensitive to online social interactions in NT, but to novelty in the ASD group. These data suggest reduced and atypical neural sensitivity to online social interactions in individuals with autism.
\end{abstract}

Keywords: social interaction; autism; fMRI.

\section*{Introduction}

Social interactions provide a rich opportunity to learn from others beginning early in infancy and continuing throughout one's life. Individuals with autism engage in fewer interactions than their typically developing peers and reduced social engagement predicts later delays in language and social abilities (e.g., Mundy, Sigman, \& Kasari, 1990). A central question in the study of autism is what underlies this reduced engagement in social interactions. Some have proposed that social interactions are inherently rewarding, and thus motivating, for neurotypical (NT) individuals but not for those with autism spectrum disorders (ASD) (e.g., Chevallier, Kohls, Troiani, Brodkin, \& Schultz, 2012; Dawson et al., 2002). Similarly, others suggest that, unlike NT individuals, social stimuli fail to capture the attention of those with autism (e.g., Klin, Jones, Schultz, \& Volkmar, 2003). Others still suggest difficulties with social interactions arise from impairments in theory of mind, or reasoning about another person's thoughts (Baron-Cohen, Leslie, \& Frith, 1985).

While evidence exists to support each of these claims, most of the empirical data come from studies using proxies for social interactions, such as a picture, video, or vignette of a person or characters. While important, these offline methods may be missing the processes at the root of ASD, namely social interactions or engagement with others. For example, difficulties interpreting or predicting a social partner's behavior are thought to underlie real-world difficulties in communication; however, offline tasks in which individuals must predict a fictional character's action based on false beliefs often fail to find differences between autism and neurotypical groups in behavioral reports (e.g., Senju, Southgate, White, \& Frith, 2009) and brain activation patterns (Dufour et al., 2012). Interestingly, while offline reasoning processes appear to be relatively intact, individuals with autism fail to spontaneously anticipate the location of an actor's reach based on a false belief (Senju et al., 2009) - a process more akin to real-world use of belief inferences to predict behavior. Furthermore, even for neurotypical individuals, social or communicative behavior in the context of an interaction, as compared to mere observation, may be quantitatively and/or qualitatively different from offline social communication (e.g., Clark \& Brennan, 1999; Pönkänen, Alhoniemi, Leppänen, \& Hietanen, 2011; Redcay et al., 2010; Risko et al., 2012; Schilbach et al., 2012; Sebanz, Bekkering, \& Knoblich, 2006; Shimada \& Hiraki, 2006) Thus, like others (e.g., Schilbach et al., 2012), we argue for a second-person neuroscience approach to understand core difficulties with social interaction in individuals with autism.

Using a novel method for collecting fMRI data during an online social interaction, we previously demonstrated that brain systems supporting reward processing, social cognition, and attention were engaged more when interacting with another person in a real-time face-to-face interaction (i.e. the Live condition) than during a video replay of the experimenter from the same interaction (Recorded-Same condition) or video replay of the experimenter taken from a different scan session (RecordedNovel condition) (Redcay et al., 2010). Thus, this paradigm provides a method to examine the extent to which reward, attention, and social-cognitive systems are engaged during simple social interactions in individuals with autism, and as such can provide insight into the proposed mechanisms underlying atypical social interactions.

The goals of the current study were to 1) replicate findings from Redcay et al., (2010) in a new neurotypical sample, 2) determine what is driving the difference between live and recorded conditions (i.e., novelty or social contingency), and 3) examine whether reward, attention, or social-cognitive systems (or some combination) show an atypical response profile in individuals with autism. To investigate these questions, we examined the response profiles for each condition of interest (Live, RecordedSame, Recorded-Novel) within the regions of interest identified in the previous study for the contrast of Live vs. Recorded conditions (Redcay et al., 2010). A greater response to Live interactions as compared to the same video replay (Recorded-Same) may simply be due to the novelty of the interaction. Thus, the critical comparison to isolate brain regions sensitive to contingent social interaction, independent of novelty, is Live vs. Recorded-Novel. In both of these conditions, the participant sees the experimenter moving and talking in novel ways with novel objects; the only difference is that in the Live condition, the experimenter's actions are contingent on real-time communication with the participant. Based on our previous study, we predicted that regions within social, attention, and reward networks would be differentially recruited during the Live condition in the NT group. Given the hypotheses discussed above, we predicted reduced differentiation between Live and Recorded conditions in the ASD group within regions associated with reward and social cognition.

\section*{Methods}

\section*{Participants}

All participants provided written, informed consent as approved by the Committee on the Use of Humans as Experimental Subjects (COUHES) at the Massachusetts Institute of Technology and were compensated monetarily for their participation. Participants were excluded if they had a history of neurological or psychiatric disorders or any contraindication for MRI scanning. IQ data were collected using the Kaufman Brief Intelligence Test (K-BIT).

Table 1: Participant Information.
\begin{tabular}{ccccc}
\hline Group & n & Age (yrs) & Sex & FIQ \\
\hline ASD & 15 & \(28.4 \pm 7.1\) & 11 M & \(119.5 \pm 14.8\) \\
NT & 15 & \(27.4 \pm 6.2\) & 11 M & \(117.5 \pm 12.3\)
\end{tabular}

Participants with Autism Eighteen adults with highfunctioning ASD participated in the current experiment. All participants met criteria for ASD (autism or spectrum) on the Autism Diagnostic Observation Schedule (ADOS), Module 4. Three participants were excluded because of an inability to perform the task (2) or excessive movement during the scan (criteria described below).

Neurotypical Participants Fifteen NT participants were recruited to match the ASD participants on age and sex.

Verbal, nonverbal, and full-scale IQ scores did not differ significantly between ASD and NT participants (IQ data from 1 ASD and 4 NT are missing).

\section*{Study Design}

Prior to each scanning session the experimenter administered consents, screening forms, and IQ assessments in order for all participants to have some familiarity with the same experimenter in the face-to-face fMRI task.

Live face-to-face set-up During fMRI data acquisition participants were able to see and hear an experimenter in the control room. For extensive details on the audio-visual setup see Redcay et al., 2010. Briefly, during the Live conditions, a real-time video and audio feed of the experimenter was provided to the participant. For all conditions, the experimenter viewed a real-time video feed of the participant's eye through use of a camera from an eye-tracker at the back of the scanner bore. With this dual video set-up both experimenter and participant could interact in real-time. The timing of dual video capture and presentation was implemented using Psychtoolbox extensions in Matlab 7.8 (Brainard, 1997; Pelli, 1997). This dual video capture capability allowed for post-scan coding of the participants eye-movements as well as with the experimenter's actions throughout the experiment.

Figure 1. Example of a social interaction block for Live, Recorded-Same, and Recorded-Novel conditions. Video frames are presented to illustrate the sequence of events.

Social Interaction Task During fMRI data collection, participants engaged in a social interaction task, in which the experimenter prompted them to choose one of two buckets (via eye movements) in the context of a highlyscripted interaction (Figure 1). During 'Live' conditions these interactions occurred in real-time while 'Recorded' conditions involved video replays. Participants were told whether they were in the Live or Recorded conditions both via a green or red square around the screen, respectively, and a text prompt before the start of the block and above the video of the experimenter throughout the block. Importantly, they were told to play along with the experimenter's requests during the Recorded conditions even though she could not see them. During the Recorded-

Same condition, the same video of the experimenter from the previous Live condition was replayed to the participant, serving as a perfect control for perceptual complexity. During the Recorded-Novel condition a novel video from a previous interaction with a different participant was presented, controlling for the novelty of the live interaction.
fMRI design Conditions were presented in a blocked design with each block lasting 40 seconds. Each run contained two repetitions of each condition (i.e., Live, Recorded-Same, Recorded-Novel) alternating in a pseudo-counterbalanced order (with the caveat that Live had to precede RecordedSame). To allow for the opening and closing of video capture devices, the first and last 2.5 seconds of each block were modeled but not analyzed. Runs contained 3 blocks of a 20 -second resting baseline at the beginning, middle, and end of each run. All participants completed four experimental runs except for one participant in the ASD group who completed 3.

\section*{Data acquisition and analyses}

Data acquisition Data were collected on a 3T Siemens Tim Trio scanner at the Athinoula A. Martinos Imaging center at the McGovern Institute for Brain Research at the Massachusetts Institute of Technology. Functional imaging data were collected using a T2*-weighted gradient echoplanar image sequence with a voxel resolution of \(3.1 \times 3.1 \times 4.0 \mathrm{~mm}(\mathrm{TR}=2 \mathrm{~s}, \mathrm{TE}=30 \mathrm{~ms}, 32\) slices). Siemens PACE online motion correction was used to adjust for head movement ( \(<8 \mathrm{~mm}\) ). T1-weighted structural images were collected with 128 slices axially ( \(\mathrm{TE}=3.39 \mathrm{~ms}, \mathrm{TR}=2530\) \(\mathrm{ms}, 1.3 \mathrm{~mm}\) isotropic voxels).
fMRI analyses fMRI data were analyzed using SPM8 (http://www.fil.ion.ucl.ac.uk/spm) and in-house Matlab scripts. Preprocessing steps included 1) realignment of all data to the first volume of the first run using a 6-degree rigid spatial transformation, 2) spatial smoothing with a 5 mm full width half maximum Gaussian filter, 3) spatial normalization to a standard EPI template in Montreal Neurological Institute (MNI) space using a 12-parameter affine transformation. A high pass filter of \(260 \mathrm{~s}(1 / 260 \mathrm{~Hz})\) was applied to the functional data to model low-frequency signals unrelated to the task. 260 seconds was chosen because it is the length from the beginning of the first block to the end of the last in each run. Motion artifacts were estimated using the artifact detection toolbox (ART). A volume exceeding 1 mm (across rotational and translational directions) of movement between timepoints or intensity greater than 3 SD was marked as an outlier. Participants with more than \(15 \%\) outlier timepoints across any experimental run were removed (1 ASD participant).

Whole-brain first-level analyses were performed within each subject using the general linear model. The model included conditions of interest (Live, Rec-Same, RecNovel) as well as conditions not of interest (the 2.5 seconds at the beginning and end of each block and the text prompt
preceding each block). Nuisance regressors included the degree of deviation at each time point for the 6 -motion directions (roll, pitch, yaw, \(x, y, z\) ) and any outlier timepoints identified. Contrasts of interest included each condition of interest vs. fixation as well as the Live condition compared to Rec-Same and Rec-Novel separately and compared to both recorded conditions combined (Recorded). Contrasts of Rec-Novel to Rec-Same were also included and all reverse contrasts were modeled (e.g., Recorded vs. Live).

Second level random effects analyses were conducted via voxel-wise whole-brain t-tests (within and between sample) for each contrast of interest and region of interest analyses. All within-sample whole-brain tests were corrected at \(\mathrm{p}<.05\) using nonparametric permutation analyses (snpm5b). All between-group whole-brain tests are thresholded at \(\mathrm{p}<.001\) (uncorrected) with a cluster correction corresponding to \(\mathrm{p}<.05\) ( \(\mathrm{k}=192 \mathrm{~mm}^{3}\) ). Cluster size was determined using AFNI's 3dClustSim program (Cox, 1996).

Region of interests were created from previously published data using this same social interaction task (Redcay et al., 2010). These data included a sample of 16 typically developing adults ( 7 male ; 18-29 years) who were not part of the sample in the current study. Region of interests included voxels that were significantly more engaged during the Live than Recorded conditions ( \(\mathrm{p}<.05\), corrected) and intersected with a sphere ( 6 mm radius) surrounding the peak coordinate for each region identified in the group contrast of Live-Recorded (Redcay et al., 2010). Parameter estimates from the first-level analyses for each condition of interest from each subject were extracted from each of these 21 regions of interest. Repeatedmeasures ANOVAs were run for each ROI with condition (Live, Rec-Same, Rec-Novel) as the repeated measure and group (ASD, NT) as the between-subjects measure. The Greenhouse-Geisser correction was used when the assumption of sphericity was violated. For all regions showing a significant effect of condition or significant group x condition interaction, follow-up paired t-tests were conducted within each group for the contrasts Live vs. RecSame, Live vs. Rec-Novel, and Rec-Novel vs. Rec-Same.

Post-scan video coding Following data collection, videos from 9 ASD and 10 NT participants were coded for several behavioral variables, including the onset and duration of eye movements during the event periods in which the experimenter requested a response from the participant. Videos from the remainder of the participants were lost or not collected at the time of the fMRI session due to technical difficulties in video recording. The number and duration of eye movements were compared between groups and between conditions using separate two-way repeated measures ANOVAs.

\section*{Results}

Eye movements do not differ by condition or group No significant main effects or interactions were found for either the total number or duration of eye movements during the

Live, Rec-Same, and Rec-Novel conditions. These data suggest differences between conditions were not due to lowlevel differences in eye movement behavior.

Replication of previous study in new TD sample Wholebrain and ROI analyses comparing the Live and Recorded conditions revealed many similarities but also some differences from the sample published in a previous paper (Redcay et al., 2010). In general a smaller number of areas were recruited during the Live vs. Recorded contrast than reported in the previous study. Specifically, subcortical regions associated with reward and anterior temporal regions did not show differential recruitment during the Live condition. However, regions within dorsal medial prefrontal cortex (dMPFC), which did not meet threshold for significance in the 2010 paper, were significant in the current NT sample. Regions showing a greater response to Live than Recorded conditions (in both samples) included bilateral posterior STS, dorsal anterior cingulate (dACC), dorsal medial prefrontal cortex (dMPFC), thalamus, and left cerebellum (Figure 2, top).

Next, we compared parameter estimates for Live and Recorded conditions within the ROIs from the previous study using one-way paired samples t-tests ( \(p<.05\), Bonferroni corrected). Nine of the 21 regions revealed a pattern of significantly greater activation in Live as compared to Recorded conditions: dorsal anterior cingulate (dACC) \(t(14)=2.95, \quad p<.011, \quad\) anterior cingulate cortex/medial prefrontal cortex (ACC) \(t(14)=3.26, p<.006\), left cerebellum (L CBLM) \(t(14)=3.68, p<.002\), left lingual gyrus \(t(14)=3.01, p<.009\), left insula \(t(14)=4.96, p<.0001\), left middle temporal gyrus (L MT) \(t(14)=2.7, p<.017\), right insula \(t(14)=3.61, p<.003\), right posterior superior temporal sulcus (RpSTS) \(t(14)=5.65, p<.000\), right temporoparietal junction (RTPJ) \(t(14)=3.30, p<.005\), and supplementary motor area (SMA) \(t(14)=3.58, p<.003\).

Figure 2. Whole-brain random effects analyses for the contrast Live \(>\) Recorded within NT (top) and ASD (bottom) groups are displayed on a template brain in MNI space. A direct statistical comparison between groups for the Live \(>\) Recorded contrast is shown in the right panel.

Whole brain comparisons between ASD and NT Only the right pSTS showed a significantly greater response during the Live as compared to Recorded conditions in the ASD group (Figure 2, bottom). Direct statistical comparison of the Live vs. Recorded contrast between groups revealed significantly greater activation in the NT group in the left
posterior STS and bilateral cerebellum. Significantly greater activation was seen in the ASD than NT group for the LiveRecorded contrast within the left angular gyrus (AG) and right putamen; however, this effect was driven by greater deactivation in the NT group during Live conditions rather than differential engagement of these regions in ASD.

Figure 3. Region of interest analyses. The statistical parametric map for the contrast Live \(>\) Recorded from a separate group of healthy typically-developing participants (Redcay et al., 2010) is displayed on a template brain registered in MNI space. Each region showing a significant main effect of condition in the new sample (ASD and NT) is marked with a yellow circle. Response profiles for each condition (Live=blue, Recorded-Same=orange, RecordedNovel=red) for the NT (solid bar) and ASD (open bar) groups are displayed for these ROIs. Brain images and bar plots are grouped by patterns for the NT and ASD groups.

Region of interest analyses Two-way repeated measures ANOVA for each of the 21 ROIs revealed significant main effects of condition (Live, Rec-Same, Rec-Novel) in nine of the ten regions as reported above (dACC, ACC, LCBLM, LIns, RIns, RpSTS, RTPJ, SMA, LMT) and a significant group by condition interaction in one region, the anterior cingulate cortex \((F(1.6,30)=6.1, p<.008)\) (Figure 3).

Within-group condition comparisons allowed for investigation of whether regions were sensitive to the social contingency of a live interaction (i.e. Live \(>\) Recorded-Novel and Live \(>\) Recorded-Same) or to the novelty of the interaction (i.e. Live \(>\) Recorded-Same or RecordedNovel \(>\) Recorded-Same).

Salience network sensitive to online interactions in NT but novelty in ASD Within the NT group, 6 regions showed a pattern of sensitivity to Live as compared to Recorded-Novel and Recorded-Same conditions, suggesting
these regions are sensitive to online social interaction. These regions included those associated with the salience network (e.g., Seeley et al., 2007), namely the dorsal anterior cingulate (dACC), bilateral insula, and supplementary motor area (SMA), as well as regions associated with social cognition including the RpSTS extending into the RTPJ. Of these six regions, the ASD group demonstrated no difference between conditions within left insula and dACC (Figure 3, top left) and a pattern of sensitivity to novelty but not social interaction in the right insula, SMA, and ACC (Figure 3, top right). Like the NT group, the ASD group showed a significant effect of social interaction (i.e. Live \(>\) Recorded-Novel and Live \(>\) Recorded-Same) in the right \(\mathrm{pSTS} / \mathrm{RTPJ}\) (Figure 3, bottom left).

Three regions were sensitive to novelty but not live interaction specifically in both ASD and NT groups. Within the NT group, the left cerebellum, left middle temporal gyrus (MT), and left anterior STS (aSTS) demonstrated a pattern of sensitivity to novelty (i.e. Live \(>\) Recorded-Same and Recorded-Novel \(>\) RecordedSame) that was not specific to online interactions (i.e. Live is not different from Recorded-Novel). Left MT and left aSTS demonstrated a pattern consistent with novelty in the ASD group in that Recorded-Novel was greater than Recorded-Same. Further, the region within the left cerebellum showed a greater response to Live than Recorded-Same in ASD (Figure 3, bottom right).

\section*{Discussion}

The goals of the current study were to replicate previous findings using a novel interactive method and to determine whether reward, attention, and/or social-cognitive networks in autism showed a lack of sensitivity to online social interactions. We replicated the finding of a greater response to Live than Recorded conditions in many regions associated with social cognition and attention, as previously seen. Surprisingly, however, reward-related regions were not differentially sensitive to live interactions in the current sample of NT or ASD participants.

Social-cognitive areas show typical response in ASD Our hypothesis was that regions associated with social cognition, such as bilateral TPJ, posterior STS, and amygdala would not be modulated by condition in the ASD group. Some support for this hypothesis was found in the whole-brain between-group comparisons (Figure 2). The left pSTS was recruited significantly more for Live than Recorded conditions in NT than ASD groups. However, whole-brain and region of interest analyses revealed no differences between groups within right posterior superior temporal cortex (RpSTS cluster extending into RTPJ). For both NT and ASD groups this region was recruited across all three conditions but the greatest response was seen in the Live condition and no differences were found between the Recorded conditions. It is possible (and indeed likely) that group differences might have emerged if the social
interaction had required mental state inferences and/or been less predictable. Nonetheless, these findings suggest that in a simple social interaction, posterior superior temporal regions are sensitive to social contingency in both NT and ASD samples.

Salience network sensitive to live interactions in NT, but not ASD Regions within attention networks, specifically the salience network, revealed the greatest differences between groups in the region of interest analyses. We found a significantly greater response in the Live condition as compared to both Recorded conditions within regions thought to be part of a personal salience network, including bilateral insula and dorsal anterior cingulate (e.g., Seeley et al., 2007) in NT individuals but not individuals with ASD. In fact, within the dorsal anterior cingulate cortex a significant group \(x\) condition interaction revealed sensitivity to novelty, but not live interaction, in the ASD group. This salience network is engaged during tasks of empathy (Bernhardt \& Singer, 2012), affective pain (Singer et al., 2004), error processing and task-onset (Dosenbach et al., 2006) and can be identified through task-free intrinsic connectivity analyses (Seeley et al., 2007). Seeley et al., (2007) propose that these regions are important for associating incoming sensory stimuli with "markers" to aid in the decision of what to do next through interaction with other control, attention, and emotion networks. One possibility is that in NT individuals, interaction with another person in real-time provides a salient cue to enhance attention to the stimuli or task at hand via the salience network. This is analogous to theories suggesting social interactions "gate" learning (e.g., Kuhl, 2007; Meltzoff, Kuhl, Movellan, \& Sejnowski, 2009). For individuals with ASD, however, the novelty of the visual stimulus engages the salience network rather than the social contingency. These data are consistent with the proposal by Mundy and colleagues (e.g., Mundy, 2003) that atypical socialexecutive networks, of which the dorsal anterior cingulate plays a primary role, may characterize autism. Thus, these data may provide a neurobiological correlate for how social interactions are less "special" in individuals with autism. These findings also underscore the importance of examining the interaction of social and attention processes, instead of treating them as separate processes and systems.

\section*{Future Directions}

While the results are intriguing, the current study has several limitations that need to be addressed in future work. First, the interaction was highly scripted and simplified. Future studies should examine whether increasing the unpredictability or required mental state inferences within the interaction would lead to greater differences between groups within social-cognitive brain regions. Similarly, future studies should explicitly engage reward systems during real-time social interaction to help explain the discrepancy in activation of reward systems between these studies. Finally, it will be critical to examine the
developmental trajectory of atypical responses to social interactions within the salience network to determine whether reduced neural sensitivity underlies the emergence of the autistic phenotype.

\section*{Acknowledgments}

\title{
Smooth Dynamics, Good Performance in Cognitive-Agent Congestion Problems
}

\author{
David Reitter, Penn State University \\ Paul Scerri, Carnegie Mellon University
}

\begin{abstract}
In a congestion game, individuals exhaust a common resource out of selfish behavior. In this scenario, drivers create traffic jams by choosing the shortest route according to their individual knowledge. They can avoid them by communicating their belief states about the traffic situation in real-time through a peer-to-peer network, assuming unlimited bandwidth. We study two potential, cognitively inspired models of human behavior: 1) categorization (quantized memorization and communication), which dampens communication and belief adoption, but leads to undesired oscillations and lower performance. 2) Instance-based blending with memory decay, which achieves good dynamics and near-optimal performance without the same bandwidth needs. We argue that this supports our hypothesis of co-adaptation of cognitive function and communicating communities.
\end{abstract}

\section*{Introduction}

In many situations, crowds of interacting human individuals share resources such as food, roads, electricity, internet bandwidth, or airtime in a conversation. Similarly there are many interesting domains that require robots or agents to simultaneously learn to utilize common resources. When the actions of one agent impact the outcomes of another agent, individual learning often leads to complex system dynamics. A canonical example of this problem is cooperative path planning(Burgard, Moors, Fox, Simmons, \& Thrun, 2000), where agents using the same routes negatively interfere with one other, but many other domains have been studied including soccer(Kalyanakrishnan, Liu, \& Stone, 2007) and markets(Tesfatsion \& Judd, 2006).

Computational-cognitive models of social behavior require a combination of cognitive architectures and multiagent design and analytics. In this paper, we investigate the effect of memory decay and instance-based learning and decision-making a system of communicating, simulated individuals.

Based on the rational assumption that human cognitive function has adapted to its environment, we hypothesize that memory function improves system dynamics in communication networks. We predict that forgetting improves, rather than impedes, performance in situations where crowds use finite common resources. This is also a core problem in multi-agent learning: one agent's behavior may impact the outcome for another agent. The collective behavior of a learning system and individual reward can vary wildly and unpredictably. Human-controlled road networks exhibit similar traffic jams, though rarely with the same catastrophic consequences the multi-agent simulations suggest. An emerg-
ing property of the human-based system is adaptation and damping. We will use a multi-agent system in which each agent is implemented as a model of (relevant) human behavior, namely learning from observations and information obtained by others, and estimating quantities (or categorizing) based on current knowledge.

In our scenario, individual models repeatedly choose roads in a road network to get them from home to work. The time taken to traverse a road is a function of the number of other agents on the road when the agent begins to traverse the road.

The first contribution of this work is to apply humaninspired instance-based learning (IBL, Gonzalez, Lerch, \& Lebiere, 2003) algorithm to the problem of multi-agent learning on the road congestion problem. The IBL model treats each trip from home to work as several instances of road segments and weighs instances based on several factors including recency when estimating time to traverse a road. We found that the agents using IBL do much better than the agents using an alternative, category-based model and about the same as agents using a communication intensive averaging model.

Second, this paper examines the dynamics of mixed human-machine systems. We demonstrate that the overall system performance is improved by even a relatively small number of the IBL agents and that there were no negative effects on either type of agent. When there were only a few IBL agents in the system, they performed relatively better than the ternary agents, but when there were many IBL agents all agents performed about the same.

Finally, the third contribution of this work is to show how changes to the underlying system, in addition to changes due to learning, impact performance. One might expect that more numerical approaches will respond to change more quickly and effectively than a learner relying on experiences. However, we found no evidence of this. Instead, IBL agents reacted very quickly and appropriately to underlying change, far better than the ternary agents. From these experiments we can see potential for using IBL in multi-agent learning settings and exploring these other settings is a key area of future focus.

Cognitive models have been combined to explain learning in team settings, primarily in a qualitative way (Sun, 2008). Reitter and Lebiere (2012) used decay in a model implemented within a cognitive architecture to show that decayed memory improves agent perfor-
mance in a foraging scenario with multiple, communicating agents. Instance-based learning within cognitive models has been shown to explain human behavior in a number of cognitive decision-making tasks (Lebiere, Wallach, \& West, 2000; Erev et al., 2010).

\section*{Scenario Framework}

The framework for the scenario (Scerri, to appear) consists of agents \(A\), places \(P\) and edges \(G\) over some number of iterations. Each agent \(a \in A\) has some place, \(p_{\text {home }} \in P\) where it starts each iteration and some place \(p_{\text {work }} \in P\) where it must get to each iteration or day. To get to \(p_{\text {work }}\) it must use edges connecting places. Individual edges \(g \in G\) connect exactly two places. The agents task is to get from \(p_{\text {home }}\) to \(p_{\text {work }}\) most quickly each iteration.

The time that it will take an agent to traverse an edge depends purely on the number of agents already on the edge when it gets to the edge. Specifically, we choose a simplified function to model limited resources that are affected by congestion: the time taken by an agent is \(10+n_{\text {already }}^{3}\), where \(n_{\text {already }}\) is the number of agents on the edge when the agent reaches it. The simulation randomizes the order the agents execute so that in one iteration an agent might be the first on the edge and have a very short travel time and another iteration it might be tenth onto the edge and have a very long travel time, even if none of the agents change their routes.

This framework has two important features. First, the agents will get very different perspectives on speed of a edge, based on exactly when they get onto the edge. Hence, either many iterations or cooperation is needed to create an accurate model. Second, busy edges heavily penalize the agents, just a few extra agents on a edge will dramatically slow the last few agents down again making cooperation important.

For experimental purposes, there are only ten different \(p_{\text {home }}\) and \(p_{\text {work }}\) for 200 agents. This makes for more interesting traffic congestion problems, with more extreme cases, and requires more coordination among the agents, but, as was shown in (Scerri, to appear) does not qualitatively change the system dynamics.

In every iteration, each agent uses a model of the graph to plan a path from \(p_{\text {home }}\) to \(p_{\text {work }}\). The agents use a standard A* algorithm (Russell, Norvig, \& Artificial Intelligence, 1995) to do the planning based on their current model of edge traversal times. Agents are risk neutral, trying to minimize expected travel time. They then execute their plan without adapting to observed conditions. At the end of an iteration, the agents can communicate about what they observed. The model the agent plans with and the information it communicates are described below.

It is assumed that each agent plans selfishly, but communicates truthfully and cooperatively. We are inter-
ested in two primary metrics. First, the average time it takes for an agent to get from \(p_{\text {home }}\) to \(p_{\text {work }}\). Second, as the agents build their models and adapt their plans to the changing models, the average transit time will change. As a secondary measure, we are interested in the change in average transit time over time.

Communication Network The agents are organized into a social network where they can only communicate directly with a small subset of the rest of the agents. Information is propagated through the network in a peer-to-peer manner. Unless otherwise noted below, we use a random network with degree 5 to connect the agents.

\section*{Model Path Planning}

The cognitive agents have to choose a path that will most quickly get them to their destination, based on experiences so far and from experiences communicated from other agents. The optimal strategy might be one that considers likely plans by others and the changes they will make, given their previous experiences. However, this is typically infeasible, and theoretically the game-theoretic Traveller's Dilemma (Basu, 1994) applies: If one agent \(A\) anticipates another agent \(B\) 's reaction, \(A\) would also anticipate \(B\) 's anticipation of \(A\) 's reaction, and so on. Rational players will end up with a poor solution (finite game), or they will be faced with a computation that does not scale.

Any accurate model of crowd cooperation needs to deal with limited communication bandwidth, learn (quickly) to achieve acceptable performance, adapt to changing network dynamics. In the following we describe two cognitively plausible models for reasoning about the road network, as well as an optimal one with high bandwidth needs. Earlier work has shown path-planning in a model in the cognitive architecture ACT-R (Reitter \& Lebiere, 2010). However, here we focus on the memory components only and keep the path planning algorithm (A* planning) constant to facilitate meaningful comparison.

Categorizing Model: Ternary We include two cognitively plausible models at the agent level. The first, ternary, forms its belief about a road segment as a category: slow, medium or fast. The model keeps, for each edge, a normalized frequency distribution of the observed categories, decayed over time. Specifically, for each edge \(e\), the model is \(M_{e}=\left\{p_{\text {slow }}, p_{\text {medium }}, p_{\text {fast }}\right\}, p_{\text {slow }}+\) \(p_{\text {medium }}+p_{\text {fast }}=1\). When an individual gets an observation of a particular category it adds \(\beta_{\text {local }}\) for a local observation and \(\beta\) for a communicated observation to the relevant \(p\) and then normalizes.

The models assume the most probable category, \(\max M\) for planning. In the following experiments, an edge in a particular category is assumed to take time 300, 156 and 12 for \(p_{\text {slow }}, p_{\text {medium }}\) and \(p_{\text {fast }}\), respectively, cor-

Figure 1: Ternary, IBL and Average models.
responding to the average time when approximately 3,7 and 11 agents also use the edge reasonable approximation of the typical expectations. When max \(M\) changes for an edge, i.e., when the individual's belief about an edge changes categories, it communicates the new category to its direct neighbors in the social network.

Instance-based learning model The second model implements a cognitively motivated aggregation mechanism that forms their beliefs. As in the ternary model, its communications are quantized and occur whenever its belief about a road changes. The same A* algorithm is used to plan paths. However, this model's estimates about the speed of each road are based on instancebased learning. IBL stores a datapoint (episode) with the speed of a road whenever it is traveled or when agents receive a communication. (A commute involves many such roads.) A speed estimate can then be derived as the average of all episodes associated with the road, weighted by the episode's activation. Activation is determined by a function that rewards experience (a large set of episodes), but discounts older information (decay). Activation has been shown to predict the availability of information in human memory (Anderson \& Lebiere, 1998).

In detail, activation of an episode \(e\) consisting of a road speed (utility) and time, \(\left\langle u_{e}, t_{e}\right\rangle\) is given as
\[
A_{e}=\left(t-t_{e}\right)^{-0.5}
\]
\(t\) is the current time. The decay exponent is the default that is empirically realistic in human experiments. Our implementation uses an highly precise approximation of the above activation function that omits to store all but the \(n\) latest episodes. If a road is represented by a series

Figure 2: Rate of belief changes.

Figure 3: A histogram of the variance in estimates per road for each of the model types.
of episodes \(R\) involving the road, then the expected speed of a road, \(U(R)\) is derived as
\[
U(R)=\frac{\sum_{e \in R} u_{e} e^{A_{e} / T}}{\sum e^{A_{e} / T}}
\]
\(T=0.25\) is a parameter (temperature). If \(R\) is empty, we assume a default speed, \(U_{\beta}\) for the road. The agent's performance is sensitive to \(U_{\beta}\), which represents a measure of pessimism (we do not optimize \(U_{\beta}\) and choose 0.0 as the most optimistic value).

Instance-based learning and the activation function have several desirable properties in our context. Activation increases during early iterations and allows the model to quickly differentiate between fast and slow roads. Activation is less affected by presentation of changes concerning frequently travelled roads.

Figure 4: Average travel times for IBL model agents as the communication network is varied.

Averaging Model The Averaging Model is included to provide a form of non-cognitive empirical ceiling: it is information-hungry, assuming that communication is free and unconstrained. It is the simplest model an agent can have of the graph is to store the average time taken by agents traversing that edge. Since the utilization of an edge will change over time, a moving average is used to keep the model updated with respect to the current situation.

The agents estimate for an edge is simply \(e_{i}^{\prime}=\alpha e_{i}+\) \((1-\alpha) o b s\), where \(e_{i}\) is the current estimate for the edge and obs is the new observation for the edge, whether communicated or observed locally. In this paper, we use \(\alpha=0.95\).

\section*{Empirical Evaluation}

In this section, we empirically examine the three models on the congestion problem described in Section 2. The evaluation is split out into three parts, with each part aimed at looking in depth at one of the hypotheses introduced in Section 1. Unless otherwise stated, for each experiment below we use the following experimental parameters.

\section*{Instance-Based Multi-Agent Learning}

The key challenge for multi-agent learning is that all the agents are simultaneously learning, making the learning environment non-stationary. Learning from instances in a non-stationary environment is not an intuitively effective technique. However, humans, who arguably use a type of IBL, are highly capable of learning in non-stationary environments. Our first experiments are aimed at looking at the performance of IBL on the congestion problem. Figure 1 compares the IBL, Ternary and Average models. Each model shows some improve-
ment over time and some initial poor performance as the space is explored. The highly communication intensive and, for a human, computationally challenging Average model and the IBL model achieve about the same final level of performance and have about the same initially poor performance. Both do better than the Ternary model in the long run, although the Ternary model more quickly finds decent solutions.

Since the IBL and Average models end with about the same performance, it is tempting to conclude that they work in about the same way. However, Figures 2 and 3 show that they actually achieve the result with quite different dynamics. Figure 2 shows the average number of agents that change the path they take from the day before. The ternary model oscillates because beliefs take some time to change. More interestingly, IBL consistently changes more than Average. IBL agents change paths substantially more often, but the net result is the same as the Average agents. It is infeasible to determine exactly what is occurring, but it appears that IBL agents switch between approximately equal paths due to the noise in their relatively sparse data, while the Average agents have aggregated more data leading to more stable choices.

Figure 3 shows a snapshot of the variance in beliefs of the agents at the end of the 200 days. Specifically, for each road segment we computed the variance in the time the agents estimate it would take to traverse that road. These variances were then discretized and presented as a histogram, with variances \(>50\) put in the last bin for clarity. The higher the variance the more the agents disagreed about how long it would take to traverse the road. Each of the three models lead to distinctly different patterns. The Ternary case often has all agents in agreement and never has large disagreements between agents due to the way beliefs cascade across the network and because the agents only allow a road estimate to have one of three values. The Average model shows slightly lower variance overall than IBL, though the IBL has many more roads with very high variance, indicating complete disagreement. It is insightful to see that better performance was had when the agents had different models of the environment, many of which must actually be wrong. We can conclude that Average and IBL achieve approximately the same results, with very different algorithms and with distinctly different internal dynamics.

Conceptually, the cognitive model (IBL) does several things differently to Ternary. To try to understand what the cause of the different behavior was, we manipulated Ternary in several different ways. First, we artificially prevent Ternary agents from changing each step to mimic the IBL's preference for reusing previous paths. Second, we decay the learning rate so later data has less effect on Ternary, to mimic the way IBL instances aggre-

Figure 5: Travel times for different arrangements (lefts) of IBL and Ternary agents. Adding roads over time (right).
gate. Finally, we change the default value for Ternary for unknown roads to match the default for IBL. We found that each of these changes improved Ternary performance, but preventing them from changing each step had the biggest effect. The qualitative equivalent of this in human decision-making would be status-quo effects or confirmation biases, while IBL's implementation more directly reflects properties of human memory.

Figure 4 shows how communication networks influence the IBL agents. Curiously, blocking communication works similarly well as communication on fully connected and random network structures. These networks share information most evenly across the team, while ring and, to a lesser degree, small worlds networks compartmentalize information into neighborhoods. Although the effect is not very big, the data represents many simulation runs so the differences are not due to noise.

We see that complete, random networks do very well. A post-hoc explanation is that these networks enable the agents to communicate freely; agents have up-todate information about congested roads. (The random networks were dense - each node has a degree of 5.) The networks without connections also do well, perhaps surprisingly so. Here, agents may adapt more slowly, and only to first-hand experience. In conjunction with the instance-based learner, this may also be a working strategy to avoid congestion. However, communication helps avoid a consistent initial spike, which we expect to be due to decision-making based on shared ground truth: everyone decides to use the fastest roads.

\section*{IBL and Ternary Models Interacting}

IBL agents can be thought of as a simple model for how human learning might occur and Ternary agents can be thought of as a reasonable, low communication agent approach to cooperative learning. Future systems are likely to have humans and agents learning together and
influencing each other. Hence, it is informative to look at what happens when IBL and Ternary agents are learning on the network at the same time. Varying the ratio of IBL to Ternary agents, we found that it takes relatively few IBL agents to give the whole system an improvement in performance. Having different types of learners in the same system not only does not hurt performance, it actually helps the weaker learners do better.

In the case of mixed Random graph networks of IBL and Ternary agents, we find that when there are only a few IBL agents they have a noticeable advantage over the Ternary agents, i.e., although they are using the same roads and are all interfering with each other, the IBL agents do relatively better. This advantage has disappeared when there are equal numbers of IBL and Ternary agents. The effect disappears smoothly as the number of IBL agents increases. If we think of IBL agents as being similar to humans and Ternary as being more like agents, this experiment hints that a small number of humans in an otherwise agent-dominated environment may do relatively better than the agents, and that they, as shown above, may improve the whole system's performance.

\section*{Disruptions}

Intuitively, learning from instances is likely to behave differently to learning moving numerical estimates when there are changes to the underlying system. Here we look at two different types of disruption to the underlying system, the addition of roads and the addition of agents, and the effects on the dynamics for each of the agent types. In the first case, one new road is randomly added every 20 days. The resulting dynamics are shown in Figure 5 over 200 days (left) and just for an early (center) and a late (right) road addition. Both Average and IBL spike dramatically as they try to exploit the new road, but then go back to their original paths after finding it to be unhelpful - for most of them because they

Figure 6: The impact of adding agents over time on average performance.
all tried it at once. The Ternary model is more robust because of the information sharing, but also takes longer to recover. Figure 6 shows the travel times as five new Ternary agents are added each 20 days, starting with 150 agents to make the result more comparable to other results. Both the Average and IBL agents jump when the new agents are added, but then smoothly improve performance. The Ternary agents are more dramatically effected by the change and do not adapt quickly. As the environment gets more congested and the original agents have built up more learning data, it is appears that IBL is more affected by the disruptions. This is unsurprising as its learning rate is effectively lower at this point.

\section*{Discussion and Future Work}

The cognitive, IBL agents benefit from a relatively simple learning model, combining a preference for wellknown roads and exploration of unseen roads. These cognitive agents can, with relatively limited communication volume, spread across the road network and efficiently use shared resources. What may be key to the cognitive agent's performance is limited sharing of knowledge: because agents do not have access to precise road utility estimates of their neighbors, and because they only receive updates when the neighbor's (quantized) beliefs change, they may arrive at heterogeneous conclusions about which roads are best. This leads them to spread out more, without sacrificing much individual performance. Under this scenario, agents do not need to misrepresent their knowledge states to their neighbors.

When combined in the same system, IBL agents and ternary agents actually helped each other rather than hurting performance. This is promising for future human-agent systems that will learn with distinctly different approaches. Notice that the agents are generally
moving to a Nash Equilibrium, where, at least according to their local models, they have no incentive to change behavior. However even if the agents do reach an equilibrium, the outcome may be far from the socially optimal solution (Hagstrom \& Abrams, 2001).

Understanding the emerging effects of cognitive decision-making in these networked simulations will allow us to spell out clear predictions to investigate crowd behavior empirically. The performance of cognitive agents that are based on empirically informed constraints of memory decay, instance-based learning and blending suggests that the mechanisms are not merely a rational adaptation to static information in the environment, but to dynamic resources and a social communication system. They enable us to maintain external, distributed memory without the devastating effects of cyclic, mutual adaptation.

\begin{abstract}
The current study examines the generalization of the Category Adjustment Model (CAM) across scales along two dimensions: time and distance. Participants were presented with geologic time and astronomical distance information either conventionally or using the hierarchical alignment model. Participants provided with hierarchically structured magnitude information for time and distances were more accurate on similar estimations at large scales than participants given the same content in a conventional manner. Patterns in event and distance estimation, along with overall group differences, are consistent with the CAM; suggesting people use hierarchically organized categorical information when estimating across scales and dimensions, and providing salient category boundary information improves estimation. Findings suggest a common representation of scale information for temporal, spatial, and abstract (numeric) magnitudes. Patterns of abstract magnitude estimations are consistent with segmented linear models of scale representation. Implications of the CAM in scale representation and the hierarchical alignment model in education are discussed.
\end{abstract}

Keywords: Category Adjustment Model; Hierarchical Alignment; Scale Representation

\section*{Introduction}

The Category Adjustment Model (CAM) is an adaptive Bayesian account for the pattern of systematic biases observed in recall of metric quantities due to category membership (Huttenlocher, Hedges, \& Prohaska, 1988; Huttenlocher, Hedges, Vevea, 2000). The CAM posits 1D, 2D, and 3D magnitudes are stored in a hierarchical combination of metric and categorical information. In the absence of lower-level information (e.g., precise metric information), people use higher-level categories to aide in estimation. Variation in estimation, therefore, occurs due to imprecision of category boundaries. Recall is biased towards the 'prototype' of the respective category. For example, when recalling the position of an object in a circular display, participants naturally divide the circle into mental quadrants and the recalled location is biased towards the center (or prototype) of the relevant quadrant (Huttenlocher, Hedges, \& Duncan, 1991).

The CAM predicts recall patterns on a range of dimensions (e.g., fatness of fish, grayness of squares, and lengths of lines (Huttenlocher, et al., 2000), events
(Huttenlocher, et al., 1988), and even social dimensions such as perception of facial expressions (Roberson, Damjanovic, \& Pilling, 2007) and judgments of gender and ethnicity (Huart, Corneille, \& Becquart, 2005)). However, there is limited research examining the CAM's predictive capability for a given dimension (such as temporal and spatial scales) across different scales (such as from human scales through to scales outside of human perception). Science education research has identified conceptual categories for spatial and temporal scales outside of human perception (e.g., Trend, 2001; Tretter, Jones, Andre, Negishi, \& Minogue, 2006), suggesting people may conceptualize magnitude information at relatively small and large temporal and spatial scales using a combination of metric and categorical information. Resnick, et al. (2012) experimentally assessed the role of categories in estimations of large temporal magnitudes. Participants who were provided with salient hierarchically organized event boundaries fostered a linear representation of events on the Geologic Time Scale compared to those who received the same information about the events without the salient hierarchical structure. Aligned with the CAM, this finding suggests the use of hierarchically organized category boundaries in the representation of events at larger temporal scales.

The current study aims to add to this relatively sparse literature by examining the generalization of the CAM across scales and dimensions. Two main objectives are to replicate research on memory for large temporal magnitudes (geologic time), and extend research to another dimension: space. Astronomical distance (a spatial magnitude at a large scale) was chosen for two reasons. There is already extensive research on CAM and spatial distance; demonstrating spatial distances at familiar scales are stored in a combination of metric and categorical information (e.g., Huttenlocher, et al., 1991; Huttenlocher, et al., 2000). Additionally, while the precise nature of the relationship is unclear, there is a systematic relationship between time and distance (e.g., Clark, 1973; Gentner, 2001), suggesting that time and distance at human scales are represented and estimated in the same way. Thus, if temporal and spatial dimensions across familiar and relatively larger scales are represented in a similar way, an analogous pattern of memory performance would be expected.

Relevant to the current study, the CAM makes two predictions. First, estimations of temporal and spatial magnitude should be biased towards the prototype of each event or object's category. There is evidence that suggests people with a moderate amount of knowledge regarding geologic time (e.g., in-service science teachers), divide the Geologic Time Scale (4.6 billion years) into three categories: 'extremely ancient', 'less ancient', and 'geologically recent' (Trend, 2001). It is beyond the scope of this paper to identify and characterize the types of categories used by novices to represent large temporal and spatial magnitudes. Rather, the current study will assess if providing salient internal structure of magnitude relations, through the use of the hierarchical alignment activity (Resnick, et al., 2012), improves estimation of large temporal and spatial magnitudes. In this way, the current study examines a second prediction of the CAM: people with salient internal structure of magnitude relations within hierarchically organized category boundaries should have more linear representations of magnitude compared to those who do not.

The current study also examines patterns of abstract (numeric) magnitude estimation (i.e., not content-specific) at the same scale as geologic time and astronomical distance. One common property of time and distance is they are both one-dimensional vectors (e.g., Clark, 1973; Gentner, 2001), as is abstract magnitude. Similar patterns in overestimation of small magnitudes and underestimation of large magnitudes are found with estimations of geologic events (Libarkin, Kurdziel, \& Anderson, 2007), astronomical distance (Miller \& Brewer, 2010), and abstract magnitude (Siegler \& Opfer, 2003). Studies of abstract magnitude suggest this pattern of errors may be due to compressive effects of unfamiliar magnitudes on a mental number line (see Barth \& Paladino, 2011 and Opfer, Siegler \& Young, 2011 for discussion of competing models). Consistent with the scale of geologic time and astronomical distances, the current study will examine abstract magnitude at two scales: million and billion. Number word frequency studies suggest that there may be differences in the representation of the million and billion scales, because the frequency of occurrence influences the structure of representation and the number 'million' appears more frequently than 'billion' (e.g., Dehaene \& Mehler, 1992). Thus, sampling from across the million and billion scales may reveal potential representational differences between the two scales.

While research has not explicitly examined the CAM in abstract (numeric) magnitude representation, there are a number of studies that look at the role of the subjective categorization of numbers in estimation (e.g., Laski \& Siegler, 2007; Mix, Huttenlocher, \& Levine, 2002; Siegler \& Robinson, 1982). Findings suggest that individual numbers can serve both as their own distinct category (a specific quantity of something) as well as part of a set of numbers (e.g., 'small' versus 'big' numbers) (Mix, et al., 2002). Further, children who spread numbers evenly across
group dimensions were more accurate on an abstract magnitude task than those who grouped more numbers into one 'big' category (Siegler \& Robinson, 1982). The current study will examine if the presentation of salient category boundaries in specific dimensions transfers to abstract magnitude representation. Because participants will be working with magnitudes with temporal and spatial content, transfer to abstract magnitude should occur. If the CAM accounts for abstract magnitude at large scales, similar patterns of estimation are expected for geologic time, astronomical distance, and abstract magnitude.

\section*{Methods}

\section*{Participants}

Forty participants were recruited from an undergraduate psychology experiment pool (20 in the hierarchical (experimental) group and 20 in the conventional (control) group). The demographics of the participants were consistent with a large urban American university.

Hierarchical Design In the hierarchical alignment condition, participants completed the same hierarchical alignment activity developed by Resnick and colleagues (2012), which is based on the progressive alignment model (Kotovsky and Gentner, 1996; Thompson \& Opfer, 2010). Participants made ten separate time lines, aligning time to a horizontal one meter space. They began with a familiar personal time scale, working through different historic and geologic time lines, up to the full Geologic Time Scale. For each time line, participants were given a partially completed time line, and were required to label the time line's length (in years) and locate where all previous time lines would begin on the current time line (see Figure 1).

Hierarchical organization highlights how each temporal scale is related to the other scales. Practice mapping magnitude relations across scales provides internal structure of magnitude relations within each scale. Thus, the hierarchical organization helps to populate each scale with additional categorical boundary information.

The current study developed a new analog version of the temporal hierarchical alignment activity for spatial distances (see Table 1 and Figure 1). For the hierarchical alignment of spatial distances, participants align ten increasingly larger scales of distance to a one meter space, beginning with a familiar distance. The hierarchical alignment condition takes approximately 45 minutes to complete.

Conventional Design The study sought to contrast the intervention with a realistic training program similar to one that might be used to instruct students in a classroom on these scales. Common pedagogical approaches to teaching geologic time (Libarkin, et al., 2007) and astronomical distances (Miller \& Brewer, 2010) are to create spatial analogies, such as placing events or objects in the correct sequence. Participants completed ten separate puzzles, placing the events/objects into the correct sequence. The
puzzles were made up of pieces of paper, half containing magnitude information and half with the respective category information. Participants were required to match the magnitude information with the corresponding category information for each scale, and place the scales in the correct sequence. The first puzzle represented the first temporal/spatial scale (see Table 1), with each puzzle representing an increased amount of magnitude. The tenth and final puzzle represented all of geologic time/distance to Makemake. The conventional condition took approximately 45 minutes to complete.

The conventional and hierarchical conditions were aligned on the following properties: number of scales, number of times participant identifies each scale (i.e., the first scale is identified ten times; the last scale is identified once), progressive increase of magnitude, information provided about each event/object, and total length of time on task. Thus, the only difference between conditions was the hierarchical alignment of scale information.

One potential difference between the temporal and spatial information was identified. Participants are likely to be familiar with thinking about temporal scales extending back hundreds of years ago; learning about recent human history is common. However, participants may not have the same level of familiarity with conceptualizing the vertical nature of the spatial scales. Because it is likely people have more experience traveling parallel to Earth's surface, or 'horizontally', as opposed to traveling vertically away from Earth's surface, we used this horizontal experience as an initial introduction of the vertical scale. As a way to familiarize participants with the vertical scale, a horizontal map was presented for each of the first three scales in both the hierarchical and conventional conditions. The maps showed an eleven, fifty-two, and four-hundred mile radius extending out from the university where the study took place. To engage the participants in grounding this scale to their personal experience, participants were asked if they had been anywhere on that radius or if they were familiar with the area. Because participants likely do not have experience thinking about larger temporal scales, no map was provided for the remainder of the spatial scales.

Table 1. List of Temporal and Spatial Scales, including category names and magnitude information
\begin{tabular}{|l|l|l|l|}
\hline Temporal Scale & \multicolumn{1}{|c|}{ Years } & \multicolumn{1}{c|}{ Spatial Scale } & \multicolumn{1}{c|}{ Miles } \\
\hline Personal & 20 & Troposphere & 11 \\
\hline Human Lifespan & 75 & Middle Atmosphere & 52 \\
\hline American History & 519 & Exosphere & 400 \\
\hline Recorded History & 5,512 & Inner Van Allen Radiation Belt & 6,000 \\
\hline Human Evolution & \(6,000,000\) & 3753 Cruithne (quasi-satellite) & \(8,450,000\) \\
\hline Cenozoic & \(65,000,000\) & Mercury & \(57,000,000\) \\
\hline Phanerozoic & \(542,000,000\) & Saturn & \(777,000,000\) \\
\hline Proterozoic & \(2,500,000,000\) & Neptune & \(2,700,000,000\) \\
\hline Archean & \(3,800,000,000\) & Pluto & \(3,580,000,000\) \\
\hline Hadean & \(4,600,000,000\) & Makemake (dwarf planet) & \(4,800,000,000\) \\
\hline
\end{tabular}

Figure 1. Example of a temporal and spatial number line at the thousands scale in the hierarchical condition. Note: the three previous temporal and spatial number lines are located relative to the current scale.

Procedure In a two-hour session, participants were presented with information about time and distance, with both presented as either hierarchically or conventionally (~90 minutes). Participants across conditions then completed the same assessment measures ( \(\sim 30\) minutes).

Measures A series of line estimation tasks were developed to assess participants' representations of geologic time, astronomical distances, and abstract (numeric) magnitude. Line estimation tasks are commonly used to assess mental scaling of abstract magnitude (e.g., Ebersbach, et al., 2008; Siegler \& Booth, 2004).

To measure representation of events on the Geologic Time Scale, an item from the Geoscience Concept Inventory (GCI), a reliable and valid instrument measuring a range of geoscience knowledge (Libarkin, et al., 2005), was adapted as a number line task. The GCI item presents participants with five time lines, with the following four geologic events placed in different locations: life appears, dinosaurs appear, dinosaurs disappear, and humans appear. Participants are required to choose the correct linear representation, with the other four time lines representing common misconceptions. In order to capture more variance in participants' representations, the GCI item was adapted so that participants were given a blank time line (anchored by 'present day' and 'Earth forms'), and asked to locate the same four events as used in the GCI item.

To measure representation of objects on an astronomical scale, an item was developed as an analog to the geologic event time line described above. Here, participants were presented with a blank number line (anchored by 'Earth's surface' and 'Makemake'), and asked to locate four objects on the same scale as on the event time line: Pluto, Mars, Mercury, and Cruithne.

To measure representation of abstract (numeric) magnitude (not content specific) a series of line estimation
tasks were given. Participants were given a sentence stating when/where an event/object was, and then asked to locate that magnitude on the number line (e.g., "Venus is 26 million miles away from Earth. Please draw on the line provided where Venus is located."). These items were framed in terms of objects and events to match the form of the other experimental measures. These estimations are considered estimations of abstract magnitude because the participants are explicitly given a magnitude to place on the number line; no recall is required. The questions provide the numerical values and ask for an estimation of the appropriate location on a spatial scale. To assess representations of the millions and billions scale, participants were asked to estimate two 'events' and two 'objects' on a 4.6 billion scale, and two 'events' and two 'objects' on a 542 million scale.

\section*{Results}

Participants in the hierarchical condition were more accurate overall on the event time line estimation task \((\mathrm{t}(38)=2.67\), \(\mathrm{p}=.01\) ) and the object distance task ( \(\mathrm{t}(38)=3.02, \mathrm{p}=.01\) ) compared with participants from the conventional condition. On both tasks, this effect is driven primarily by the estimation of the \(2^{\text {nd }}\) and \(3^{\text {rd }}\) events/objects. Participants across conditions performed similarly when placing the \(1^{\text {st }}\) (life appears/Pluto) and \(4^{\text {th }}\) (humans appear/Cruithne) events/objects on the number line ( \(p>.05\) ). However, participants in the hierarchical condition were significantly more accurate when placing the \(2^{\text {nd }}\) (dinosaurs appear) \((\mathrm{t}(38)=2.79, \mathrm{p}=.01)\) and \(3^{\text {rd }}\) (dinosaurs disappear) \((\mathrm{t}(38)=2.53, \mathrm{p}=.02)\) events on the time line, and the \(2^{\text {nd }}\) (Mars) \((\mathrm{t}(38)=3.38, \mathrm{p}<.01)\) and \(3^{\text {rd }}\) (Mercury) \((\mathrm{t}(38)=2.79\), \(\mathrm{p}=.01\) ) objects on the number line compared to the conventional condition (see Figure 2).

Performance across groups on the object distance estimation task was significantly more accurate than on the event time line estimation task \((\mathrm{t}(39)=2.85, \mathrm{p}=.01)\).

The eight abstract (numeric) magnitude line estimation tasks were highly correlated (rs > .529, \(\mathrm{p}<.01\) ) and had strong internal consistency (Cronbach's alpha=.94). There was no difference in performance when estimating abstract magnitude when estimations were temporally framed compared with spatially framed ( \(\mathrm{p}>.05\) ). Given the high correlations, strong internal consistency, and no performance differences between items that were temporally and spatially framed; a single abstract magnitude scale was created. Participants from the hierarchical condition were significantly more accurate on the abstract magnitude scale ( \(\mu\) error \(=11.50 \mathrm{~mm}\) ) than the conventional condition ( \(\mu\) error \(=30.14 \mathrm{~mm})(\mathrm{t}(25.38)=2.58, \mathrm{p}=.02)\). That the participants from the hierarchical condition are more accurate on the abstract magnitude scale than participants from the conventional condition is consistent for estimations on both the million and billion scales. Across conditions, participants were significantly more accurate when making estimations on the millions scale ( \(\mu\) error \(=14.73 \mathrm{~mm}\) )
compared with estimations on the billions scale ( \(\mu\) error \(=\) \(26 \mathrm{~mm})(\mathrm{t}(39)=3.45, \mathrm{p}<.001)\).

Figure 2. Average error (mm) for hierarchical and conventional conditions on the event and object line estimation tasks. For the event/object line estimation tasks, \(1^{\text {st }}=\) Life/Pluto, \(2^{\text {nd }}=\) Dinosaurs appear/Mars, \(3^{\text {rd }}=\) Dinosaurs disappear/Mercury, and \(4^{\text {th }}=\) Humans appear/Cruithne, respectively.

\section*{Discussion}

The current study successfully replicated the Resnick, et al. (2012) findings; participants provided with hierarchically structured event information were more accurate on event time line estimations than participants given the same content in a conventional manner. Here we found a similar result for astronomical distances and abstract (numeric) magnitude. These findings are aligned with the CAM, suggesting people use hierarchically organized categorical information when making estimations across scales and across dimensions; and that providing people with more salient category boundary information improves estimation.

In both the event time line and object distance tasks, participants across conditions were relatively accurate in identifying the location of the \(1^{\text {st }}\) (Life appears/Pluto) and \(4^{\text {th }}\) (Humans appear/Cruithne) events/objects (respectively). This may be because the \(1^{\text {st }}\) and \(4^{\text {th }}\) events/objects are anchored by the relatively close flanks of the number line itself ('top' and 'bottom'), whereas the \(2^{\text {nd }}\) (Dinosaurs appear/Mars) and \(3^{\text {rd }}\) (Dinosaurs disappear/Mercury) events/objects (respectively) may not be naturally perceived in these same salient categories; they are located 'somewhere in between'. Consistent with this interpretation, participants from the conventional condition demonstrate more bias in estimation towards the center of the number line than the participants from the hierarchical condition (as seen in the overestimation of the \(2^{\text {nd }}\) and \(3^{\text {rd }}\) events/objects). This finding is aligned with the three-category representation of geologic time advocated by Trend (2001), as well as predictions of biases towards the middle of these categories by the CAM. However, more research is needed to further identify and characterize categories used in the representation of geologic time and astronomical distances.

Participants across conditions were significantly more accurate on the object distance task ( \(\mu\) error \(=33.76 \mathrm{~mm}\) ) than the event time line task ( \(\mu\) error \(=45.45 \mathrm{~mm}\) ) ( \(\mathrm{t}(39\) ) \(=2.85, \mathrm{p}=.01\) ). Participants across conditions also were more accurate on the abstract (numeric) magnitude task ( \(\mu\) error \(=22.7\) ) compared to the event time line task \((\mathrm{t}(39)=5.55, \mathrm{p}<.001)\) and the object distance task \((\mathrm{t}(39)=2.96, \mathrm{p}=.01)\). One explanation for this pattern of differences in performance is that temporal, spatial, and abstract magnitudes are represented differently (see Agrillo, Ranpura, \& Butterworth, 2010 and Walsh, 2003 for a discussion on a general magnitude system). Alternatively, it may be the case that temporal, spatial, and abstract magnitudes are all represented in a similar way, but preexisting knowledge (and misconceptions) bias the subjective categories people use to make estimations. For example, consistent with participants being better at the object distance task compared to the event time line task, that geologic time is often neglected in the classroom (Dodick, 2007; Trend, 2001) and learning about the solar system is commonplace, it seems likely participants did have more knowledge of the solar system than geologic time. Related, the first three base analogies (tens, hundreds, thousands) may be differentially familiar to participants for temporal and spatial magnitudes. While temporal and spatial scales of magnitude were aligned, participants may be more familiar with traveling tens, hundred, and even thousands of miles; whereas participants could have only personally experienced years at the tens scale (no participants were over one hundred years old). Alternatively, mapping the vertical distances onto a horizontal map, and not having an analogous temporal activity, may have contributed to the observed domain differences. Future research should examine unfamiliar scales, both in content and magnitude. One may use an unfamiliar solar system, which would have a different time-course and different celestial objects.

Findings from the abstract magnitude task are consistent with the segmented number line model of scale representation (Ebersbach, et al., 2008; Landy, Silbert, \& Goldin, 2012). The segmented linear model posits separate linear functions for familiar versus unfamiliar magnitudes when estimated magnitude is plotted against actual magnitude. Ebersbach and colleagues (2008) found young children had a fairly accurate linear slope for smaller, familiar numbers, and a separate shallower linear slope for larger, unfamiliar numbers. While there were not enough estimations in the current study to carefully characterize the slope function, participants across conditions had a more accurate linear slope for estimations made on the million scale, and, while still linear, were significantly less accurate on estimation on the billion scale (overestimation). More research is needed examining estimations at large scales for detailed modeling of these slope functions.

That the hierarchical condition transferred to estimations about abstract magnitudes, suggests that people use categorical information when making these types of estimations. While there are some studies that look at the
subjective categorization of numbers (Laski \& Siegler, 2007; Mix, Huttenlocher, \& Levine, 2002; Siegler \& Robinson, 1982), there has not been previous work mapping the CAM onto number line estimations and scale representation. While more direct and explicit research is needed, we speculate that the CAM could serve as a unifying model for currently competing theories (e.g., logarithmic-to-linear, power function with anchor points, segmented linear). Category boundaries may serve as distinct anchor points, with adults possessing more precise categories (at the individual numbers level) compared with children. Whereas young children may have many numbers in one "big" or "unfamiliar" category, adults may possess counting strategies for numbers within "unfamiliar" scales. Thus, the CAM offers an account for the overestimation of unfamiliar magnitudes that maintain linearity within the scale. More extensive research is needed to identify types of categories used in scale representation to see if a CAM can predict the changing pattern of bias in number line estimations that occurs with development.

An implication of the current findings is the hierarchical alignment model is an effective way to teach about scales outside of human perception. Understanding scale information is important, as fundamental concepts in many disciplines require understanding of scales outside of human experience. "Size and scale" have been identified by the new National Research Council Framework for K-12 Science Education (2011) and the Benchmarks for Science Literacy (AAAS, 1993) as a fundamental and unifying theme of science education. Having a linear representation of scale is predictive of performance on a range of standardized tests in mathematics (Siegler \& Booth, 2004). Unfortunately, understanding large scales is difficult (e.g., Libarkin, et al., 2005; Tretter, et al., 2006). Undergraduate students, even those in science, technology, engineering, and mathematics majors, have difficulty mastering concepts of size and scale (Drane et al., 2008). While people are fairly accurate on identifying correct sequences, they fail to understand the magnitude between the events (Tretter, et al., 2006) and objects (Jones, et al., 2008). By providing a salient internal structure of magnitude boundaries, the hierarchical alignment activity may be an effective classroom tool to help foster a linear representation of scales like geologic time and astronomical distance.

\title{
English Words Are Processed Like Objects
}

\begin{abstract}
This experiment sought to explore the theory that familiar English words are processed similarly to objects. To do this, we looked for object-based attentional facilitation where cues in a different location to the target still facilitate target detection as long as they are inside the same object. Participants were shown two English words in an array, and cues and targets were embedded inside them. Reaction times for target detection were measured. It was found that in horizontally presented English words, cues presented in a different location to the target still facilitated target detection if they occurred inside the same word This was not the case for vertically oriented words. It was concluded that familiar words in a familiar orientation are indeed processed in a similar way to objects. These findings may be indicative that the cortical networks that evolved for object processing are also involved in the processing of words.
\end{abstract}

Keywords: object based; attention; reading;

\section*{Introduction}

It has been long understood that humans are capable of focussing their visual attention in one place in preference over another. This is commonly described as spatial attention. However, humans also have the capacity to allocate their attention to a particular object regardless of where it happens to be located (Blake \& Sekuler, 2006). This is known as object based attention. In day to day scenarios these two types of visual attention will interact and overlap. However, how object based attention contributes to the process of reading (if at all) is not well understood.
Egly, Driver, \& Rafal, (1994) conducted a study on attention within objects. Participants saw a \(2 \times 2\) array with a fixation point in the middle. The array contained 2 rectangular shapes which each spanned two of the quadrants. These shapes could be oriented with either both of them vertical or both of them horizontal. Within the individual cells of the array very brief cues and targets were presented. Participants had to detect the onset of a grey target square following presentation of a 100 ms brightening cue. They had 3 possible cuing conditions in their experiment. In the valid condition, the cue and the target would appear in the same location. In the invalid within-object condition, the cue and the target were in different locations, but still within the same object. In the invalid different-object condition, the cue and the
target were in different locations and within different objects. The targets in both of the invalid conditions were the same distance from their cue, and they were equally often oriented vertically as horizontally. The corner to corner diagonal separation of the cue and target was not used due to non-equal distance.

Egly et al. (1994) successfully manipulated the deployment of attention. The valid trial types were consistently responded to the fastest of all trial types, indicating that the cues were successful in heightening attention at their location. The crucial point came in the comparison of the 2 invalid trial types. Despite being the same distance away from the cue and subject to the same variations of orientation, the within-object invalid trials were responded to faster than the different-object invalid trials. This suggests that an advantage was conferred upon the invalid-within object trials simply due to the presence of a shape containing both cue and target locations. This has been described as "Object Based Attention" - that attending to a cue within an object will heighten attention deployment to the whole object, including non-cued locations. More recently Luo, Lupiáñez, Funes, \& Fu (2011) replicated these findings, and found that these object-based effects could be expected to be present even at very short stimulus onset asynchronies. They also highlighted problems in using cues and targets which contain implicit spatial information - something which was deliberately avoided in this study.
Li \& Logan (2008) sought to explore how object based attention relates to reading. They performed an almost direct replication of Egly et al. (1994), but replaced the shapes with 2-character Chinese words. The words could be oriented either horizontally or vertically in their experiment, following the rules in the Chinese writing system. The study was a target detection task with three conditions of cue-target relationship. The cues could be valid, invalid but within the same word, and invalid and located in a different word. Replicating Egly et al. (1994), Li and Logan (2008) found that valid trials were responded to fastest. Comparing the invalid trials it was found that invalid targets occurring within the same word as the cue were responded to faster than invalid targets occurring within a different word from the cue. This successful replication of Egly et al. (1994) and may be taken as evidence that words are treated like objects inasmuch that cues falling within a word measurably facilitate target detection
elsewhere within that word, presumably through elevated attentional deployment.
Li and Logan have demonstrated that the visual contiguity of shapes can be "simulated" by the abstract lexical contiguity of words. There were no physical connections between the characters in their array, and yet the participants clearly treated them as in some way connected. One way of explaining this is that the participants were treating the 2 -character words as if they were a single object. However, their findings might not be easily translatable into English reading processes. Chinese is both more visually dense than English, and more spatially plastic in that the character meaning is not necessarily extracted in a left-toright fashion. Traditionally, it could also be written legally both left-to-right and top-to-bottom, although that has become much rarer. As a consequence the importance of serial order and direction could be said to be comparatively lower than in English, whereas the importance of what lexical groups the symbols form could be said to be greater. This may lend itself well to an object based decoding strategy. Would the within-word benefit carry over to English? We devised a study to try and answer that question. In our study, we stuck as close as possible to the method employed by Li and Logan. There is no English equivalent to the many 2-character words available in Chinese, so in our experiment we transitioned to using 4character English words. Each quadrant of the 2x2 array would contain 2 characters. In our experiment, the words were presented either horizontally or vertically. In particular it would be interesting to see what effect the more linear and less dense script of English has on the effects found in comparison with Chinese. Can an object based account explain reading single words generally, or is it only a special-case phenomenon?

\section*{Method}

\section*{Participants}

The participants in this study were 25 female and 7 male students from the University of Dundee. They were paid in course credits for their time. Their ages ranged from 17 to 40. All participants were fluent in English. This experiment utilized a within subjects design so all participants were exposed to all conditions of the stimuli. An additional 4 participants were tested but their data was not included due to abnormally high error rates.

\section*{Apparatus}

Stimuli were presented through an 18 " monitor running at 100 Hz and detection responses were recorded on a gamepad, with the response button pressed by the dominant hand. An SR Research

Eyelink-1000 desk-based eye tracker recorded monocular eye position at 1000 Hz . A deskmounted chinrest kept participants' eyes 60 cm from the screen and both their peripheral vision and vision in their non-dominant eye were eliminated through blinkered spectacles.

\section*{Stimuli}

288 4-character words with a lemma frequency of at least 200 per 16 million were selected using the CELEX word database (Baayen, Piepenbrock, \& Gulikers, 1995). The 288 stimuli words were used to create 144 test arrays containing 2 words each. Each of these arrays was used only once per subject. The letters were printed lowercase in black, 46 point Monaco. Targets were background colour patches that were red and cues were background colour patches that were green. Cues and targets would always span 2 characters of the 4 character word in which they occurred. Stimuli arrays were assembled from several bitmaps and controlled using a variable grid. Individual bitmaps were created for each word, the fixation cross, the cue and the target.

\section*{Design}

The experiment consisted of an individually randomized sequence of 144 trials: 72 valid trials (cue and target were the same two letters), 24 invalid-within trials (cue and target were different letter pairs in the same word), 24 invalid-between trials (cue and target were in different words but never in diagonally opposed letter pairs, to maintain equidistance between cue and target across all invalid trials; see Figure 1), and 20 catch trials (no target appeared). Half of the arrays were horizontally oriented and half were vertically oriented for each subject. All stimulus arrays appeared only once per subject. In the horizontal version of the experiment the arrays were configured in the traditional left-to-right writing mode of English. In the vertical version of the experiment, the array was configured in a more novel top-to-bottom writing mode

\section*{Task and Procedure}

After giving informed consent the eye tracker was calibrated on the participant's dominant eye, determined via majority result from the Miles, Porta, and Camera tests (Roth, Lora, \& Heilman, 1992). Peripheral vision and non-dominant eye were occluded with blinkered spectacles. Participants were informed that they would be periodically asked about the last array they had seen in order to highlight the importance of actually reading the words onscreen.

Figure 1 gives a schematic representation of trial events. The start array for each trial contained two
words. These were presented for 1500 ms , followed by an additional fixation cross for 300 ms . Participants were told to read the words silently and then fixate the cross. The eye tracker was used to ensure participants were indeed looking at the fixation cross. A green colour patch was flashed behind the first or last 2 letters of one of the words for 100 ms to cue attention to this location. Following a further 100 ms of displaying the array with words and the fixation cross but no cue or target, a red target would appear under the first or last two characters one of the words. The trial proceeded only if fixation was within the region in which the cues and targets would appear during this cue-target onset asynchrony, or else an error
message appeared and the trial was discarded. Participants were instructed to press the response button as soon as they were aware of the appearance of the target, but to avoid pressing the response button when there was no target. Thus this was a simple go/no-go task. The time from the target onset to the button press was the reaction time (RT). Participants were instructed to respond as fast as possible to each target and to refrain from responding in catch trials. Responses were issued via a gamepad held in front of the participant, as close to their midline as possible. The response button was pressed with the dominant hand. If no response was issued a new trial started after 3000 ms.

Figure 1. Trial sequence, illustrating an invalid-between word trial in the horizontal condition, and an invalidwithin word trial in the vertical condition. Not drawn to scale

\section*{Results}

\section*{Performance Data}

The miss rate for present targets was extremely low, less than 5\%. Because of this false alarm rates on catch trials (which tended to be higher) were used as a criterion to remove underperforming subjects. Any participants who achieved less than \(75 \%\) correct on catch trials were removed from the data. 4 participants were removed from the data for this reason. This left 32 participants who responded correctly to catch trials \(86 \%\) of the time.

\section*{Reaction Time Data}

Outlier reaction times were removed through the application of a \(100-700 \mathrm{~ms}\) reaction time filter. Less than \(2 \%\) of the most extreme scores were removed by this filter. Filtered reaction times from all participants were analysed using a 2 (word orientation) by 3 (levels of validity) repeated measures ANOVA. There was a significant main effect of validity \(\quad(F(2,62)=3.163, \quad p=.049)\), indicating that on average validly cued trials tended to be responded to fast. Additionally there was a significant interaction between word orientation and validity \(\quad(F(1.624,50.352)=3.507, \quad \mathrm{p}=.047\) (Greenhouse-Geisser transformed)). Simple planned comparisons in SPSS were used to explore these effects. Since it was necessary that we demonstrate that cuing had an effect, both classes
of invalid trial were compared to valid trials which should always be the fastest. The difference between reaction times for Invalid Between trials and Valid trials was significant when both orientations were analysed together ( \(\mathrm{F}(1\), \(31)=4.705, \mathrm{p}=.038\) ), indicating that Invalid Between trials were always slow compared to valid trials. However, it was found that there was only a marginally significant difference between reaction times for Invalid Within trials and Valid trials when both horizontal and vertical trials were analysed together \(\mathrm{F}(1,32)=3.828, \mathrm{p}=.059)\). Looking at the graph it is evident that there is a big difference between horizontal and vertical reaction times for Invalid Within trials. This discrepancy was studied using post-hoc Bonferoni corrected t-tests where it was found that on Invalid Within trials, targets inside horizontal words were responded to significantly faster than targets inside vertical words \((\mathrm{t}(31)=2.901, \mathrm{p}<.05)\). However, on both the Invalid Between and Valid trials were was no significant difference between targets inside horizontal and vertical words \((\mathrm{t}(31)=0.385, \mathrm{p}>.05\) and \(t(31)=0.697, p>.05\) respectively). Thus, only on the trials containing horizontally oriented words did participants respond quickly to invalidly cued targets that occurred inside the same word as the cue. This is in accord with what would be expected from object based facilitation since cues inside a word are improving reaction times for targets elsewhere in that word.

Figure 2. Reaction times for each level of validity and each word orientation. Error bars represent 1 standard error.

\section*{Discussion}

This experiment was partially successful in replicating Li \& Logan's (2008) Chinese experiment, using a typologically different language, English. Whilst they found that in both the horizontal and vertical orientations invalid cues within the same word as the target facilitated reaction times, we found this effect only in the horizontal orientation. For horizontally oriented words, invalid cues that occurred inside the same word as the target facilitated target detection reaction times up to a level that was almost indistinguishable from true valid cuing. This indicates that a cue landing anywhere within a horizontally oriented English word will elevate attention levels to the whole word and thereby facilitate target detection in non-cued locations. This supports the idea that words can be treated like objects because this is an "object based effect". However, this effect was not present when the words were oriented vertically.

Since it can be shown that English words have attentional properties of the sort that would normally be associated with objects, this can be seen as evidence for the role of object based attention in reading. However it is of interest that we were unsuccessful in demonstrating this effect in the vertical orientation, where invalid but within word cues were responded to just as slowly as invalid different word cues. The fact that Li and Logan (2008) managed to show this effect in Chinese, whereas we were unsuccessful in doing so for English may be related to the properties of the two languages. It is evident that characters in English and Chinese are very different visually, but they are also processed in different ways. In Chinese there are radicals embedded inside characters that provide phonological and semantic information about that character to the reader, and they are not necessarily read in a strictly linear, left to right fashion. Likewise up until fairly recently Chinese could legitimately be written either left to right, or top to bottom. This is now rare in mainland China but still encountered in other Chinese reading countries. Conversely, top to bottom writing is fairly novel in English. As a consequence it is fair to say that Chinese readers will be much more receptive to seeing Chinese written top to bottom than English readers will be to seeing their language written top to bottom. In English, it would appear that the object based representation of a word which produces these effects is only activated when viewing the word in the familiar orientation. This would imply that when written in the vertical format, English words are decoded using an alternative method which does not produce object based attentional effects.

There are some criticisms that could be levelled at this study. Unlike Li and Logan (2008) background colour patches were used instead of character illumination. This was done in an attempt to control the stimulus intensity of the cues and targets. If we had illuminated letters then the number of pixels that changed colour for any given cue or target would vary wildly from trial to trial based on which
letters occupied that slot. Using the background colour patches enabled us to ensure a much more constant degree of stimulus intensity. However this approach did force certain compromises. In order to have the same size, shape and location of cues/targets between the horizontal and vertical trials it was unavoidable that there would be a better fit in one orientation, in our case horizontal (see Figure 1). There is a possibility that this poor fit may go some way to account for the differences between the horizontal and vertical trials. Also, this was not an experiment that actually involved reading per se. The words that were on screen did not have any bearing on how participants tackled the target detection task. The experimenter did take some steps to ensure the participants were not ignoring the words outright by asking participants to identify the previous pair of words they had just seen. If a participant was repeatedly unable to answer these questions, their data would have been removed. However, no participants needed to be removed for this reason. Nonetheless, the requirement of being able to identify the previously shown array is not nearly as high level as what would typically be considered a reading task.

Consequently, a new experiment is proposed that ensures that cues and targets fit both orientations of words equally well, and goes to additional lengths to ensure participants were actually reading words. Following every trial, participants could be asked to use the previously seen words in a sentence. This would enhance the level of processing the words were subjected to. A further experiment could do exactly the opposite, reproduce this task using non-lexical symbol strings. This would remove reading as a component entirely and address the possibility that these effects are artefacts of tasks where cues and targets are embedded inside letter-like stimuli.

\section*{Conclusion}

This study found evidence that supports the idea that words are sometimes treated as if they were objects by the human attentional system. Reaction time effects normally associated with objects were observed using English words when they were presented horizontally. Thus, the lexical contiguity of words must have been acting in a similar way to the visual contiguity of objects. These findings may support the idea that the parts of the brain that evolved to cope with object perception are at least a part of the network deployed to assist in the novel process of reading.

\begin{abstract}
The artificial neural network class of self-organizing maps (SOMs) is a powerful and promising cognitive modeling tool in the study of the brain and its disorders. Under this premise, this paper proposes a novel modification of the standard SOM algorithm in the form of an oscillating Topological Neighborhood (TN) width function. Existing research in neuroscience indicates that SOMs with oscillating TN width could exhibit higher biological plausibility than standard TN width SOMs. In this paper, two neuro-developmental disorders, autism and schizophrenia, are modeled, based on existing neurocomputational theories, using both SOM approaches. The simulation results demonstrate that there is significant equivalence between standard and oscillating TN width SOM modeling in terms of map formation behavior, output and structure. The theoretical and computational arguments presented validate the proposed SOM modification within a cognitive modeling framework.
\end{abstract}

\section*{Introduction}

Computational modeling offers a powerful way to study cognition and behavior. It has been applied to numerous areas of psychology and provides a more promising framework than those based on verbal models in terms of methodological diversity and applicability potential (Sun, Coward \& Zenzen, 2005). An ever-increasing number of computational modeling studies are dedicated to the modeling of cognitive and developmental phenomena using artificial neural networks (Thomas \& Karmiloff-Smith, 2003; Polk \& Seifert, 2002; Parks, Levine \& Long, 1998).

Shultz (2003) provides a comparative evaluation of the different computational neural network systems used to model cognitive developmental phenomena. An important class of such modeling networks is the self-organizing feature map; it is based on a Hebbian-type (Hebb, 1949) unsupervised neural learning mechanism and uniquely resembles topographic cortical maps in the brain to which has directly comparable structure and output characteristics (Spitzer, 1995b; Livingstone \& Hubel, 1988; Blasdel \& Salama, 1986; Merzenich \& Kaas, 1980). Willshaw and von der Malsburg (1976) originally proposed the self-organizing neural network to account for the retinotopic mapping problem. Kohonen's version (2001) -commonly abbreviated to 'SOM'-, however, possesses significant computational
characteristics and a range of powerful properties, particularly relevant to understanding and modeling of cortical brain maps, including approximation of the input space, topological ordering, density matching, and feature selection (Haykin, 1999).

This study investigates cognitive modeling aspects of modeling neuro-developmental disorders using SOM neural networks. The first section presents the SOM modeling framework used in this work, and introduces a novel modification in the SOM formation algorithm with significant cognitive modeling implications. In the subsequent two sections, core biological and behavioral characteristics of two mental disorders, autism and schizophrenia, respectively, are modeled using a prototype SOM model. The last section provides a discussion of the computational and theoretical parameters of the SOM modeling employed in the paper.

\section*{The SOM Modeling Framework}

\section*{Aspects of SOM Neural Networks}

A SOM is a non-linear unsupervised-learning computational neural network consisting of two layers. It has the capacity to map an input 'environmental' layer, consisting of patterns of fixed but arbitrary dimension, onto a (usually) one or two dimensional lattice 'representational' layer. The representation of environmental input in the output layer (called the map) is performed in a topologically ordered fashion, maintaining the non-linear input data distribution, and involves dimensionality reduction. Figure 1 shows an abstract depiction of a two-dimensional SOM; each input layer pattern vector connects fully with the map neurons.

Figure 1: A two-dimensional SOM.

The SOM neural network formation (training) process has four parts (as described in Haykin (1999)): synaptic weight initialization of the output lattice; neuron competition; neuron cooperation; and synaptic adaptation. The last three are sequenced within a loop for a finite number of 'epochs', in which input patterns are presented and weights adjusted until the weights converge.

During the competition phase, a winning neuron for the current input pattern is determined, based on a Euclidean distance metric. In the cooperation phase the winning neuron becomes the center of a cooperative process extending around an area according to a topological neighborhood (TN) function. In the synaptic adaptation phase, the weights of the map neurons within the TN of the winning neuron are updated 'towards' the current input pattern at an intensity determined by their lateral distance to the winning neuron as well as an exponentially decaying learning rate function.

From a cognitive modeling perspective, it is of particular interest to examine the neurobiological relevance of the SOM formation process at the implementation level of the neuron lateral interaction and inhibition mechanism. The standard SOM algorithm (Haykin, 1999) employs a translation invariant Gaussian TN function with an exponentially decreasing width, as illustrated in Figure 2.

Figure 2: Decreasing TN width around a winning neuron (dark grey neuron) in a two-dimensional SOM.

The TN width function can be expressed by the formula
\[
\sigma(n)=\sigma_{0} \cdot \exp \left(-\frac{n}{\tau_{1}}\right), \quad n=1,2, \ldots, t
\]
where \(\sigma_{0}\) is the initial TN width, \(\tau_{1}\) is a time constant, \(t\) is the number of epochs, and \(n\) is the current epoch.

The fact that only neurons close to the winning neuron have their weights changed significantly (implemented at the biological neural network level by a mixture of excitation and lateral inhibition) has a measurable impact on the representational structure of the SOM. A number of SOM cognitive models of brain disorders center around the key role of TN width and its exegetic biological significance (Gustafsson, 1997; Spitzer, 1999).

\section*{Oscillating TN width SOM}

The SOM cooperative phase involves local neuronal interactions via group Hebbian activation regulated by lateral inhibition. In general, neural synchrony and communication at the local and long-range level is an important aspect of brain functioning; neural oscillation,
particularly correlated to inhibitory neural activity, is increasingly considered to be of paramount importance to neural information processing and central to a number of studies of mental disorders including schizophrenia and autism (Schnitzler \& Gross, 2005; Wang, 2010). Neuronal group oscillatory synchrony is linked to inhibitory interneuron rhythmic modulation of the firing rate of excitatory neurons, at the local interaction neuronal level (Cardin, Carlen, Meletis, Knoblich, Zhang, Deisseroth, Tsai \& Moore 2009). Last, synchronous oscillatory activity of neighboring inhibitory interneurons may be supported by sub-threshold oscillatory behavior (Llinas, 1988).

In line with the relevant research on neural oscillation outlined above, this paper introduces a modification with increased biological plausibility in the SOM cooperative phase, as previously reported in a preliminary study (Revithis, 2011). Specifically, the original TN width function, part of the overall TN function, is replaced by a new TN width function that exhibits local exponential decrease instead of global. In this way the TN width oscillates continuously throughout the SOM formation process. Oscillation is necessary in a biologically plausible model, otherwise learning would cease when the TN approached zero. The oscillation consists of a concatenation of exponentially decreasing original TN width -temporally shortened- 'function instances'; thus, in the same number of epochs (i.e., one SOM training session) multiple function instances will fit, as shown in Figure 3.

Figure 3: SOM oscillating TN width.
The new function can be expressed as
\[
\sigma^{\prime}(n)=\sigma_{0} \cdot \exp \left(-\frac{(n+1) \bmod t^{\prime}}{\tau_{1}^{\prime}}\right), \quad n=0,1,2, \ldots, t-1
\]
where \(\sigma_{0}\) is the initial TN width, \(\tau_{1}^{\prime}\) is a time constant, and \(n\) is the current epoch. The constant \(t^{\prime}=t / c\), where \(c\) is the oscillation constant determining how many times the TN width will reset to \(\sigma_{0}\) and start decreasing again.

\section*{IPSOM}

IPSOM (Interlocking Puzzle SOM) is a complex-weightencoding prototype SOM spatial behavioral model of how humans complete interlocking puzzles (Revithis, Wilson \& Marcus, 2006). When trained, using a representative sample of puzzle completion sessions, it forms a behavioral SOM of the statistically dominant patterns (strategies) of puzzle completion. A 6x6 IPSOM has been evaluated for the case of \(4 \times 5\) puzzles against a simulated group of people. Each 'virtual' person used one of four predetermined puzzle completion strategies, illustrated in Figure 4.

Each radar-graph in Figure 4 depicts the order of puzzle completion for each pattern (H, V, PH, PV). The radial axis shows the encoded numerical position values on the puzzle board (i.e., which puzzle piece), and the angular axis shows the discrete completion sequence numbers (i.e., which piece is first, second, etc.) By connecting the points on the graph, a distinct visual pattern is formed. Attached to each graph, a puzzle board contains the puzzle completion order conventionally. The design principles behind the selected strategies were the generation of a small number of straightforward, real-life-based patterns, the utilization of topological clustering, and emphasizing the basic strategy of determining the board periphery during the puzzle completion. IPSOM was conclusively found to be efficient in modeling the behavioral domain.

Figure 4: IPSOM training set patterns (strategies).
In this paper, IPSOM is employed as a modeling test-bed for cortical map spatial perception. The working hypothesis is that IPSOM is not only a behavioral model but also a cognitive model of how humans perceive puzzle completion strategies when presented with puzzle completion examples. It is assumed that an average person would form an internal representation of the dominant strategies; a cortical map would retain the domain specific knowledge, modeled by a trained SOM. IPSOM is expected to represent the training patterns in a topologically ordered fashion, where neighboring patterns are also visually similar (Figure 5).

\section*{Modeling Aspects of Autism using IPSOM}

\section*{A Neural Circuit Theory of Autism}

Autism, a pervasive developmental disorder, has been studied for over 50 years by an expanding interdisciplinary research community. The current diagnostic tools (DSM-IV and ICD-10) dictate a socio-psychological behavioral approach that does not inform of the causes of autism; nevertheless, it is considered to be neurobiological in nature (Coleman \& Gillberg 2012).

Autism is associated with atypical perception and its internal representation. Sensory input often fails to integrate into existing memory due to abstraction impairment; there is difficulty in detecting the important features among the nonessential details; elaborating on internal representations is also problematic, where it appears that central executive control is required (Frith, 2003).

Gustafsson's (1997) neural circuit theory of autism is based on these empirically based concepts of autistic perception and proposes a neural-level explanation for the lack of drive for central coherence, a key element in autistic behavior (Frith, 2003). Neurological deficiencies in the formation of brain cortical maps give rise to autistic attributes. This leads to problematic feature extraction since "autistic raw data memory" operates in place of "feature memory" due to "inadequate cortical feature maps". Raw data memory is intrinsically linked at the behavioral level to the diagnostic criteria for autism (Gustafsson, 1997). Autistic maps lack feature distinction and preservation, and fail to provide an internal representation of salient perceptual data leading to raw data memory that lacks sophisticated representations.

According to Gustafsson (1997), SOMs provide a biologically plausible way to model characteristics of 'autistic' cortical maps. A SOM can represent input features just as a cortical map in the brain retains salient perceptual stimuli, and can exhibit similar deficiencies to an autistic cortical map if its formation mechanism is impaired.

\section*{The Autistic IPSOM}

The modeling premise of the SOM autistic impairment is suggested not by the biological map, but by its model. Gustafsson (1997) argued that a biologically plausible cause of impairment in a SOM is the application of excessive lateral feedback inhibitory synaptic strengths. The latter can degrade the map's generalization and feature representation capacity, resulting in high sensory discrimination and feature specificity, even to the point of instability, leading to the formation of inadequate or even undeveloped maps.

This modeling premise can be expressed as a TN premature narrowing during SOM training; TN can be regarded as the "source of power" (Sun \& Ling, 1997) in the autistic model. The initial TN width \(\left(\sigma_{0}\right)\) in the TN width function affects the map's representational capacity in a directly applicable way to Gustafsson's theory (Revithis \& Tagalakis, 2012). A non-autistic cortical map is expected to
represent all the dominant puzzle completion strategies with smooth transition between them. This can be modeled using IPSOM in its original parameter configuration.

After the incorporation of TN parameter modifications on IPSOM, an evaluation was performed. A series of groups of controlled simulations were executed with the initial width of the TN function set to a typical value of \(\sigma_{0}=3\) (i.e., equal to the network's radius, as suggested by Haykin (1999)) for one group, and reduced to \(\sigma_{0}=1.15\) for another group. Both groups were executed twice, using a standard TN width function, in one simulation series, and an oscillating TN width function in a second one. The results (discussed next) from over 150 simulations confirm that, for large \(\sigma_{0}\), the resulting IPSOM exhibits efficient representation of the input space, whereas IPSOM training, using a small \(\sigma_{0}\), forms a map with autistic structural characteristics. The results also support the hypothesis that the oscillating TN width IPSOM is equivalent to the standard TN width IPSOM in modeling autistic traits.

Figure 6: Standard TN width IPSOM map characteristics.
Figure 6 depicts IPSOM neurons after training, using a standard TN width function, for \(\sigma_{0}=3\) (top) and \(\sigma_{0}=1.15\) (bottom). The leftmost 3D graphs, and the 2D graphs in the middle, depict the Euclidean distance of pattern H to each neuron in the map. The darker and closer to the horizontal 3D base-plane (map) areas signify smaller distance and, thus, higher representational accuracy for pattern H. A \(\sigma_{0}=3\) facilitates a smoother transition from pattern H to other patterns in the map, whereas a \(\sigma_{0}=1.15\) results in steeper increase of the Euclidean distance indicating transitional pattern impairment. The rightmost combined-concentric radar graphs depict five neighboring IPSOM neurons for \(\sigma_{0}=3\) (top) and \(\sigma_{0}=1.15\) (bottom). A \(\sigma_{0}=3\) facilitates smoother transition from Pattern H to V , whereas for \(\sigma_{0}=1.15\) neurons are tightly grouped in two patterns (H and V) with impaired transition and generalization capacity.

Figure 7 depicts IPSOM neurons after training, using an oscillating TN width function, for \(\sigma_{0}=3\) (top) and \(\sigma_{0}=1.15\) (bottom). The observations that can be made are identical to the ones of Figure 6.

Figure 7: Oscillating TN width IPSOM map characteristics.
The illustrated example-simulation-results of Figures 6 and 7 are representative of the totality of simulation results obtained in terms of the observed characteristics. Patterns H and V , which were used for the rightmost concentric radar graphs, were selected to better demonstrate IPSOM's transitional behavior due to their relatively low correlation significance amongst IPSOM training set patterns (Table 1).

\section*{Using IPSOM to Model Delusions}

\section*{Acute and Chronic Delusions in Schizophrenia}

Modern studies on schizophrenia span approximately a century. There has been a continuous evolution of the understanding of this mental disorder and currently it is widely considered to be a progressive neuro-developmental disorder. Amongst its common positive psychotic symptoms are delusions (Green, 2001).

Spitzer has argued (1995a, 1995b, 1999) that SOM neural networks can provide a model of brain cortical function, and implement lateral inhibition, an essential feature of cortical maps. Furthermore, he proposed a neurocomputational exegetic framework for delusions based on the concepts of neuromodulation and neuroplasticity in relation to formation and operation of sensory and higher-order computational maps in the cortex.
Specifically, according to this approach, neuromodulator activity in the brain is associated with the signal-to-noise
ratio at the neuronal level, from an information-theoretic perspective. High neuromodulator activity can lead to an increase of focusing in neuronal activation and is associated with acute delusional states; such focusing can be modeled via excessive SOM lateral inhibition. Chronic delusions can then be regarded as the result of the establishment of entrenched cortical maps via sustained acute delusional states due to brain neuroplasticity.

\section*{IPSOM Modeling of Delusions}

According to Spitzer (1995a), a decisive factor in the clinical phenomenon of acute delusions is the level of cortical neuromodulator activity; this affects modulation of signal-to-noise ratio. In a SOM model of delusions it is possible to regulate the level of neuronal activation focusing associated with the signal-to-noise ratio by controlling SOM lateral inhibition. This can be achieved by controlling the width of TN during SOM formation. TN can be regarded as the "source of power" (Sun \& Ling, 1997) in this model.

Similar to the autistic model, the working hypothesis is that the initial TN width \(\left(\sigma_{0}\right)\) in the TN width function affects the map's behavior in a way applicable to Spitzer's theory. Inducing acute delusions in IPSOM can be realized via modifying the cooperation phase of the SOM algorithm in the model to employ a significant TN narrowing.

A series of groups of controlled simulations were executed with the initial width of the TN function set to a typical value of \(\sigma_{0}=3\) for one group, and reduced to \(\sigma_{0}=1.15\) for another group, as in the autistic model. Both groups were executed twice, using a standard TN width function, in one simulation series, and an oscillating TN width function in a second one. The results (discussed next) from over 150 simulations confirm that, for large \(\sigma_{0}\), the resulting IPSOM exhibits typical representation of the input space; when a small \(\sigma_{0}\) is used, however, the map's formation behavior is atypical and retains structures corresponding to chronic delusions. The results also support the hypothesis that the oscillating TN width IPSOM is equivalent to the standard TN width IPSOM in modeling delusions.

Entrenched SOM structures that could give rise to chronic delusions can be identified by comparing 'suspected' formed IPSOM maps with their untrained (initial) state. A 'delusional' structure can plausibly be seen as a number of trained neurons representing neither a transitional pattern nor an input space pattern, or, excessively representing an input space pattern (the latter can be regarded as compromising the SOM density matching property (Haykin, 1999)). Furthermore, representational resistance to change can also be interpreted as a characteristic of established (chronic) delusional structures (Spitzer, 1995a).

Figure 8 depicts four snapshot graphs of the same part of the IPSOM map for different initial parameters. In graph A we see the situation before training - essentially random patterns, and the remaining three depict the map's area after training for different \(\sigma_{0}\) value and TN width function configurations. By comparing IPSOM's untrained graph with its standard TN width trained counterpart (graph C) we
immediately observe the perseverance of a number of initial 'blank' patterns. A number of IPSOM neurons represent either the original initial 'blank' pattern or a distorted version of it. In the oscillating TN width case (graph B) there is also an excessive representation of the V pattern (cf. Figure 4). The observed 'delusional' flags, especially the resistance to environmental change, are prominent in the IPSOM trained graph using a very small \(\sigma_{0}\) (graph D).

Figure 8: Induced delusional structure on IPSOM.

\section*{Discussion}

The significance of TN in SOM cognitive modeling has theoretical and practical implications. In this paper, a modified TN width function with increased biological plausibility (paramount to modeling) was introduced and simulation results, based on the IPSOM prototype, on two models of neuro-developmental disorders were presented.

The modeling significance of the oscillating TN width function is associated not only with the initial TN width \(\left(\sigma_{0}\right)\) parameter but, primarily, with the TN width 'area' covered throughout the SOM training. What is considered 'narrow' or 'wide' TN during SOM formation is -from a different perspective- a function of the TN width area covered.

Figure 9: Standard and Oscillating TN width areas.

In Figure 9, both the standard and the oscillating TN width functions are overlaid in both graphs. The TN width area has as an upper bound the corresponding TN width function and as a lower bound the epoch (horizontal) axis.

Mathematically, the TN width area is expressed as
\[
\sigma(\mathrm{x}) \operatorname{area}=\int \sigma_{0} \cdot e^{\left(-\frac{x}{\tau}\right)} d x=\sigma_{0} \cdot(-\tau) \cdot e^{\left(-\frac{x}{\tau}\right)}+\mathrm{C}, \sigma_{0}, \tau \in \mathrm{R}
\]

To calculate the area for a given TN width function, \(\sigma_{0}\), and number of epochs \(t\), the following formula was used:
\[
\sigma(\mathrm{x}) \text { area }=\int_{0}^{t} \sigma_{0} \cdot e^{\left(-\frac{x}{\tau}\right)} d x
\]

In the standard \& oscillating TN width IPSOM simulation results, the calculated \(\sigma(x)\) area (for the same \(\sigma_{0}\) ) remained unchanged irrespective of the TN width function used. This verifies the output equivalence between the two modeling approaches. Furthermore, when, in the oscillating TN width function simulations, the \(\sigma_{0}\) value was reduced to \(\sigma_{0}^{\prime}\), the calculated \(\sigma(x)\) area was significantly smaller (Figure 9, right graph) and resulted in an IPSOM map with more pronounced delusional structures (Figure 8, graph D). This demonstrates the computational and cognitive modeling significance of the TN width area.

In conclusion, it is important to note that making a link between the biological and computational levels, in such modeling studies, often requires a sequence of finely drawn associations across disparate disciplines. However indirect and interdisciplinary such a link may be, the methodology and tools to construct it have long been available, and an effort was made in this study to illustrate it.

\begin{abstract}
Verbal analogies produced during naturally occurring instructional discourse in mathematics were explored using techniques borrowed from studies of language in use (see Wortham \& Rymes, 2003). Close examination of two eighth-grade instructional analogies reveals that the language practices of analogy are instrumental in shaping recipients' relational re-representation of objects being compared, in particular through markers of indexicality and poetic parallel structure. At the same time, close examination of the communicative interactions reveals that these devices may reduce the burden on recipients' reasoning to the point that they may appear successful at solving the verbal analogy, but their responses can be explained by facility in verbal interaction rather than in mathematical reasoning. These data provide thereby new insights into the "analogical paradox," the finding that analogies are commonly successful as vehicles for interactionally producing and displaying understanding of new information in everyday contexts but generally problematic when measured for their effects on reasoning in controlled laboratory settings (Dunbar, 1998). We identify a tension between interactional and cognitive success of everyday communicative analogies, meaning that those that are most likely to be interactionally successful may lead to less cognitive engagement for analogy recipients.
\end{abstract}

Keywords: analogy; analogical reasoning; language, linguistic anthropology

\section*{Introduction}

Analogy is the process of identifying shared relational similarities across contexts or representations, and has been theorized as integral to humans' everyday flexibility and higher order adaptive thinking (Doumas \& Hummel, 2012). Analogy has also been empirically identified as a regular practice within everyday communication in contexts including scientific biology laboratories (Dunbar, 1995, 1999), political discourse (Blanchette \& Dunbar, 1997, 2001) and classrooms (English, 2004; Richland, Holyoak \& Stigler, 2004; Richland, Zur \& Holyoak, 2007).

At the same time, basic analogical problem solving and transfer in the laboratory is notoriously unreliable and often unsuccessful (e.g., Gick \& Holyoak, 1980, 1983). These differences between analogy production
in the lab and in everyday interaction led Dunbar (1998) to speculate about the "analogical paradox," the insight that analogy is often rare and difficult to produce in the laboratory, but frequent and effective in everyday talk.

The current paper draws on linguistic anthropological methods for studying the empirical details of everyday interactions to better understand this paradox. The analysis uses techniques borrowed from the linguistic anthropology of education (Wortham \& Rymes, 2003), applying studies of language-in-use to educational discourse. Following this, language is conceptualized here as a performative activity that carries pragmatic as well as referentio-semantic meaning (Austin, 1962; Hymes, 1972,). In using analogies, teachers in mathematics instruction provide not only information regarding the denotational and other forms of semantic content of the lexical and grammatical structures of the talk they use. They also, simultaneously, signal to their student-audiences how, in the specific and actual moments of their use, their talk is to be understood as a move in the turn-by-turn exchange that is constituting the particular instructional discourse of which it is a part, and to which they will be expected to respond "appropriately." Most often, in instructional discourses using analogies, the "appropriate" student response will also be a response that is treated by the instructor as proof of the student's effective "correct" (referentio-semantic) understanding and reasoning based on the analogy's denotational content. But sometimes the pragmatically appropriate response is not the same as referentio-semantically "correct" one, revealing how the student in such exchanges is orienting and responding to two orders of meaning at once.

For example, consider an instructional analogy that is initially expressed as: "Lets say that I loaned you twenty five dollars and then I loaned you twenty five more dollars, what would you owe me?" Such an analogy source pragmatically indicates that the learner should not encode the analogs as a truthful representation of the facts as they exist in the context of use but rather as a proposed hypothetical situation shared between the teacher and student. In a classroom context involving an elementary school teacher instructing his student about negative numbers, a student might respond in a pragmatically adequate and
semantically "correct" manner with the same answer, "I'd be down fifty dollars." But in an ethics classroom in high school, in which the teacher was instructing about coercion, a semantically "correct" answer "I'd be down fifty dollars," may not be pragmatically adequate.

Linguistic anthropology of education builds from this notion of language in use to demonstrate that many instructional activities rely upon not only the linguistic production of educational content but also the form and participatory patterns of the construction. Lexical form, grammatico-syntactical structures, and the phenomenal features of speech and text as produced in real time can simultaneously signal social, political, discursive, participatory and other kinds of meaning to participants in a social interaction (e.g. Duranti, 1997). The use of such linguistic devices enables the speaker to provide pragmatic and metapragmatic cues, which simultaneously constitute the speech, while at the same time informing recipients how they should be interpreting that speech and preparing to respond to it (Goffman, 1974; 1981, Hymes 1972, Silverstein 1979, 1993). In educational contexts this is particularly important because classroom interaction not only affects the relationships between classroom actors, but it also impacts the cognitive activity performed by students during learning situations.

The current manuscript describes analyses of two classroom analogies that were identified from a larger corpus as illustrative of the verbal analogies produced in instruction. They are transcribed using conventions borrowed from conversation analysis (Sacks, Scheglof \& Jefferson, 1974). Within those transcripts, two linguistic resources were identified as both common to and particularly meaningful of the production of the verbal structure-mapping: indexicality and parallel structure.

Indexicality. All linguistic features, when used, have the capacity to index, or point to, aspects of their contexts of use as ways of shaping their conceptual meaning to competent members of a speech community (Ochs, 1992). Deictic indexes are those such as, "you," that have minimal semantic meaning aside from the precise context of the talk (Hanks, 1992, see also Silverstein 1976; Horn, 1988). As phrased by Hanks: "their basic communicative function is to individuate or single out objects of reference or address in terms of their relation to the current interactive context in which the utterance occurs" (1992: 47).

Thus the use of deictics makes the semantic meaning of an utterance inexplicable without the immediate context, which imposes a further burden on interaction participants to comprehend the multiple levels of meaning intended by the speaker. For instance, the use of the word "you" in the following phrase, "If you are having trouble, raise your hand" carries 1) semantic meaning - that the speech in question is intended to be directed to someone else (second person, not marked as singular or plural in

English) who is proposed as its addressee, and 2) a contextually specific, interactional meaning - the teacher is inviting those in the presumed range of hearing - here perhaps a group or subgroup of classroom students - to take up the position of addressee, and to respond, provided they interpret the qualification "having trouble" as applicable to them.

This study will examine the role of indexicality in teachers' discursive work to help students produce certain constrained representations of information in order to create comparable analogs. This carefully crafted relational re-representation is essential, because the major identified problem in doing analogy is noticing the relevance of mapping the relational structure from one analog to another (see Gick \& Holyoak, 1980, 1983). Thus if one's mental representation of a particular object in the world does not align with another system, the reasoner will likely fail to notice the relevant higher order structure mapping between them. Indexes that mark the irreal, or hypothetical nature of the source representation are illustrated in the first analogy described below. In so doing, and much as in the "Let's say..." example used above, the interacting students in the first analogy described are invited by the teacher to construct a particular source analog that does not have to reflect all the perceptual and relational characteristics of reality, but rather to isolate and highlight the key relationship depicted in the discourse.

Competent members of a speech community are highly skilled at interpreting indexical talk, though participants who are not fully members of that speech community (e.g., English Language Learner students), or students under high processing load to hold mathematical representations in mind, may find this a challenge that reduces their available resources to interpret a conceptually demanding analogy.

Poetic Structure. Second, this analysis takes up the reflexive capacity of language to serve, simultaneously as both the content of communication and commentary upon that content, particularly in the ways in which aesthetic forms such as rhyming, prosody, and even tempo can shape how semantico-referential content is to be interpreted and responded to by recipients and addressees (Lucy, 1993, 1999). One such example is discerned in the parallel structuring of discursive clauses in sequences of moments of actual speech and textual production, deploying what some have called the poetic dimension of meaning-making in language. (Jakobson, 1960; Silverstein, 1985) The notion of poetic structure and its regular and repeated occurrence in verbal analogy is particularly relevant to the current analysis, insofar as it offers yet another discursive channel for conveying the intended comparison between two systems of similarly structured relationships. In this sense, the poetic dimension of parallel structuring in verbal analogy becomes iconic of the semantic content of the speech, and the proposed
relationship between source and target that the instructor endeavors to produce by it. Parallel structure of speech serves as a pragmatic index for the analogical structure mapping itself.

The forthcoming analysis more closely examines the affordances and routines of indexicality and parallel structure within the discourse structures of analogy speech events. The paper will attempt to show that language mediates the activity of analogy in classroom mathematics instruction. In particular, it shows how the resources of indexicality and parallel structure are frequently instrumental in the outcomes of students' learning experiences during instructional analogies. The analysis will explore how teachers use indexicality and parallel structure to draw students into creating mental re-representations of the source and target objects as distinct relational systems by situating them in hypothetical, temporally defined, and/or spatial worlds that are then systematically aligned and mapped together. These can produce the dual, conflicting functions of drawing recipients' attention to relational similarity and increasing the likelihood that they will notice and successfully complete analogical structure mapping. At the same time, the high levels of structure provided by the language can reduce the mathematical, semantic learning potential for students.

\section*{Methods}

\section*{Sample}

The analogies analyzed in this paper are a subset of verbal analogies identified and coded in larger studies of classroom teachers' use of relational comparisons in videotaped U.S., Japanese, and Hong Kong Chinese eighth-grade mathematics lessons (Richland, Holyoak \& Stigler, 2004; Richland, Zur \& Holyoak, 2007). A randomized probability sample of all \(8^{\text {th }}\) grade mathematics lessons taught in the United States was videotaped as part of the Third International Mathematics and Science Study (Stigler et al, 1999). In a secondary analyses of these data, a random subset of the U.S. lessons were further analyzed by trained and reliable coders to identify and categorize analogy usage using frequency coding. Key representative analogies within these units of analysis were transcribed using conventions of conversation analysis (Sacks, Schegloff \& Jefferson, 1974).

Indexicality and parallel structure are analyzed in two analogies selected from this corpus of data. These analogies were selected because they are typical of the 298 U.S. analogies identified and coded, and for their clarity in revealing common and potentially consequential discursive constructions. They were not selected for their mathematical sophistication or efficacy, and should not be construed as ideal examples of the potential for analogy to support classroom mathematics learning. Many of the more mathematically sophisticated analogies follow similar
patterns but included more extended discussion, making their length prohibitive for a paper-length analysis of several examples. The first analogy demonstrates how parallel structure can provide a poetic representation of the analogical structure mapping itself. The second analogy also invokes parallel structure, but further reveals the role of indexicality in constructing source representations and structure-mapping during production of analogies by drawing on irrealis, space, and time, and the second

\section*{Analogy Segment 1: Poetic Structure}

Analogy 1 demonstrates how the linguistic form of an analogy can generate participation and model conceptual mapping. This teacher aligns the mathematical concepts of generating equivalence across the equal sign with converting fractions to like denominators. These are different concept areas within algebra, though procedures used for manipulating these structures are similar. The analogy arises while the teacher is at the chalkboard instructing students about how to make fractions equivalent. She is teaching the rule that when one multiplies the bottom number of a fraction times a number, one must multiply the top number times the same number to retain the same fraction. She depicts this on the board in an example, where she multiplies both the numerator and the denominator times four to determine that \(2 / 4\) is equivalent to \(8 / 16\). The analogy the teacher makes between these concept areas is fairly procedural and does not engage in the relationship between the deep mathematical structure of these concepts, however it is interactionally successful and students are able to complete the teachers' designedly incomplete utterances throughout the analogy (Koshik, 2001).

The organizational structure of language, beyond its denotational and indexical meaning, can play an important role in the interactional and conceptual consequences of language in use (e.g. Jakobson, 1960; 1971[1966]). One constitutive factor of Jakobson's (1960) model of a speech event, is the poetic feature of language. He uses this category to foreground the aesthetic or perceptual features of talk, arguing that these carry their own functionality. The role of parallel structure is particularly relevant to analogy in use, since the conceptual basis for analogy is the development of relevant parallels between the conceptual structure of source and target objects. Teachers regularly invoked parallel structure in the lexical and grammatical construction of the analogical mappings, thus creating grammatical metaphors for the conceptual mapping being constructed. Parallel structure within the discursive form in this way may thus serve as reflexive language cues to listeners, such that the form of the structural parallelism within the utterance serve a guiding function, leading talk recipients to infer that the
ensuing talk should be mentally represented as a set of parallel structures (Lucy, 1999).

Figure 1. Analogy between operating on equations and fractions.

The teacher begins this analogy following a procedural explanation of how to multiply the same number to the denominator and the numerator in order to produce an equivalent fraction with a new denominator. The teacher begins with the token "okay," marking a transition between the prior expository talk and the ensuing discourse. This indicates that this is a distinct unit of talk. She then indexes that she is designing a comparison with the comparative marker "just like," followed by the referent "equations" to signal the source of the comparison.

The teacher then constructs parallel structure between the utterances in lines 2-4 and lines 8-10. Analogies are frequently formalized as \(\mathrm{A}: \mathrm{B}:: \mathrm{C}: \mathrm{D}\) ("A" is to " B " as " C " is to " D "), and this teacher implements that formal relationship in the following pattern of talk: "whatever you do to \((A)\) you have to do to \((B)\) " and "whatever you do to \((C)\) you have to do to \((D)\)." The statements are lexically identical around the arguments \((A, B, C, D)\), which are conceptually similar objects. "Whatever you do to one side, you have to do to the other, whatever you do to the numerator, you have to do to the denominator."

The parallel structure is further supported by the teacher's gesture that builds on culturally standard spatial representations of fractions and equations. For equations, "one side," "and the other" are typically depicted as horizontal objects to the left or right of the other. For fractions, "denominator" and "numerator" are vertical objects, one below and above the other.

These symbolic representations are reiterated by the teacher's gestures. In accordance with her verbalization of the source "whatever you do to one side you have to do to the other" she moves her hands to her left and then her right. In construction of the target she mirrors the opposing movements to signal the numerator and the denominator, and moves her hands from towards herself to away from herself. The teacher first designs
the relationship between the A and B components of the source (one side of an equation and the other) and then the relationship between the C and D components of the target (the numerator and the denominator). The overarching lesson has been focusing on equivalence, so it is clear from the setting of this talk that "have to" implies 'have to in order to maintain equivalence between the two sides.'

The parallel structure is compelling to the analogy recipients and they demonstrate uptake of the parallel structure and appropriate inferences based on acquisition of the relational structure of the talk. The teacher leaves a micro-pause as invitation to participation for students in lines 4 and 10, requesting their participation in generating the \(B\) and \(D\) terms of the parallel structure. In both cases multiple students within the classroom enter the discourse, and in both cases the audible set of students respond appropriately with the correct lexical item to complete the conceptual relationship signaled by the parallel structure. In line six students also demonstrated acquisition of the parallel structure, and overlapped with the teacher in production of the completion of the phrase using the modifier "to" preceding "the other".

These utterances provide evidence that these students are participating actively in the parallel structure, as well as the corresponding mathematically relevant relational mapping designed by the teacher. Their answers are not necessarily based on problem solving, though, but rather they may be mapping the structure highlighted by the teacher's gesture and parallel discursive structure from a known source object to a corresponding target.

\section*{Analogy Segment 2: Indexicality}

The following transcript, shown in Figure 2, provides a second example of the role of hypothetical contexts in construction of analogy. Of particular interest in this analogy is the teacher's persistence in indexing an alternative context that is familiar to her student recipients.

The teacher initiates this analogy to help a student determine whether the summation of two negative numbers results in a negative or a positive sign in front of the solution number. Answering this question is the target of this analogy, and the teacher invokes the familiar schema of losing money as a source.

This is a one-on-one interaction between one student and the teacher during the seatwork portion of this lesson. The student has raised her hand and indicated difficulty to the teacher, who then comes to her assistance. Approximately half of the analogies identified in the coding study were constructed following students' demonstration of difficulty with the mathematics. Many of these looked similar to this analogy.
```

T: You're- you're saying
(..) what's a, negative eighty eight if you lose
(..) let's say you have um (..)
you're playing marb-
well, uh people don't play marbles anymore.
T: Let's say you're (..) you got money, all right,
and you lose eighty eight cents
and then you lose five cents.
What have you lost altogether?
Ninety three cents.
Right.
So you wouldn't want to say plus ninety three.
: Want to subtract ninety three.

```

Figure 2. Analogy between losing money and subtracting negative numbers.

In lines 1 through 8 the student is voicing her confusion, though the details of the language are difficult to capture in the recording. In line 10 this teacher begins to signal that she is going to re-represent the question entered by the student. She begins with "you're - you're saying" which suggests a reformulation of the students' question, but then after a brief pause she begins again with: "what's a, negative eighty eight if you lose..." The lexical item "lose" indexes possession and change of that status, and is not a mathematical term. This choice of term signals that she is representing the students' mathematical question in an alternative domain. Next she pauses briefly and begins again. This time the teacher uses a plural pronoun "let's" indexing that both she and the student will participate in the reformulation of the student's mathematical question and uses the frame "lets say you have um." The teacher indexes the hypothetical (irrealis) frame through the lexical item "say," indicating that this is a reformulation in a world not exactly the same as the one inhabited by the student's initial question. Again, however, she aborts this reconstruction and after a brief pause reformulates with the frame "you're playing marb-."

Once again the teacher decides to discontinue this representation and the setting of marbles because, as she states, "people don't play marbles anymore." This statement reveals that it is important to her that the context she indexes as a frame for her reformulation of the students' question is one that the student regularly inhabits or is familiar with. After several attempts to initiate this representation of the student's original question, the teacher signals an alternative context through a shift in semantic as well as indexical word use, and settles on a hypothetical reformulation.

In lines 15 through 17 the teacher completes her representation of the irrealis source analog. She says "let's say you're (..) you got money," and indexes the student's nonverbal concurrence with the phrase "all right." Once again the teacher uses the plural "lets say" construction to signal that this is a reformulation of the original math problem, and that this is instead of the marble-playing context referenced immediately prior. The teacher continues by embedding the student's
original mathematical question in the context she is building in which the student's possession of money is the relevant feature "you lose eighty eight cents and then you lose five cents." She develops the source context as a hypothetical world in which the important point is that the student has money. The construction "lets say you're, you got money" suggests that regardless of whether this student actually has money, the teacher is indexing this possible world in which this student has 88 cents and loses 5 cents. These are the same numerical amounts as in the original target problem, yet they are situated within this hypothetical frame.

The question "what have you lost altogether" in line 18 is a reformulation of the target and requires the same mathematical computation, but the contextualization and the lexical item "lost" indexes that this problem is distinct from the mathematical problem and is located within the domain of money.

In line 19 the student answers appropriately to the hypothetical context of the source analog using the monetary unit, "cents" to describe the numerical solution. She indicates that she is embodying the "you" from inside the hypothetical possible world represented by the teacher, as she answers the questions "what have you lost altogether" without hesitation and with the correct number.

Finally, the teacher guides the student in transitioning from her facility with the hypothetical world of her monetary loss to the veridical world of the math problem. Still using the student as a reference point, in line 21 she says "so you wouldn't want to say plus ninety-three." The teacher's use of the term "plus" and the transitional item "so" index the mathematical world, and appropriately the student responds with: "want to subtract ninety-three." This correct answer is stated without markers of money, and specifically the term "subtract" is used for the same computational meaning as "lost" was in the earlier line 18. Thus the student has made the relevant conceptual inference that adding negatives results in a negative number, and she has made the interactional inference that she is now in the realm of the math problem, where she had previously inferred the context of her monetary loss.

Thus in this analogy, like in the prior example, the teacher's language denotationally constructs an analogy between a familiar and an unknown context, but her discourse also indexes both interactional and semantic mappings. Thus the student must exercise conceptual mapping and inferences at multiple levels. She must interpret her role in the analogy, as well as multiple levels of the mathematical comparison. The teacher indexes levels of comparison between the numbers as well as hypothetical to veridical worlds, and between a world where the student is within the context to where she external to the math and writes a mathematical
answer. The teacher's work to find a source context that is familiar and a realistic hypothetical situation may facilitate these levels of inference, enabling the student to draw inferences from the more familiar space to the more novel space.

The source analog of losing money thus provides a meaningful structure for this student to interpret the nature of addition between negative numbers, a concept that is currently unfamiliar to her. Her success within a few seconds demonstrates that this is a striking resource for meaning-making. The conceptual structure of negative numbers is typically challenging for learners, and this teacher has led to an extremely rapid successful completion of a target problem following confusion.

At the same time, this rapid transformation is somewhat troubling from a learning standpoint. The mathematical nature of this analogy is not deeply conceptual, nor is it clear that the student will be able to generalize this understanding to a new problem in which the teacher has not highly designed a source analog for the student. The student herself will have to relationally re-represent the current problem as a source for a subsequent problem, and her ability to do so remains to be seen.

This reveals a powerful tension between the interactional success of an analogy produced in conversation, and the goal to produce deep thinking and conceptual abstraction from an analogy. The teachers' highly constrained representations of the source analogs improve the likelihood that recipients will use the alignment they have been provided. At the same time, this may limit the need for effortful relational integration and structure mapping on the part of students, potentially limiting future ability for transfer and generalization.

Overall, these examples are both successful interactions in which students reason analogically to respond as pragmatically and mathematically intended by their instructor. Regarding learning, however, the pragmatic and referentio-semantical efficacy of the interaction are impossible to disentangle. The interactions may have prompted minimally effortful relational integration because the source objects were highly relationally re-represented by the teacher. That relational re-representation in the first example created a parallel poetic structure between the source and target representations, which required structure-mapping but could be accomplished through attention to the pragmatics, rather than only referentio-semantic/ mathematical content as one might suppose if solely examining the source and target representations being compared. This suggests that the analogical paradox may be at least partly explained by the grammatical, interactional pragmatics of everyday verbal analogies.

\begin{abstract}
Combinatoriality-the recombination of a small set of basic forms to create an infinite number of meaningful units-has long been seen as a core design feature of language, but its origins remain uncertain. Two hypotheses have been suggested. The first is that combinatoriality is a necessary solution to the problem of conveying a large number of meanings; the second is that it arises as a consequence of conventionalisation. We tested these hypotheses in an experimental-semiotics study. Our results supported the hypothesis based on conventionalisation but offered little support for the hypothesis based on the number of meanings.
\end{abstract}

Keywords: Experimental semiotics; Human communication; Language.

In the vast majority of languages, a small set of basic meaningless forms (typically phonemes) are recombined to create an infinite number of meaningful units (typically morphemes). This property, which we shall refer to as combinatoriality, has been identified as a core design feature of language (Abler, 1989; Hockett, 1960; Hurford, 2002; Jackendoff, 1999; Martinet, 1960; Studdert-Kennedy \& Goldstein, 2003). Its origins, however, are unclear.

\section*{Explaining combinatoriality}

\section*{Set-size}

Any communication system must employ a set of signs: mappings between signals (such as vocalisations or manual gestures) and referents (the things in the world to which the signals refer). A long-standing explanation for combinatoriality concerns the size of this set. If the signals in the set are distinguished on the basis of analogue contrasts, it will become harder to distinguish them as the set increases in size; restructuring the system in terms of discrete forms is an efficient solution to this problem (Hockett, 1960; Nowak, Krakauer, \& Dress, 1999; Studdert-Kennedy, 2000). If this is the case, we should expect combinatoriality to increase as set-size increases.

\section*{Mimesis and transparency}

Recent research on Al-Sayyid Bedouin Sign Language (ABSL) raises a problem for explanations of combinatoriality based on set-size. ABSL is a fully fledged language, which does not differ substantially from other languages in terms of set-size, but which exhibits very little combinatoriality (Sandler, Aronoff, Meir, \& Padden, 2011). Furthermore,
while other known sign languages do exhibit combinatoriality, they tend to employ sets of basic forms that are an order of magnitude larger than those employed in spoken languages (Liddell \& Johnson, 1989).

Another difference between spoken and signed languages is the degree to which they afford mimesis-that is, the degree to which signals are intuitively motivated by what they refer to. In sign language mimesis is both richer and much more frequent than in speech (Fusellier-Souza, 2006; Perniss, Thompson, \& Vigliocco, 2010; Meier, 2002; Taub, 2001).

Sandler et al. (2011) suggested that the beginnings of combinatorial structure in ABSL may be explained by conventionalisation, whereby the signals becomes less transparently mimetic. The ABSL sign for LEMON involves a transparently mimetic signal, in which the signer mimes the act of squeezing a lemon. Since there is more than one way to squeeze a lemon, the form of the signal varies among signers (Sandler et al., 2011, p. 519), but this does not hinder communication so long as the signal remains transparently mimetic. If this transparency is lost, however, the form of the sign can no longer vary to the same extent, but also no longer needs to be constrained by the referent. It is then more efficient to structure signals according to basic sensory-motor constraints, which are best satisfied by a small set of forms (Studdert-Kennedy \& Goldstein, 2003).

\section*{Two pathways}

It should be noted that the two explanations for the emergence of combinatoriality illustrated above are not mutually exclusive. It is possible that the emergence of combinatoriality is related to both set-size and transparency and that there is a complex relationship between the three. Since signs are easier to establish if there is greater opportunity for grounding them in something familiar (Galantucci, 2005; Scott-Phillips, Kirby, \& Ritchie, 2009), and transparent signs are by definition grounded, greater transparency should allow rapid growth in set-size, which-as suggested above-may in turn encourage greater combinatoriality. On the other hand, Sandler et al. (2011) explain combinatoriality as a response to low transparency. In other words, there is reason to expect both low transparency and high transparency to lead ultimately to combinatoriality, albeit by different routes. This may go some way to explaining the ubiquity of combinato-
rial structure in the world's languages. Moreover, given that the route from high transparency to combinatoriality is more indirect, it seems likely that combinatoriality takes longer to arise in systems that afford highly transparent signs. This may explain why ABSL still exhibits so little combinatoriality.

\section*{Investigating combinatoriality in the laboratory}

It is very rare for linguists to have the opportunity to observe and record a new language in its early stages, making such insights as Sandler et al.'s on the origin of combinatoriality very hard to come by. Moreover, new languages tend to emerge in unusual cultural settings, making generalisation difficult. An alternative approach, which has been referred to as Experimental Semiotics, is to study the emergence of novel communication systems under laboratory conditions (Galantucci, Garrod, \& Roberts, 2012). Del Giudice (2012) and Verhoef (2012), for example, examined the emergence of combinatoriality in sign systems in diffusion chains, but without any pressure to communicate. Here we present data from a laboratory study in which combinatoriality emerged in sign systems used by pairs of participants to communicate with each other.

\section*{Method}

Participants 12 pairs of participants (4 female-female; 4 male-male; 4 mixed) participated in the study for course credit or monetary compensation.

The game Participants played a cooperative guessing game, sitting in separate locations with the same set of four images (henceforth referents) displayed in random locations in a 5-by-5 grid on a video monitor (see Figure 1). The game consisted of a series of rounds. In each round, one player would play as "sender" and the other as "receiver". The sender was informed of a target referent and had to convey this referent to the receiver so that the receiver could select it on their screen. If the receiver selected the correct target the round was counted as successful; if not, the round was counted as unsuccessful. Since the players played in separate locations over the internet, they could not speak to each other directly. Instead, the sender could communicate with the receiver exclusively through the use of a digitising pad and a magnetic stylus. The tracings that the sender made on this pad were transformed into on-screen signals in a systematic way: While the horizontal component of the tracings determined the horizontal component of the signal seen on the screen, the vertical component of the tracing was ignored and replaced by a simple downward movement at a constant rate (Figure 2a). The resulting signals were relayed to the screens of both players in real time. Players could not use this pad as an effective drawing or writing device (Figure 2b), even after prolonged practice, and to succeed at the task pairs of players had to cooperatively develop novel forms of communication (Galantucci, 2005).To help them in this, both players received feedback after each selection. Specifically, the receiver was shown what the target image had been and the sender was

Figure 1: Screenshot from early stage of game. The screen on the left was the Sender's screen; the screen on the right was the Receiver's.
shown which image the receiver had selected. After the feedback phase, the next round began. Players swapped sender and receiver roles after each round.

The referents were presented as targets in a random order: Pairs iterated through four referents twice every eight rounds (in random order). A performance score was kept updated for each referent, based on the proportion of successful rounds in the cycle. If a pair had at least \(75 \%\) success on each of the four referents, the number of referents in the set was increased to eight, and the cycle length was increased accordingly to 16 rounds. The referent set and cycle length continued to be incremented in this way until either players had mastered a set of 20 referents or two hours of playing had elapsed.

Figure 2: (a) How the drawings players produced on the digitising pad appeared on screen. (b) How common graphic symbols drawn on the digitising pad appeared on the screen

Referents The referents used were black silhouettes of animals (see Figure 3). These silhouettes afforded the opportunity to develop signals with some degree of transparency, in which, for example, features of the silhouette (e.g. the trunk of the elephant) could be represented by a feature of the signal (e.g. a long curved line). However, the way in which their tracings were transformed did not allow players to reproduce the animal silhouettes or even to create simple drawings. In terms of the hypotheses described above, in other words, it was biased towards relatively low-transparency signals.

Figure 3: Referents used in the game. The top row shows the referents that were visible to players at the start of the game.

\section*{Results}

\section*{Measures}

All of the events in the game were recorded and three measures were derived from this data set: Set-size, Transparency, and Combinatoriality.
Set-size Following the experiment, a sign-set was constructed for each player. This consisted of every referent on which the dyad had reached at least \(75 \%\) success, paired with the last successful signal the player in question had used to communicate it. The Set-size for a pair was computed as the mean of the Set-sizes for the two players in the pair. The mean Set-size for the 12 pairs was 14.67 ( \(\mathrm{SD}=3.75\) ); the smallest sign-set contained six signs, and the largest contained 20.
Transparency The more transparent the relationship between a signal and a referent, the easier it should be for an independent judge to match them up. Four judges, who had no previous familiarity with the signs or with the purpose of the study, matched signals with referents. This was done as follows. First, the judges gained an understanding of the game by playing a few rounds themselves (as both sender and receiver, with pictures of faces as referents). Then they were shown a display containing one player's signals (as playable videos) along with the referents they referred to. Their task was to match the former with the latter. To give them as much opportunity as possible to detect relationships between signals and referents, judges were permitted to take as long as they liked and to change their minds as often as they liked. Once they had finished, another player's sign-set would appear. (The order in which the sign-sets appeared was randomised.) Each judge evaluated one sign-set from every pair of players ( 12 sets in total) and every sign-set was shown to two judges. The number of correct matches made by each judge for each player's sign-set provided an indication of the set's Transparency to that judge. This was converted to a zscore by subtracting the mean number of correct matches we

Figure 4: Correlations between: a) Transparency (T) and Set-size (S); b) Combinatoriality (C) and Set-size; c) Transparency and Combinatoriality; d) Transparency and Combinatoriality, with Set-size partialled out.
would expect, for that size of set, by chance and dividing the result by the standard deviation of that mean. Since every player sign-set was rated by two judges, the mean of the zscores for the two judges was taken as the Transparency index for the set in question. Finally, the Transparency for a pair sign-set was computed as the mean of the Transparency for the two players in the pair. The overall mean Transparency for the 12 pairs was .73 ( \(\mathrm{SD}=.76\) ), ranging from -.25 to 2.5 .

Combinatoriality Combinatoriality was measured using a slightly modified version of the Form Recombination Index used by Galantucci, Kroos, and Rhodes (2010). This measure breaks a sign into forms (parts of a sign divided by empty space). Forms within the sign are then compared with each other to remove duplicates, and the remaining forms are compared with all other forms in the system. The number of matches among these forms is then divided by the total number of comparisons to produce an index ranging from 0 to 1 (where 0 corresponds to a complete absence of Combinatoriality and 1 corresponds to maximal Combinatoriality). A system in which a small number of unique forms are reused many times will have higher Combinatoriality than a system in which a large number of forms are reused little. The mean Combinatoriality for the 12 pairs was \(.06(\mathrm{SD}=.04)\), ranging from . 01 to . 17 .

Correlations As can be seen in Figure 4, there was a strong positive correlation between Set-size and Transparency, r(10) \(=.65, p=.02\), a weak positive correlation between Set-
size and Combinatoriality, \(\mathrm{r}(10)=.33, p=.3\), and a negative correlation between Transparency and Combinatoriality, \(\mathrm{r}(10)=-.26, p=.42\). The strong correlation between Set-size and Transparency supports the hypothesis suggested above that more transparent signs are easier to ground, leading sign systems to grow faster. The presence of this correlation, however, poses a problem for interpreting the correlation between Transparency and Combinatoriality. That is, the positive correlation between Set-size and Combinatoriality interferes-via the positive correlation between Set-size and Transparency-with the negative correlation between Transparency and Combinatoriality. We therefore partialed out Setsize from the latter, and this revealed a much stronger correlation, \(\mathrm{r}(9)=-.65, p=.01\). This result is consistent with the hypothesis that Combinatoriality emerges as a response to low Transparency. The general pattern of results is also consistent with the hypothesis that high Transparency leads to Combinatoriality via Set-size, but the correlation between Set-size and Combinatoriality is too weak to say anything conclusive in this regard.

\section*{Conclusion}

Theoretical work and research on ABSL suggest two hypotheses to explain the emergence of combinatoriality. The first is that it arises as a solution to the problem of conveying a large number of meanings (Hockett, 1960; Nowak et al., 1999; Studdert-Kennedy, 2000). The second is that it arises as a consequence of conventionalisation, as mimetic signs lose transparency (Sandler et al., 2011). As in other experimental-semiotic studies (Galantucci et al., 2010; Del Giudice, 2012) our analysis of laboratory data did not lend much support to the first hypothesis (although, as suggested by Galantucci et al., 2010, it is possible that set-size exercises an effect on combinatoriality only after some threshold is reached). Our analysis lends the most support to the second hypothesis: Combinatoriality arises when signals loseor never possess-a mimetic link with their referents.

\begin{abstract}
Miscommunication is often regarded as noise or uninformative in psycholinguistic research. However, Coupland et al. (1991) suggest that miscommunication can provide rich information about how interlocutors come to communicate successfully. Successful communication necessarily needs the individuals involved to coordinate and update their mutual knowledge, experiences, beliefs, and assumptions. However, the process of updating this information may be ridden with unsuccessful attempts that eventually help interlocutors reach a common goal. This study evaluates the relative contribution of linguistic factors to communicative success, based on verbal grounding (e.g., mutual agreement on a referent) and visual congruency (e.g., interlocutor's visual environments match or mismatch) during a collaborative task. We show that varying levels of communicative success are laden with rich linguistic information that may uncover interesting aspects of successful and less successful communication.
\end{abstract}

Keywords: Joint action; grounding; successful communication; miscommunication; psycholinguistics.

\section*{Introduction}

Interactive language, in particular face-to-face interactive conversation, is the most canonical form of language use (Clark, 1992; Goodwin \& Duranti, 1992). In interactive conversation, interlocutors are typically both speakers and listeners (addressees) and they often are conversing to achieve joint goals. Nonetheless, most research on human language processing focuses on the speaker and the listener as individual cognitive agents in non-interactive tasks.

There are important exceptions. For example, a large body of work has used the Edinburgh Map Task (Brown et al., 1983) to address a range of psycholinguistic issues. In this task two interlocutors collaborate, with the director guiding the matcher to reproduce a route printed on the director's map. Aist and colleagues developed a "fruit cart" domain as a vehicle for eliciting human language production for (a) dialogue system research and development and (b) psycholinguistic research (Aist, Campana Allen, Swift \& Tanenhaus, 2012). Senft \((2002,2007)\) developed a number of domains to evaluate lexical choice in spatial terms during
a space game and tinker toy task for cross-cultural analysis. Brown-Schmidt, Tanenhaus and colleagues have adopted a complementary strategy, using targeted language games to produce trial-like structure in unrestricted interactive conversation to address specific psycholinguistic issues with real-time response measures, such as visual world eyetracking (e.g., Brown-Schmidt, Gunlogson \& Tanenhaus, 2008; Brown-Schmidt \& Tanenhaus, 2008).

In this paper we provide a preliminary report on a project using a new domain intended to examine how referential domains are constructed, updated, accepted and rejected during a goal-driven task, with naïve participants and unrestricted speech. Here we examine how the language used in grounding might be diagnostic of, and contribute to, miscommunication.

The domain is similar to those discussed by Sentf (2002) and is designed to allow a face-to-face interaction through a barrier separating the two participants. This task involves a collaborative dyadic interaction that required participants to instruct each other in building a \(\mathrm{b} \bullet \operatorname{loc}^{\bullet} \mathrm{o}^{\mathrm{TM}}\) animal figure from abstract three-dimensional puzzle-like pieces (see Figure 1 for an image of the animals; Methods for full task description).

The \(\mathrm{b} \cdot \operatorname{loc} \cdot \mathrm{o}^{\mathrm{TM}}\) paradigm was created to serve a number of purposes. First, we wanted a domain that would lend itself to investigating both generation and interpretation of referring expressions. Secondly, we wanted to observe how referring expressions change when the goals change. For example, during the build stage pieces that were initially referred to using conceptual pacts, such as "the Christmas tree" would eventually assume a different identity, "the body" (see the green item on the left of Figure 2). This domain offers a rich domain for investigating grounding.

The domain creates a corpus that contained frequent communication failures (e.g., confusions and misunderstandings) that had to be resolved. These failures in communication are often regarded as noise and therefore uninformative in psycholinguistic research (Coupland, Giles, \& Weimann, 1991; Keysar, 2007). However, as

Coupland et al. (1991) argue, communication failure could provide valuable information about how interlocutors come to communicate successfully, much like speech errors can provide important insights into planning processes in language production.

Successful communication necessarily requires interlocutors to coordinate and regularly update their mutual knowledge, experiences, beliefs, and assumptions (e.g., Clark \& Carlson, 1982; Clark \& Marshal, 1981). However, the process of updating this information may be riddled with unsuccessful attempts that eventually help the interlocutors reach a common goal.

Some researchers have provided insights into how interlocutors might resolve communication problems (e.g., through ambiguity resolution or asking clarification questions; see Clark \& Brennan, 1991; Haywood, Pickering \& Branigan, 2004; Levelt, 1983; Pickering \& Garrod, 2004; Roche, Dale, Jaeger, \& Kreuz, under revision). However, the literature has minimally, at best, explored the rich information these failures could provide. For example, interlocutors' language is often ambiguous because ambiguity minimizes effort in production and because a speaker can usually assume that her addressee can rapidly use context to infer her intended meaning, perhaps because it is easier on the production system (e.g., Bard et al., 2007; Bock, 1986). This can result in utterances that initially appear to be egocentric. However, once an interlocutor realizes that her ambiguity might reduce the success of the interaction, she almost immediately adapts her utterances to eliminate the type of ambiguity that was confusing for her listener (Roche, Dale, Jaeger \& Kreuz, under revision).

Despite these efforts, the focus of the existing literature has been primarily on the successful exchange of information and largely ignores what happens when interlocutors' shared knowledge becomes de-coupled. Yet, miscommunication occurs regularly and can directly impact the quality and effectiveness of an interaction (McTear, 2008). Therefore, the current study provides a preliminary analysis of how language reflects and perhaps influences communicative successes and failures.

\section*{Methods}

\section*{Participants}

Participants were 20 dyads of paid undergraduate students ( \(N=40\); females \(=26\); mean age \(=19\) years) from the University of Rochester. Participants were native speakers of American English. All reported normal to corrected vision and no speech or hearing impairments.

\section*{Stimuli}

The experiment included two types of \(b \cdot l o c \cdot 0^{\mathrm{TM}}\) animal figures (see Figure 1).

Figure 1: Images of the grasshopper (left) and lizard (right) animal figures used in the task.

The grasshopper figure consisted of 25 pieces, and the lizard figure consisted of 28 pieces. Each animal piece was abstract and did not have a proscribed name (see Figure 2 for example pieces).

Figure 2: Sample of items from the animal figures.
Instruction Cards Each animal figure had a set of instruction cards, each corresponding to one step of the building process. The grasshopper and lizard figures consisted of 13 and 15 instructions cards each, respectively (see Figure 3 for sample instruction cards).

Figure 3: Sample of the animal figure instruction cards (right: grasshopper; left: lizard).

Conditions We had a between-subjects condition, in which dyads instructed each other in collaboratively building an animal (lizard or grasshopper), but were separated by a partition \({ }^{1}\).

Data Recording Three digital cameras recorded the participant interaction from different angles (left, centerwide, right). All video files were time-aligned and compressed into a single .mov file using Final Cut Pro.

\section*{Procedures}

Participants were seated across from each other, separated by a partition. The participants were given identical sets of \(\mathrm{b} \cdot \mathrm{loc}^{\cdot} \cdot \mathrm{o}^{\mathrm{TM}}\) pieces on identical workspaces. Workspaces featured a flat, white surface with a black box outline drawn in each corner. Participants were told that they would be working together to build identical objects. They were not, however, told what the resulting object would become. The

\footnotetext{
\({ }^{1}\) The design of the experiment was more complex, including a non-hidden phase that was not analyzed here. In the full design, the animals were counterbalanced across the possible conditions. For the purpose of the present analyses, only a subset of the data is included here.
}
experiment was divided into two phases: an Item Phase and a Building Phase.

During the Item Phase, the participants moved the individual \(\mathrm{b} \cdot \operatorname{loc}^{\bullet} \mathrm{o}^{\mathrm{TM}}\) pieces into the four boxes on their workspace. They were told that their workspaces had to match before they could proceed to the next phase. They were further instructed to take turns and decide together how to separate their items.

Once the workspaces matched, they were allowed to continue to the Build Phase. During the Build Phase, each participant was given half of the instruction cards in a predefined order. Participants alternated giving instructions. They were told that they could ask each other questions and, more generally, talk freely with one another. The majority of pairs successfully built matching objects. The unsuccessful pairs made only minor errors (e.g., wrong orientation of the animal's legs).

\section*{Measures}

Transcription and coding of various behaviors were annotated from a single workable file that contained a compressed version of the video files from the three different angles (left, center-wide, right) to aid in coding.

\section*{Coded Measures}

The video files of each dyad's interactions were transcribed. After transcription, additional measures were coded and included the following categories: confirmed and negated utterances, visual congruency, and several standard LIWC categories (Linguistic Inquiry and Word Count; Pennebaker, Booth, \& Francis, 2001).

Confirmed and Negated Utterances: We divided utterances that presented new information into two categories according to whether they were confirmed (e.g., yes, uh huh) or negated by the addressee. An utterance was coded as Confirmed if the partner indicated acceptance of the new information with an explicit confirmation (e.g., with a variant of yes) similar to the Common Ground Units described by Nakatani and Traum (1999). At each turn, \(T_{1}\) presented a new piece of information. Once \(T_{2}\) accepted this information it was coded as a Confirmed utterance. For example:
\(\mathrm{T}_{1}\) : Uh, that piece, uh it's in the, the center of box three, it looks like a bell.
\(\mathrm{T}_{2}\) : Mhm.
An utterance was coded as Negated if presentation of new information by \(T_{1}\) was negated or rejected by the \(T_{2}\). For example:
\(\mathrm{T}_{1}\) : Ok, so what was the? Put it three rows down.
\(\mathrm{T}_{2}\) : No, no, no, no, no, three squares to the right.
Visual Congruence. We coded the participants' workspaces as either matching or mismatching (congruent) or
mismatching (incongruent) throughout the task (e.g., the orientation of the object being described). Here we focus on within-trial instances of congruent and incongruent targets. Congruency and Confirmed/Negated utterances were used to create a \(2 \times 2\) contingency table of the different types of communicative success (see next section).

Communicative Success was measured relative to the congruent and incongruent physical environments in conjunction with the verbal acknowledgement of the information presented. Often, interlocutors believed their objects were congruent when in fact they mismatched in ways that interfered with the goal in that trial. A contingency table illustrates the four types of outcomes created by crossing confirmed and negated utterances with object congruency: Confirmed Congruent (CC), Confirmed Incongruent (CI), Negated Congruent (NC), and Negated Incongruent (NI; see Table 1 for the outcome labels).

A CC outcome is an instance of Successful Communication. The new information is confirmed (and acted upon) and the objects are indeed visually congruent. For example, one member of the pair says, "Yes, I got it," when in fact she did "get" it. A CI (Unrecognized Miscommunication) outcome occurs when one of the participants accepts the information presented, but the objects in her visual workspace do not match those of her partner (e.g., saying, "Yes, I got it," when she did not actually "get" it). The pair believes they have successfully communicated, but in fact they have not. A NC outcome (Unrecognized Success) occurs when a participant negates her partner's statement, but her visual workspace objects matches her partner's (e.g., saying, "No, I didn't get it," when she actually did "get" it). The pair has actually succeeded but believe they have not. Finally, in an NI outcome, the pair has recognized the miscommunication. Recognized Miscommunication occurs when at least one of the participants fails to ground, and their visual workspace objects do not match (e.g., saying, "No, I didn't get it," when in fact she did not "get" it).

Table 1: Communicative Success Outcome Variables.
\begin{tabular}{lrr}
\hline Acceptance Type & & Visual Environment \\
\cline { 2 - 3 } Confirmation & Congruent & Incongruent \\
\cline { 2 - 3 } & Successful & Unrecognized \\
Communication & Miscommunication \\
Negated & Unrecognized & Recognized \\
& Success & Miscommunication \\
\hline
\end{tabular}

LIWC Categories were selected to determine the types of linguistic categories that contribute to the varying outcomes. Given the nature of the predetermined LIWC categories, we do not venture to argue that this provides a thorough linguistic analysis of miscommunication. The main objective was to use these general categories as a firstpass attempt to see what linguistic patterns emerge as
miscommunication unfolds. These included the words per statement, assent, negation (i.e., different than "Negated" described above), cognitive mechanisms, personal pronouns, spatial, and perceptual linguistic forms. The LIWC categories are structured to distinguish at most general predicate classes (e.g., cognitive mechanisms) as well as linguistic particles whose function conveys degrees of interlocutor agreement (e.g., assent, negation).

Within the predetermined LIWC categories, we also created novel subcategories for assent and negation that included specific words (see Table 2 for the categories evaluated and examples within a category). Assent and negation were subdivided because it seemed at the time of transcription that varying forms of these categories could interact in interesting ways depending on the type of success.

Table 2: LIWC and linguistic category examples.
\begin{tabular}{lcr}
\hline Category & Subcategories & Example \\
\hline Negation & Strong Negation & No, nope \\
& Weak Negation & Don't, didn't \\
\cline { 2 - 3 } Personal Pronoun & First Person & I, We \\
& Second Person & You \\
\cline { 2 - 3 } Cognitive & Insight & Think, know \\
Mechanism & Certainty & Always, never \\
\cline { 2 - 3 } Physical & Perceptual & See, hear, feel \\
& Spatial & Top, bottom \\
\cline { 2 - 3 } Assent & Strong Yes & Yes, okay \\
& Weak Yes & Mhm, uh huh \\
\hline
\end{tabular}

\section*{Results}

We first established that, as expected, assenting and negating words were associated with visual congruency. We used a mixed logit model (Jaeger, 2008) to evaluate the proportion of visual incongruency, as predicted by assenting and negating words (LIWC categories), with trial set as a covariate and dyad as a random effect. The results from this analysis revealed that there were significantly fewer assenting words ( \(b=-.177, z=-4.973, p<.001\) ), but more negating words \((b=.392, z=5.210, p<.001)\) when visual incongruence occurred (see Figure 4 for means and standard errors for assent and negation for the visual congruency categories). Nonetheless, it is striking how often assenting words are used when the objects are incongruent.

Figure 4. Mean and standard errors for negation and assent categories for the visual congruency measure.

In order to further explore the relationship between language and outcome, we examined the four different outcomes [Successful Communication (SC), Unrecognized Miscommunication (UM), Unrecognized Success (US) and Recognized Miscommunication (RM)] as predicted by words per statement, assent (strong yes and weak yes), negation (strong and weak negation), and LIWC category measures (personal pronouns, cognitive mechanisms, perceptual, and spatial categories; Croissant, 2012). The results from this model suggest that the measures successfully predict the different outcomes \(\left(x^{2}=1105.9, p<\right.\) . 001 ; see Figure 5 for the proportion of occurrence within each category). Additionally, the evaluation of the significant odds ratios below represent the comparison of each linguistic category relative to the SC trials and are provided with regards to each of the types of communicative success (see Table 3 for results).

Figure 5. Mean and standard errors of the proportion of occurrence within each of the types of communicative outcomes.

Table 3: Significant predictors for the four outcomes, with SC as the reference category: \({ }^{*} p<.05 ;{ }^{* *} p<.01,{ }^{* * *} p<.001\).
\begin{tabular}{llrr}
\hline & Linguistic Category & Odds Ratio & t-value \\
\hline US & WPS & 1.053 & \(4.083^{* * *}\) \\
& Weak Yes & 1.589 & \(2.528^{* *}\) \\
& Strong Negation & 129.907 & \(13.621^{* * *}\) \\
& Weak Negation & 17.439 & \(10.9857^{* * *}\) \\

\hline
\end{tabular}

\section*{Conclusions}

Overall, our results suggest that interlocutors use language in interesting ways when they are having problems with communication. The results for words per statement suggest that using more words can be both helpful and harmful. For example, during US (Unrecognized Success) and RM (Recognized Miscommunication), interlocutors use more words. This might suggest that explaining things too extensively may prevent the listener from encoding all of the information presented due to the limits of processing load. This overload may then result in loss of essential information leading to a communication breakdown. However, fewer words per statement were also associated with UM (Unrecognized Miscommunication) relative to SC (Successful Communication). This might suggest that not providing enough detailed information may furnish the listener with insufficient information to reject the speaker's statement when necessary.

Interlocutors' use of personal pronouns (i.e., \(I\), you, and we) may be indicative of a unique role of perspective taking in creating and repairing unsuccessful communication, as seen in US, UM, and RM. Specifically, there were more instances of saying \(I\) and you, during UM (and you for RM), suggesting that the talkers may be attempting to reconcile differing perspectives. Additionally, the increased occurrence of we during US suggests that interlocutors attempt to find a shared perspective when a "minor mishap" occurs. These findings are interesting given a common interpretation of speakers as primarily egocentric (e.g., Keysar, 2007). While there was no difference in the use of personal pronouns during Successful Communication (SC), it would seem as if dyads tended to respond somewhat egocentrically during instances of less-than-successful communication. However, miscommunicating may have allowed them to (1) remedy a communication breakdown by highlighting their individual and shared perspectives and (2) access more information. Thus, it appears that a dyad may reference their partner's point of view to help re-couple their perspectives.

Additionally, use of spatial terminology increased during Unrecognized Miscommunication (UM). Anecdotally, we noticed that participants' interpretation of each other's use of spatial orientation was often problematic. For example, one participant's use of the word "top" was often not the same as her partner's, especially when the animal pieces were not similarly oriented in space. This type of mistake was not quickly realized, and it was not until a "major catastrophe" happened (i.e., they could not continue with the build until the problem was resolved) that they were able to reconcile each other's meanings of spatial terms. Although intuitively simple, the uses of spatial terms appear to be highly perspective-dependent and can result in communication problems if interlocutors' perspectives are not aligned.

Participants appear to use assent and negation differently during various outcomes. The use of strong and weak confirmation words (such as yes and mhm) may carry
different meaning depending on the context. One explanation of how interlocutors may use the varying forms of confirming and negating words may be that these words help the talker keep track of what they are doing and how they understand it while simultaneously communicating their state of mind to their partner (e.g., saying yes and no to themselves while trying to interpret an instruction). This may be especially important when the talker is confused about how to describe something. In these cases, confirming and negating words may cue the listener to help the talker find the best way to describe something. Therefore, an indirect expression of confirmation and negation may be a cue to the mental state of the speaker.

Alternatively, a confirmation may sometimes be a social nicety. Anecdotally, participants sometimes use a weak form of yes while clearly ignoring their partner (e.g., doing something completely different or unrelated to the current instruction). In these cases, the confirmation may be a socially acceptable filler word used to mask his or her inattention.

Finally, insight words (e.g., think, know) are more prevalent during both Unrecognized Success (US) and Recognized Miscommunication (RM). The prevalence of these words in the US outcomes is particularly interesting. This may indicate some degree of uncertainty. Additionally, interlocutors were more likely to use certainty words during Recognized Miscommunication (RM).

Some of our results are clearly expected given both common sense and previous observations (e.g. see Senft, 2002 for similar results for a tinker-toy task with Trobriand Islanders). For example, interlocutors confirm to ground and they negate to indicate confusion. Nonetheless, there are clearly subtle differences in the language used when participants are grounding successfully (SC) and incorrectly (UM). RM results in an increase in spatial language that reflects a negotiation about differences in perspective. This indicates that interlocutors recognize the importance of shared perspective to resolve confusion when communication is unsuccessful. Speakers may say less and appear to disregard listeners' perspective in an attempt to balance egocentrism and audience needs; providing less detail allows speakers to sample the space of the interaction cheaply and easily, while listeners' requests for additional information continually refine speakers' understanding of listeners' needs.

The main outcome of this preliminary analysis is that different communicative outcomes are associated with subtle differences in language use. This provides insight into how language reflects and influences how miscommunication is recognized and resolved. In order to establish this, however, we will need to investigate whether the language used in miscommunication predicts more global measures of success in the task. For example, RM might result in strategies that will improve performance because it forces interlocutors to negotiate about and resolve alignment of their perspectives. In contrast, failures to recognize the correct state (US) might result either in
interlocutors discounting each other's confirmations or alternatively becoming more sensitive to subtle cues that their interlocutor is uncertain.

While this initial pass of the \(\mathrm{b} \cdot \mathrm{loc}^{\bullet} \mathrm{o}^{\mathrm{TM}}\) corpus (currently lacking measures of reliability for our coding procedure) should be interpreted mindfully, our findings do provide interesting preliminary insights into how lexical choice influences communicative success. Additionally, the categories investigated with LIWC may seem somewhat arbitrary, but the category labels selected were standard and validated LIWC labels (e.g., cognitive mechanisms). In the current form, these categories are not meant to map onto any specific linguistic forms or stages of language processing. Nevertheless, we view the patterns that emerged through these categories as a springboard for more thorough analyses. For example, within the categories of negation and assent, we can next look at specific forms of confirmation to study how they emerge as a function of certainty. Further analyses of the corpus should provide data that will help evaluate these hypotheses.

\begin{abstract}
The current experiment investigated the effects of target size and symmetry on the dynamics of precision aiming. Participants were asked to sit on a chair and point at the center of four different targets (a small and big square target, and a horizontal and vertical rectangular target). The aiming movements were assessed using linear (root mean square) and non-linear fractal statistics (DFA and MFDFA). We found that participants spontaneously exhibited more movement in target dimensions with less spatial constraint (i.e., larger target dimensions). These larger movements, however, were more deterministic than the movements accompanying the smaller targets, indicating that more variation in aiming does not necessarily mean more random. Finally, even though participants' movements were multifractal, the different manipulations and task constraints had no effect on the width of the multifractal spectrum. These results suggest that human performance emerges from the complex relationship and interactions that exist between the perception and action capabilities of the human body and the physical environment.

\section*{Introduction}

Accuracy in tasks such as pistol shooting and archery depends on a person's ability to precisely aim at intended targets, which requires meticulous and refined control of the body and its relationship to the environment around it. Scholz, Schöner and Latash (2000) showed that expert shooters arrange the different components in their body into a motor synergy, coupling certain components to each other and therefore minimizing the necessary movements in order to be more precise. Complimentary research efforts have studied how different task constraints or elements of the physical environment affect how people move their bodies in order to aim precisely, such as target size (Ramenzoni et
al., 2011) or distance (Balasubramaniam, Riley \& Turvey, 2000). However, the effect that such environmental factors have on how people organize their bodies to achieve precision aiming has not yet been revealed in full detail.

Psychologists have traditionally evaluated the impact of task constraints on precision aiming (e.g., target size) using linear statistical tools, such as summarizing effects in means and standard deviations. Recently, statistical techniques allowing researchers to examine more complex aspects of such behavior have come to the fore, most notably, techniques that allow researchers to uncover the fractal structure in movement and behavioral variability (Gilden, 2001; Ihlen, 2012; Delignières \& Marmelat, 2013). Fractal or \(1 / f\) scaling refers to patterns in the variability of behavior that are long-term correlated such that deviations early in a recorded behavior are correlated with deviations that occur much later in the behavior. This kind of structure in variability is often referred to as "pink noise", denoting its difference from the highly irregular or random fluctuations of "white noise" and the highly regular or deterministic fluctuations of "brown noise" (see Figure 1). The degree to which a behavioral measurement series exhibits fractal scaling can be summarized by the Hurst exponent. The Hurst exponent \((H)\) for white noise is 0.5 and for brown noise is 1.5 , with pink noise in-between ( \(H \approx 1\) ) (Ihlen, 2012). Pink noise has been associated with signs of healthy functioning (for a review, Van Orden, Kloos \& Wallot, 2009) in different human movement tasks, such as tapping (Kello et al., 2007; Delignières, Torre \& Lemoine, 2008; Torre, Balasubramaniam \& Delignieres, 2010), stimulusresponse tasks (Holden, Choi, Amazeen \& Van Orden, 2010), postural sway (Schmit, Regis \& Riley, 2005; Schmit et. al., 2006), walking (Hausdorff, 2007) and eye-movement behavior (Coey et al., 2012).

It is becoming increasingly apparent, however, that human behavior may in fact exhibit even more complex patterns of fluctuation than those that can be ascertained from standard fractal analysis. In these cases, the patterns cannot be captured by a single \(H\), as the fractal scaling in the behavior might change over time during the course of measurement, or might be different at different scales of variability (Kantelhardt et al., 2002). Such "multifractal" patterns must, therefore, be characterized by their "multifractal spectrum"; a range of \(H\) values that collectively capture the complex structure inherent in a behavioral time series (e.g., Kuznetsov \& Wallot, 2011; Kuznetsov et al., 2012). This spectrum of \(H\) can either be time-dependent or independent. When it is time-dependent it shows a pattern of long-range correlation where sections of rapid fluctuation are interspersed with sections of slow fluctuation and it is associated with intermittent processes (Kuznetsov \& Wallot, 2011). Multifractal spectrums can also be time-independent due to the behavior being sampled having a frequency distribution with a long tail (Kantelhardt et. al., 2002).

These statistical properties are of interest to cognitive scientists primarily because they reveal something more about the underlying causal structure of human performance than do means and standard deviations (Gilden, 2001; Hausdorff, 2007; Kello et. al., 2007; Holden et. al., 2010; Kuznetsov \& Wallot, 2011). For instance, the presence of monofractal or multifractal structure in human performance can provide insight about the degree to which a behavioral process is self-organized or emerges from interactiondominant dynamics (Kuznetsov \& Wallot, 2011; Van Orden et. al., 2009). Traditional linear statistical tools assume behavior to be static and self-contained, while monofractal and multifractal analyses reveal the strong relationship or coupling between people and their environment (Holden et. al., 2010).

Figure 1: (a) sample time series of white noise depicting highly irregular or random fluctuations; brown noise, with highly regular or deterministic variability; and pink noise, located somewhere between random and deterministic fluctuations. (b) Plots obtained from a detrended fluctuations analysis (DFA) where the mean root mean square (RMS) is plotted against the window size both in log coordinates. The slope of the best fit line gives us the Hurst \((H)\) exponent.

It is for these reasons that the variation in human performance is seen as a balance between task constraints and a person's ability or between involuntary and voluntary control (Van Orden et. al., 2009; Kloos \& Van Orden, 2010). The embedded nature of human behavior can also be revealed by changes in monofractal or multifractal structure that result from subtle and sometimes non-obvious changes in environmental context or constraints (Chen et al., 2001; Balasubramaniam et. al., 2000; Ramenzoni et. al., 2011; Holden et. al., 2010). Depending on the nature of the task and the different constraints, the variability in behavior can go from overly random to more deterministic, or from overly deterministic to more random (Van Orden et. al., 2009; Kloos \& Van Orden, 2010). However, the specific direction of change in variability is not yet fully understood and further study is needed.

The current study investigates the effect that subtle changes in the shape and symmetry of targets have on the dynamics of a participant's precision aiming movements. Participants were instructed to complete the same precision aiming task, with the exact same instructions (i.e., point at the center of the target) over repeated trials. On any given trail, however, the shape and symmetry of the target was subtly changed to investigate how small changes in environmental task constraints can spontaneously reorganize the structure and variability of human behavior. In addition to performing a standard linear variability analysis (i.e., examined the RMS of movement), we conducted both a monofractal and multifractal analysis to better understand the effects that different targets had on the aiming movements of participants, and whether their movements became more deterministic or more random as constraints changed.

\section*{Materials and Method}

\section*{Participants}

Ten undergraduate students from the University of Cincinnati participated in the study for partial course credit.

\section*{Task, Materials and Procedures}

Participants in this experiment were asked to point at targets presented on a display screen. There were four different grey colored targets: a big symmetric ( \(6 \mathrm{~cm} \times 6 \mathrm{~cm}\) ), a small symmetric ( \(3 \mathrm{~cm} \times 3 \mathrm{~cm}\) ), a vertical ( \(3 \mathrm{~cm} \times 6 \mathrm{~cm}\) ), and a horizontal ( \(6 \mathrm{~cm} \times 3 \mathrm{~cm}\) ). Asymmetric targets matched the dimensions of the small symmetric in the strictly constrained dimension and the big symmetric in the loosely constrained dimension (see Figure 2b), therefore the visual angle for both the big symmetric and the vertical targets was \(3.12^{\circ}\) and for the small symmetric and horizontal targets \(1.56^{\circ}\). Additionally, the pointer had a visual angle of \(0.93^{\circ}\) When participants arrived they were greeted and then informed that for this experiment, a sensor would be attached to their index finger which would control the location of a small red square ( \(1.8 \mathrm{~cm} \times 1.8 \mathrm{~cm}\) ) presented directly in front of them on a display screen. This sensor was part of a wired Polhemus magnetic motion tracking system (Polhemus Ltd, VT) and tracked and recorded the movements of the participants at 120 Hz . Once the sensor was attached, participants were seated on a chair located 110 cm away from the TV (Figure 2a).

There were a total of 16 trials; these were completed in blocks of four trials, such that each of the four targets was viewed in each block. The target viewed on any given trial in a four trial block was randomized. The participants were informed that their goal for the experiment was to hold the red square they controlled with the motion sensor in the center of the presented target for the 45 second length of each trial. For each trial, the participant was asked to start pointing at the center of the target, and then the trial started with the Polhemus system being calibrated and the recording of their movement. Participants were instructed to keep their left hand in their lap. After the participants were informed of the number of trials they were to complete, they were given about 25 seconds of practice controlling the red square with the large square target presented on the screen. Once the participant felt comfortable with the procedure, all 16 trials were completed with long breaks given if needed between every block of four trials, between each trial the participant was allowed to lower their hand and place it on their lap. Once the experiment was completed, participants were thanked for their time and debriefed.

\section*{Signal Processing and Measures}

To examine the impact the different targets had on the participants' pointing movements, the first 4096 data points of the X (frontal, side-side movement) and Y (sagittal, updown movement) position time series were extracted for analysis. The Z (back-and-forth) dimension of movement
had little to no effect on task performance and was therefore not analyzed. Each dimension was analyzed separately to better understand the effect that the different target constraints posed on each of the degrees of freedom used by the participants.

Movement Variability. The root mean square (RMS) was calculated of both the X and Y position time series to examine the effects of the target manipulations on the stability of a participant's pointing movements.

Figure 2: (a) Experiment set-up and (b) the four different targets used in the experiment

Fractal Analysis. Detrended fluctuations analysis (DFA) was employed to calculate the monofractal dimension of the X and Y positional time series for each trial. Detailed explanations of this method can be found in several articles (Delignières et. al., 2006; Ihlen, 2012; Delignières \& Marmelat, 2013). Essentially, the time series is divided into windows of a particular size and the average variation (i.e., RMS) around a linear trend is calculated within each window. This procedure is then repeated for windows of different sizes. These averaged RMS are then plotted against the associated window size on log-coordinates. The slope of the best-fit line in this log-log plot represents the scaling relation and corresponds to the Hurst Exponent (H) of the time series (see Figure 1). For the current data we employed \(50 \%\) overlapping window sizes from 16 to 1024 points. Additionally, surrogate time series were created for each time series by randomly shuffling the data points and then a DFA analysis was done to determine whether the fractal dimension observed was time-dependent and therefore a characteristic of long-range correlation.

Multifractal Analysis. Multifractal detrended fluctuation analysis (MFDFA) was used to determine the multifractal dimension present in each time series. This method follows the same steps as DFA, but does so with a scaling parameter \((q)\) that allows for a calculation of \(H\) at different scales of variation in the time series. The final outcome of this procedure is the "width" of all the different \(H\) exponents present in the time series. If this width is equal to 0 , then the monofractal dimension is enough to completely describe the behavior. For the current data we employed \(50 \%\) overlapping window sizes from 16 to 1024 points and examined \(q\) 's from -3.0 to +3.0 in .5 steps. The surrogate time series created were also analyzed through MFDFA to determine whether the spectrum observed was due to timedependent fluctuations, or due to the frequency distribution of the behavior being sampled having a long tail.

Statistical Analyses. One way analyses of variance were computed for each measure in order to understand the effect that the different targets had on participants' behavior. If there was a significant difference, Tukey HSD post-hoc tests were performed.

Results

Figure 3: Mean root mean square of movement in the (a) X dimension (side-to-side) and in the (b) Y dimension (updown) depending on target type. The error bars represent standard error of the mean.

\section*{RMS}

Target type had a significant impact on the amount of side-to-side movement, \(F(3,156)=3.96, p=.009, \eta_{\mathrm{p}}^{2}=.07\). Post-hoc tests revealed that there was significantly more movement for the horizontal target ( \(M=.071\) ) compared to the small symmetric target ( \(M=.051, p=.003\) ), and the vertical target ( \(M=.052, p=.006\); see Figure 3a), indicating that participants naturally exhibited more movement in the direction of less constraint.

Type of target also had a significant influence on the root mean square value of movement in the up-down direction, \(F(3,156)=10.43, p<.001, \eta_{\mathrm{p}}^{2}=.167\). Post-hoc tests showed that there was significantly more up-and-down movement for the big symmetrical target ( \(M=.069\) ) compared to the small symmetric ( \(M=.051, p=.03\) ) and the horizontal targets ( \(M=.05, p=.03\) ). There was also significantly more up-down movement for the vertical target ( \(M=.097\) ) compared to the small symmetric ( \(p<.001\) ) and the horizontal targets ( \(p<.001\); see Figure 3b). Again, participants' movements seemed to spontaneously increase in the Y plane when the target was loosely constrained in this dimension as well. Thus, consistent with the result for the X dimension of movement, increases in participant movement variability appear to be a natural and spontaneous effect of the target size and shape.

Figure 4: Mean Hurst, \(H\), of (a) side-to-side movement and (b) up-down movement depending on target type. The error bars represent standard error of the mean.

\section*{Fractal Analysis}

The analysis of the monofractal dimension, \(H\), calculated using DFA, revealed that target type had a significant influence on the fractal structure of the participants' side-toside movement, \(F(3,156)=17.20, p<.001, \eta_{\mathrm{p}}{ }^{2}=.25\). Post hoc tests revealed that side-to-side movement in the big symmetric target was significantly "browner" ( \(H=1.26\) ) than for the small symmetric target ( \(H=1.19 ; p<.001\) ) and vertical target ( \(H=1.21\); \(p=.003\) ). Furthermore, the side-to-side movement of participants was significantly browner when pointing at the horizontal target \((H=1.28)\) than when pointing at the small symmetric target ( \(p<.001\) ) and vertical target ( \(p<.001\); see Figure 4a). This mirrors the results for RMS above, with participants' movement being browner in the targets where the X plane was loosely constrained and suggests that their movements became more deterministic when more freedom was allowed in the task. In other words, the participants moved more, but this increase in movement was also an increase in the level of determinism.

The fractal structure of the up-down movement of participants was significantly affected by the type of target they had to point at, \(F(3,156)=38.47, p<.001, \eta_{\mathrm{p}}^{2}=.43\). Post hoc tests revealed that participants' up-down movements were significantly browner when pointing at the vertical target ( \(H=1.31\) ) than the big symmetric target ( \(H=\) 1.25; \(p=.01\) ), the horizontal target ( \(H=1.15 ; p<.001\) ) or the small symmetric target ( \(H=1.16 ; p<.001\); see Figure 4b). Consistent with the fractal analysis of \(X\) and the RMS for Y above, participants' movements were pinker in structure when the target was more constrained in the intended plane. This suggests that participants' movements became less correlated in time with increases in task constraint.

The DFA analysis of the surrogate time series resulted in white noise ( \(H \approx .5\) ) for every trial wiping out any correlation present in the collected data. This indicates that the above monofractal analysis performed on the recorded data is time-dependent and not an analysis artifact.

\section*{Multifractal Analysis}

Participants' movements were found to be multifractal, with a one-sample \(t\)-tests demonstrating that the multifactal spectrum width for each movement dimension and for each target types were significantly different from zero (all \(t(39)\) \(>24.16, p<.001\) ). Although there was no effect of target type on multi-fractal width for participants' side-to-side movement, \((F(3,156)=.76, p=.518)\), an effect of target type on multi-fractal width was found for the participants' up-down movement \(\left(F(3,156)=3.07, p=.03, \quad \eta_{\mathrm{p}}^{2}=.06\right)\). Pot-hoc analyses, however, revealed that the only significant difference was that participants' movement while pointing at the small symmetric target had a significantly wider Hurst spectrum ( \(H\) width \(=.57\) ) than while pointing at the vertical target ( \(H\) width \(=.50, p=.04\) ). Therefore, even though precision aiming shows multifractal spectrum
characteristics, this measure does not capture the effects that size and symmetry of target have on the behavior as well as RMS and monofractal analyses do.

The surrogate time series also had a multifractal spectrum ( \(H\) width \(\approx .42\) ) which suggests that the multifractal spectrum present in the data is not time-dependent, but rather is the result of the behavior having a long-tailed frequency distribution (Kantelhardt et. al., 2002).

\section*{Discussion}

Our data indicate that changing some task constraints, while leaving the rest of the experiment the same, does change human performance behavior. In general, even though the participants in the current study were always told to point at the center of the target, they moved around more if more target space was available. In other words, looser constraints brought about more spontaneous movement variability. Additionally, this increase in movement variability brought about a more deterministic behavior, where looser constraints in a certain dimension resulted in a structure of variability closer to brown noise. This deterministic behavior was also shown to be the result of time-dependent long-range correlations. Finally, a multifractal analysis showed that the behavior was even more complex and that it could be represented by a multifractal spectrum, however, this multifractal spectrum did not characterize the influence of the different task constraints. Furthermore, the multifractal spectrum did not show a time-dependent pattern, it was instead due to the frequency distribution of the fluctuations of participants' movements.

These results support the idea that participants' behavior in the precision aiming task exhibit the characteristics of a strong relationship or coupling between the person and the environment, such that subtle changes in constraints bring about changes in the underlying dynamics of the movement. Additionally, the results are similar to those obtained by Balasubramaniam and colleagues (2000) where participants increased their overall movement in dimensions where more freedom was present, but that in turn this spontaneous increase in movement was more deterministic in nature. However, studies in different tasks, such as tapping or walking to a metronome have found the opposite results in which stricter control results in more random variability (for a review see Van Orden et. al., 2009 and Kloos \& Van Orden, 2010). One idea that has been supported by the data available so far is that people's movement variability is a result of the balancing between involuntary control (overly random) and voluntary control (overly deterministic) that arises during a specific task in a specific context (Van Orden et. al., 2009; Kloos \& Van Orden, 2010). If this is indeed the case, the results of the present study would suggest that participants impose further voluntary control to counteract the increase in spontaneous movement, so that they are able to successfully stay inside the target boundary. However, further research is needed to better understand the mutual influence that task constraints and participants’ ability play on the production of a certain behavior.

In general, the results of the present study bring into question the standard belief in cognitive science of behavior being the result of participants' voluntary and cognitive control alone. Instead, it points to a more embodied or interaction-dominant approach in which participants and their physical environment interact and mutually influence each other. It is therefore objectionable to try to study behaviors by only looking at the participant and ignoring the environment. Instead the focus of research should be the coupling or relationship between the person and its physical environment.

\begin{abstract}
Spatial cognition research has recently made much progress in understanding the cognitive representations and processes underlying human wayfinding. Many theoretical assumptions about the concept of landmark salience have been established. In this context it is important to define perceptual (or visual) and structural landmark salience. Structural salience is defined as the position of a landmark at an intersection. Perceptual salience is defined as the visual characteristic of a landmark. It must "stand out" from its surrounding to be perceptually salient. We investigated the influence of perceptual salience and the combination of perceptual and structural salience in landmark selection. We show for a spatial arrangement of four objects that the different object is preferred almost always. If the same spatial arrangement is interpreted as an intersection with a directional information, the participants' preference is influenced by structural as well as perceptual salience. Findings are discussed within the context of landmark salience.
\end{abstract}

Keywords: landmark; perceptual salience; structural salience

\section*{Introduction}

Human wayfinding is a particularly active field of spatial cognition research. People often have to navigate through new or familiar environments and that they, of course, do not want to get lost. Another reason is that wayfinding research is important for many basic and applied research fields, for instance, the study of spatial long-term memory and the development of user-friendly navigation systems.

One of the central concepts in spatial cognition research is the landmark and the question how it can be defined. Consequently, several definitions and theories about the nature of landmarks and their characteristics exist. The most common assumption is that the potential landmark must have a high contrast to its immediate or wider surrounding (e.g., Presson \& Montello, 1988; Janzen \& van Turennout, 2004; Caduff \& Timpf, 2008). Anything can serve as a landmark; natural, artificial, or man-made objects along a route that help us to find the way. Landmarks are helpful in wayfinding because they "stand out" of the environment, can serve as anchors (Couclelis, Golledge, \& Tobler, 1987), are better remembered if a change of direction is required (Lee, Tappe \& Klippel, 2002; Lee, Klippel \& Tappe, 2003), and increase the quality of a route description (Denis, Pazzaglia, Cornoldi, \& Bertolo, 1999).

The present paper is concerned with the salience of landmarks. The term "salience" is mostly referred to perceptual psychology (e.g., Treisman \& Gelade, 1980) and means that a salient object needs to stand out compared to other objects (e.g., different color or orientation). We here distinguish two kinds of landmark salience: structural salience and perceptual salience.

\section*{Structural salience}

Structural aspects of landmarks refer to the contexts of landmarks in navigational tasks and may be divided into different aspects or gradations. It is generally accepted that landmarks must have a "prominent location in the environment" (Sorrows \& Hirtle, 1999; p. 46). Furthermore, they can be separated into global and local landmarks (Steck \& Mallot, 2000). Local landmarks are situated directly along the path and intersections (Klippel \& Winter, 2005). Those at an intersection may again be divided, based on the route in the navigational task, into landmarks at a decision point or non-decision point, where a direction change is necessary/possible (Michon \& Denis, 2001).

Here we concentrate on landmarks directly located at an intersection were a decision is required (Lee et al., 2002; Peters, Wu, \& Winter, 2010). In this context we define structural salience as a preference of a wayfinder for a landmark to be located at a specific position at an intersection. Strictly speaking structural salience is thereby not a property of a landmark itself but of its position at an intersection. Therefore we have to address the question how an intersection can be defined. A typical or even prototypical intersection is a cross intersection. At such intersections four possible positions for landmarks are available (figure 1).

The true (physical) position of a landmark, on the right or on the left of the observer, is less important than the position in dependence to the direction of the turn to be made at the intersection. So the four positions can be defined as the positions before and behind the intersection and in direction or opposite to the direction of turn (see also Hamburger, Dienelt, Strickrodt, \& Röser, 2013) and will be abbreviated as "turn based" in the following. The preferred positions for a landmark at such a prototypical intersection from an allocentric perspective are in direction of the turn with the main focus before the intersection (figure 2). These results
serve as our reference for the influence of structural salience at the positions of a four-way-intersection.

Figure 1: Schematic visualization of a prototypical intersection with two orthogonal streets.

Figure 2: Results (landmark position preference over all intersections) for the structural salience (optimal landmark position) from two previous experiments (only position preference without landmarks: Röser, Hamburger, Krumnack, \& Knauff, 2012 [left]; shape-color-combinations as landmarks: Röser, Krumnack, Hamburger, \& Knauff, 2012 [right]). Here the turn based positions are depicted.

\section*{Perceptual salience}

Sorrows and Hirtle (1999) defined visual (perceptual) salience as the inherent visual object characteristics and stated that "[...] these may include the features of contrast with surroundings [...]." (p. 45). Caduff and Timpf (2008) provided a different definition and they understood perceptual salience as a bottom-up salience with the components location-based and attention-based attention, and the scene context. Other authors demonstrated that, for example, different colors, orientations, and shapes deploy attention (Raubal \& Winter, 2002; Wolfe \& Horowitz, 2004) what implies that these features could have a high visual salience. Also Treisman and Gelade (1980) showed that objects that stand out from their environment quickly reach the focus of attention.

Based on these concepts our definition of perceptual salience is a contrast-based approach where the observerbased contrast to the surrounding of the object is central. Strictly speaking an object is perceptually salient if it is an outlier, meaning that it is sufficiently different in comparison to the other objects available.

In our prior experiments (Röser, Hamburger, et al., 2012; Röser, Krumnack, et al., 2012) all landmark material was created to have the same perceptual salience and therefore the perceptual salience of a landmark should not have had an effect on landmark choices. In such a setting the perceptual contrast between the objects should be equal, no object should stand out.

\section*{Cognitive salience}

The focus of this study is not on cognitive (also defined as semantic) salience but it should not be neglected. It can be defined as the meaning or prototypically of an object (Sorrows \& Hirtle, 1999). Again the contrast is important or the degree of recognizability and the idiosyncratic relevance (Caduff \& Timpf, 2008). We assume that these factors do not play any role if the material is simple enough and is related to a single perceptual/cognitive category, like colors or simple geometrical shapes (by the same argument as for the perceptual salience, see above).

\section*{Experiments}

The main aim of the present paper is to explore which object in an environment people prefer to use as a landmark in wayfinding. In particular we want to answer the following questions: How important is a high perceptual contrast for the choice of a landmark at a decision point? And, what is the influence of the position of an object on landmark choices in a setting where one object clearly stands out? We investigated two independent factors: To vary the perceptual salience of potential landmarks we used objects in different colors, shapes, and different orientations. To vary the structural salience of potential landmarks the objects were located at different positions at an intersection. In a pilot study we examined how visual aspects of objects influence their perceptual salience in an arrangement similar to figure 1 but without any navigational context. In the main experiment we combine perceptual and structural salience by adding a navigational context to the arrangement.

\section*{Pilot Study - Perceptual salience}

We investigated the distribution of perceptual salience of an array of objects. Therefore, we presented groups of different stimuli and asked the participants which of them stands out most in contrast to the other ones (which one is the outlier?). This is based on our definition of perceptual salience as the contrast of an object to its surrounding. The goal was to establish a baseline of perceptual salience to use as a reference for further experiments.

\section*{Methods}

\section*{Participants}

A total of 20 students ( 16 females) with a mean age of 24 years (range: 20-41) participated. All participants provided informed written consent. All had normal or corrected-tonormal visual acuity and color vision. They received course credit or money for participation.

\section*{Material}

For this study we used a basic setting with four objects placed in a square with the same distance between each other (see figure 3). This setting resembles an intersection, but participants were not explicitly made aware of the resemblance and were not given any navigational context.

To vary the perceptual salience of potential landmarks we used objects in different colors, different shapes, and different orientations. The colors were always presented using the same shape, a simple cross (figure 3). In 24 items three identical colors and one outlier color (green and red; blue and yellow; red and yellow) were shown. Each color combination was presented eight times; half of them with three crosses of the first color and one cross of the second color and vice versa. The position of the outlier was counter-balanced over the four positions.

For the different shapes we used the same logic: 24 items with three identical shapes (e.g., a square; always in black, see figure 3) and one outlier shape (e.g., a triangle), again balanced over the four positions. For the different orientations of shapes four identical forms were used (see figure 3). Here the difference lies in the orientation: Either three shapes are orientated vertically and the outlier is rotated 15 deg to the right or the three identically oriented objects are rotated 15 deg to the right and the outlier is orientated vertically. Again, the outliers are shown once at each of the four positions.

Distractors were presented in addition. Twelve identical colors or shapes and twelve different ones served as distractors. For the different orientations twelve items with identical forms in different orientations (+/- 15 deg, +/- 30 deg) and twelve with different shapes in different orientations served as distractors.
In sum this resulted in 144 images of different stimulus material, 72 as experimental material and 72 distractors. All images were presented in succession in a random order on a custom computer screen (22'). Superlab 4.0 (Cedrus Corporation 1991-2006) was used for running the study and for data recording.

Figure 3: Example for the color material (left), different shapes (center), and shapes with different orientations (right).

\section*{Procedure}

Participants received instructions on the computer screen. It was explained that four objects will be shown at a time and in a fixed arrangement. Participants were instructed to indicate the outlier which stands out most to them. To select any object they should press the according response key on the keyboard.

\section*{Results}

\section*{Distributions}

The analysis of the distribution, preference of the objects over all variations, showed no significant variation from an equal distribution \(\left(\chi^{2}(3)=0.281, p=.963\right.\); each is preferred in
\(25 \%\) of the cases; we here used not a per 100 system, due to the fact, that the chi-square test is highly sensitive to the sample size, but rather a per 20 system, based on the sample size [ \(N=20]\); that means that each participant is weighted with one and the individual distribution is correspondingly adjusted).

\section*{Outliers}

The follow-up data analysis is based on the preference of the outlier compared to the other three objects (equal). For this we merged the preferences of all participants over all images with three equal and one different stimulus and for all positions of the outliers (table 1).

Table 1: Results of the statistical analyses. Chance level ( \(25 \%\) ) would mean that every position is preferred equally often, or one position is chosen all the time.

\end{tabular}

\section*{Discussion}

With the present study we investigated whether participants prefer to indicate objects that differ perceptually from the surrounding in the display similar to an intersection. As our results indicate, participants prefer to indicate the object with different perceptual properties, the outliers. Based on our definition of perceptual salience as a contrast to the surrounding, the results may be considered as a measurement of perceptual salience. Colors and shapes had the highest perceptual salience in this study in contrast to the different orientations. This could be due to the fact that the contrast to the surrounding is for the different orientations not as high as for the colors and shapes.
In the main experiment we examine the effect of perceptual differences in a wayfinding context.

\section*{Main experiment - Perceptual and structural salience}

With the main experiment we aim to examine how perceptual and structural saliences affect each other.
Based on the pilot study we now used the objects with the highest perceptual salience: colors in combination with different positions at an intersection in a navigational context. In this way we intend to investigate whether perceptual differences of landmarks influence the position preference or structural salience as determined by earlier experiments (see Figure 2).

\section*{Methods}

\section*{Participants}

A total of 20 students ( 14 females) with a mean age of 22.5 years (range: 18-31) participated. All participants provided informed written consent. They had normal or corrected-tonormal visual acuity and normal color vision. They received course credit or money for participation.

\section*{Material}

The navigational task used for this experiment was based on the virtual environment Squareland (Hamburger \& Knauff, 2011). We used a \(5 \times 6\) square setting from an allocentric (bird-eye) perspective (figure 4).

Figure 4: Maze including the path from the start to the sixth intersection. At the intersection four landmarks are depicted. On the right the answer instruction (which key to press) is given.

The route through the maze consisted of sixteen intersections: with equal numbers of left and right turns. This represented a route length people can imagine and remember in a virtual setting (e.g., Hamburger, Röser, Bukow, \& Knauff, 2011). The arrangement of the four objects was equivalent to the pilot study (equal distance between them and in the corners of the four squares).

As before, at each intersection (array) four colored objects were used including one outlier. In order to ensure that each combination of colors was presented only once, we needed a total of sixteen color combinations with sufficiently different hues. So we used the color circle and chose each color 22.5 deg away from the next one. The respective complementary color was used as the outlier. Color combinations were distributed randomly over the path. The positions of the outlier objects were systematically varied based on the turn direction. A second version of the maze with inversed colors (identical and outlier) was created. Additionally, for both versions the direction of turn was switched for each intersection, resulting in overall four different mazes. Each participant was randomly assigned to one of them. The participants performed the experiment on a custom computer screen (22'). Superlab 4.0 (Cedrus Corporation 1991-2006) was used for running the experiment and for data recording.

\section*{Procedure}

The instruction explained that the participants would see a path through a maze where at each intersection four different objects are presented. They should imagine that they have to give a route description based on the information they see. They were instructed to decide/ indicate at each intersection which object they are going to use for the route description. To select one object they had to press the corresponding key on the keyboard. The response keys were presented next to each slide at an exemplary intersection (figure 4). Subsequently, the instruction was repeated and supplemented with a pictorial explanation. After this example the experimental phase started with the path being presented from the start to the first intersection, including the route direction for this intersection and four colored crosses placed at the four positions. After each decision participants saw the next intersection and again the path from the start to this intersection and direction of turn and the four colors became visible and so on.

\section*{Results}

Outliers
To find whether outliers were selected more often as landmarks compared to the other objects, participants' responses were analyzed. The outliers were selected with a mean of \(66 \%\) and therefore significantly more often, compared to the remaining objects \((t(19)=2.281, p=.034)\). This result is also statistically different from chance level (25\%; \(t(19)=5.589, p<.001\) ).

\section*{Distributions}

In figure 5 (center) the turn based positions are presented. The distribution over all positions and intersections in the maze revealed a marginally significant variation from an equal (each is preferred in \(25 \%\) of the cases) distribution \(\left(\chi^{2}(3)=7.016, p=.071\right.\); again we used a per 20 system, based on the sample size [ \(N=20\) ], see above).

For each of the four positions the outlier is chosen in at least \(50 \%\) of the cases if the outlier is located at that position (figure 5 left). If the outlier is not to be found at that position, the position without the outlier is chosen in at least \(2 \%\) of the cases (figure 5 right).

In a last step the distributions for the four variations of outlier positions were analyzed separately. Here, for all four variations a significant difference from chance level was obtained (see figure 5 bottom; position: top, opposite to the direction of the turn: \(\chi^{2}(3)=10.175, p=.017\); position: top, in the direction of the turn: \(\chi^{2}(3)=12.100, p<.001\); position: bottom, opposite to the direction of the turn: \(\chi^{2}(3)=13.575\), \(p<.001\); position: bottom, in the direction of the turn: \(\left.\chi^{2}(3)=56.075, p<.001\right)\). In summary, for the single positions it could be emphasized that for each position the outliers were chosen in a minimum of \(50 \%\) of the cases and furthermore the ideal position, before the intersection in the direction of the turn, is minimally preferred in \(1 / 3\) of the
cases. If the outliers were placed on this ideal position it was almost always chosen.

Figure 5: Results for the different analyses. On the left and the right side (top section) each position could reach a value of \(100 \%\). The four positions in the middle add up to \(100 \%\).

\section*{Discussion}

The results could be interpreted from two different perspectives. On the one hand they revealed a clear preference of the perceptually salient object. The single outliers are preferred in \(66 \%\) of the cases, which is much higher than chance (25\%). This represents the importance of the perceptual salience for landmarks. On the other hand, the preference over all positions and intersections (merged for all single positions) are not distributed equally (see figure 5, middle). There is a preference for the position before the intersection and in the direction of the turn. Thus, the perceptual salience as well as the structural salience influence the preference of the positions. How they interact will be analyzed in the following section.

\section*{General Discussion}

Our previous findings revealed a position preference which we presented as the structural salience. The position before the intersection and in the direction of the turn was preferred. The pilot study revealed an object preference depending on the perceptual salience. There, the outlier colors were preferred in \(92.5 \%\) which is more or less equally distributed over the four positions. Here the objects differ from each other and the positions are unimportant. In the main experiment the combination of the perceptual (object preference) and the structural salience (position preference) influenced the participants' selections. In figure 6 these results are contrasted.

It is very interesting that the results do not reveal the same distribution as in the pilot study (figure 6, left), because it is -from a perceptual point of view- inconsequential not to
prefer the outliers. The preference for the outliers decreased from \(92.5 \%\) in the pilot study to \(66 \%\) in the main experiment. Therefore it seems that navigational context, in particular the turn based position of a landmark, also influenced the participants' preferences. In other words, not only the differentiation between objects plays an important role in landmark selection but also the position of the object.

Figure 6: Object preferences of the pilot study with colors (left); data of the main experiment (center); data of the previous experiments (Röser, Hamburger et al., 2012; Röser, Krumnack et al., 2012) for position preference (right).

In this work we used one fixed factor of perceptual salience, outliers consisting of complementary colors (the contrast to the surrounding could not be higher) to observe its interaction with structural aspects of wayfinding. In further experiments we will address the possibility to vary the perceptual salience and take a look at the effects on the resulting distributions. Two possibilities remain: on the one hand the perceptual salience of a landmark has a simple yes or no (existing or non-existing) character. Then the results should be similar. Or, on the other hand the perceptual salience of a landmark is gradual. Then the results should change continuously. Whatever the case may be, it seems clear that the influence of the perceptual salience could hardly be increased by using other colors, because the contrast used here with the complementary colors, is the strongest color contrast possible. Additionally, the pilot study showed that the contrasting color is preferred in almost all cases. We may therefore conclude that the perceptual salience of the outlier object was as high as possible and any variation probably leads to a lower impact (at least its influence may not be higher). But even if an object is extremely "eye-catching" in a non-navigational setting, once we enter a navigational task it seems that the structural salience provides a strong and almost permanent influence on the choice of landmarks at an intersection. The position of an object at an intersection might therefore be as important for it being chosen as landmark as the contrast to its surrounding.

The comparison of the results of the two experiments clearly shows that the question which object is the most appropriate landmark cannot be reduced to the question which object is the most noticeable. The fact that an object has a high contrast to its surrounding does not guarantee its
choice as a landmark. This supports Sorrows and Hirtle's (1999) concept of "prominence of spatial location" (p. 45) as a factor of visual salience and Caduff and Timpf's (2008) scene context of visual salience and/or contextual salience.

\section*{Obstacles in wayfinding research}

Because of the abstract and artificial setting of our experiments, transfers to other wayfinding research is difficult. Nothegger, Winter, and Raubal (2004) for example used real environments for their wayfinding experiments. But, the experimental control in such experiments is difficult or even impossible (e.g., which information did participants pay attention to?). Particularly the structural aspects of intersections in real environments are determined by a lot of factors (visibility; view direction; occlusion, etc). This is why we chose to limit ourselves to such an abstract setting. Our study serves as a basic research approach, examining the underlying aspects and will serve as a basis for further and more realistic (but controlled) experiments.

\begin{abstract}
Influential work on human thinking suggests that our judgment is often biased because we minimize cognitive effort and intuitively substitute hard questions by easier ones. Recent work with adults who solved the bat-and-ball problem, one of the most publicized examples of the substitution bias, suggests that people realize they are doing this and notice their mistake. In the present paper we look at the development of this substitution bias sensitivity. A group of young adolescents solved standard and isomorphic control versions of the bat-and-ball problem in which reasoners experience no intuitive pull to substitute. Adults have been shown to be less confident in their substituted, erroneous bat-and-ball answer than in their answer on the control version that does not give rise to the substitution. However, the present study established that this critical confidence drop was less pronounced for young adolescents. This implies that in contrast with adults, young adolescents do not yet fully acknowledge the questionable nature of their biased answer and remain more oblivious to the substitution. That is, young adolescent reasoners seem to behave more like happy fools who blindly answer erroneous questions without realizing it.
\end{abstract}

Keywords: Decision-making; Bias; Development

\section*{Introduction}

Human reasoners have been characterized as cognitive misers who show a strong tendency to rely on fast, intuitive processing rather than on more demanding, deliberate thinking (Evans, 2008; Kahneman, 2011). Although the fast and effortless nature of intuitive processing can sometimes be useful, it can also bias our reasoning. It has been argued that the key to this bias is a process of so-called attribute substitution - when people are confronted with a difficult question they often intuitively answer an easier one instead (e.g., Kahneman, 2011; Kahneman \& Frederick, 2002). Consider the following example:

A bat and a ball together cost \(\$ 1.10\). The bat costs \(\$ 1\) more than the ball. How much does the ball cost?

When you try to answer this problem, the intuitive answer that immediately springs to mind is " 10 cents".

Indeed, about \(80 \%\) of university students who are asked to solve the "bat-and-ball" problem give the " 10 cents" answer (e.g., Bourgeois-Gironde \& Vanderhenst, 2009). But it is wrong. Obviously, if the ball were to cost 10 cents, the bat would cost \(\$ 1.10\) (i.e., \(\$ 1\) more) and then the total cost would be \(\$ 1.20\), rather than the required \(\$ 1.10\). The correct response is " 5 cents", of course (i.e., the bat costs \(\$ 1.05\) ). The explanation for the widespread " 10 cents" bias in terms of attribute substitution is that people substitute the critical relational "more than" statement by a simpler absolute statement. That is, "the bat costs \(\$ 1\) more than the ball" is read as "the bat costs \(\$ 1\) ". Hence, rather than working out the sum, people naturally parse \(\$ 1.10\), into \(\$ 1\) and 10 cents which is easier to do. In other words, because of the substitution people give the correct answer to the wrong question.

The bat-and-ball problem is considered a paradigmatic example of people's cognitive miserliness (e.g., BourgeoisGironde \& Vanderhenst, 2009; Kahneman, 2011; Kahneman \& Frederick, 2002; Toplak, West, \& Stanovich, 2011). After all, the problem is really not that hard. Clearly, if people would reflect upon it for even a moment they would surely realize their error and notice that a 10 cents ball and a bat that costs a dollar more cannot total to \(\$ 1.10\). Hence, the problem with attribute substitution seems to be that people do typically not notice that they are substituting and do not realize their error (Kahneman \& Frederick, 2005; Thompson, 2009; Toplak et al., 2011). This can sketch a somewhat bleak picture of human rationality: Not only do we often fail to reason correctly, much like happy fools, we do not even seem to realize that we are making a mistake.

However, the fact that decision-makers do not deliberately reflect upon their response does not necessarily imply that they are not detecting the substitution process. That is, although people might not engage in deliberate processing and might not know what the correct answer is, it is still possible that they have some minimal substitution sensitivity and at least notice that their substituted " 10 cents" response is not completely warranted (e.g., Alter, Oppenheimer, Epley, \& Eyre, 2007; De Neys, 2012; De

Neys \& Bonefon, 2013; Oppenheimer, 2008; Thompson \& Morsanyi, 2012).

De Neys, Rossi, and Houdé (2013) recently tested this hypothesis. They designed a control version of the bat-andball problem that does not give rise to attribute substitution. Consider the following example:

\section*{A magazine and a banana together cost \(\$ 2.90\). The magazine costs \(\$ 2\). How much does the banana cost?}

People will tend to parse the \(\$ 2.90\) into \(\$ 2\) and 90 cents just as naturally as they parse \(\$ 1.10\) in the standard version. However, the control version no longer contains the relative statement (" \(\$ 2\) more than the banana") that triggers the substitution. That is, in the control version De Neys et al. explicitly presented the easier statement that participants were supposed to be unconsciously substituting. After solving each version participants were asked to indicate their response confidence. De Neys et al., reasoned that if participants are completely unaware that they are substituting when solving the standard version, the standard and control version should be isomorphic and response confidence should not differ. However, if people are indeed not completely oblivious to the substitution and have some minimal awareness of the questionable nature of their answer, response confidence should be lower after solving the standard version.

De Neys et al. (2013) observed that biased "10 cents" reasoners showed a decreased confidence in the correctness of their answer on the standard bat-and-ball problem. The authors interpreted this as showing that although reasoners often fail to deliberately reflect on their answer, they nevertheless intuitively sense that their response is questionable and are not oblivious to the substitution (see De Neys, 2012, for related suggestions). In the present study we use a developmental approach to validate this claim. Note that a key processing requisite for detecting an unwarranted substitution is that one monitors one's reasoning for conflict between an intuitively cued substituted question and the original phrasing (De Neys \& Glumicic, 2008; Kahneman, 2011). Now, developmental studies in the cognitive control field have established that such basic error or conflict monitoring abilities increase spectacularly throughout adolescence (e.g., Davies et al., 2004; Fitzgerald et al., 2010; Santesso \& Segalowitz, 2008). This has been linked to the late maturation of the Anterior Cingulate Cortex, the brain structure that is supposed to be mediating the monitoring process (e.g., Botvinick, Cohen, \& Carter, 2004; De Neys, Vartanian, \& Goel, 2008; Santesso \& Segalowitz, 2008). In general, this suggests that younger reasoners should be less efficient at detecting the biased nature of their substituted judgments than adults. In other words, if adults' decreased confidence in the De Neys et al. (2013) study indeed results from a successful substitution monitoring or sensitivity, one can also predict that the confidence effects should be less pronounced for younger, adolescent reasoners. More specifically, when younger reasoners give a biased response on the standard version of
the bat-and-ball problem, they should show a higher confidence in the correctness of their substituted answer than adult reasoners. Of course, on the control version that does not give rise to attribute substitution, any differential age-related substitution sensitivity, should not affect the confidence ratings.

To test this hypothesis we presented a group of young adolescents with the standard and control version of the bat-and-ball problem and recorded their response confidence. The performance of this group of adolescents was contrasted with that of the adults in the original De Neys et al. (2013) study. At a theoretical level, this will help us to validate De Neys et al.'s substitution claims. Clearly, from a developmental point of view, it is also important to start documenting possible age-related differences in substitution detection skills in its own right.

\section*{Experiment}

\section*{Method}

Participants. A total of 115 adolescents (average age \(=\) 14.89 years, \(\mathrm{SE}=.03\) ) participated in the study. All participants were Grade 9 students in a local middle school in the Paris region. Performance of these adolescents was contrasted with the performance of the 248 adult undergraduates (average age \(=22\) years, \(\mathrm{SE}=.18\) ) in the study of De Neys et al. (2013).

Material and Procedure. Material and procedure were based on the study of De Neys et al. (2013). All participants were presented with a standard and control version of the bat-and-ball problem. The problems were translated in French and adjusted to the European test context (see Appendix). To minimize surface similarity, we also modified the superficial item content of the two problems (i.e., one problem stated that a pencil and eraser together cost \(\$ 1.10\), the other that a magazine and banana together cost \(\$ 2.90\) ). Both problems were printed on separate pages of a booklet. To make sure that the differential item content did not affect the findings, the item content and control status of the problem were completely crossed. For half of the sample we used the pencil/eraser \(/ \$ 1.10\) content in the standard version and magazine/banana/ \(\$ 2.90\) content in the control version. For the other half of the sample the content of the two presented problems was switched. Presentation order of the control and standard version was also counterbalanced: Approximately half of the participants solved the control version first, whereas the other half started with the standard version \({ }^{1}\). An overview of the material is presented in the Appendix.

Immediately after participants wrote down their answer they were asked to indicate how confident they were that

\footnotetext{
\({ }^{1}\) Note that when the problem content and presentation order factors were entered as additional control factors in our main analyses the reported effects were not affected.
}
their response was correct by writing down a number between 0 (totally not sure) and \(100 \%\) (totally sure). Note that we only intend to use this measure to contrast people's relative confidence difference in the standard and control versions. Obviously, the confidence ratings will be but a proxy of people's phenomenal confidence state. The response scale is not immune to measurement biases such as end preferences or social desirability effects (e.g., Berk, 2006). For example, since it might be hard to openly admit that one has given a response that one is not confident about, mere social desirability can drive people's estimates upwards. This implies that one needs to be cautious when interpreting absolute confidence levels. However, such interpretative complications can be sidestepped when contrasting the relative rating difference in two conditions. Any general response scale bias should affect the ratings in both conditions. Consequently, our analyses focus on the relative confidence contrast and we refrain from making claims based on the absolute confidence levels.

\section*{Results and Discussion}

Accuracy. Adolescents' and adults' scores on the standard and control bat-and-ball problem version were entered in a 2 (problem version, within-subjects) x 2 (age group, between subjects) mixed model ANOVA. As expected, there was a main effect of the Problem Version factor, F(1, 361) = \(1027.74, \mathrm{p}<.0001, \eta^{2} \mathrm{p}=.74\). In line with previous studies, overall only \(20 \%\) ( \(\mathrm{SE}=2.2 \%\) ) of participants managed to solve the standard bat-and-ball problem correctly. However, the control version that did not give rise to substitution was solved correctly by \(99 \%\) ( \(\mathrm{SE}=.5 \%\) ) of the participants. Accuracy did not differ in the two age groups; the Age Group and Age Group x Problem Version interaction did not reach significance, both Fs \(<1\).

Note that incorrect responses on the standard version were almost exclusively (i.e., 361 out of 363 responses) of the " 10 cents" type suggesting that biased participants were not simply making a random guess but indeed engaged in the postulated substitution process \({ }^{2}\).

Confidence ratings. Our crucial question concerned participants' response confidence. A first analysis focused on the response confidence of reasoners who substituted and gave the erroneous " 10 cents" response on the standard version. These participants' confidence ratings were entered in a 2 (problem version, within-subjects) x 2 (age group, between subjects) mixed model ANOVA. Results showed that there was a main effect of the Problem Version factor. As De Neys et al. (2013) already established, overall, people's confidence in their erroneous " 10 cents" response was lower than the confidence in their control version answer that did not give rise to the substitution, \(F(1,285)=\)

\footnotetext{
\({ }^{2}\) The few incorrectly solved control trials and the "non-10 cents" incorrectly solved standard trials were discarded for the subsequent confidence analyses.
}
57.9, \(\mathrm{p}<.0001, \eta^{2} \mathrm{p}=.17\). However, the critical finding was that this effect was indeed less clear for adolescent reasoners. As Figure 1 (top panel) shows, the Age Group and Problem Version factor tended to interact, F(1, 285) = 3.78, \(\mathrm{p}<.055, \eta^{2} \mathrm{p}=.01\), and there was also a main effect of the Age Group factor, \(\mathrm{F}(1,285)=5.11, \mathrm{p}<.025, \eta^{2} \mathrm{p}=.02\).

Follow-up analyses established that in contrast with biased adolescents, biased adults showed specifically more doubt in the correctness of their response when solving the standard bat-and-ball version, \(F(1,285)=5.02, \mathrm{p}<.05, \eta^{2} \mathrm{p}\) \(=.02\). On the control problem, that did not give rise to attribute substitution, both age groups' confidence did not differ, \(F(1,285)=1.16, p=.28\). This establishes that the critical lower confidence ratings on the standard problem in the adult group are not confounded by a general age-related confidence decrease but result from a differential substitution sensitivity. When adults and adolescents do not substitute, their confidence does also not differ. Clearly, if adults would simply show overall more doubt in their judgments, their confidence ratings on the control problem should have been lower too.

"10 cents" biased reasoners

Figure 1. Response confidence on standard and control versions of the bat-and-ball problem for participants who answered the standard problem incorrectly (" 10 cents" biased reasoners, top panel) and correctly (" 5 cents" correct reasoners, bottom panel) in the two age groups. Error bars are standard errors.

This conclusion is further supported when we focus on the confidence ratings of those participants who did not substitute on the standard problem and solved it correctly. Confidence ratings for these participants were also subjected
to a 2 (problem version, within-subjects) x 2 (age group, between subjects) mixed model ANOVA. Results are shown in Figure 1 (bottom panel). As Figure 1 shows, overall the problem version effect on the confidence ratings (i.e., \(93 \%\) standard vs. \(97 \%\) control) was far less clear for correct than for biased reasoners, \(\mathrm{F}(1,68)=5.02, \mathrm{p}<.05, \eta^{2} \mathrm{p}=.02\). In and by itself this is not surprising. Indeed, it makes sense that people who actively reflected upon their judgment and resisted the substitution also knew that their response was likely to be correct. The critical point here is that in this analysis neither the Problem Version \(x\) Age Group interaction, nor the main effect of Age Group were significant, both Fs < 1. Hence, here too, adolescents and adults who did not substitute and reasoned correctly did not show a differential response confidence. This further strengthens the claim that the age-related decreased response confidence on the standard problem that we observed for biased reasoners results from an increased substitution bias sensitivity.

\section*{General Discussion}

The present study indicates that human reasoners become more sensitive to substitution bias throughout their development. The previously observed lowered response confidence after solving the standard bat-and-ball problem, was less clear for biased adolescents. That is, in contrast with adults, 15 -year old adolescents seem to have a harder time detecting the erroneous nature of their substituted judgment. This pattern fits with basic cognitive control studies that indicate that adolescents' basic error or conflict monitoring skills are not fully developed (e.g., Davies et al., 2004; Fitzgerald et al., 2010; Santesso \& Segalowitz, 2008). With respect to attribute substitution during reasoning this implies that young adolescents do not yet fully acknowledge the questionable nature of their biased answer and remain more oblivious to the substitution. In that sense, adolescents do seem to behave like happy fools who blindly answer erroneous questions without realizing it.

We mentioned that our study can have important implications for the developmental field. Some ten years ago, Markovits and Barrouillet (2004) noted in a special developmental issue of the journal Thinking and Reasoning that although reasoning and decision-making were once one of the prime research areas for developmental scientists, interest had faded in more recent years. Markovits and Barrouillet suggested that one of the reasons for this decline was the rise of the "Heuristics and Biases" research program and its demonstration of the widespread bias in human reasoning. This massive bias seemed to point to a developmental standstill in human reasoning. That is, if even the vast majority of educated university students fail to solve basic reasoning problems, one might easily get the impression that there doesn't seem to be a lot of development going on. At first sight, our developmental study might have seem to strengthen this conclusion. Indeed, when looking at the accuracy rates we did not find
any age-related improvement. Adults seemed to perform as badly as adolescents. However, looking closely at the substitution detection process and confidence data suggests that the lack of development is more apparent than real. Although both adults and adolescents are indeed biased most of the time, our findings indicate that an important difference between the age groups is that adults at least detect that their responses are biased. Consistent with recent insights in the developmental field (e.g., Brainerd, Reyna, \& Ceci, 2008; Klaczynski, Byrnes, \& Jacobs, 2001; Houdé, 2007; Reyna \& Farley, 2006; Reyna et al., 2003) this differential substitution bias awareness argues against the idea of a developmental standstill in human reasoning.

It is important to clarify some potential misconceptions and critiques about our work. For example, some critics might spontaneously argue that since our control bat-andball version is easier than the standard version our findings with adults are trivial since they simply show that people are more confident when answering an easy question than when answering a hard question. It is important to stress that this critique is begging the question. The crucial question is of course whether or not people realize that the classic version is hard. That is, the control version presents the easier statement that participants are supposed to be unconsciously substituting. What we want to know is whether or not people note this substitution. If people do not notice it, then the two problems should be isomorphic and they should be considered equally hard. In other words, arguing that adults notice that the classic problem is harder than the control problem underscores the point that they are not oblivious to the substitution.

A related spontaneous critique is that our confidence findings might result from mere guessing rather than from substitution sensitivity. In general, if people do not know an answer to a problem and guess, they presumable realize this and will also give a low confidence rating. Hence, a critic might argue that the lower confidence in adult groups does not necessarily point to substitution sensitivity but merely to a rather trivial "guessing awareness". However, this critique is readily discarded. In the present study more than \(99 \%\) of the erroneous bat-and-ball responses were of the " 10 cents" type. This is the response that people should pick if they engage in the postulated substitution process. Clearly, if people were biased and less confident because they were merely guessing, we should have observed much more random erroneous answers.

In the present study we focused on the bat-and-ball problem because it is one of the most vetted and paradigmatic examples of people's substitution bias (e.g., Bourgeois-Gironde \& Vanderhenst, 2009; Kahneman, 2011; Kahneman \& Frederick, 2002; Toplak, West, \& Stanovich, 2011). However, attribute substitution has also been proposed as an explanation for people's judgment errors in other classic reasoning tasks such as the base-rate neglect or conjunction fallacy task (Kahneman \& Frederick, 2002). Although it has been argued that these task might be less suited to test substitution claims (e.g., Bourgeois-Gironde \&

Vanderhenst, 2009; see also Pennycook, Fugelsang, Koehler, 2012; Klauer \& Singmann, 2012), one might nevertheless wonder whether the present findings can be generalized across these tasks. Some emerging evidence suggests they might. For example, a recent study showed that when adult reasoners give a biased response to standard conjunction or base-rate neglect problems, they also indicate to be less confident about their response compared to control problems. Consistent with the present findings, these effects were not always observed in younger samples (e.g., De Neys, Cromheeke, \& Osman, 2011; see also De Neys \& Feremans, 2013). This gives us some initial indication of the generality of the present findings.

With the present paper we hope to have presented a critical building block to stimulate further research on the development of substitution sensitivity. Our intial data suggest that although most adolescents and adults fall trap to substitution bias, adult reasoners at least detect their bias and realize that their response is questionable. We believe that the potentially severe consequences of adolescents' bias detection difficulties should become a primary research focus for developmental and educational scientists.

\begin{abstract}
This study evaluates how people represent "even if" conditionals when they have to integrate them with previous "if then" conditionals and also make an inference. The terms in the premises were ordered to facilitate their integration (Figure 1: If A then B; Even if B C). In half the cases, the "even if" conditional was expressed with a negation instead of an affirmation (If A then B; Even if not B C). Participants had to infer what followed, given A or C. Previous results showed that in comprehension tasks, where information had to be integrated, counterfactual conditionals seemed to be represented with just one situation (B and C). By contrast, when people had to make inferences with these conditionals, they seemed to represent two situations. In any case, counterfactual seem to be represented with two situations (B and \(C\), and not B and C). In our task, people had to do both: to infer and to integrate. Results showed that the use of negations and the direction in the inference had an effect on the endorsed inferences, but the two factors did not interact. The need to integrate premises did not block access to the two "even if" situations in an inference task.
\end{abstract}

Keywords: semifactual conditionals; directionality; mental models.

\section*{Introduction}

Some previous results have shown that when people make inferences with a semifactual conditional, they represent two mental models. For example, the conditional "Even if it had been raining she would have gone to the party": people seem to represent the factual case "It was not raining and she went to the party" and the hypothetical case "It was raining and she went to the party" (see Moreno-Ríos, García-Madruga \& Byrne, 2008). Semifactual conditionals are similar to counterfactual conditionals, but with different initial representations: given "If A had been the case then B would have been the case" people think about two possibilities from the outset, noting one as the 'facts' (not-A and not-B) and the other as 'imagined' (A and B) possibilities (Johnson-Laird \& Byrne, 2002). Forinstance, if we take the above example: "If it had been sunny then she would have gone to the party" we see that this sentence suggests, on the one hand, the representation that really "It was not sunny and she did not go to the party" and, on the other hand, the possibility that "It was sunny and she went to the party". Results with reasoning tasks are consistent with the two initial representations proposed. However, priming studies (Santamaría, Espino \& Byrne,
2005) evidenced that when people read an "even if A B" semifactual, they are primed to read a subsequent 'not-A and B ' conjunction more quickly than when they have read a factual "if A then B" conditional, whereas they read 'A and \(B^{\prime}\) just as quickly after reading the semifactual as after the factual conditional. Unexpectedly, these authors found that "if" counterfactuals did not prime the 'not-A and not-B' possibility more than "even if" semifactuals. That happened only with counterfactual conditionals and not with semifactual conditionals (see also, Gómez-Veiga, GarcíaMadruga \& Moreno-Ríos, 2010). Gómez-Veiga et al. (2010) proposed that it is possible that the comprehension tasks lead to a less exhaustive representation than inference tasks with only one part of the information. One possible cause is that in the comprehension task, the conditional information must be integrated with the information given previously. That is, the comprehension task could induce a simpler strategy to avoid the working memory load using just one of the two mental models.

In the present study, we use an inference task with a semifactual "even if" conditional preceded by a related "if then" conditional. We study how people make inferences integrating the information given by the premises. We chose the simplest way of ordering the terms in the premises: Figure 1 (If A then B; Even if B C). Figure 1 has been shown to be the easiest configuration of terms in premises to facilitate integration with conditional premises (e.g., Bara, Bucciarelli \& Johnson-Laird, 1995). Also, we include sentences with a negation in the first term of the "even if" conditional. If people represent only the terms, the integration is not possible in this condition. For example, consider "If the sky was overcast it was raining" (If A then B), "Even if it had not been raining she would have gone to the party" (Even if not B C). People can consider the simple situation of "not raining" mentioned in the "even if" conditional, or they can also think of the actual situation: "It was raining and she went to the party". Different responses are expected depending on whether people manage to consider all the representations derived from the "if then" and "even if" conditionals (see Table 1, Complete representation) or just a set of possible situations (some mental models), as assumed by the mental model theory (see Table 1, Initial representation).

Some studies on the integration of premises with different relational statements in deduction (e.g., Oberauer, Hörnig, Weidenfeld \& Wilhelm, 2005; Oberauer \& Wilhelm, 2000)
have shown that the directionality in the inference is a factor that depends on the inner directionality represented in the mental models, and this could influence the conclusion (see Oberauer et al., 2005). Oberauer and Wilhelm (2000), using picture verification tasks (sentence-picture), found that "if then" conditionals have an inherent forward directionality: people seem to process "if A then \(B\) " in a preferred order, from \(A\) to \(B\). Inferences based on \(A\) or on not \(A\) are faster and easier than those based on B or not B.

Table 1: Some possible sets of representations of the premises. Every line represents a mental model. The symbol \(\neg\) means "negation". The "*" symbol for "even if" representation is the hypothesised model (simplest representation of "even if").

\end{tabular}

Another basic result in deductive research is that reasoning with negative propositions is harder than with affirmative propositions (for example, see Evans, Newstead \& Byrne, 1993). Therefore, we would expect an increase in the number of errors and nothing follows responses for the backward inferences than the forward ones, and the same for inferences with negative premises. Therefore, inferences could be influenced in an additive way by directionality and by the negation, but they will be determined by the predicted representations of the premises and their integration.

\section*{Predictions}

We evaluate whether people create double representations to make inferences from semifactual conditionals when they have to integrate this information with a previous "if then" conditional. Different predictions are obtained according to
whether people are able to look for all the alternatives, just consider one alternative from each conditional or represent two mental models from "even if" conditionals. Table 2 shows the different predictions for each condition.

Table 2: Conclusions predicted for inferences after the integration of premises. See text for description. The inference can be endorsed when the end terms ( A and C ) can be connected and lead to one unique conclusion. In other cases, the correct conclusion is "nothing follows". Parentheses are used when middle terms do not match.
\begin{tabular}{|c|c|c|c|}
\hline Forward/ backward inferences & Double represt. & Simple represt. & Complete represt. \\
\hline Affirmative Given A, then C ? & C & C & \[
\begin{aligned}
& \mathrm{C} \\
& \text { A B, B C }
\end{aligned}
\] \\
\hline Affirmative Given C, then A? & A B, B C & A & \[
\begin{aligned}
& \text { Nothing } \\
& \text { follows } \\
& \text { A B, B C } \\
& \neg \text { A B, B C } \\
& \neg \text { A } \neg \mathrm{B}, \neg \text { B C }
\end{aligned}
\] \\
\hline Negative Given A, then C ? & \begin{tabular}{l}
C \\
A B, B C
\end{tabular} & Nothing follows
\[
\mathrm{AB},(\neg \mathrm{BC})
\] & Nothing follows A B, B C \(\mathrm{AB}, \mathrm{B} \neg \mathrm{C}\) \\
\hline Negative Given C, then A ? & A B, B C & Nothing follows
\[
\mathrm{AB},(\neg \mathrm{BC})
\] & Nothing follows
\[
\begin{gathered}
\neg \mathrm{A} \\
\neg \mathrm{~B}, \\
\neg \mathrm{~B} \\
\neg \mathrm{~B} \\
\text { B C } \\
\text { A } \\
\text { B, B C } \\
\text { C }
\end{gathered}
\] \\
\hline
\end{tabular}

There are three columns for each of the three possibilities for representing "even if" (as shown in Table 1): two possibilities, one possibility and all the possibilities. The first two rows represent predictions for affirmatives and the second two for negative "even if". In every case, for forward inferences (given A, what follows? C, not C or nothing follows) and for backward inferences (given C, what follows? A, not A or nothing follows). For example, the first column shows the prediction if people construct a double representation for "even if" conditionals. In the third row we can find predictions for a negative "even if" in a backward inference. Therefore, the structure is: If A then B; Even if not \(\mathrm{B} C\); given A , what follows? People will conclude "C", because there is one and only one way to connect a representation from "if then" \((\mathrm{AB})\) and another
from "even if" (BC) (see Table 1). However, if people represent "even if" with just one mental model (see Table 2, second column third row), they cannot match the terms between the representations of the two premises ( AB , not BC ) and the prediction of the conclusion is "nothing follows". The same conclusion, but for a different reason, is predicted if people can access all the situations consistent with the conditionals (see Table 2, third column, third row). In this case, there are two possible ways to connect the representations, which lead to different conclusions ( AB , \(B C\) and \(A B, B\) not \(C\) ).
If we consider the polarity (affirmative and negative) and the directionality (forward and backward) we can make predictions about the endorsed inferences depending on the set of mental models represented. In general, following previous studies, we would expect the directionality (inherent to conditionals) and polarity (difficulty in processing negative propositions) to have an effect on the difficulty in making inferences. In addition, the nature of the representation should influence the frequency of endorsed inferences. If people represent the two mental models for "even if", no interaction is predicted between polarity and directionality. If people represent just one initial model from every conditional, one effect of polarity will be found in the "nothing follows" conclusion. Finally, if people were able to represent a complete set of possibilities, we would predict an interaction between directionality and polarity in the inferences endorsed (more in affirmative; actually only one in the forward direction condition) and in the "nothing follows" conclusion.

\section*{Method}

\section*{Participants}

Participants were 51 students from Granada University, enrolled in the second year of a psychology degree, who took part for course credits. All participants were native Spanish speakers without any previous training in logic.

\section*{Materials}

Thirty two syllogisms were constructed, half of them (those of interest in this experiment) with the following structure: Eight syllogisms with the form "If A then B; Even if there had been B there would have been C", and another eight that included a negation in the second premise "If A then B; Even if there had not been B there would have been C". Sixteen other fillers were included with a different structure "If C then B; Even if there had been/not been B there would have been A". The sentences were about professions. For example:
Premise 1. "If there was a biologist then there was a lawyer"
Premise 2. "Even if there had been a lawyer there would have been an engineer"
Premise 3. "There was a biologist, therefore..."

Conclusions. Response 1. "There was an engineer", Response 2. "There was not an engineer", Response 3. "Nothing follows".

\section*{Procedure}

All the sentences were presented on a computer screen. Each premise and the conclusion were shown on a separate screen and participants decided by pressing the space bar when to turn to the next statement. After the two conditionals had been presented, a third premise was shown: A in half the trials (and C in the backward condition trials). After that, a screen with three options was shown, with C , not C and nothing follows (A, not A , and nothing follows in the backward condition trials). Participants had to press keys 1, 2, or 3 to choose their respective responses.

\section*{Results}

An analysis of variance (ANOVA) for repeated measures was carried out by participants with the following factors: Directionality (forward and backward) and Semifactual polarity (affirmative and negative). The same analyses were carried out for endorsed inferences (given A, C is accepted and given C , A is accepted) and for nothing follows responses. Results are shown in Table 3.

Table 3: Percentage of endorsed inferences (given A, then C in the forward condition, and given C , then A in the backward condition) and nothing follows responses for affirmative "even if" and negative "even if" in the second premise.
\begin{tabular}{lll}
\hline \begin{tabular}{l} 
Direction \\

\end{tabular} & Forward & Backward \\
\hline
\end{tabular}

Semifactual Affirmative Negative Affirmative Negative
polarity

Endorsed inferences

Nothing
follows \(\quad 22(3.4) \quad 22(3.0) \quad 39(4.2) \quad 37(3.9)\) inferences
* The values in brackets show standard deviation.

The analysis of nothing follows shows only effect of directionality but no other effects \(\left(\mathrm{F}(1,50)=12.98 ; \eta_{\mathrm{p}}{ }^{2}=.19\right.\); \(\mathrm{p}<.001\) ). More inferences were endorsed for forward than for backward conditions ( \(\mathrm{F}(1,50)=10.6 ; \eta_{\mathrm{p}}^{2}=.17 ; \mathrm{p}<.01\) ) and for affirmative than negative conditions \(\left(\mathrm{F}(1,50)=5.4 ; \eta_{\mathrm{p}}{ }^{2}=.4\right.\); \(\mathrm{p}<.05\) ), but again, they did not interact \(\left(\mathrm{F}(1,50)=.01 ; \eta_{\mathrm{p}}{ }^{2}=0\right.\); \(\mathrm{p}<.9\) ). The lack of this interaction is consistent with the double representation of "even if" conditionals.

\section*{Discussion}

The task used in this study required not only inferring from a conditional but also integrating information before doing so. The frequency of correct responses is low. The working memory capacity, motivation and other factors could have influenced this overall frequency. In any case, we were able to contrast our prediction because the frequency of the inferences in the different conditions varied.

The present study shows that people seem to use two mental representations with "even if" conditionals when they have to integrate this information with other information given previously by a conditional. These results are obtained when the terms in the two conditionals are arranged so that they can be easily connected (Figure 1). A main result seems to stand out clearly. The conclusions in the negative forward and backward conditions (If A then B; Even if not B C) were not blocked. In fact, no differences in the "nothing follows" responses were obtained in this condition regarding the affirmative control condition (If A then B; Even if B C).

Also, we could see that there was an effect of the direction and of the negation in the acceptance of the inferences, but not an interaction between the two factors. That is, the representation alone cannot entirely explain the results of this study. These effects are consistent with previous studies: the forward directionality of "if then" conditionals (see Oberauer et al., 2005) and the effect of negations in reducing the endorsed inferences (Evans et al., 1993). When we introduce a negative proposition, it becomes more difficult to understand the sentences (higher working memory load) and the errors will increase. For example, people could conclude not A when actually they should conclude A. Actually, this kind of error was more frequent for negative sentences, but no differences were obtained for "nothing follows" conclusions.

Oberauer et al. (2005) maintain that the directionality of the conditionals must be represented in the conditional. In our case, only when the direction of the inference matches the direction in the mental model is the inference easier. The present results are consistent with this proposal.

Moreover, the present results do not imply that people always construct a double representation when they make inferences and integrate "if then" and "even if" conditionals. For example, results could be different when the order of the terms makes it more difficult to integrate the premises (for example using a different figure). Also, the time for reading the premises and the time for the conclusion could inform us about the principles that are operating in the integration of premises. For example, at this point we do not know whether "even if" could lead to the apodosis as the "relatum" or if it is the protasis as happens with "if then" clauses.

This is a preliminary study and we cannot prove that the present results can be generalised to conditionals with other content (such as advice, promises, obligations, etc.). The content and the context of conditionals have been shown to influence the mental representation accessed in deduction (see Johnson-Laird \& Byrne, 2002; Handley \& Feeney, 2004). Also, we used an evaluation of conclusions task, but not a generation of conclusions task. We do not expect that
if instead we had used, for example, a generation of conclusion task, it would have led to different initial representations. However, again, this question has not been tested at this point in the research.

The present results are part of a research project that studies how premises are integrated and how we represent semifactual expressions.

\title{
What, When and How do the Models of Conceptual Change Explain?
}

\begin{abstract}
There are certain theoretical issues in conceptual change research that are still puzzling researchers. First, there is no agreement on what kinds of changes in belief and concept systems constitute conceptual change. Second, there is no consensus on what the mechanisms of conceptual change are. Third, there is no common understanding how to explain, model and describe in an exact way these underlying mechanisms. In this paper, we offer a diagnostic analysis these issues by reviewing current theories of conceptual change in a framework of mechanistic explanations of cognitive phenomena, and present a possible sketch for explanations of conceptual change.
\end{abstract}

Keywords: Conceptual Change; Explanation; Cognitive Mechanisms

\section*{Introduction}

Concepts enable thought, reasoning and problem solving. Acquiring new concepts or reorganizing the conceptual framework one uses to think about a domain is a powerful kind of learning. This sort of learning is known as conceptual change.

Conceptual change is one of the most studied fields in science education, and there are hundreds, if not thousands studies, on this topic. However, there are still some foundational issues in conceptual change research on which no clear consensus has emerged, and that are still puzzling most of the researchers. Firstly, there is no agreement on what kinds of changes in belief and concept systems actually constitute conceptual change. Secondly, there is no consensus on what the mechanisms of conceptual change are. Also, when compared to the level of detail at which, say, basic visual processing is understood, often the descriptions of these "mechanisms of conceptual change" are quite shallow and offer no exact specification of the precise structure of mechanisms.

As Clement (2008) remarks, there are very few, if any, models of conceptual change, in which the mechanisms of conceptual change are specified in sufficient detail. This suggests that many of the current accounts might not in a
strict sense qualify as sufficient for explanation and manipulation of learning phenomena involving conceptual change.

Moreover, having numerous loose filler terms in an explanation does not only threaten to undermine its explanatory power, but filler terms may also be barriers to scientific progress when they veil failures of understanding (Craver, 2006, 2007). If, for example, the terms "reassign" or "assimilation" are used to stand for processes with largely unknown properties, then we really do not explain what happens. Instead, we have a possible sketch for an explanation. If this sketch is taken to be genuinely explanatory, then - in the worst case scenario - it is possible that we have only an illusion of explanation instead of having a genuine one (Rosenblitz \& Keil, 2002; also Craver, 2006).

In what follows, we analyse the explanations of conceptual change from a philosophical point of view. Our analysis is partially based on the so-called "mechanistic account of explanation" (Bechtel \& Richardson, 1993; Machamer et al., 2000; Craver, 2006,2007). This mechanistic approach has not previously been applied to explanations of conceptual change.

However, it should be emphasized that the focus of this paper is only on cognitive accounts of conceptual change. There are other accounts of conceptual change that examine conceptual change from socio-cultural, emotional or motivational perspectives. However, explanation of cognitive phenomena is a unique form of explanation, and it is an open question, whether it is possible to extend this form of explanation to cover explanation involving interpersonal dynamics etc. This topic is, however, beyond the scope of this paper.

\section*{Variable Accounts of Conceptual Change}

The study of conceptual change has focused, on the one hand, on the acquisition of commonsense concepts in childhood (e.g. Carey, Spelke) and on the other hand, the
acquisition of scientific concepts in science education, especially at the secondary and tertiary level (Chi, 1992; Chi et al, 1994; Vosniadou, 1992; DiSessa,1993).

In this paper we examine the latter form of research, in which conceptual change is seen as a specific kind of learning process, in which a student does not merely accumulate more knowledge, but her conceptions of phenomena in a certain domain undergo a restructuring process that affects ontological commitments, inferential relations, and standards of explanation (Posner et al, 1982; Carey, 1985; Chi, 1992; Vosniadou, 1994; diSessa, 1993). In a nutshell, this sort of conceptual change can be characterized as transformation process of the initial knowledge-state (a commonsense picture of the world) to one of various outcome knowledge states. The outcome state can be an accurate scientific conception (when the learning process has been successful) or, when the learning process has not been successful, one of a number misconceptions (when it has not).

One difficulty with conceptual change research is that there are a huge number of different accounts of the details conceptual change, and they all characterize conceptual change different ways. In the literature \({ }^{1}\), there are different views on the learner's initial and outcome conceptions, on the trajectories along which change occurs, on the mechanisms that are underlying the conceptual change, on the obstacles of learning and also on the factors that support the change.However, on the basis of a careful reading, the literature seems to suggest that there are roughly three "major" kinds of conceptual change. These different kinds, or forms, of conceptual change can be titled as revision, reinterpretation and invention:

Revision. In some cases conceptual change seem to require a revision of an existing conceptual system. For example, Chi and her colleagues suggest that conceptual change takes the form of category shift (Chi, 1992, 2008; Chi et al, 1994). Another example of this form of conceptual change is described by Thagard's "tree jumping", in which conceptual change happens when hierarchies of concepts are reorganized by shifting a concept from one branch of a hierarchical tree of concepts to another. Also in DiSessa's Knowledge in Pieces- account conceptual change is understood as a form of revisionary process, because conceptual change is seen as a process that integrates initially piecemeal, incoherent (sub)conceptual system by complex process of organizing and reorganizing the elements of the system (diSessa, 1993, 2002,2004).

Reinterpretation. In some cases conceptual requires that a learner gives a new interpretation for a domain. For example, according to Ohlsson (2009) conceptual change occurs when a learner uses analogical transfer to map conceptual system from one domain to new domain to which it has not previously been applied, and to which some other conceptual system had been predominant. Another examples of conceptual change as a form of reinterpretation

\footnotetext{
\({ }^{1}\) For example, for an analysis of the various types or accounts of conceptual change, see Chinn and Samarapungavan (2009).
}
are described by Carey's differentiations (when initially undifferentiated concept is differentiated) and coalescence (when initially distinct concepts are subsumed by a same concept).

Invention. In some cases conceptual change requires construction or production of a novel (for the learner) conceptual system. For example, Carey \((1985,2011)\) describes a form of conceptual change, in which a learner constructs a new set of concepts from already existing concepts by "bootstrapping" in way that makes novel concepts incommensurable with the earlier concepts, because the content of new concepts cannot be captured in terms of any previously possessed concepts. The first stage of bootstrapping, or "Quinian bootstrapping", occurs when a learner encounters a set of explicit public symbols, such as sentences of a scientific theory. These public symbols, "the placeholders", are not initially mapped onto any already existing concepts that a learner holds. Rather, for a learner they are either partially or completely uninterpreted. During the process of learning, these placeholders are then taken up by various "modeling processes", which includes abstract forms of theoretical inference such as analogical reasoning, abduction and induction etc. The idea is that a learner constructs the interpretation or the content for a placeholder by using these different mechanisms. At the end of the process, the placeholders will have conceptual content in virtue of acquiring a stable conceptual role in a new theoretical structure.

Conceptual change as an umbrella term. This variety of different kinds of conceptual change might reasonably be taken to indicate that "conceptual change" is a sort of umbrella term, which covers several types of phenomena instead of referring to a singular type of learning. This would entail that there cannot be a singular "grand theory" of conceptual change, which could explain all possible instances and trajectories of conceptual change.

Instead, explaining conceptual change seems to require that different learning trajectories are explained by referring to different mix of underlying mechanisms and processes (see also Chinn \& Samarapungavan, 2009; Ohlsson, 2009b). These learning trajectories can be considered conceptual change because the learning is seen in some way "radical". However, this does not necessarily indicate that these different phenomena are instances of a common explanandum i.e. a common learning phenomenon, which the various mechanisms would account for. Instead, if one used this as a reason for adopting the umbrella term, it would be merely a pragmatic reason.

\section*{Towards the Explanation of Conceptual Change}

The explanans and explanandum. In the case of conceptual change research, it is not always apparent, what the explanandum (the thing to be explained) and what the explanans (the things that explain) are. For example, Mayer
(2002, p. 671) defines conceptual change as "the mechanism underlying meaningful learning". On this view, meaningful learning would be the explanandum, and conceptual change would be the mechanism that explains the meaningful learning. However, others seem to think of conceptual change as the thing that should be explained, and the explanation should be given in terms of underlying mechanisms. For example, Chinn and Samarapungavan (2009) emphasize this view, when they argue that there are many routes (with many underlying cognitive mechanisms) to conceptual change.

We emphasize the latter view, according to which the explanandum is conceptual change (a learning episode that can be observed behaviorally, e.g. as correct responding to diagnostic questions), and the explanans is given in terms of underlying cognitive mechanisms for variety of reasons.

\section*{Dissection of Explanation.}

From a philosophical point of view, explanation of cognitive phenomenon typically involves at least (1) the characterization of the specific cognitive task performed by a system, (2) the descriptions of how certain cognitive mechanisms execute, produce or sustain the phenomenon to be explained. In some cases, explanation in cognitive science also requires the (3) description of how cognitive mechanisms are implemented in cognitive systems or why it makes rational (or evolutionary) sense that the phenomenon should be sustained in the first place.

Explanation step 1: The characterization of the specific cognitive task. In cognitive explanations of behavioral phenomena, the description for the task is given by characterizing the information processing task, and it answers to questions such as: "What is the cognitive goal of this process" or "What is the cognitive task of this competence?"

This aspect of explanation is important for two reasons; it not only characterizes the cognitive task in a specific way, but it creates also some constraints for the possible underlying mechanisms. This aspect of explanation characterizes, why certain - but not all - learning mechanism are appropriate for fulfilling the cognitive task.

The task of conceptual change. So, what is the task of conceptual change? Even if the issue of the task is not often expressed explicitly in current literature, many seem to echo the same normative intuition that the task of conceptual change is to reorganize the conceptual system in a way that makes - in a case of successful learning - somehow "better". Depending on the larger picture of conceptual change, different authors have described this "better" different ways.

One early formulation can be found in the seminal paper by Posner et al. (1982), where they propose that conceptual change makes the system "more fruitful, intelligible and plausible" etc. (Posner et al, 1982). In their paper, intelligible means roughly that the new conception must be clear enough to make sense to the learner. Plausible means the new conception must be seen as believable, and even
true. Fruitful means the new conception must appear potentially productive to the learner for solving problems and seek for new intellectual directions. The approach Posner et al. propose is based on the Kuhnian idea of paradigm shifts and their emphasis of the conceptual ecology of a student. By conceptual ecology Posner and collegues meant the framework of a learner's conceptions and "cognitive mechanisms", such as analogies, metaphors, explanatory anomalies and so on (Posner et al, 1982; Strike \& Posner, 1992). So, according to this view, conceptual change happens if the changes make the ecology "better" i.e. more productive and fruitful, and it increases the ability to solve problems.

Sometimes this "better" is interpreted in terms of utility. For example, Stellan Ohlsson recently proposed that some forms of conceptual change make the conceptual system more useful (Ohlsson, 2009). In Ohlsson's account cognitive utility measures the usefulness of a knowledge system for a learner. The basic idea is that in a situation, where there are competing knowledge systems, the system that requires less cognitive load, and leads to faster, more efficient and more cognitively satisfactory end states, will become associated with higher strength and will be easier to activate (Ohlsson, 2009). Over time, the system will become the person's "standard way of looking at the target domain" (Ohlsson, 2009).

In some cases, the task of conceptual change is given also in terms of coherence. For instance diSessa (1993, 2002, 2004) describes novice knowledge as a weakly organized system that is highly context dependent and internally inconsistent, thereby lacking internal coherence. In diSessa's account commonsense physical knowledge is organized into p-prims, empirical typologies or low-level abstractions of everyday experience. For example, according to this knowledge-in-pieces- account novices' knowledge systems are fragmented and consist of loosely connected pieces, which often lacks not only coherence but are also employed with little co-ordination (diSessa 1993, 2002, 2004). In diSessa's and colleagues account, the task of conceptual change is to integrate the piecemeal structure of a conceptual system in a way that increases the internal coherence of the system (diSessa, 1993, 2002, 2004).

Coherence, of course, is as Disessa himself writes, "a vague word", but as he continues, "one important core meaning (of coherence) has inherently to do with relations; that is, the meaning of coherence requires an articulation of structure." (diSessa, 2008). Even if the term is often left unspecified in the context of conceptual change studies, a useful description for conceptual coherence can be found, for example, from Thagard and Verbeugt (1998, also Thagard et al, 2002). Thagard and Verbeugt defines coherence as follows: (i) Conceptual coherence is a symmetric relation between the pairs of concept, (ii) a concept coheres with another concept if they are positively associated i.e. if there are objects to which they both apply, (iii) the applicability of a concept to an object may be given perceptually or by some other reliable source, (iv) a concept
incoheres with another concept, if they are negatively associated, i.e. if an object falling under one concept tends not to fall under the other concept. Finally (v) the applicability of a concept to an object depends on the applicability of other concepts. Even if Thagard and Verbeugt speak explicitly about coherence of concepts, there is no reason a priori, why their description of coherence could not be applied to the elements of subconceptual systems or more complex entities, such as elements of belief or knowledge systems.

These three approaches are perhaps the most widely accepted descriptions for the task of conceptual change. In an ideal account, these descriptions would be given in an exact way, but at least to our knowledge there are not any exact formulations of conceptual change available. In addition, philosophically speaking, it is still an open question, what is it about fruitfulness, plausibility, utility or coherence that makes the learning task as an instance of conceptual change. Perhaps, very roughly, one might say that conceptual change happens when a student does not merely accumulate more knowledge, but her conceptions of phenomena in a certain domain undergo a restructuring process that affects the conceptual system in a way that increases utility, plausibility or coherence of that system.

Explanation step 2: The Mechanisms of Conceptual Change. Now, let's move to the second step of explanation. This aspect of explanation answers questions like: "how does the mechanism transform the input to generate the output (step by step)?". In the literature of mechanistic explanations, there are several attempts to specify this notion of "cognitive mechanisms". For example, Bechtel (2008) defines cognitive mechanisms as follows: A (cognitive) mechanism is a structure performing a (information processing) function in virtue of its components parts, component operations, and their organization \({ }^{2}\). Typically in the case of hard core cognitive explanations, these mechanisms are given descriptions by specifying the precise algorithms or by other formal means.

The mechanisms of conceptual change. In the literature, there are many suggestions for the "mechanisms" of conceptual change. For example, Chi talks about categorization and recategorization, while Carey speaks about differentiation, coalescence and bootstrapping. Vosniadou focuses on accommodation and assimilation, Thagard writes about branch jumping and tree jumping, and Ohlsson focuses on resubsumption.

However, often these purported mechanisms of conceptual change are rarely specified with sufficient (computational) detail (for discussion, see Rusanen and Pöyhönen, 2012). The descriptions of these mechanisms are often quite shallow and offer no information about the precise structure of mechanisms. For example, Chi describes conceptual change as a form of recategorization process by saying that "[c]ategorizing is the process of identifying or

\footnotetext{
\({ }^{2}\) There are some controversies about the precise definition of cognitive mechanisms. See Piccinini, 2006, also Shagrir, 2002; Lappi \& Rusanen, 2011.
}
assigning a concept to category to which it belongs"(Chi 2008, 62), and by writing how "Conceptual change is the process of removing misconceptions... (which) are, in fact, miscategorizations of concepts" and "conceptual change is merely a process of reassigning or shifting a miscategorized concept from one category to another" (Chi, 2008, 62, italics added).

However, Chi offers no description of how "identifying" or "assigning" actually happens, or what kind of cognitive mechanisms they actually are. From an explanatory point of view, this is problematic. Genuinely explanatory models are models, in which the phenomenon is explained by giving an accurate and sufficient description of how a (causal) mechanism, a hierarchical system composed of component parts and their properties sustains or produces the phenomenon (Bechtel and Richardson, 1993; Machamer at al., 2000; Craver, 2006, 2007). In addition, genuine explanations offer the ability to say not merely how the system in fact behaves, but to say how it would behave under a variety of circumstances or interventions (Craver 2000, Craver 2007, Woodward 2003).

So, even if even if these "identifyings", "assignings" and "categorizings" (or any other similar "ings"), were constantly referred as mechanisms, they often fail to satisfy the requirements for genuine mechanism descriptions, becausee the structure of these mechanisms is not specified in a detail. Instead, often the purported "mechanisms" are, or include, more or less filler terms. Filler terms describe only the relationship between the input and the output of the process, but they offer little specific information of how the change was brought about.

If a mechanistic model is incomplete, and it includes filler terms, it should rather be called a "mechanism sketch" than a genuine explanation (Craver, 2006, 2007). Philosophically speaking, having numerous filler terms in an explanation does not only threaten to undermine its explanatory power, but filler terms may also be barriers to scientific progress when they veil failures of understanding (Craver, 2006, 2007). If, for example, the term "assign" is used to stand for a process with largely unknown properties, then we really do not explain what happens, but in the worst case scenario we may also have only an illusion of explanation (Craver, 2006; Rozenblitz \& Keil, 2002).

The details of mechanisms. In addition, when the details of these mechanisms (reorganisation, bootstrapping, resubsumption, category shifts, etc.) is analyzed, they are often just collections of some more basic cognitive mechanisms (such as categorization, mapping, transfer, assimilation, accomodation, analogical reasoning, inductive inference, abduction and so forth), which are ultimately thought to be responsible for the conceptual change.

For example, in Stellan Ohlsson's (2009) account conceptual change happens, when a person uses analogical transfer to map conceptual system from one domain A to a new domain B, which has been earlier conceptualized by another system. According to Ohlsson's model, if the new
system is evaluated to be more useful, the target domain is reinterpreted by it.

As Ohlsson says, the resubsumption theory "does not introduce any cognitive processes that are specific to conceptual change" and "no special purpose cognitive mechanism kicks in to produce conceptual change" (Ohlsson, 2009, p. 32). Instead, resubsumption is simply a process, which involves analogical reasoning, transfer, analogy, transfer, different kinds of mapping and interpretation and all these familiar cognitive mechanisms.

From the explanatory point of view, this is not shocking news. It is quite common, as for example Bechtel and Richardson (1993) emphasize, that complex mechanisms are, and often must be, decomposed into simpler (or more basic) submechanisms that are ultimately responsible for the orchestrated functioning of the higher level mechanism (Bechtel \& Richardson, 1993, see also Craver, 2007). However, if the submechanisms are finally doing the explanatory work, they should be given a proper description. If they are not described in a detail, then we really have no explanation as to how conceptual change happens.

Evaluation of relevance. Given the complexity of cognitive processes in general, and especially the complexity of conceptual change, in practice it is really difficult to distinguish those underlying submechanisms (attentional- , memory- , reasoning-, mapping mechanisms etc. ) that are doing the explanatory work from those which are not. As Ohlsson emphasizes (Ohlsson, 2009b, p. 70), a theory of conceptual change just cannot be the list of all possible mechanisms underlying conceptual change, but it must also constraint mechanisms in theoretically principled way. In other words, what we need is a theoretically principled way to evaluate the relevance of submechanisms.

This is, of course, a very difficult demand. Philosophically speaking, one possible line might be to argue that the relevance for a certain mechanism - or certain mechanisms - could be evaluated by knowing how the mechanism`s inputs and outputs interact with their context i.e. by knowing its causal (as opposed to say, intentional relations) with the environment \({ }^{3}\). A natural way to continue this argument would be to refer to the manipulationist account i.e. to argue following Woodward (2003) that those mechanisms are relevant, which do not only have impact on how the cognitive system of a learner in fact behaves, but which have impact also on how it would behave under a variety of circumstances or interventions.

However, it seems to be that in the case of conceptual change - and in genuinely cognitive explanations in general - the explanatory relevance must also be described at least partially by referring the task of the conceptual change as well. A theory of conceptual change should be able to tell, why certain mechanisms are required or are appropriate for achieving conceptual change, and why some other aren't.

The task level description is needed to characterize representational requirements and constraints for the descriptions of appropriate learning mechanisms. If one thinks that the task should define in terms of utility, then one should characterize those mechanisms that are responsible for "utility making". However, for doing this, the task level - utility, coherence, intelligibility - must be specified first, and then this specification provides justification to relevance claims concerning the specific mix of concrete mechanisms underlying conceptual change.

\section*{Concluding remarks}

Conceptual change is organizing a multiplicity of learning mechanisms to achieve learning that makes the conceptual system "better" by way of creating new (for the learner) concepts. These concepts do not "pop" into existence in a miraculous way but are typically gradually and sometimes painfully crafted by the cognitive mechanisms from existing material.

According to the mechanistic account, explanation requires that the mechanisms responsible for a certain type of conceptual change should be specified in a detail. This can be really challenging in the case of conceptual change. Conceptual change is a really complex cognitive process, and it may involve a hierarchical collection of many different submechanisms. Some of those are better "known" (categorization, inductive reasoning), some of those aren't (mapping mechanisms). In addition, there are many different forms of conceptual change, and they may involve several different mechanisms.

However, as also Ohlsson emphasizes (Ohlsson, 2009b), a theory of conceptual change cannot just be the list of all possible mechanisms, but it must also make some constraints for the list of explanatory relevant mechanisms. A theory of conceptual change should be able to tell, why certain mechanisms are required or appropriate for conceptual change, and why some other aren't. For this reason, the task level also matters. The task level identifies the learning episode as conceptual change by identifying the relevant type of difference between initial state (no concept) and outcome (has concept) is an essential part of explanation because it provides not only the characterization for the explanandum of explanation, but it is also needed to evaluate the explanatory relevance of mechanisms.

\begin{abstract}
Parallel Distributed Processing (PDP) models have been widely used for modeling cognitive tasks where accuracy or reaction time were the dependent performance measures. However, only few PDP models have attempted to model more brain-related data like event related potentials (ERPs). In this paper, we take a step towards using ERP data for model fitting by proposing a PDP model, which can successfully replicate various known ERP effects. Specifically, we introduce a PDP-equivalent of the N400 ERP measure and apply it to a simple PDP model of early bilingual word acquisition as bilingual word acquisition tasks provide several well-established N400 effects that can be used for model validation. We then analyze the dynamics of the network to show why and how the network can capture each of the targeted N400 effects. Furthermore, we qualitatively compare model-generated and empirical N400 peak values for L2 words.
\end{abstract}

Keywords: PDP, bilingualism, L2 word acquisition, event related potential (ERP), N400

\section*{Introduction}

In a recent paper, Laszlo \& Plaut (2012) proposed a way to capture N400 ERP word reading data in a parallel distributed processing (PDP) connectionist network whose architecture was based on two neurally plausible characteristics: neurons can either be excitatory or inhibitory, but not both, and inhibitory connections can only occur within layers, but not between (as the range of inhibitory connections in the brain is shorter than that of excitatory connections). Given these two constraints, the model generated cycle-based time-course data that reflected the temporal evolution of the N400 response, replicating the "orthographic neighborhood size" effect that words with larger orthographic neighborhood size elicit larger N400s compared to words with smaller neighborhood size. However, it is currently unclear whether this model would also capture various other known N400 word effects such as those obtained in the context of bilingual word processing.

In this paper, we propose a PDP architecture for a PDP model of bilingual word processing, which can successfully capture several known N400 effects in early bilingual word processing, including the "orthographic neighborhood size" effect in addition to other known effects such as the "pseudoword effect".

\section*{Background}

Two important aspects of any bilingual processing model are the representations of lexical items in the first (L1) and second (L2) language and their requisite connections to concepts. Research on word processing during the early stages of L2 acquisition has revealed important constraints about storage and processing of conceptual and lexical information in the bilingual brain. Studies using speeded translation tasks, for example, show L2 learners are faster to translate from L2 to L1 (e.g., translating tenedor to fork in native English learners of Spanish) than from L1 to L2 (translating fork to tenedor) (e.g., Kroll \&Stewart, 1994). These behavioral results indicate that adult bilinguals appear to associate new L2 words with their L1 translation equivalents in order to facilitate semantic access to these new words.

This bootstrapping of L2 into the already established L1 language system involves an asymmetrical representation of the two languages, accounted for in Kroll \& Stewart's Revised Hierarchical Model (RHM) (depicted in Figure 1).

Figure 1: The RHM (Kroll \& Stewart, 1994). Solid lines indicate strong connections and dashed lines indicate weak connections.

The RHM assumes a separate lexicon for L1 and L2 with orthographic and phonological representations, each of which is connected to a single amodal conceptual store. In early second language learners, the L1 lexicon is assumed to be much larger than the L2 lexicon and evidence from picture naming tasks in bilinguals suggests that the strength of the links between the two lexicons and the conceptual store are also asymmetrical, with L1 having stronger connections to semantics than does L2 (e.g., Kroll \& Peck, 1998). Both the lexical level asymmetry and the concept-tolexicon asymmetry between L1 and L2 are modeled in the RHM by disproportionately weighted links (see Figure 1). Adhering to the behavioral data, the link from the L2 lexicon to the L1 lexicon is much stronger than the link from L1 to L2, just as the link between the L1 lexicon and conceptual store is much stronger than the link between the L2 lexicon and the conceptual store.

However, behavioral data is often insufficient for distinguishing between different processing mechanisms. Hence, electrophysiological measures such as event-related potentials (ERPs) with their fine-grained temporal resolution can uncover particular neural activity elicited during language tasks that might only be associated with a particular class of model architectures. In particular, the N400, which is a negative-going centroparietally distributed ERP component peaking around 400 ms after stimulus onset, has been shown to index lexico-semantic integration during word processing. Hence, it provides a robust measure of changes in processing activity in the brain as language learning takes place and can thus be used to flesh out conceptual proposals like the RHM in computational architectures such as the PDP connectionist models. We will, in particular, focus on four aspects of monolingual and bilingual word processing for which N400 effects have been reported in the literature: (A1) L1/L2 words versus L1/L2 pseudowords (i.e., pronounceable L1/L2 non-words that adhere to the orthographic rules of L1/L2); (A2) L1/L2 word repetition effects; (A3) variations in L1/L2 word neighborhood size; and (A4) L1 vs. early L2 word processing differences.

Regarding (A1), it is well-known that L1 pseudowords elicit larger N400s than L1 words (e.g., Holcomb \& Neville, 1990). Moreover, L2 learners showed larger N400s to L2 pseudowords than to L2 words after only 14 hours of classroom learning, mimicking L1 pseudoword effects (e.g., McLaughlin et al., 2004; however, note that McLaughlin and colleagues did not find any behavioral evidence of L2 words and pseudoword discrimination, thus supporting the use of ERPs over behavioral measures for adjudicating model architectures).

Regarding (A2), repeated words reliably elicit smaller N400 amplitudes than their first presentation (e.g., Rugg, 1985). This attenuation of the N400 reflects the increased ease of lexico-semantic integration upon the second and subsequent presentations of a word (possibly due to residual activation of the lexical item and/or facilitatory feedback from the activated concept).

Regarding (A3), words with large numbers of orthographic neighbors (e.g., words that differ from the target by only one letter) elicit larger N400s than words with smaller neighborhood size (e.g., Holcomb et al., 2002). Notably, the effect occurs within as well as across languages, i.e., L1 influencing L2 and vice versa (Midgley et al., 2008).

And finally (A4), N400s can be used as a measure of how closely L2 processing matches that of L1 processing. For example, Midgley and colleagues found that both EnglishFrench and French-English bilinguals who had intermediate L2 experience displayed smaller N400s to L2 words than to L1 words (2009). Balanced bilinguals did not show any N400 differences between L1 and L2 word processing. This result might be in part explained by (A3). Given that the L1 lexicon contains more word forms than the L2 lexicon, L1 words generally have larger neighborhood sizes than L2 words. The larger neighborhood sizes of L1 items in comparison to L2 items may contribute to larger N400 amplitudes for L1 words over L2 words.

\section*{Model Description}

We start with four hypotheses, (H1) through (H4), about the possible principles responsible for each corresponding N400 effect (i.e., (A1), (A2), (A3), and (A4)) in the context of a RHM-like PDP architecture and then add connections within and between layers of the network based on the hypothesized mechanisms.

\section*{Hypotheses:}
(H1) Pseudowords have no word-level representations and thus no connections to concept nodes or nodes within the lexical layer.
(H2) Concept nodes keep a residual activation between repeated word presentations and can thus be activated faster in subsequent presentations of the same word compared to the first presentation.
(H3) Lexical inputs with more orthographic neighbors should activate more concepts early on. This should lead to increased competition among concepts and thus to reduced overall activations later on, which can be facilitated via inhibitory connections in the concept layer.
(H4) After some training (when fairly strong, direct L2 lexical-to-concept connections are in place), L2 words should elicit a larger initial target concept activation than L1 words. This can be accomplished via L2-to-L1 word connections that are stronger than those from L1-to-L2 words.

Based on the RHM framework, we developed a PDP model with bidirectional excitatory lexical-to-concept connections, top-down inhibitory concept-to-lexical connections and inhibitory concept-to-concept connections (see Figure 2). As in the (Laszlo \& Plaut, 2012) model, we
use IAC units (with standard parameter values for \(\min =-.2\), max \(=1\), and rest \(=-.1\) activation levels as well as decay rate \(=.1\) ). For simplicity, we limit input words to 5 letters, thus requiring 5 clusters of 26 input letters per word (for the English alphabet). All letters in each cluster \(i\) have excitatory connections to words that contain them in the \(i\)-th slot and inhibitory connections to all words with a different letter in the \(i\)-th position.

Figure 2: Model architecture. The thickness of links indicates the strength of connections.

L1 versus L2. To account for larger L1 vs. L2 word neighborhoods, we include more L1 words with a larger neighborhood size in the model compared to L2 words.

Pseudowords versus words. Pseudowords have no representation at the lexical or semantic layer.

Repetition. We model repetition effects by performing the following sequence \(r\) times: input word \(i\) is presented for \(n\) cycles (where \(n\) should be large enough to allow the N400 signal, to be defined below, to reach its peak). Then the input is removed and the network is updated for \(d\) cycles to let all node activations decay, after which point the whole process is repeated, but without resetting any activation values. We thus have three critical modeling parameters that need to be set appropriately: \(r, n\), and \(d\).

Filtering word length artifacts. Assuming that each constituent letter contributes equally to a word's activation level, all connection weights from each letter in a word have the same strength. However, because words have different lengths, the overall incoming activation would be different if we were to use the same connection weights for all letter-to-word connections as longer words would get a higher activation than shorter words, everything else being equal. To avoid this effect, we scale the letter-to- word connection weight \(c\) by the length \(|W|\) of the word \(W: w_{L, W}=c /|W|\). We also needed to make sure that the input letters
corresponding to a given target lexical item will only activate the orthographic neighbors and not the other words that differ from the target word in more than one letter. In order to do so, we made the strength of inhibitory and excitatory letter-to-word connections the same, so that if a word is different from the target word in more than one letter (for four-letter words), it receives zero or less than zero netinput from the letter nodes. In addition, none of the five-letter/three-letter words were similar to a four-letter word in 3 or more slots.

\section*{Definition of PDP N400 Measure}

Based on the semantic interpretation of the N400 signal (Laszlo \& Fedemeier, 2011), we define the networkequivalent of the N 400 as the magnitude of overall activation change (differential) in positively activated (potential) concept nodes (potential). Specifically, we calculate the sum of all positive concept activations at each cycle and compute the change between two consecutive cycles as the N400 (the discrete equivalent to the derivative of the potential given by the summed concept node activations).

\section*{Experimental Bilingual ERP Data}

We collected ERP measures from 14 native English speakers who were enrolled in a first semester "Introductory Spanish" class at Tufts University ( 9 females, mean age 18.4). Participants viewed Spanish words (e.g., HOLA, GATO) and Spanish pseudowords (e.g., SERO, AGOL) one at a time as part of a lexical decision task. The Spanish words were a set of non-cognates taken from the textbook used in class. Factors of length, English bi-gram frequency, and English neighborhood size were balanced between the words and pseudowords used in the study. Averaged ERPs were computed for all word and pseudoword stimuli for each participant at 29 scalp sites. Single item ERPs were formed by averaging to time-locked stimuli across participants. The mean amplitude averaged across a subset of centroparietal electrodes (including: Cz, Pz, C3, CP5, CP1, P3, C4, CP6, CP2, P4) between \(300-500 \mathrm{~ms}\) was used to quantify the N400 effect. The mean amplitude between \(300-500 \mathrm{~ms}\) was used to quantify the N 400 effect. Additionally, N400 measures for single items were calculated using the mean amplitude between item-specific temporal windows, ranging from 250 ms to 500 ms .

\section*{Modeling Results}

We selected a subset of 14 four-letter L2 words from all L2 words used in the ERP experiment and included all their L1 translations as well as their L1 neighbors to be able to account for the cross-language orthographic neighborhood size effects. Since some of the L1 words were 5 letters in length, we included 5 clusters of letters in the model.

Figure 3: Sum of semantic activation (top row) and the N400 amplitude (bottom row), over 75 update cycles in response to three words: "son" (L1 word in black), "azul" (L2 word in blue), and "sero" (L2 pseudoword in red).

Figure 3 shows the shape of the N400 signal generated by the model along with the time-course of the summed concept nodes' activations during the whole word exposure. Note that the change in total concept activation is proportional to the maximum value of the N 400 generated.

The right column in Figure 3 reveals three distinct phases in the dynamic of the overall semantic activation in our network: (a) charge (positive overall change), (b) discharge (negative overall change), and (c) stabilization. Furthermore, since inhibitory connections only originate from concept nodes, any significant flow of inhibition can only come after an initial flow of activation, i.e., until concept nodes have reached sufficiently strong activations.

Charge. The activation of the target concept and concepts associated with orthographic neighbors or its associated word-level node initially start to increase, followed by the feedback from excitatory and inhibitory connections to word-level nodes causing the activation of the target word to
gradually increase and the activations of its orthographic neighbors to decrease.

Discharge. The overall semantic activation decreases as a result of inhibition exerted by significantly activated concept nodes.

Stabilization. Eventually, the overall activation levels of the network stabilize.

We searched for values for the various connections that would allow the model to capture the N400 effects: concept-to-L1 \(=(.6,-2), \quad\) concept-to-L2 \(=(.8,-.2), \quad\) concept-toconcept \(=(0,-.6)\), L1-to-concept \(=1\), L2-to-concept \(=.8\), L1-to\(\mathrm{L} 2=.1\), L2-to-L1=1, letter-to-(3letterWord) \(=(.8,-.8)\), letter-to-(4letterWord) \(=(.6,-.6)\), letter-to-(5letterWord) \(=(.48,-.48)\) (the first element of each tuple is the excitatory weight value between related items, and the second element is the inhibitory weight value between the unrelated items).

For all simulations, we took the maximum peak value as the measure for comparing N400 signals to the empirical data. Furthermore, since several factors can influence the N400 value, we investigated only one factor at a time while keeping the others fixed.

Figure 4: N400 data for repetitions of "son" using first: \(r=3, n=30, d=30\), second: \(r=1, n=30, d=70\), and then \(n=30\) (see text for details).

Figure 4 shows that the model replicates the repetition effect (A2), i.e., maximum N400 values (peaks) after the first exposure are all smaller than the first peak.

Figure 5 shows that the model is able to replicate the neighborhood size effect regardless of lexical type: L1, L2, and pseudowords.

Figure 6 shows the replication of (A4) - in all cases - and the replication of (A1) - in all cases except for (a) and (b). Furthermore, Figure 4 suggests that the replication of (A1) and (A4) is dependent on neighborhood size: as the neighborhood size increases, the network replicates (A1) more strongly, while showing weaker replication of (A4). The network best replicates (A4) for L2 words of \(n\) Size \(=0\).

Figure 5: Neighborhood size effects within three categories: in order L1, L2, Pseudowords, shown by mean N400s of words with \(n\) orthographic neighbors: \(0=\) black, \(1=\) blue, \(2=\) green, \(3=\) cyan, \(4=\) red, \(5=\) yellow, \(6=\) magenta, \& \(10=\) black stars.

Figure 6: Mean N400 signals for words sharing the same neighborhood size ( \(n\) Size): a) \(n \operatorname{Size}=0\), b) \(n \operatorname{Size}=1\), c) \(n S i z e=2\), d) \(n S i z e=3\), e) \(n S i z e=5\), f) \(n S i z e=6\), in three categories: L1 words in black, L2 words in blue, and L2 pseudowords in red. Note that there was no L2 word of \(n S i z e=1\), no pseudoword of \(n S i z e=2\), and no L1 word of \(n\) Size \(=3\).

Note that the correlation value (corr=.2135) between the maximum N400 values (for L2 words) generated by the model and those collected in the experiments shows that the model does not yet quantitatively fit the empirically obtained ERP values, despite qualitatively replicating ERP effects.

\section*{Discussion}

The model succeeded in capturing qualitatively all four ERP effects. Furthermore, the results confirm that the (A1) and (A4) effects are dependent on neighborhood size as suggested in (Midgley et al, 2008 and Holcomb \& Neville, 1990). However, the model allows for a different explanation from that of Midgley et al. who hypothesized that the overall lower N400 for L2 words compared to L1 words might be caused by the smaller neighborhood size of L2 words compared to L1 words, everything else being equal. Specifically, the model shows that this difference can also be obtained with identical neighborhood sizes based on the generally higher initial activation induced at the target concept in response to an L2 input word (compared to that of an L1 input word). This higher initial activation tends to suppress the other concept nodes, thus leading to an overall lower ERP and thus lower N400. Hence, it is likely that both neighborhood size and difference of initial target concept activation via L1 or L2 words contribute to the smaller N400 for L2 words (compared to L1 words).

Note that all simulation results where obtained by considering N400 peak values only, but other measures are certainly possible (e.g., the integral of the N400 signal over the \(300-500 \mathrm{msec}\) time frame or the average value over the same period). This is left for future work.

\section*{Conclusion}

We have developed a PDP model based on Kroll \& Stewart's Revised Hierarchical Model (RHM) of bilingual word processing and tested it against well-established N400 effects. The model succeeded in qualitatively replicating language, neighborhood size, pseudoword, and repetition effects. However, the model did not quite replicate the N400 results from our empirical experiments, as shown by a fairly low correlation between the ERPs of the model and empirical data. Future work will focus on exploring the model's parameter space to determine if better model fits are possible with the given model architecture. In addition, we will investigate simpler model architectures and the extent to which they may succeed in replicating some of the N400 effects. We will also investigate alternative definitions of N400 (e.g., including the lexical level activations) as well as exploring the use of average N 400 amplitudes rather than peak values.

\begin{abstract}
Language use is an important part of a negotiation. Prior research has shown that similarity in language use is conducive to reaching agreements. This paper uses Latent Semantic Analysis to explore how the similarity of language use develops and changes over the time course of a threeparty negotiation. Results support theories that suggest that a gradual alignment of semantic representation increases the likelihood that parties will form a coalition.
\end{abstract}

Keywords: Negotiation, Coalition Formation, Linguistic Entrainment, Psycholinguistics, Latent Semantic Analysis.

\section*{Introduction}

The language used by parties in a negotiation is a crucial aspect of their negotiation strategy and can greatly affect the outcome of the negotiation. Research over the past few decades has demonstrated that an agreement in a negotiation is often preceded by convergence in language use among the negotiating parties (cf. Miller, 2005). In the context of multi-party negotiation, such convergence is evident between the parties that reach an agreement, but not the excluded parties (Huffaker, Swaab, and Diermeier, 2011).

In this paper we extend the results of Huffaker et al. by analyzing the similarity of adjacent conversation moves. This type of analysis enables us to look at the time course of coalition formation and not just at the overall similarity of language use between participants.

Multi-party negotiation is naturally more complex than that a two-party negotiation (Bazerman et al., 2000). This is especially true since an agreement can be reached among a subset of the negotiating parties. Therefore being excluded from an agreement is a real possibility. Nevertheless, partial coalition agreements are often less desirable than agreements that involve the group as a whole because they are less efficient or do not use all of the available resources. However, even being part of a partial agreement is more preferable than no agreement at all or of being excluded from an agreement reached by others.

The added complexity of multi-party negotiation has been shown to affect the patterns of language use in such negotiations. Following the framework of Communication Accommodation Theory (CAT; cf. Giles et al., 2007), Huffaker et al. (2011) demonstrates how the formation of coalition is affected by specific aspects of language use by the negotiating parties. Specifically, they find that partners to a coalition show more similarity in language use than
participants who were not part of a coalition. The use of assents was also found to correlate positively with being a part of the coalition agreement. In contrast, the use of negative emotion words was a detrimental predictor to being a part of a coalition.

These results are congruent with empirical findings in psycholinguistics that show that in successful dialogues the representations and language used by dialogue partners tend to converge over time (e.g., Brennan and Clark, 1996). However, while Huffaker et al. show that similarity in language use is a factor in the outcome of the negotiation, they use the entire negotiation as the unit of analysis. Consequently, their results do not explore the time course of this similarity. This paper aims to extend their results by looking at whether the language used by the participants changes over time.

On the one hand, theories of entrainment and alignment in language use by dialogue participants, such as that put forth by Pickering and Garrod (2004), argue that language similarity is the result of gradual alignment of language use by the participants in the negotiation. The better the alignment the more likely the aligned parties would be to form a coalition. Such theories would lead to the prediction that language similarity should increase over the course of the negotiation and ultimately result in the parties forming a coalition.

In contrast, Swaab et al. (2011) shows that language mimicry during a negotiation is a factor in the outcome of the negotiation, but only when it occurred early in the negotiation. Therefore, we might expect that early similarity in language use might lead to the forming of a coalition later on.

It is also possible that both of these factors contribute to the effect that similarity in language use has on the resulting coalition. If that is the case we would expect to find not only that eventual coalition partners show more similar language early on than non-coalition partners, but that this difference increases over time.

\section*{Measuring similarity in language use}

Convergence of language use in a dialogue or negotiation has traditionally been measured by hand coding the transcripts of negotiation dialogue. Such hand coding is time consuming and, to a certain degree, requires the coders to interpret the language used by the negotiators. In contrast, the metric we use in this paper is automatically derived by
using the Latent Semantic Analysis cosine similarity of a pair of utterances. Such a measure has been used in the past as a measure of textual coherence (Foltz, Kintsch, and Landauer, 1998) and as a measure of linguistic entrainment (Huffaker et al., 2006).

LSA vectors for individual words are generated based on the co-occurrence patterns of words in large corpora. These vectors identify points in a high-dimensional space (100 dimensions in this case). The more likely two words are to co-occur with similar words the closer they will be in the space. For example, the vectors for sun and moon are fairly close together and show a cosine similarity of .53 whereas man and moon are not very similar and show a cosine similarity of .03 . Moreover, when several word vectors from a single utterance are combined together, as was done in this study, the result identifies a point in space that represents the overall topic of the utterance.

It is important to note that this kind of automatic measure ignores certain linguistic elements that a coder might use. For instance, the use of negation is generally ignored, while sarcasm and metaphors are often misrepresented. However, since we are interested in the convergence of language use that is, whether participants are using similar language to convey their (sometimes opposing) ideas, this type of analysis seems appropriate.

\section*{Method}

\section*{Huffaker et al. (2011)}

The data used in this paper comes from a study reported by Huffaker et al. (2011). They patterned their study after a pure coalition game outlined by Raiffa (1982). In that study, 180 MBA students were divided into 60 three-person groups. Within each group, participants were assigned to one of three roles ( \(\mathrm{A}, \mathrm{B}, \mathrm{C}\) ) and instructed that they were to use an online chat room to negotiate a split of that payoff amongst themselves. Participants were unaware of the identities of the other participants in the negotiation.

Table 1: Payoff Table in the Negotiation Game from Huffaker et al. (2011)
\begin{tabular}{lr}
\hline Possible Agreements & Total Payoff \\
\hline A alone & \(\$ 0\) \\
B alone & \(\$ 0\) \\
C alone & \(\$ 0\) \\
A and B & \(\$ 118,000\) \\
A and C & \(\$ 84,000\) \\
B and C & \(\$ 50,000\) \\
A, B, and C & \(\$ 121,000\) \\
\hline
\end{tabular}

Note: A, B, and C represent the participants in the negotiation. The payoff is split between the parties that reach the described final agreement.

All participants were provided with the payoff table in advance of the negotiation (see Table 1). As is evident from the table, different coalition formations receive different
payoffs, and if no coalition is formed no participant receives any payoff. The participants were allowed to negotiate how the payoff is distributed between them. These payoff options provide incentives for the participants to join up with another participant so that they can take advantage of the resulting weak bargaining position of the third participant. However, the payoff table is designed so that the third player can always make an attractive offer to one of the members of the initial coalition to induce a defection from the preliminary agreement. Consequently, participants are incentivized not only to be a part of a forming coalition, but also to ensure that it is a stable coalition and that their partner(s) will not defect.

Participants in the experiment were placed at computers in different rooms so that their only means of communication with each other was through the provided chat software. They logged into a public chat room to begin the negotiation process.

The software also allowed participants to move from the public chat room to three private chat rooms. That is, participant A could move into one of the private chat rooms together with participant B so that they could negotiate without participant C being privy to the content of the negotiation. However, all participants were alerted whenever a participant entered or exited a chat room so that the excluded participant was always aware that the two other participants might be negotiating in private. This mimics some of the real-world aspects of a negotiation, where parties are often able to communicate in private, but the fact that they communicated in private is common knowledge. A private exchange of information can also provide an indication that the two parties are forming a coalition.

\section*{Semantic Analysis}

The analysis in this paper is based on the transcripts of these negotiations. An LSA vector was computed for each individual utterance by using vector addition to combine the vectors of all of the content-bearing words in the utterance. When an utterance did not include any content-bearing words, a null vector was used to represent it. The vector space used for this analysis was generated by Infomap (http://infomap-nlp.sourceforge.net/ ; Schütze, 1997) using the written part of the British National Corpus.

Next, the correlation of the vectors representing temporally adjacent utterances was computed \({ }^{1}\). These correlations were not computed when one of the utterances had a null vector or when the two utterances did not occur in the same chat context (i.e., when they occurred in different chat rooms).

In some cases identical vectors represented adjacent entries. These were generally the result of statements such as "I agree" or "X is present" and were found either at the

\footnotetext{
\({ }^{1}\) Because the first dimension of LSA vector spaces tends to correlate with the frequency and length of the text it was dropped from the analysis (cf. Hu et al., 2007)
}
very beginning or the very end of the negotiation. They were dropped from the analysis because they did not appear to represent a meaningful part of the negotiation. That is, they did not represent linguistic convergence between participants but rather formulaic utterances that occurred mostly before the negotiation started or after it has concluded. Regardless, the results presented here are quantitatively and qualitatively similar whether these data points are included or excluded.

In order to test for convergence in language use we categorized the utterance pairs based on the two participants that contributed to them. We predicted that participants who were included in the resulting agreement would have more similar language use than those who included a participant who were excluded from the agreement. For example, if an AB agreement was reached, utterance pairs between A and \(B\) would be predicted to have more similar language use (i.e., utterance-to-utterance correlation) than those between A and C or B and C . Consequently, we divided the utterance pairs to those in which both participants were included in the final coalition (successful utterances) and those in which at one of the participants was excluded from the coalition (unsuccessful utterances). Importantly, when the final agreement included all parties, all of the utterance pairs were considered to be successful. In contrast, when no agreement was reached all of the utterances were considered to be unsuccessful.

Because the parties are unfamiliar to each other when they enter the negotiation we also expected that this difference would emerge over the course of the negotiation and become apparent only once a coalition begins to form. Therefore, we divided the utterance pairs based on their position in the negotiation \({ }^{2}\) - If the first utterance of the pair occurred in the initial half of the negotiation it was classified as an early utterance whereas utterances that occurred in the second half of the negotiation were considered late utterances.

\section*{Results}

As mentioned above, we derived two distinct hypotheses:
1. Following accounts of linguistic entrainment (e.g., Pickering and Garrod, 2004), we hypothesized that coalition formation will be accompanied by the alignment of language use. Consequently, if linguistic entrainment occurs as part of the formation of a coalition, successful utterances should become more similar to their responses than unsuccessful

\footnotetext{
\({ }^{2}\) For the purposes of this analysis we use a coarse grain division of time (halves) because some of the discussions consist of relatively few utterances (under 50). This is adequate for the purpose of our basic hypotheses, but does not provide a good sense of how the utterance-to-utterance similarity changes over time. It is possible to utilize smaller time units in an analysis of this type to gain further insight into the temporal progression of the negotiation (e.g. Figure 2). Essentially, the choice of temporal units for analysis represents a tradeoff between precision and statistical power.
}
utterances would be to their responses late in the negotiation. This will result in a significant interaction between the type of utterance and its position in the negotiation.
2. Following the literature on the effectiveness of mimicry in negotiations (e.g., Swaab, et al. 2011), we hypothesized that early mimicry would result in a higher likelihood of eventual success in the negotiation. Therefore, if mimicry is an effective tool in these negotiations, successful utterances should be more similar to their responses than unsuccessful ones early in the negotiation.

To test these hypotheses we conducted a \(2 \times 2\) ANOVA. The type of utterance (successful vs. unsuccessful) and its position in the negotiation (early utterance vs. late utterance) were the independent variables. The dependent measure was the average utterance-to-utterance correlation for utterance pairs conforming to the condition within a particular session. The means for each of the conditions can be seen in Figure 1.

There was no significant difference in similarity of language use between early utterances ( \(M=0.15, S D=0.08\) ) and late utterances \((M=0.14, S D=0.09)(F(1,186)<1\), n.s. \()\). There was a slight trend where successful utterances ( \(M=0.15, S D=0.08\) ) showed more similar language use than unsuccessful utterances \(\quad(M=0.13, \quad S D=0.09) \quad(F(1\), 186) \(=2.86\), \(\mathrm{MSE}=0.01, p=0.093\) ).

Figure 1: Similarity of Language use by utterance pair type and position in the negotiation. Error bars represent standard error.

More importantly, the interaction between utterance pair type and position was significant - The difference in language use between successful and unsuccessful utterances was greater for late utterances than early utterances \(\quad(F(1, \quad 186)=7.15, \quad M S E=0.01, \quad p<.01)\). Furthermore, Tukey HSD tests identified a significant

Figure 2: Mean similarity of language use by utterance pair type over the course of the negotiations. Each time period corresponds to \(10 \%\) of the negotiation (calculated individually for each negotiation). Error bars represent standard error.
difference between late successful utterances ( \(M=0.16\), \(S D=0.08\) ) and late unsuccessful utterances ( \(M=0.11\), \(S D=0.09\) ) ( \(D=0.051, ~ p<.01\) ) but not between early successful utterances \((M=0.14, S D=0.07)\) and early unsuccessful utterances ( \(M=0.15, S D=0.10\) ) ( \(D=-0.01\), n.s.). This result provides support for accounts in which a gradual alignment in language use and semantic representation leads to a likelihood of forming a coalition (Hypothesis 1). However, we found no support for accounts in which early similarity in language use (e.g., mimicry) leads to the formation of a coalition (Hypothesis 2).

Interestingly, while there appears to be a slight increase in the utterance-to-utterance similarity of successful utterance pairs from the first half to the second half of the negotiation, the observed interaction seems to be driven more by an unexpected decrease in the utterance-to-utterance similarity of unsuccessful utterances.

It might be possible to shed some light on this unexpected result be examining how the similarity of language use unfolds (Figure 2). A qualitative examination of the trends shows some evidence for early alignments of language use between the first \(20 \%\) of the negotiation and the next \(20 \%\) among all parties. However, the striking difference between the successful and unsuccessful utterance pairs is most evident starting around the \(60 \%\) point of the negotiation, on average. At this point there is a sharp drop in the similarity in language use of unsuccessful utterances. It appears that at that time period in the negotiation the coalitions are starting to form or have already formed (see Table 2 for sample of successful and unsuccessful utterances from that time period).

Table 2: Sample utterances from the \(60 \%\) slice of the negotiation (each utterance is from a different session)

\section*{Successful Utterances}
\begin{tabular}{l|l}
\hline \(\mathbf{1}\) & Do you still agree on our terms? \\
\(\mathbf{2}\) & So lets talk about the split. \\
\(\mathbf{3}\) & We can partner 3 ways and give them 3 k \\
\(\mathbf{4}\) & I presume you would rather do \(72 / 28\), right? \\
\(\mathbf{5}\) & Can we say \(\mathbf{6 9}\) to A, 48 to B and 4 to C to get a deal \\
\hline
\end{tabular}

\section*{Unsuccessful Utterances}

\section*{Discussion}

The analysis presented here, based on data collected by Huffaker et al. (2010), supports the hypothesis that the gradual alignment in language use is a contributing factor in reaching an agreement over the course of a negotiation. Participants in the study that were part of the final coalition showed more similar language use in the second half of the experiment than participants that were not part of the final coalition.

Interestingly, while the predicted interaction was found, the observed effect was somewhat different than expected. It appears that the major shift in language use leading to, or immediately following, the formation of a coalition is more likely to be a reduction in the utterance-to-utterance similarity for the excluded parties rather than an increase among the included parties. The causes for this require further study, but it seems possible that this is due to a change in the pattern of language use that the excluded party is not a part of. For instance, after agreeing to form a coalition, the parties might shift to discussing how to split the payoff while the excluded party might still attempt to convince one of the other participants to join a coalition.

The results of this paper seem to suggest that multi-party negotiations, while more complex than two-party negotiations and dialogues, follow many of the same patterns as their simpler counterparts. However, the added dynamics of such a negotiation also allows researchers to examine topics that are often difficult to explore when only two parties are involved in a linguistic exchange. In this case, it appears that when a party to the conversation or negotiation is "left behind", it might also fall out of linguistic alignment with the other participants.

Nevertheless, there is much room left for further analysis. While the initial analysis reported here provides some promising results, it is not conclusive. Furthermore, it opens the door for additional questions. For instance, it is possible that a 2-party coalition would be more likely to form during a private exchange rather than a public one. However, because of the relatively short length of some of the negotiations (under 50 utterances divided among the three parties), we elected not to separate the discussions based on whether they were part of a public exchange or a private one.

Another possible avenue for future investigation is to explore whether the patterns of linguistic entrainment differ based on the emerging final coalition. For instance, would a final 3-party coalition show a pattern consistent with a particular 2-party coalition up to some point at which the final participant in the negotiation also joins in? This is an interesting, if complicated, question that we leave open for future research.

\section*{Acknowledgements}

We would like to thank David Huffaker and Roderick Swaab for sharing the data from their study.

\title{
Interpreting Covariation in Causal Structure Learning
}

\begin{abstract}
Recent studies have shown that people use covariation information to infer causal structure. However, there is little information about how people derive causal directionality from covariation. The present study is designed to provide further evidence about the role of covariation in causal structure learning. In Experiment 1, where covariation between two variables was systematically manipulated, participants were asked to observe the states of bacteria (present or absent) and to infer their causal relationship. We found that judgments of causal structure varied as a function of covariation, and that participants interpreted covariation according to necessity of causation. In Experiment 2, participants who received information about high causal strength interpreted covariation according to sufficiency of causation. These results demonstrate that prior knowledge modulates interpretation of covariation and suggest that domain-general covariation information and domain-specific prior knowledge of causal relations interact in causal structure learning.
\end{abstract}

Keywords: causal learning; covariation; prior knowledge; necessity; sufficiency.

\section*{Introduction}

Causal knowledge enables us to explain past events, to control the present environment, and to predict future outcomes. Using this knowledge, we can achieve desired outcomes and avoid undesired consequences. Many psychological studies have investigated how people acquire and use knowledge of causality (Gopnik \& Schulz, 2007; Sloman, 2005; see also Holyoak \& Cheng, 2011, for a review). Despite the importance of causal knowledge, it is often difficult to determine the casual structure among events. For example, imagine that someone feels unmotivated and makes slow progress on their work. In this situation, it is unknown whether the lack of motivation leads to slow progress, or whether slow progress causes lack of motivation. Furthermore, it is also possible that motivation and work progress are unrelated. Given this ambiguity, how do people learn causal structure?

Hume (1739/2000) argued that causal relations are unobservable and must be induced from observable events. Information about covariation among events serves as a fundamental cue for inferring causal structure. Covariation is represented as the pattern of occurrences and nonoccurrences for binary variables. Figure 1 shows a standard contingency table where the letters in each cell ( \(a, b, c, d\) )
represent the joint frequencies for one value of event X and one value of event Y. It is generally accepted that objective measure of contingency is described by \(\Delta P\), as shown in Equation 1 (Jenkins \& Ward, 1965).
\[
\begin{equation*}
\Delta P=P(Y \mid X)-P(Y \mid \neg X)=\frac{a}{a+b}-\frac{c}{c+d} \tag{1}
\end{equation*}
\]

In this equation, \(P(\mathrm{Y} \mid \mathrm{X})\) is the probability of Y given the presence of X , and \(P(\mathrm{Y} \mid \neg \mathrm{X})\) is the probability of Y given the absence of X . Values of \(\Delta P\) range from -1 to +1 . Positive \(\Delta P\) values indicate a generative causal relation; negative \(\Delta P\) values indicate a preventive causal relation. When a causal relation exists, strong covariation between the cause and the effect is expected. By contrast, lack of covariation indicates that two variables are unrelated (i.e., \(\Delta P\) does not differ significantly from zero). Many studies have focused on how people estimate causal strength between the candidate cause and the effect, and the results have shown that people are quite sensitive to covariation information (e.g., Wasserman, Elek, Chatlosh, \& Baker, 1993). However, covariation itself is inadequate for inferring a unique causal structure: when event X covaries with event Y , it is difficult to determine whether X causes Y , or vice versa.

When combined with additional information, covariation becomes a more useful cue to causal structure. First, temporal order in which people observe the occurrence of events facilitates learning causal directionality. As causes are often observed prior to their effects, when event X precedes event Y, it is highly probable that X causes Y. For example, if becoming unmotivated precedes making slow

Figure 1: A contingency table summarizing the covariation between two binary variables. The letters in each cell indicate frequencies of co-occurrence for the two states of events X and Y .
progress on work, temporal order information suggests that decreased motivation causes slow progress. Second, information about the absence of hidden causes also makes covariation cues more useful. When event X covaries with event Y, three possible causal structures are supposed (i.e., \(\mathrm{X} \rightarrow \mathrm{Y}, \mathrm{X} \leftarrow \mathrm{Y}\), or \(\mathrm{X} \leftarrow \mathrm{Z} \rightarrow \mathrm{Y})\). The possibility that both events are caused by a hidden common cause, \(Z\), can be excluded if it is known that there are no hidden causes. If event \(X\) exists alone, necessity of causation indicates that \(X\) causes Y (i.e., \(\mathrm{X} \rightarrow \mathrm{Y}\) ). This is because nothing happens without a cause (i.e., \(P(\) Effect \(\mid \neg\) Cause) \(=0)\). Therefore, events that exist alone must be a cause variable, not an effect variable. In contrast to necessity of causation, sufficiency of causation draws the opposite conclusion that event Y causes event X in above situation (i.e., \(\mathrm{X} \leftarrow \mathrm{Y}\) ). Since sufficiency of causation assumes that causes always accompany their effects (i.e., \(P(\) Effect \(\mid\) Cause \()=1\) ), events that occur alone must be an effect variable, not a cause variable. Given that there is no factor that affects both motivation and work progress and that motivation changes spontaneously, in previous example, necessity of causation suggests that decreased motivation causes slow progress and sufficiency of causation indicates that slow progress causes decreased motivation.

Recent studies on causal structure learning have revealed the importance of covariation (e.g., Deverett \& Kemp, 2012; Mayrhofer \& Waldmann, 2011; Rottman \& Keil, 2012; Saito \& Shimazaki, 2012). For instance, Saito and Shimazaki (2012) demonstrated that people judge simple causal structure on the basis of covariation information, but the use of covariation is modulated by task complexity. The experimental task was to observe the states of bacteria and to infer their causal relationship. Participants were instructed that temporal order was unreliable and that there were no hidden causes. In the simple causal structure condition, covariation was favored over temporal order as the basis for inferring causal structure; in contrast, temporal order was more influential in the complex causal structure condition. In addition, Mayrhofer and Waldmann (2011, Experiment 1) reported that people can differentiate common cause models (e.g., \(\mathrm{X} \leftarrow \mathrm{Z} \rightarrow \mathrm{Y}\) ) from common effect models (e.g., \(\mathrm{X} \rightarrow \mathrm{Z} \leftarrow \mathrm{Y}\) ) on the basis of covariation information. Although these recent studies show the ability to infer causal directionality from covariation, how people use covariation to induce causal directionality is still not well-understood. Therefore, it is valuable to study how people make structure judgments according to covariation.

The purpose of the present study is to investigate how people interpret covariation information in causal structure learning. In Experiment 1, we systematically manipulated covariation between two variables and asked participants to make causal structure judgments. Although causal structure between two variables is not determined by covariation alone, this situation enables us to examine whether participants have some sort of tendency in inferring causal directionality from covariation. In Experiment 2, we gave participants different information about causal relations and
investigated whether prior knowledge changed their interpretation of covariation.

\section*{Experiment 1}

Experiment 1 investigated how people interpret covariation when judging causal structure. The experimental task was to observe the occurrence of two fictitious bacteria and to infer their causal relationship. We manipulated covariation information by varying the number of occurrences and nonoccurrences of each bacterium.

\section*{Method}

Participants and Design Forty-three undergraduates from Kwansei Gakuin University received course credit for participating in this experiment. Two additional participants were excluded from the analyses due to misunderstanding of the instructions. Excluding these participants did not alter the general pattern of results.

Covariation information was systematically manipulated within participants. There were 15 covariation conditions (see Table 1) based on the combinations of five levels (1.00, .75, .50, .25, .00) of the conditional probabilities \(P(\mathrm{Y} \mid \mathrm{X})\) and \(P(\mathrm{Y} \mid \neg \mathrm{X})\). The difference between \(P(\mathrm{Y} \mid \mathrm{X})\) and \(P(\mathrm{Y} \mid \neg \mathrm{X})\) for each condition yielded five levels of nonnegative \(\Delta P\) values (1.00, .75, .50, .25, .00). Each participant completed the causal learning task for all covariation conditions.
Instructions Participants received verbal and written instructions in Japanese, and were asked to confirm that they understood the instructions. An English translation of outlines of the instructions was provided below:

Imagine that you are a scientist attempting to reveal a causal relationship between two types of newly discovered bacteria (These bacteria have the same shapes but different colors to conjure up an image of cell divisions). The term "causal relationship" means a relationship where one bacterium propagates the other bacterium (i.e., generative causal relationship). It is unknown whether one bacterium propagates the other, or whether these bacteria are unrelated. To investigate the relationship between the bacteria, you are going to observe the appearance of the bacteria. The states of the bacteria should help you consider the causal relationship between them.

Your task is to observe the occurrences and nonoccurrences of these bacteria and to infer their causal relationship. Note that the experimental task does not require any knowledge of biology. (The remaining instructions describe how to progress through the learning phase and test phase.)

Learning Phase Participants observed the states of bacteria (present or absent) to infer their causal relationship. On each trial, a button labeled "NEXT" was displayed on the screen. After clicking the button, information about the states of both bacteria X and Y was provided. The presence of a
bacterium was indicated by the appearance of the bacterium; in contrast, the absence of a bacterium was represented by the appearance of the bacterium labeled with a cross mark. The screen was returned to its primary state (i.e., "NEXT") 1 s after the bacteria appeared.

There were 16 trials for each covariation condition. Bacterium X was present on eight trials and was absent on eight trials (i.e., \(P(\mathrm{X})=.50\) ). Two conditional probabilities, \(P(\mathrm{Y} \mid \mathrm{X})\) and \(P(\mathrm{Y} \mid \neg \mathrm{X})\), were set to one of five levels in each condition (Table 1) The difference between these probabilities yielded five levels of nonnegative \(\Delta P \mathrm{~s}(\Delta P=\) \(P(\mathrm{Y} \mid \mathrm{X})-P(\mathrm{Y} \mid \neg \mathrm{X})\) ). Each condition was described through the difference between the two conditional probabilities. For example, in the \(.75-.00\) condition (i.e., \(P(\mathrm{Y} \mid \mathrm{X})=.75\), \(P(\mathrm{Y} \mid \neg \mathrm{X})=.00\) ), bacteria X and Y were both present on six trials. Bacteria X and Y were both absent on eight trials, and on two trials bacterium X was present and bacterium Y was absent. The order of trials and conditions was randomized within participants. To familiarize participants with the procedure, several practice trials were performed prior to the learning phase. Participants were informed that the information in the practice trials was irrelevant to the learning phase.
Test Phase After observing 16 cases, participants were asked two yes/no questions about the causal structure. They were asked whether bacterium X caused bacterium Y , and whether bacterium Y caused bacterium X. Then, after a brief delay, participants began the learning and test phases for the next covariation condition. They were instructed that judgments should be made independently of their answers on prior problems.

\section*{Results and Discussion}

Combining the answers on the two test questions yields four types of causal models: (1) X causes Y, (2) Y causes X, (3)
bidirectional, and (4) independent. The percentage of responses in each condition is shown in Table 1. Although causal structure could not be uniquely determined in all conditions, participants' judgments varied greatly. A loglinear model analysis on the 15 (covariation conditions) \(\times 4\) (causal models) cross table revealed a significant interaction between covariation condition and causal model, \(\chi^{2}(42)=\) 291.37, \(p<.001\).

In order to explore the interaction between covariation information and causal judgments in greater detail, we conducted a correspondence analysis. The contributions of dimensions 1 and 2 are \(63.75 \%\) and \(20.29 \%\), respectively, and their cumulative contribution is \(84.05 \%\). Therefore, we created scatter plots in two dimensions (Figure 2). As can be seen from Figure 2, each judgment is closely related to specific conditions. Most participants concluded that X caused Y in the \(.25-.00, .50-.00\), and \(.75-.00\) conditions and that Y caused X in the \(1.00-1.00,1.00-.75,1.00-.50\), and 1.00-. 25 conditions. Bidirectional causal relationships were only inferred in the \(1.00-.00\) condition. X and Y were judged to be independent in the other conditions.

Participants' judgments are explained in terms of necessity of causation (cf. Pearl, 2000). Necessity represents the degree to which the cause is necessary for the effect; in contrast, sufficiency is the degree to which the cause is sufficient for the effect. Pearl (2000) introduced three indices that assess causality: the probability of necessity \((P N)\), the probability of sufficiency \((P S)\), and the probability of necessity and sufficiency ( \(P N S\) ). These indices are easily calculated when the covariation information given does not include both the case where the effect is present in the absence of the cause (i.e., cell b), and the case where the effect is absent despite the presence of the cause (i.e., cell c). There also cannot be any common factors that have an

\end{tabular}
influence on both events X and Y . Under these conditions, the probability of necessity, \(P N\), is calculated according to the following equation:
\[
\begin{equation*}
P N=\frac{P(Y \mid X)-P(Y \mid \neg X)}{P(Y \mid X)} \tag{2}
\end{equation*}
\]

When event X generates event Y (i.e., \(\Delta P>0\) ), values of \(P N\) become higher as the probability of Y given the absence of \(\mathrm{X}, P(\mathrm{Y} \mid \neg \mathrm{X})\), decreases. This reflects the fact that necessity of causation assumes that the base rate of the effect is low (i.e., \(P(\) Effect \(\mid \neg\) Cause \()=0)\). In contrast, the probability of sufficiency, \(P S\), is based on the assumption that causes always accompany their effects (i.e., \(P(\) Effect \(\mid\) Cause \()=1)\) and is defined as follows:
\[
\begin{equation*}
P S=\frac{P(Y \mid X)-P(Y \mid \neg X)}{1-P(Y \mid \neg X)} \tag{3}
\end{equation*}
\]

The probability of necessity and sufficiency, \(P N S\), takes both necessity and sufficiency aspects of causal relations into account:
\(P N S=P(Y \mid X)-P(Y \mid \neg X)\)

These indices are calculated on the basis of the causal direction from event X to event Y . Therefore, indices based on inverse direction are calculated by interchanging the rows and columns of the \(2 \times 2\) contingency table. When index values based on the direction from X to Y (e.g., \(P N\) from \(X\) to \(Y\) ) are compared with those based on the direction from Y to X (e.g., \(P N\) from Y to X ) and causal directionality is inferred by higher agreement with the conception (i.e., higher values), the three indices lead to different interpretations (see Table 1). For example, in

Figure 2: Results of correspondence analysis.
the \(.25-.00, .50-.00\), and \(.75-.00\) conditions, \(P N\) predicts that X causes Y. In contrast, in the 1.00-.75, 1.00-.50, and \(1.00-.25\) conditions, \(P N\) makes the opposite prediction. On the basis of responses in the conditions where the three indices are defined, we classified participants into one of five clusters: necessity, sufficiency, necessity and sufficiency, random, and unclassified. These classifications were made by rates of agreement between judgments and index predictions (1 for predicted judgments, 0 for unpredicted judgments). When participants had the same rate of agreement for different clusters, they were included in the unclassified cluster. As a result, more than half of the participants (55.81\%) were classified to the necessity cluster and \(27.91 \%\) of participants were classified in the sufficiency cluster. There were few participants in the other clusters \(\mathbf{~} 6.98 \%\) in the necessity and sufficiency cluster; \(2.33 \%\) in the random cluster; \(6.98 \%\) in the unclassified cluster). This suggests that most people interpret covariation information according to necessity.

However, these results are inconsistent with recent work suggesting that people judge causal relations on the basis of sufficiency (Mayrhofer \& Waldmann, 2011). Sufficiency of causation assumes that causal relations are deterministic (i.e., \(P(\) Effect \(\mid\) Cause \()=1\) ). According to sufficiency, the presence of event X in the absence of event Y is interpreted as an indication that X does not cause Y . Therefore, when covariation information includes such cases, it is suggested that Y causes X (i.e., \(\mathrm{X} \leftarrow \mathrm{Y}\) ). On the other hand, necessity of causation assumes that all events have a cause (i.e., \(P(\) Effect \(\mid \neg\) Cause \()=0)\) and such cases are taken as evidence that \(Y\) does not cause \(X\). In contrast to sufficiency, necessity indicates that X causes Y (i.e., \(\mathrm{X} \rightarrow \mathrm{Y}\) ) in the situation described above. Thus, judgments of causal directionality between two variables depend on the interpretation of covariation. In a second experiment, Mayrhofer and Waldmann (2011) had participants observe communications between two mind-reading aliens, and asked them to infer causal directionality. Covariation information included the case where two aliens X and Y thought the same thing, and the case where only one alien thought something (e.g., X) and the other alien thought nothing (e.g., \(\neg \mathrm{Y}\) ). Whereas sufficiency would suggest that alien Y transferred his thought to alien X (i.e., \(\mathrm{X} \leftarrow \mathrm{Y}\) ), necessity favors the opposite conclusion (i.e., \(\mathrm{X} \rightarrow \mathrm{Y}\) ). More participants concluded that \(Y\) caused X , suggesting that people judge causal relations on the basis of sufficiency.

These conflicting findings could be due to differences in prior knowledge about causal relations. Sufficiency of causation requires high causal strength, whereas necessity of causation requires the low base rate of the effect. If participants expect the effect's base rate to be low before the learning phase, covariation information is likely to be interpreted according to necessity. In contrast, prior knowledge about high causal strength might lead to an interpretation based on sufficiency. Indeed, it is difficult to imagine that the effect bacterium could occur in the absence of the cause bacterium in the bacteria story. That is,
participants will believe that bacteria do not arise spontaneously (i.e., \(P(\) Effect \(\mid \neg\) Cause \()=0\) ) and therefore, think the bacterium that exists alone must be a cause. In the alien story, however, such a situation is more plausible: an alien has the potential to think spontaneously, regardless of whether a cause alien is present (i.e., \(P(\) Effect \(\mid \neg\) Cause \()>0\) ). Participants will assume multiple causes in the alien cover story and regard the single-occurrence of the thought as an effect. Since necessity and sufficiency differ in their assumption about the base rate of effect and causal strength, differences in prior knowledge about these parameters might result in different judgments of causal structure based on covariation. We test this hypothesis in Experiment 2.

\section*{Experiment 2}

Experiment 1 demonstrated that participants made different judgments as a function of covariation. Whereas the results of Experiment 1 indicate that people interpret covariation information according to necessity of causation, Mayrhofer and Waldmann (2011) suggest that people interpret covariation according to sufficiency of causation. Experiment 2 was designed to investigate the effect of prior knowledge on interpretation of covariation information. The experimental procedure was similar to that of Experiment 1, but participants received different instructions about causal relations. We expected that additional instructions about high causal strength would lead to interpretations based on sufficiency of causation, and that participants who were not given additional instructions would infer causal structure according to necessity of causation.

\section*{Method}

Participants and Design Twenty-four undergraduates from Kwansei Gakuin University participated in the experiment and received course credit. None of them took part in Experiment 1. They were randomly assigned to either the sufficiency instruction or control group.
Procedure Each participant observed the states of bacteria (present or absent) and inferred their causal relationship. The procedure was the same as Experiment 1, with the following exceptions. First, participants in the sufficiency instruction group received additional instructions that emphasized the sufficiency of causation. In addition, to ensure that participants remembered this additional information, they were allowed to re-read the instructions during the learning and test phases. Finally, covariation information was manipulated within a context where
inferences could be uniquely identified as being made according to necessity or sufficiency.

In the instructions, the cover story was explained and participants were told to determine the causal relationship between two newly discovered bacteria. For participants in the sufficiency instruction group, instructions stated that the cause bacterium always accompanied the effect bacterium when one bacterium propagates the other bacterium (i.e., \(P(\) Effect \(\mid\) Cause \()=1)\), and that there are other causes in the environment that can produce the bacteria (i.e., \(P(\) Effect \(\mid \neg\) Cause \()>0)\). This information was not provided for participants in the control group.

In the learning phase, participants observed the states of bacteria on 16 trials. Six covariation conditions (.25-.00, . 50-. \(00, .75-.00,1.00-.75,1.00-.50\), and \(1.00-.25\) ) were used to determine whether participants interpreted covariation according to necessity ( \(P N\) ) or sufficiency ( \(P S\) ). Participants performed each condition twice in order to counterbalance the role of bacteria.

In the test phase, participants were told to judge the causal relationship in the same way as in Experiment 1. After a brief delay, participants completed the learning and test phases for the next condition. They were instructed that judgments should be made independently of their answers on prior problems.

\section*{Results and Discussion}

Participants' responses were analyzed in a manner similar to Experiment 1. First, judgments were categorized as one of four types of causal models. Next, we classified participants into one of five clusters (i.e., necessity, sufficiency, necessity and sufficiency, random, and unclassified) according to whether their judgments were predicted by \(P N, P S\), or \(P N S\). Table 2 shows the number of participants assigned to each cluster. Participants in the sufficiency instruction group were largely divided into the necessity cluster and sufficiency cluster. In contrast, almost all participants in the control group were assigned to the necessity cluster, replicating Experiment 1 where the majority of participants interpreted covariation on the basis of necessity. Fisher's exact test confirmed that there were significantly more judgments according to sufficiency of causation for participants in the sufficiency instruction group than the control group ( \(p<.05\) ). Although some participants still interpreted covariation according to necessity, these results indicate that prior knowledge modulated the interpretation of covariation information.

In summary, Experiment 2 showed that judgments of

Table 2: Number of participants assigned to each cluster in Experiment 2
\begin{tabular}{cccccc}
\hline & Necessity & Sufficiency & \begin{tabular}{c} 
Necessity and \\
Sufficiency
\end{tabular} & Random & Unclassified \\
\hline Sufficiency instruction & 4 & 6 & 0 & 1 & 1 \\
Group & 10 & 1 & 0 & 0 & 1 \\
\hline Control group & & & & & \\
\hline
\end{tabular}
causal structure were largely affected by prior knowledge about causal relations. When participants were informed about high causal strength, they were more likely to infer causal directionality on the basis of sufficiency; in contrast, participants not given additional instructions always judged causal structure according to necessity. These results bridge the gap between the results showing that judgments of causal structure are based on necessity (Experiment 1) and those showing that judgments of causal structure are based on sufficiency (Mayrhofer \& Waldmann, 2011).

\section*{General Discussion}

Recent studies have shown that people use covariation to infer causal directionality. However, there is little information about how people infer causal directionality from covariation. The present study was designed to investigate how people make causal structure judgments on the basis of covariation. Experiment 1 demonstrated that judgments of causal structure vary as a function of covariation, and that participants' answers can be explained in terms of necessity of causation. Experiment 2 showed that prior knowledge about high causal strength led more participants to interpret covariation according to sufficiency. The results of Experiment 2 are consistent with both findings concerning necessity interpretation of covariation (Experiment 1) and sufficiency interpretation of covariation (Mayrhofer \& Waldmann, 2011). These results reveal the importance of interpretations of covariation information in causal structure learning.

The results of the present study are closely related to the finding that learners flexibly interpret covariation during causal learning (Luhmann \& Ahn, 2011). Luhmann and Ahn (2011) asked participants whether they interpreted single pieces of covariation information as evidence of generative or preventive causal relations. The results showed that observations from Cell A can be interpreted as evidence for either a generative or preventive causal relation. These studies share the view that covariation information is flexibly interpreted, but focus on different aspects of causal learning. Whereas Luhmann and Ahn (2011) focused on learning causal strength, the present study addressed learning causal structure. An intriguing question for future research is to ask participants whether they interpret covariation as evidence for X causes Y or Y causes X .

The difference between a necessity interpretation of covariation in the bacteria story (Experiment 1) and a sufficiency interpretation in the mind-reading aliens story (Mayrhofer \& Waldmann, 2011) can be regarded as an interaction between domain-general causal inference and domain-specific knowledge. Whereas covariation is thought to be domain-general information, prior knowledge about causal relations seems to differ between the two stories. The results of Experiment 2 demonstrate that the basis for interpreting covariation can change from necessity to sufficiency when information about high causal strength is provided, but it remains unknown whether there are conditions that will change participants' basis for
interpretation from sufficiency to necessity. Another key question for future research is to investigate whether information about low base rate of the effect encourages a necessity interpretation of covariation in the mind-reading aliens cover story. Future research will provide further evidence about interactions between domain-general covariation and domain-specific prior knowledge.

\begin{abstract}
In this paper we investigate the effect of power on prosocial decision-making. While previous research has thoroughly investigated this relation in Western cultures, we focus our research on the role of power in an understudied MiddleEastern culture. Existing literature suggest an inverse relationship between feeling of power and prosocial behavior, where generally people in high levels of power tend to act less sympathetically in their decisions and demonstrate declined levels of perspective taking towards others. Our findings demonstrate that, unlike their Western counterparts, Iranian participants show significantly higher levels of altruism when in a high-power situation perceived as legitimate. On the other hand, under illegitimate power conditions, participants primed with high-power act significantly less compassionately in comparison to their low-power counterparts. We believe these findings have great impact in studying social hierarchies and behavior in cross-cultural settings.
\end{abstract}

Keywords: altruism; power prime; social hierarchy; decisionmaking; cross-cultural differences

\section*{Introduction}

The beloved of the Almighty are the rich who have the humility of the poor, and the poor who have the magnanimity of the rich.
-Saadi, \(13^{\text {th }}\) century Persian poet
Persian literature comprises a rich collection of myths, stories, and poems praising altruism and courtesy, especially among the powerful. Iranian children are encultured with stories, in which great kings and leaders are portrayed as generous, altruistic individuals. Such cultural products, created over generations, store and transmit cultural wisdom, and affect different aspects of people's judgment and decision-making (Weber, Hsee \& Sokolowska, 1998). Although the Iranian society has undergone a vast amount of societal change over the past decades, aspects of deeper cultural behavior have been transmitted through such cultural products, as tangible and public representations of the Iranian culture (Javidan \& Dastmalchian, 2003).

Several lines of research associate power with selfinterested behavior; linking it to lack of perspective taking (Galinsky, Magee, Inesi \& Gruenfeld, 2006), egoism (Batson, 1991) and moral reasoning (Lammers, Stapel \& Galinsky, 2010), among others. However, we argue that many of these findings are based on Western cultures,
relying on WEIRD populations (Henrich, Heine \& Norenzayan, 2010). It has been widely discussed that many models and theories of decision-making are based on cultural assumptions and may not be universally applicable (e.g. Dastmalchian, Javidan \& Alam, 2001; Jones, 2010; Henrich, et al., 2010; Hofstede, 1980). Arnett (2008) argues that the majority of psychological research focuses on American subjects, thus, neglecting \(95 \%\) of the world's population, a majority of whom live in vastly different societies. Further, limiting psychological models to small populations not only restricts the range that predictor variables can take, but also affectively limits discovery of other variables not yet included in the model (Weber \& Hsee, 2000).

In this study, we explore how power is associated with altruistic and sympathetic behavior among Iranians. Specifically, we aim to understand how legitimate as opposed to illegitimate feeling of power may affect prosocial decision-making. In other words, not only when, but also why do "the rich have the humility of the poor"?

\section*{Theories of Power}

In the study of social relationships, power is often referred to as the fundamental concept and basic force of behavior (Fiske, 1993; Kemper, 1991). Power is also closely related to the structures of personality (Wiggins \& Broughton, 1985). Thus, a wide range of research has focused on understanding how power influences various aspects of cognition, such as stereotyping (Fiske, 1993), social decision making (Gruenfeld, 1995), and perspective taking (Galinsky et al., 2006).

It has been widely argued that feeling of power results in displaying self-centered attitudes towards others, causing declined levels of perspective taking (Galinsky et al, 2006) and altruism (Batson, 1991). For example, in a recent study, Galinsky et al. (2006) asked participants under a high- or low-power experimental prime to draw an \(E\) on their foreheads - a procedure created by Hass (1984) to measure visual perspective taking of others. One way to draw the \(E\) is to consider one's own perspective, resulting in a backwards \(E\) illegible to other viewers. The other way is to consider others' perspective and draw an \(E\) backwards to oneself. They report that high-power participants were almost three times more likely to draw a self-oriented \(E\) than their low-power counterparts. Power is also linked to moral
hypocrisy, a situation of imposing firm moral standards on others, while practicing more tolerant moral standards oneself (Lammers, Stapel \& Galinsky, 2010).

The Power-Approach theory (Keltner, Gruenfeld \& Anderson, 2003) suggests that power increases goal-directed behavior without conscious awareness of its effects. This increase results in the powerful having a higher tendency to act and approach (Anderson \& Berdahl, 2002; Galinsky, Gruenfeld \& Magee, 2003). Correspondingly, in the context of decision-making and negotiations, the powerful are known to display higher aspirations (Pinkley, 1995), demand more and concede less (De Dreu, 1995), and often end up with the larger share of the pie in negotiations (Giebels, De Dreu \& Van de Vliert, 2000). On the other hand, powerlessness has been reported to activate the behavioral inhibition system (Carver \& White, 1994).

Further studies have shown that the link between power and goal-directed behavior is not always such straightforward. In fact, illegitimacy of the power involved may break this link (Lammers, Galinsky, Gordijn \& Otten, 2008a). Investigating the role of legitimacy of power, Lammers et al. (2008a) assigned participants to one of four cells in a 2 (powerless, powerful) \(\times 2\) (legitimate, illegitimate) between-participant design. Participants were primed using an essay task developed by Galinsky et al. (2003), where they were randomly assigned to one of four tasks and asked to recall and write about a situation of highor low-power under legitimate or illegitimate conditions. Participants were then asked to fill out a questioner assessing their behavioral activation/inhibition.

The authors report that under legitimate power conditions, the powerful had higher levels of behavioral activation than did the powerless. That is, under legitimate conditions, "the powerful act while the powerless follow" (Lammers et al., 2008b). However, these trends were reversed in illegitimate power conditions: among participants whose sense of power was illegitimate, low-power led to higher behavioral activation than high-power. In other words, it has been argued that power hierarchies, known to be based on mutual cooperation (Arendt, 1970), may switch to force and resistance when power is perceived as illegitimate (Lenski, 1966; Mills, 2000). Therefore, when studying the behavioral effects of power, legitimacy of the power must be considered. As previously mentioned, we argue that most of the studies on power have been conducted in Western cultures and the results may not generalize to all cultures.

\section*{Power Distance in Iran}

To shed light on the relation between power and culture, we rely on two of Hofstede's (1983) cultural dimensions directly related to pro-social behavior: Power Distance and Individualism.

In every society, there are strong forces that maintain and extend existing inequalities. The Power Distance Index measures the extent to which members of society accept these inequalities and allow them to grow (Hofstede, 1983). Hofstede argues that the power distance is supported by the
social environment, culture, and both high and low power members of the society (Hofstede, 2001). Iranians score high on the Power Distance Index (Hofstede, 2001), meaning that people tend to accept a hierarchical order and respect power inequalities.

The Individualism index is a cultural dimension that determines the relation between an individual and other members of society. In countries that score high on the individualistic scale members are expected to look after themselves, whereas in more collectivist countries, members consider themselves as members of a group and work towards fulfilling goals of the group (Hofstede, 1983). A low score in the Individualism index defines Iran as a collectivistic society indicating that people often consider themselves committed to a group, be that their family, friends, or extended relationships. In such a society loyalty to the group is principal and often overrides other social guidelines (Hofstede, 1983).

Another study by Dastmalchian et al. (2001) shows similar results about power and individualism in the Iranian society. This study was conducted as part of the GLOBE project concerning leadership attributions and cultural factors (House, Javidan \& Dorfman, 2001). Cultural dimensions of this study are extensions to those defined by Hofstede (1980). Societal collectivism is defined as "the degree to which organizational and societal institutional practices encourage and reward collective distribution of resources and collective action". Accordingly, in-group collectivism refers to "the degree to which individuals express pride, loyalty, and cohesiveness in their organizations or families" (House et al., 2001). Power distance is measured similar to Hofstede's definition. Results show that Iranians tend to have relatively high levels of power distance ( \(14^{\text {th }}\) out of 61 countries examined) and in-group collectivism ( \(3^{\text {rd }}\) out of 61), whereas fairly low levels (13 \({ }^{\text {th }}\) lowest country) of societal collectivism (Dastmalchian, et al., 2001).

Both studies share a common theme; the Iranian society is reported to have high levels of power distance and collectivism; in other words, a society of strongly accepted social hierarchies where high levels of collectivism are reported when members consider others as in-groups, but show highly individualistic behaviors when others are considered out of their "group". Javidan and Dastmalchian (2003) relate this to the structure of families in Iran, where the father has nearly total power in the family and children are taught from an early age to respect and obey those in position of authority such as their teachers. Due to the strength of families and group structures, behavior is determined by whether others are considered part of the ingroup or not.

\section*{Experiment}

In this experiment, we investigate the extent to which power affects altruistic behavior among Iranians. Previous studies in Western cultures have shown that the powerful demand more and display more act and approach than the powerless,
when power was primed to be legitimate. Whereas, when illegitimate power conditions were experienced, the powerless displayed even more approach than the powerful (Lammers, et al., 2008a). We investigate the interplay between the feeling of low or high power and the perception of legitimacy of that power among Iranian participants in the Dictator's game (Bolton, Katok \& Zwick, 1998) described below. Before we discuss the Dictator's game, we layout our three main hypothesis.

In our experiment, participants were asked to recall an experience where they were in a low- or high-power position; the legitimacy of the power involved was left for participants to decide. Through this we achieved a number of goals: before and during the priming stage participants were unaware of the means of the study and that legitimacy was a factor of the study, thus causing less biased responses. Further, by allowing participants to choose the situation they write about, we were able to measure the frequency of each class of responses. Therefore, we manipulated power status and left the legitimacy to be chosen and decided about by the participant. Accordingly, we study how Iranian participants self-assess the legitimacy of their power. Some scholars have linked power to moral hypocrisy, a situation where one imposes stricter moral standards to others than oneself (Lammers, et al., 2010). On the same track we believe that more people in the high-power prime will selfevaluate their actions as legitimate, than their low power counterparts.

H1: Participants under the high-power prime will have a higher tendency to self-evaluate their power as legitimate.

In collectivist societies, for those who are considered members of the in-group, very high levels of support, altruism and consideration are shown (Hofstede, 1983). This relation especially holds between older and younger members of the group, mainly due to the fact that older members are associated higher levels of power and authority (Javidan, et al., 2003). Accordingly, while high-power members, are highly respected and obeyed, they provide support and caring for others. Javidan and Dastmalchian (2003) also report a high level of desire for generosity and compassion among Iranian managers, a desire that they believe is rooted in the strong culture of family/group collectivism as well as Islamic principles. A view that the powerful should treat subordinates kindly (as their brothers and sisters) is also highly valued in Islamic teachings (Latifi, 1997). The difference between power-classes are exaggerated by the high power distance level in the Iranian society.

On the other hand, Lammers et al. (2008a) demonstrate that conceptualization of power determines its psychological consequences and provides insight into the tendency to approach. Relying on these facts, we hypothesize that, unlike their Western counterparts, when Iranian participants evaluate the power involved in their power prime as legitimate, they will show high levels of generosity and
support towards other participants as they feel a sense of obligation to provide support to the powerless.

H2: Under legitimate power conditions, high-power participants will demand less and show higher levels of altruism compared to low-power participants, as opposed to in illegitimate power conditions.

Parallel to the above reasoning, we predict that low-power subjects will expect to receive support and consideration from (high-power) others when their sense of power is perceived as legitimate.

H3: Low-power participants who view the power involved in their situation as legitimate will demand more than lowpower participants viewing the power as illegitimate.

This pattern is consistent, but opposite of the reported findings by Lammers, et al., (2008) who show an inverse relation between power and approach when power is perceived as illegitimate. We hypothesize that among Iranian participants, legitimate high power will result in higher concessions than legitimate low power, and the reverse will be resulted for illegitimate power conditions.

\section*{Method}

Participants. Fifty-two undergraduate students at Sharif University of Technology (24 female, mean age= 21.1) participated in this study. Each participant was ran in a separate session. In return for their participation, they received 4000 Tomans and chance to enter a raffle (play the Dictator's game, explained below).

Design. The study employed a \(2 \times 2\) between subject design. The first factor was the power prime (high-power or low-power). The second factor was perceived legitimacy of power (legitimate or illegitimate). The dependent variable was the amount of money taken by the participant in the Dictator's game.

\section*{Procedure}

Priming Stage. Participants were given a high- or a lowpower experiential prime, proven to reliably manipulate the sense of power (Galinsky et al., 2003). Participants were unaware of the aim of the experiment and were told that their essays will be used in a natural language processing project. Those assigned to the high-power condition were instructed to recall a personal incident in which they had power over other individuals, they were asked to write a short essay (in Persian) explaining both the incident and how they felt at that moment. Participants assigned to the low-power condition were similarly instructed to write about a personal incident in which someone else had power over them. A short definition of power was included in the instructions as having the ability to control and influence someone else or being in a position to evaluate them (Galinsky, et al., 2006). After writing the essay, both groups
were asked to evaluate the degree of the legitimacy of the power in the situation they had written about. Specifically, they were asked whether they believed that they were entitled to that powerful or powerless position both lawfully and morally. After completing the power-priming task, the experimenter thanked participants and they were paid 4,000 Tomans. After this stage participants were asked to participate in a raffle as part of the compensation. The raffle was an altered version of the Dictator's game.

The Dictator's Game. The Dictator's game (Bolton et al., 1998) is a commonly used game for evaluating levels of altruism and prosocial behavior. In the standard form of the dictator's game, one player (the dictator) is asked to share a fixed amount of money between himself and another participant (the receiver), while both players remain anonymous. According to economic models of decisionmaking, rational players are expected to maximize their personal benefit. Thus, the dictator should take all the money, leaving nothing for the receiver. Many studies, however, have shown that dictators give between \(20 \%-30 \%\) of the money to the unknown receiver (e.g. Camerer, 2011).
For this experiment, we developed a variation of the Dictator's game. As previously mentioned, in the standard form of the game, the dictator is asked to share a fixed amount of money between himself and the receiver. Due to the design of our experiment, we needed all participants to perform the role of the dictator. Hence, participants were instructed to take as much of the money as they want, leaving the rest for future unknown participants. Specifically, in our experiment, subjects were told that they had a chance to participate in a raffle. Each participant was then presented with 5 envelopes that were shuffled in front of her. While the participant did not know how much money was in the envelopes, each contained 10,000 Tomans, in 1,000 Toman bills. Participants were then asked to choose an envelope and take as much money as they want from it. They were told, however, that the same envelopes were to be used for future (unknown) participants; thus, any amount of money they leave in the envelope will be offered to future subjects who choose that same envelope in the raffle. Participants were given complete privacy to take as much of the money as they want. After each session, participants were paid and briefed about the experiment. Then, the envelope chosen by the participant was marked with the participant's ID and put aside. The money taken from the envelopes were used as the main dependent variable in our experiment.

\section*{Results}

\section*{Perceived Legitimacy of Power}

During the power priming task participants were only instructed to write an assay about a high- or a low-power situation. In this stage nothing was mentioned about the legitimacy of the power involved. After finishing the essay participants were asked to evaluate the power involved in their situation as legitimate or illegitimate. Our findings
show that the state of power had a great impact on this evaluation.
As shown in Figure 1 and consistent with \(H 1\), we found that \(78 \%\) of participants ( \(22 / 28\) ) under a high power prime evaluated their power as legitimate, compared to \(33 \%\) of participants ( \(8 / 24\) ) under a low power prime. The difference between these conditions were significant \(\chi^{2}(1, N=52)=\) \(9.061, p=.003\). In other words, \(67 \%\) of participants reported a sense of injustice when asked to recall a situation of low-power.

Figure 1: Self-evaluation of legitimacy among participants.

\section*{Altruism}

The level of altruism among participants was calculated by the amount of money left in the raffle envelope during the Dictator's game. This is the amount of money that participants decided to leave for future participants. We measured the amount of money taken from the envelope as a numerical indicator of selfishness. In seven cases this number was negative, indicating that participants had left some of the earlier reward money ( 4,000 Tomans) as well as the money already in the envelope for the next person (note that participants viewed the Dictator's game as part of the compensation). Figure 2 displays the average amount of money taken by participants.
Using the amount of money taken as a dependent variable in a \(2 \times 2\) ANOVA, with power (low/high) as the first factor and legitimacy (legitimate/illegitimate) as the second, revealed a significant interaction between power and perceived legitimacy of power \(F(1,48)=7.652, p=.008\).

Under power conditions perceived as legitimate, highpower participants took significantly less money in the Dictator's game ( \(M=2.63, S D=0.91\) ), than low-power participants \((M=6.25, S D=1.22) t(28)=2.14, p=.042\). Thus, supporting \(H 2\), our results demonstrate high levels of altruism among the legitimate powerful and naturally higher
demands from the legitimate powerless, who expect to be supported.

When power was perceived as illegitimate, there was significant difference in the amount of money taken by the high-power ( \(M=5, S D=1.36\) ) as opposed to the low-power ( \(M=2, S D=0.81\) ) participants \(t(20)=1.91, p=.071\). Thus, supporting the second part of \(H 2\), the illegitimate powerful display declined levels of altruism and more approach, whereas the illegitimate powerless demand less.

Also, there was a significant difference between lowpower legitimate and low-power illegitimate conditions \(t(22)=2.950, p=0.007\), with participants in low-power legitimate conditions taking significantly more money than those in the low-power illegitimate condition. This result supports \(H 3\).

Figure 2: Average money taken in the Dictator's game.

\section*{Discussion}

Overall, our results show significantly different patterns than those in similar studies performed among Western participants. Iranian participants relating a situation of highpower, most often found their power to be legitimate. Some participants even used expressions such as "even though others might think what I did wasn't just, I still believe I did what was right". Our results show a consistent pattern, suggesting people often find a way to justify their actions when they stand in a high-power position. Such a claim confirms previous studies showing higher levels of moral hypocrisy among high-power individuals (Lammers, et al., 2010). On the other hand, as previously discussed, most participants under a low-power prime reported the power involved as illegitimate. For example, essays written by this class of participants included expressions such as "He had no right to do that" or "their actions were purely selfish even though they had the legal right". In this case our findings contradict prior studies on Western cultures claiming: "decreased power, results in people being less
critical on others and more critical on the self" (Lammers et al., 2010). In other words, low-power situations tend to make Iranian individuals highly critical on the holder of power, often resulting in the powerful being perceived as illegitimate.
One possible explanation for our results, relying on previously proposed features of collectivism amongst Iranians, is that when participants evaluate the power involved in their power prime as legitimate, they are naturally considering others as their in-group. In these circumstances, due to their high levels of collectivism, they become more altruistic. However, when under an illegitimate power prime, others are spontaneously considered as out-groups. In other words, inside the group, and where power is perceived as legitimate, the powerless are supported and show higher levels of approach and demand. On the other hand, when power is distributed illegitimately, others are viewed as outside the social group, the powerless fail to demand, and fall into an oppressed state similar to social inhibition described by Carver and White (1994). Our results show that in this case, legitimacy has such an effect that people experiencing a state of illegitimate low-power demand less than \(1 / 3\) of people in a similar low-power situation but who feel legitimacy in the state. In our future experiments, we plan to explore the interplay between power and in-group/out-group behavior.
Shedding light on the origins of the relation between altruism and high-power behavior among Iranians, begs a deeper discussion of religious and cultural settings. A view that the powerful should treat subordinates kindly (as their brothers and sisters) is highly valued in Islamic teachings (Latifi, 1997). Moreover, some studies suggest that Iranians commonly view their superiors in the same light as their older siblings or parents, describing the relationship between an employee and supervisor close to that of family members; therefore, managers are often expected to show support, generosity and compassion towards subordinates (Latifi, 1997; Tayeb, 1997; Javidan, et al. 2003). A high score on the power distance index further enhances this effect as social hierarchies are mutually accepted and practiced from an early age. Thus, their properties become deep aspects of social behavior.
One must take into account that the question of whether generosity is a pure act or has underlying selfish motives remains an open question. For example, various studies argue that some of the giving is due to the fact that the dictator does not want to seem selfish to the anonymous receivers (Dana, Cain, \& Dawes, 2006). In this study, we have not addressed this question; rather, we consider how altruistic behaviors are practiced in the society regardless of fundamental motives. We plan to address such issues in future studies.

\begin{abstract}
Past studies have indicated that intonation, in the sense of fundamental frequency modulation, can only enhance serial recall to the extent that it can induce a grouping effect, something that can also be induced by a simple insertion of pauses. However, in a study of spoken serial recall of ninedigit lists, we are able to show that recall is significantly better when sequences of digits are marked by specific intonation contours than when they are simply grouped by silent pauses in the signal. Thus, we found that intonation plays a role during the encoding phase, whereby items in group-final positions draw particular benefit from intonation. However, intonation does not appear to play the same role in the retrieval phase, since when subjects are instructed to imitate intonation during recall, performance shows mixed effects.
\end{abstract}

Keywords: serial recall; intonation; grouping effect; shortterm memory

\section*{Introduction}

In field research, there is a general consensus that serial recall (short-term memory in general) and prosody are closely related. Well-documented evidence of such a relationship is the grouping effect, that is, the enhanced recall of items in a list when they are presented in groups (for example, Reeves et al 2000). The grouping effect is stronger for auditory stimuli (Cowan et al 2002, Frankish 1985), as prosody plays an important role in this grouping, or patterning. Past and more recent research has aimed to ascertain the nature of these groups. In their seminal work on the auditory grouping effect, Frankish (1995) and Saito (1998) provided evidence that it can be obtained by temporal organisation of speech stimuli realised by pause insertion between groups as well as by superimposing a "natural" intonational pattern, or by manipulating pitch levels on groups of items (Frankish 1995). On the other hand, more recent studies have shown that the grouping effect in serial recall reflects rhythmic groups, referred to as the stress grouping effect, rather than intonational phrases (Reeves et al 2000, Boucher 2006, Gilbert \& Boucher 2007). It is argued that these groups correspond to the
segmentation units (chunks) listeners use in spoken language perception (Gilbert et al 2011).
Previous research dealing specifically with the role of intonation in improving serial recall suggests that it is relevant to the extent that it can induce a similar grouping effect to that obtained by pause insertion (Frankish 1995, Saito 1998). However, a number of potentially relevant aspects of intonation deserve further exploration. For instance, in the previous studies discussed above, the superimposition of a fundamental frequency (F0) contour \({ }^{1}\) on the whole sequence, or F0 manipulation on groups of items within a sequence were carried out with little control over specific tunes and their associated meanings. This is particularly relevant, since the role of intonation in signalling discourse structure is widely acknowledged, as it cues hierarchical relationships among phrases within a discourse unit (Hirschberg \& Pierrehumbert 1986). Moreover, in sequences intonation can convey information about the hierarchical structure (groups) as well as about specific positions within a group. In Italian (in particular the variety of Bari), a rich inventory of tunes is available for marking those kinds of hierarchical relationships in a sequence (Savino 2001; 2004), among which the most typical are:
- The "continuation rise" contour, a gradually rising F0 movement from the nuclear syllable up to the end of the phrase. It signals that the list has not been completed yet, and that more items are to come ("non-finality" contour);
- A high rising contour, where the rise in F0 starts before the nuclear syllable and continues rising up to the end of the phrase. It conveys the information that the current item is the penultimate in a sequence, i.e. that the end of the list is approaching ("pre-finality" contour");
- A falling contour, involving a gradual fall from the nuclear syllable until the end of the phrase. This contour marks the end of a sequence ("finality" contour).
Our aim here is to verify whether the use of specific tunes conveying such hierarchical relationships and positional

\footnotetext{
\({ }^{1}\) The F0 contour corresponds roughly to what is perceived as the pitch, or melody.
}
information within a sequence could improve immediate serial recall performance of auditory stimuli in (Bari) Italian listeners.
Another positive effect in serial recall performance reported in the literature is the salience effect. It "occurs when an item that is conspicuous on some perceptual dimension is recalled better than other items in the same ensemble in learning and memory tasks" (Reeves et al 2000: 1639). In this paper we also explore the role of pitch prominence in within-group (medial) positions in the sequence as another potential factor in serial recall enhancement.
Moreover, we evaluate whether intonation plays a specific role not only in encoding but also in retrieval of phrases, i.e. whether performance is improved when listeners imitate the tune of the input stimuli during recall.

\section*{Method and Materials}

\section*{Intonational Patterns}

In order to investigate the role of specific tunes in serial recall, we identified two intonational patterns (we called 'intonation contour A' and 'intonation contour B') characterised by F0 shapes conveying hierarchical organisation of groups, as well as positional information of items across and within groups. In a nine-digit sequence, we determined:
- 'Intonation contour A', consisting of the "continuation rise" ("non-final") contour at positions 3 and 6, and a lowfalling ("final") contour at position 9. F0 shapes of items at initial and within-group positions (positions \(2,5,7,8\) ) are not positionally marked by intonation, as they are characterised by a peak accent (taken to be the neutral unmarked pattern).
A schematisation of intonation contour A is shown in Figure 1;
- 'Intonation contour B', sharing the same intonational patterns of 'intonation contour A', except for a steep rising pitch accent at positions 2 and 5 . It can pre-signal the end of the first and the second groups, i.e. the two non-final groups within the signal. Also, because of the steep rising accentual movement, these digits sound perceptually more salient than the corresponding positions 2 and 5 in intonation contour A, where they are marked by a (neutral) peak accent instead. Another feature of contour B is a high rising ("pre-final") contour at position 8 pre-signalling both the end of the third group and the end of the whole sequence.
A schematisation of 'intonation contour B' is given in Figure 2.
These two experimental conditions were compared with two further ones, namely:
- 'Grouped by pauses' sequences, where all digits have a peak contour, and sequences are temporally grouped into three by inserting a pause at the end of each group;
- 'Ungrouped' sequences, sharing the same intonation of the 'grouped by pauses' stimuli above, but without pause grouping.
We hypothesise that serial recall performance would be
(H1) better in both intonation contours A and B and the 'grouped by pauses' conditions than in the 'ungrouped' (control) condition, due to the grouping effect;
(H2) better in both 'contour A' and 'contour B' than in the 'grouped by pauses' condition, because of the absence of intonational marking of item position in the latter condition. In particular, items in positions 3 (non-final contour=last item in the first group), 6 (non-final contour=last item in the second group), and 9 (final contour=last item in the third group and in the whole sequence) should benefit in terms of recall enhancement.
(H3) better with 'intonation contour B' than 'intonation contour A' because of the enhanced hierarchical and positional information conveyed by intonation in certain positions, namely: digits at positions 2 (pre-final contour \(=\) item at mid position in the first group), 5 (pre-final contour \(=\) item at mid position in the medial group), and 8 (pre-final contour \(=\) penultimate item in the whole sequence) This should result in an overall better recall performance of 'intonation contour B' than of 'intonation contour A' sequences.
Moreover, we hypothesise that recall performance in both intonation conditions
(H4) would be enhanced for subjects who are instructed to imitate the intonation produced in the stimuli during the recall task. This would provide some evidence that intonation plays a relevant role not only in encoding but also in retrieval of verbal material.
Our hypotheses can be summarized as follows:
Contour \(B>\) Contour \(A>\) Grouped by pauses \(>\) Ungrouped on the one hand, and Imitation > No imitation on the other.

Figure 1: Schematisation of "intonation contour A"

Figure 2: Schematisation of "intonation contour B"

\section*{Stimuli}

The sequences were created according to the four conditions ('ungrouped', 'grouped with pauses', 'intonation contour A', 'intonation contour B'), three types of spoken stimuli for each digit were created:
Type (a), where each digit was realised with a neutral F0 peak, as, for example, in digit position 1 in contours A and B (see schematisation in Figures 1-2).
Type (b), where sequences were realised with intonation contour A described above (see Figure 1)
Type (c), where sequences were produced with intonation contour B described above (see Figure 2)

All series for each of the digits were produced by a trained native speaker of Bari Italian (author MS) in the same recording session. In this way, for each digit all intonational realisations in each position (first, second, third, etc.) within each sequence type were available. They were saved as individual audio files, and used as "building blocks" for creating all the nine-digit spoken sequences under the 4 conditions. Stimuli were created by concatenating the individual audio files into nine-digit sequences. In a postediting step, care was taken that speech signal amplitude was homogeneous in all sequences.
This methodology enabled us to create stimuli which sound more natural than those produced by means of a speech synthesiser, as in Frankish (1995).
Spoken digit realisations of type (a) were used for creating sequences for the conditions 'ungrouped', and 'grouped by pauses', in the latter case by inserting a 310 ms silence after digits in positions 3 and 6 . Spoken digit renditions of the types (b) and (c) were used for creating sequences under the conditions 'intonation contour A' and 'intonation contour B', respectively.
We created 68 nine-digit lists from pseudo-random permutation of the 1-9 digits, in a way to avoid the presence of two adjacent digits in ascending or descending order, and to make sure that a digit would not appear in the same position in consecutive lists.
The concatenated nine-digit sequences were created on the basis of these lists, the duration of each sequence averaging 6.4 sec. We produced 17 stimuli for each of the four conditions, for a total amount of 68 stimuli (including 8 to be used for the training session only, 2 per condition).
All steps for the preparation of stimuli were carried out using the Praat software tool for speech analysis (Boersma \& Weenink 2001). Examples of a sequence (speech waveform and F0 contour) for each of the four conditions are shown in Figures 3-6.

\section*{Informants}

Fifty-six subjects participated in the experiment. They were undergraduate and graduate students of Psychology at the University of Bari (average age: 23.6), with no reported speech or hearing deficits. They were all native speakers of Italian, born and living in the Bari geolinguistic area. None of them had a background in phonetics or prosody.

\section*{Procedure}

Participants was tested individually in a laboratory. They were asked to listen to each sequence and recall all nine digits orally by strictly observing their serial order. Half of them were also instructed to imitate the intonation of the sequence during the recall.
Subjects were seated in front of a computer and wore a headset with headphones and microphone. Each list was preceded by a warning tone and 500 ms silence. Spoken responses were recorded directly and subjects proceeded to the next sequence by pressing the spacebar. They were also
free to take a break any time they needed during the session. A break was suggested after every block of 15 stimuli.
For each subject, the task involved recalling 60 stimuli (preceded by a short training session) i.e. 15 stimuli for each of the four conditions. The order of presentation was balanced across the subjects.
Before starting the experimental trial, participants were tested for their digit span of the WAIS-R (Wechsler 1987). This step was carried out in order to ascertain that the digit span of subjects was homogeneous across groups.
The average total duration of sessions (including the digit span test) was around 40 min . Sessions were implemented and run using SuperLab 2.0.

Figure 3: Speech waveform and F0 contour of one of the stimuli for the 'ungrouped' (control) condition.

Figure 4: Speech waveform and F0 contour of one of the stimuli for the 'grouped by pauses' condition. Vertical broken lines mark silence intervals (pauses) between groups.

Figure 5: Speech waveform and F0 contour of one of the stimuli for the 'intonation contour A' condition. Vertical broken lines mark the right edge of each group (intonational phrase)

\section*{Results and Discussion}

A mixed factors general linear model was performed with: 1) condition (within subject), 4 levels (ungrouped, grouped by pauses, intonation A , intonation B )
2) imitation of intonation (between subjects), 2 levels (yes, no)
3) serial group within the sequence (within subjects), 3 levels (first group, second group, third group)
4) within group position (within subjects), 3 levels (first position, second position, third position)
as factors.
First of all, a large effect of condition was found: F \((3 ; 159)\) \(=52.75 ; \mathrm{p}<0.001\); partial eta square \(=0.5\), performance percentages for each condition: ungrouped \(=52 \%\), grouped by pauses \(=64 \%\), intonation contour \(\mathrm{A}=70 \%\), intonation contour \(\mathrm{B}=69 \%\) ). These results are in line with our prediction in (H1), and confirm the typical grouping effect in immediate serial recall of prosodically manipulated auditory stimuli (Frankish 1995, Saito 1998).
Importantly, our hypothesis in (H2) is also verified, since results show a statistically significantly better recall performance for sequences with intonation contours A and B than for those grouped simply by pauses (post-hoc \(\mathrm{p}<0.01\) ). These results point to a specific role of intonation in serial recall that goes beyond the grouping effect induced by pauses, counter to the claims in previous studies.
We also found a significant second order interaction between condition, serial group and within-group position: \(\mathrm{F}(12 ; 636)=2.35 ; \mathrm{p}<0.01\); partial eta square \(=0.04\), with a moderate effect. Results (Figures 7-10) relating to positions in the first and second serial groups show a better performance for sequences realised with contours A and B, with respect to those grouped by pauses. The effect is particularly relevant for positions 3 and 6 (i.e. the last position in the first and second groups). This can be seen by comparing the "descending" shape of the correct response bars for groups 1 and 2 in the ungrouped condition (Figure 7), with the "dipped" shape for the same group in the remaining 3 conditions (Figures 8-10). The reverse tendency is evident for the third group, with an "ascending" shape in all conditions, pointing to an enhancement of the recency effect in all conditions.

Figure 7: Number of correct recalls (mean values) across the 3 serial groups in the sequence and the positions within each group (first POS, second POS, third POS), for the 'ungrouped' (control) condition.

Figure 8: Number of correct recalls (mean values) across the 3 serial groups in a sequence and the positions within each group (first POS, second POS, third POS), for the 'grouped by pauses' condition.

Figure 9: Number of correct recalls (mean values) across the 3 serial groups in a sequence and the positions within each group (first POS, second POS, third POS), for the 'intonation contour A' condition

Hypothesis (H3) is not confirmed by our results, as we did not obtain the expected specific effect in contour B for the second (pre-final) position within the serial groups (i.e. positions 2,5 and 8 within the sequence, where 8 is also the penultimate item position in the whole sequence).
For position 5 , the salience potentially conveyed by the steep rising pitch accent (compared to the "neutral" pitch peak in the same position in contour A) does not appear to improve recall of the medial item in a sequence.
With regard to Hypothesis H4, we did not find a main effect of the imitation of intonation, even though this factor interacts with a moderate effect with the serial groups: F (2; \(106)=5.82 ; p<0.01 ;\) partial eta square \(=0.1)\). Diagrams in

Figure 11 show that imitation of intonation improves the recall of the first group within a sequence, whereas performance decreases for the second and third serial groups. Thus, the imitation of intonation does not appear to facilitate recall, except for the digits in the first group, when the memory traces are stronger (as confirmed by low recency effects in our data).

Figure 10: Number of correct recalls (mean values) across the 3 serial groups in a sequence and the positions within each group (first POS, second POS, third POS), for the 'intonation contour B' condition

Figure 11: Number of correct recalls across the three serial groups as a function of instructions to imitate the intonation.

\section*{Conclusions}

The aim of our study was to ascertain whether the use of intonation patterns conveying hierarchical relationships among and within groups in a sequence could improve performance in an immediate serial recall task. Output
modality is oral channel, as in serial recall output modality can have a considerable influence in task performance (Penney 1979). Our results show that oral recall of spoken lists is better when auditory stimuli are intonationally marked by specific tunes than when they are simply temporally grouped by pauses. Some positions particularly benefitted from intonation: a rising non-final contour marking serial positions 3 and 6 is more effective than pauses.
On the other hand, we did not find clear evidence that a prefinal contour in positions 2 and 8 (marking penultimate position within the first group, and penultimate position within the whole sequence, respectively) can enhance recall of items in these positions, also possibly because of the masking effect of primacy and recency in adjacent positions. It also appears that the item in medial position within the whole sequence (position 5) cannot be better recalled when made perceptually salient by pitch prominence.
These results indicate that intonation can be attributed a role in the enhancement of serial recall that is not simply equivalent to the temporal structuring induced by pauses, as has so far been claimed. They also provide further support to the "language-oriented" view of Short-Term Memory (STM) as opposed to models of STM that propose a specialised memory system that is hierarchically organised (Farrell \& Lelièvre 2012).
We also found that particular intonation patterns can improve recall only in the input modality, i.e. when it is presented in auditory stimuli, but not in the output modality, i.e. when subjects are requested to imitate the intonation of the auditory stimuli whilst recalling. In the latter case, imitation cannot be construed as a supporting strategy for the recalling task. Instead it interfered with the task, resulting in a decrease in performance in the last part of the sequence, as memory traces become weaker.
Such result that imitation of the intonation does not enhance serial recall points to supporting the "language-oriented" models of Short-Term Memory.

\section*{Acknowledgments}

We would like to thank Ralf Rummer for helpful discussion and advice, and our student assistants Mirco Lacalandra and Gabriella Monticelli for help collecting the experimental data.

\title{
Is Double-Dipping an Alternative to Double-Dissociation?: Sampling Two Representational Systems Using a Single Task
}

\begin{abstract}
Dual-process models of categorization posit dissociable implicit and explicit category learning systems. Evidence in favour of these accounts is typically obtained by examining how categorization responses differ over time, with differing category structures, and by changing task demands. If these two categorization systems are activated concurrently (e.g., COVIS) then both implicit and explicit representations can be examined over the course of learning even when one system dominates category response selection. In the current study, we used subjective measures of performance (i.e., confidence reports) to continuously sample from a participant's explicit representation of the category structure while also examining changes in these reports over the course of training. Using category structures that motivate the acquisition of either explicit or implicit representations, we observed differences in confidence reports that did not correspond to changes in categorization accuracy. These findings provide evidence for categorization systems that contain different representations.
\end{abstract}

Keywords: dual-process, categorization, confidence
processing

\section*{Introduction}

Dual-process models of categorization assume that information is processed by and represented in independent cognitive systems. For instance, one such model, RULEX (Nosofsky, Gluck, Palmeri, McKinley, \& Glauthier, 1994), postulates that people categorize objects by using simple rules and by memorizing the exceptions to those rules. Similarly, another model, ATRIUM (Erickson \& Kruschke, 1998) assumes that categorization involves the combination of rule-based and exemplar-based processes whose relative contributions are mediated by an attentional gating mechanism. An alternative account provided by Love, Medin, \& Gureckis' (2004), SUSTAIN, assumes that instances of a category are stored as clusters of feature associations and these clusters are associated with a category in the context of both supervised and unsupervised learning. Moreover, the goals of the participant will also determine the nature of the representations that are formed (see the Conclusion for further discussion and implications).

Following from Logan's (1988) instance theory of automaticity, Ashby, Alfonso-Reese, Turken, and Waldron's (1998) COVIS model instead assumes that there is a competition between the verbal and implicit systems responsible for the categorization process. Evidence in favour of COVIS comes from double-dissociation paradigms which demonstrated feedback and a concurrent working memory load affect the implicit and verbal systems, respectively. In addition to predictions concerning
categorization performance, COVIS also makes claims concerning post-decisional confidence reports. To our knowledge, the implications of these claims have not been examined. The present study is directed toward exploring this prediction: The correspondence between categorization accuracy and subjective confidence should change depending on the category structure that participants are required to learn.

\section*{COVIS Categorization Systems}

COVIS has two main assumptions. First, categorization is assumed to rely on a multidimensional variant of signaldetection (SDT) referred to as general recognition theory (GRT; Ashby \& Townsend, 1986). With the provision of feedback, the category boundary divides separable or integral stimulus dimensions into discrete regions of a categorical space (e.g., Ashby \& Gott, 1988; Ashby \& Maddox, 1992). If a stimulus consists of values along a dimension greater than those specified by the criterion, it is assigned to one category. If the values are less than that specified by the criterion, it is assigned to another category. Using curve fitting, Ashby and colleagues have demonstrated that by the end of training, participants performance is well described by an optimal classifier model that employs a category boundary.

The second critical feature of COVIS is the interaction of the explicit and implicit categorization systems during response selection (Ashby \& O’Brien, 2005; Ashby et al., 1998). Initially, the hypothesis-testing system which uses executive function and working memory is assumed to dominate categorization as it can rapidly generate and test explicit, one-dimensional (rule-based) representations. Simultaneously, the implicit procedural learning system begins to associate regions of perceptual space with a category label though it does not yet dominate category response selection. As more instances of the categories are retained in memory, the process of retrieving the stimulusresponse mapping within the implicit system becomes increasingly rapid. With sufficient training, the implicit system begins to dominate category response selection. Thus, in the absence of an executive load (e.g., Waldron \& Ashby, 2001), participants will acquire rule-based category structures earlier in the course of the experiment relative to an information-integration category structures. These findings have been taken as evidence representing a qualitative change in responding rather than merely a quantitative shift in a category boundary location within a single implicit system (Ashby et al., 1998).

A critical observation concerning Ashby et al.'s (1998) dual-process account of COVIS is that although a single response results when presented with a stimulus, the resulting perceptual information activates both categorization systems. Later in training, when an implicit representation stored within the procedural-learning is used to produce responses, an explicit representation should still be produced by the hypothesis-testing system. If a method can be adopted to examine this explicit representation over the course of training, further evidence would be provided for a dual-process account of categorization. Confidence reports might be used to sample such an explicit representation over the course of learning.

\section*{Measures of Awareness of Performance}

Confidence reports and related measures were among the earliest tools used in experimental psychology to assess participants' ability to consciously monitor their performance on a given task (for a review, see Baranski \& Petrusic, 1998). Retrospective confidence reports are typically obtained by having an individual assign a numeric value corresponding to a subjective probability (e.g., 60\%) in their belief that they have provided a correct response to a primary task. The degree of correspondence between a participant's mean accuracy and assigning a subjective probability to a response is referred to as subjective calibration (e.g., Baranski \& Petrusic, 1994). Perfect calibration requires that the proportion correct (e.g., 0.6) and mean confidence are equivalent (60\%). Typically, participants are observed to deviate from ideal performance as evidenced by miscalibration. Rather than presenting a random pattern, miscalibration occurs in a systematic form in terms of either over- or underconfidence. Overconfidence is observed when confidence exceeds accuracy. This pattern is typically observed when the task requires the use of either general or conceptual knowledge. Underconfidence is observed when accuracy exceeds confidence. This pattern is typically observed in perceptual tasks (for reviews see, Lichtenstein \& Fischhoff, 1977; Kvidera \& Koustaal, 2008). There is disagreement as to whether this pattern represents task dependencies (Lichtenstein \& Fischhoff, 1977) or whether it is a result of differential accessibility of information within the systems when performing the task (Dawes, 1980).

A consideration of confidence models reveals the sources of this disagreement. The first formal models of confidence assumed a direct-scaling of primary decision information with a decisional-locus of confidence processing (e.g., Ferrel \& McGooey, 1980; Gigerenzer, Hoffrage, \& Kleinbolting, 1991; for recent models see, Pleskac \& Busemeyer, 2010). On these accounts, confidence reports are based solely on information used by the primary decision process and consequently do not require any additional processing. Importantly for the
present study, COVIS provides a similar model of confidence. Ashby et al.'s (1998) assume that confidence reports result from activation of the prefrontal cortex associated with the response alternative by the implicit system which they claim is supported by neurological studies examining cortical modulation (e.g., Frith, Friston, Liddle, \& Frackowiak, 1991). Given the direct correspondence between the implicit representation used to categorize stimuli and that used to report confidence, Ashby et al.'s (1998) direct-scaling account of confidence predicts greater correspondence between accuracy and confidence reports in the information-integration condition. This pattern would result in high levels of confidence calibration.

Furthermore, if subjective confidence is determined by an implicit representation, then greater levels of miscalibration should be observed in the rule-based condition due to a difference between the representation used to categorize stimuli and that used to report confidence. Specifically, if an implicit representation is used to report confidence and that representation is inaccurate early in training then Ashby et al.'s (1998) account would appear to imply that underconfidence should be observed when learning rule-based category structures.

In contrast to this account, an alternative class of models assumes that confidence reports require an indirect-scaling of primary decision evidence requiring additional cognitive operations. Both a post-decisional locus (e.g., Audley, 1960; Vickers \& Packer, 1980), or an alterable locus (Baranski \& Petrusic, 1998) have been considered wherein participants process confidence following the primary decision or can additionally compute it concurrently with the primary decision. If confidence reports require a secondary set of operations, it is possible that they could be affected by information other than that available to the primary decision. This would follow from the observation that performance on any task is the result of explicit and implicit processes (Jacoby, 1991).

There is considerable support that confidence reports involve a secondary set of effortful scaling operations that either integrate information from multiple sources (e.g., perceptual and conceptual) or manipulate this information in the process of scaling (Busey, Tunnicliff, Loftus, \& Loftus, 2000; Schoenherr, Leth-Steensen, \& Petrusic, 2010). For instance, Schoenherr et al. (2010) were able to alter subjective confidence independently of the primary decision. Studies investigating metamemory have also observed that subjective awareness appears to be determined by encoding and retrieval cues rather than the number of items recalled (e.g., Koriat, Sheffer, \& Ma'ayan, 2002). Given that different sources of information can affect the primary decision and confidence reports, these studies suggest that a comparison of primary decision responses and confidence reports might be an alternative means to
dissociate implicit and explicit categorization systems (see also Dienes \& Berry, 1997).

In the context of indirect-scaling models, we can predict a different pattern of miscalibration. If we disregard the direct-scaling model adopted by Ashby et al. (1998) we can still adopt some of the assumptions of COVIS to predict an alternative pattern of overconfidence. If a hypothesis-testing system is not as dependent on feedback to learn a category structure as the procedural-learning system, negative feedback should exert less of an effect when learning rulebased category structures relative to information-integration category structures. Thus, in instances where there is category overlap which result in a performance asymptote, an explicit representation of the category structure that informs confidence reports would not reflect the proportion of negative feedback that results. This would lead to overconfidence. Greater calibration would be observed in the information-integration condition due to that system's reliance on feedback and absence of an explicit category structure to bias confidence reports.

\section*{Present Study}

The present study starts from the assumption that the degree of correspondence between measures of accuracy and confidence can be used to infer the nature of representations used at different stages of the category learning process. To accomplish this, we adopted the randomization technique used by Ashby and colleagues and required participants to provide confidence report concerning the accuracy of their responses.

Two sets of predictions can be made concerning the relationship between accuracy and confidence depending on whether a direct- or indirect-scaling account of confidence is adopted. When adopting Ashby et al's (1998) directscaling model of confidence, we can expect participants to be well calibrated in the information-integration condition due to representational correspondence between the information used within the categorization system and that used to report confidence. Conversely, the rule-based condition should produce underconfidence due to the inaccurate implicit representation used to report confidence and an accurate explicit representation used to categorize stimuli.

An alternative set of prediction follows from indirectscaling models of confidence (e.g., Baranski \& Petrusic, 1998) should also be considered. First, when participants are incapable of obtaining \(100 \%\) accuracy, such as when a performance asymptote is adopted, confidence should reach the equivalent subjective probability of this performance asymptote prior to categorization accuracy. Second, if the explicit system is not as dependent upon response feedback as the implicit system, then the proportion of negative feedback observed in the rule-based condition should not affect subjective confidence reports to the same extent as the implicit-condition. Following from this, participants should
exhibit overconfidence when the category structure is readily verbalizable but category overlap is permitted. Thus, while we would expect the same comparatively high level of calibration in the information-integration condition as Ashby et al. (1998), we expect overconfidence in the rulebased condition. We also anticipate that the requirement of confidence should also increase categorization response time if it constitutes a secondary process and that these response times should be longer in the informationintegration condition relative to the rule-based condition given the need for representational change. We do not report the successful observation of these findings here due to space limitations. Rather, we limit ourselves to changes in overconfidence bias across experimental blocks.

\section*{Experiment Method}

\section*{Participants}

Eighty-eight undergraduate students participated in the study for course credit.

\section*{Materials}

Stimuli consisted of Gabor patches varying in terms of spatial frequency and orientation. Replicating the method of earlier studies (e.g., Zeithamova \& Maddox, 2007), 40 Gabor patches were created for each category for the training phase using the randomization technique by randomly sampling values from two normal distributions. Stimulus values were rescaled into stimulus dimensions with spatial frequency given by \(f=.25+\left(x_{1} / 50\right)\) and orientation given by \(o=\mathrm{x} 2(\pi / 500)\). Using these values, stimuli were generated with the Psychophysics Toolbox (Brainard, 1997) using MATLAB R2008 (MathWorks, Matick, MA) with an \(85 \%\) performance asymptote resulting from category overlap (see Figure 1). After a categorization response was provided and a confidence report was obtained, a feedback signal was presented to indicate a participant's accuracy in completing the task. Stimuli were presented to participants using E-Prime experimental software on a Dell Dimension desktop PC.

Figure 1. Information Integration Category Structure

\section*{Procedure}

The category task procedure used the randomization technique. A training phase consisted of 10 blocks of trials
with 40 exemplars from each category, and a transfer phase consisted of 2 blocks with the same 40 exemplars from each category. Participants learned either a rule-based (1D) or an information-integration (2D) category structure. In the present experiment, participants were provided with both trial-to-trial and block feedback during the training phase. In the transfer phase, participants did not receive feedback. Before trial-to-trial feedback was provided, participants reported confidence on a 6-point Likert scale from 50 (guess) to 100 (certain) scale.

\section*{Results}

Proportion Correct. As demonstrated in Figure 2, the results of categorization accuracy replicated earlier findings: 1 D rules were learned in fewer blocks then 2D rules, \(F(1\), \(83)=6.317, M S E=.039, p=.014, \eta_{p}^{2}=.071\), and accuracy increased with the number of experimental blocks, \(F(11\), \(913)=49.167, M S E=.005, p<.001, \eta_{p}^{2}=.372\) The interaction between categorization rule and experimental block was also significant, \(F(11,913)=6.891, M S E=.005\), \(p<.001, \eta_{p}^{2}=.077\). We also found that the requirement of confidence affected category learning as it interacted with block, \(F(11,913)=2.093, M S E=.005, p=.052, \eta_{p}^{2}=.025\). Although the requirement of confidence initially produced reduced performance in the first block \((M=.703, S D=\) .140) relative to no confidence \((M=.738, S D=.131)\), participants who reported confidence in the transfer phase were more accurate \((M=.866, S D=.112)\) then those who did not \((M=.829, S D=.103)\).

Confidence Reports. Due to inter-block variability resulting from individual differences in the between-subject design, we collapsed blocks into learning phases. We examined overconfidence in early phases of training across two blocks (Blocks 1 and 2) in order to compare to the two transfer blocks (Blocks 11 and 12). Two other phases of training were also examined for comparison constituting and intermediate (Blocks 3 through 6), and late phases of training (Blocks 9 through 10).

Figure 3. Overconfidence Bias across experimental blocks.

Overall, we found that the overconfidence bias differed across the learning phases, \(F(1,77)=8.842, M S E=.085, p\) \(=.004, \eta_{p}^{2}=.103\). As expected, learning phase was also found to interact with category structure, \(F(1,77)=4.539\), \(M S E=.085, p=.036, \eta_{p}^{2}=.056\). As can be seen from Figure 3, overconfidence remained relatively constant in the information-integration condition suggesting that, in general, participants did not have access to the representation that guided their performance. In contrast, an increase in overconfidence was observed in intermediate phases of training in the rule-based condition. This finding suggests that once participants identified the 1D rule, they expected to have continual improvements in performance.

\section*{Conclusions}

In the present study, we examined confidence reports as an alternative to double-dissociation paradigms. Using the randomization technique, we sought to replicate previous findings of the categorization literature such that participants would learn 1D categorization rules in fewer blocks then 2D categorization rules due to differences in the categorization systems that retain these representations. In a confidence rating paradigm, we had participants report trial-by-trial confidence after each categorization response and compared this to their accuracy. We examined whether the correspondence between accuracy and confidence (i.e., overconfidence bias) differed between category structures as well as whether this pattern changed across experimental blocks.

The results of our experiment replicate several earlier studies within categorization and confidence processing literature. Categorization performance was found to be affected by the category structure that participants learned. We observed that participants who were required to learn the rule-based category structure reached a performance asymptote faster than those who were required to learn the information-integration category structure (e.g., Ashby et al. 1998). Moreover, response latencies decreased in fewer
blocks for participants in the rule-based condition relative to those in the information-integration condition indicating that participants could more readily acquire a stimulus-response mapping for rule-based categories relative to informationintegration categories. Furthermore, these findings conform to the predictions of dual-process accounts of categorization such as COVIS (Ashby et al., 1998) allowing us to interpret the results obtained from confidence reports in a straightforward manner.

Our analysis of confidence reports also provides new evidence for dual-process accounts of categorization. In the experiment conducted here, we observed increased overconfidence in intermediate phases of training for those participants learning a rule-based category structure relative to those who learned the information-integration category structure. In general, the miscalibration observed here suggests that the representation used to report subjective confidence and that used to respond to categorize stimuli were informed by different sources of information. Greater overconfidence in the rule-based condition suggests that the category structure that participants were explicitly aware of did not contain the stimulus variability that resulted from category overlap. We would expect such a finding if the hypothesis-testing system were less reliant on feedback and could not incorporate exceptional exemplars into the explicit representation as a consequence.

Further support for the kind of representational dissociation that we predicted stems from the findings of greater calibration in the information-integration condition. In the absence of an explicit representation, the only explicit information available to participants is the proportion of feedback they have received on a trial-to-trial basis. Given that feedback is an accurate predictor of performance, less miscalibration is likely to result. Moreover, we should not expect perfect calibration if an explicit representation might be biasing confidence responses. This would occur if confidence reports incorporated multiple sources of information (Schoenherr \& Logan, 2012) or if we additionally consider that any task is determined by both explicit or implicit processes (i.e., Jacoby, 1991).

We can also consider how these findings might be accounted for by models of categorization more generally. Although it is possible that with a sufficient number of parameters, a single-process model of categorization could account for the findings of the present study, it appears more principled to assume two independent learning systems. In terms of models that posit the retention of both rules and exemplars (e.g., Nosofsky, et al., 1994; Erickson \& Kruschke, 1998) participants should be able to retain the optimal categorization rule as well as the exceptional exemplars. In the present study, one might expect that the retention of exemplars would ensure that participants would exceed the performance asymptote. There is little support
for this pattern given that performance does not significantly differ from the performance asymptote (see Figure 2).

Given the inclusion of both a categorization and confidence processing component, COVIS provides a possible explanation of the findings of the present study. COVIS posits that the evidence accumulated within the information-integration condition should be used to report confidence. For this reason, the high level of subjective calibration in the information-integration provides evidence in support of such an account. Although it does not make explicit predictions concerning the rule-based condition, it would seem that participants should be quite accurate early in training due do rapid generation and testing of explicit rule. Participants should also exhibit underconfidence due to an inaccurate implicit representation that informs subjective confidence. As noted above, this was not observed. Thus, COVIS can account for the categorization results of the present study but does not provide a sufficient account of confidence processing. The basic assumptions of two categorization systems - one explicit and one implicit - are supported by our results.

Although in some respect similar to models that retain both rules and exemplars, SUSTAIN (Supervised and Unsupervised STratified Adaptive Incremental Network; e.g., Love \& Medin, 1998; Love et al., 2004) might be better equipped to provide an explanation of the relationship between accuracy and confidence observed in the present study. A basic assumption of SUSTAIN is that clusters of features constitute a category and that there is response competition between clusters with a bias toward simple solutions. Unlike COVIS, SUSTAIN does not provide a comprehensive account of confidence processing. Love et al. (2004) note that the number of competing alternatives should reduce participant's subjective confidence. In the rule-based condition used in the present study there should be fewer clusters competing for response selection given that rule-based category structures can be identified relatively quickly. This would give rise to greater confidence. In contrast to this, the information-integration condition should have a larger number of clusters (constituting multidimensional rules) competing for response selection thereby reducing subjective confidence. On this account, however, it is not clear why exceptions would not affect confidence reports. Namely, exceptional exemplars should suggest the selection of alternative clusters thereby increasing competition and concomitantly decreasing confidence. Without a clear formulation of confidence processing within the context SUSTAIN, speculation on the adequacy of extension to accommodate our calibration results must be limited.

One promising feature of SUSTAIN is that it does allow for unsupervised learning and influences of participants' goals while learning. In our experiment we did find some evidence of better performance in the transfer phase with the
requirement of confidence reports (see Figure 2). We might expect this pattern of results if participants were monitoring their performance and consequently desired a higher level of accuracy. Thus, when asked to provide confidence reports participants might be induced to attend to the task more so than they would otherwise.

\begin{abstract}
In a world of limited resources, scarcity and rivalry are central challenges for decision makers. We examine choice behavior in competitive probability learning environments that reinforce one of two strategies. The optimality of a strategy is dependent on the behavior of a computerized opponent: if the opponent mimics participant choices, probability matching is optimal; if the opponent is indifferent, probability maximizing is optimal. We observed accurate asymptotic strategy use in both conditions suggesting participants were sensitive to the differences in opponent behavior. Moreover, the results emphasize that 'irrational' probability matching can be adaptive once such competitive pressures are taken into account. The application of reinforcement learning models to the data suggests that computational conceptualizations of opponent behavior are critical to account for the observed divergence in strategy adoption.

\section*{Introduction}

Competition is a pervasive characteristic of the world plants compete for light, water and pollination; animals are in continual competition for territory, food and mating; and even as humans we are constantly competing in sports, for social standing and companionship. Considering the ubiquity of competitive pressures in virtually all aspects of our lives, their crucial impact on the development of adaptive decision strategies in a broad range of contexts may seem self-evident. And yet, prior research has concentrated on assessing the rationality of numerous choice phenomena primarily by focusing on individual decision makers in social isolation. Consequently, observed choice inconsistencies are frequently dismissed as suboptimal with little or no regard for their adaptive potential in ecologically valid settings (see e.g., Todd \& Gigerenzer, 2007).

One such extensively studied choice anomaly is the tendency to proportionately match choices to outcome probabilities in repeated binary decisions, a phenomenon known as probability matching (for a review see Vulkan,
2000). In a typical setup a decision maker repeatedly has two choice options available, one of which is the correct choice with greater probability than its alternative, e.g. \(p\left(\mathrm{~A}_{1}\right)=.7\) and \(p\left(\mathrm{~A}_{2}\right)=.3\), and correct predictions are rewarded with monetary payoffs. Assuming the outcome probabilities are stationary and irrespective of prior events or subjects' behavior, \(A_{1}\) is the superior choice option throughout and, following an initial period of probability learning, should be chosen exclusively. By contrast, the frequently observed probability (over-) matching tendency results in inferior prediction accuracies and payoffs and is therefore considered fallacious within context-independent interpretations of rational choice behavior (Vulkan, 2000).

\section*{Probability Matching in Competitive Environments}

What seems irrational in individualized context-free environments, however, can be optimal in ecologically more valid situations that take prospective social interactions into account (Gallistel, 1990; Gigerenzer, 2000). That is to say, when decision makers seek to exploit limited resources under natural circumstances (e.g. forage for food or make money), they are rarely alone but typically in fierce competition for the exploitation of these resources with other agents. The more individual agents then choose the seemingly richest resource, the smaller each one's share. In nature, this situation cannot remain stable as natural selection would favor those agents who sometimes chose options with potentially scarce resources that are exploitable under less competition (Gallistel, 1990).

Following this line of argument, it has been suggested that agents should distribute their choices among resources relative to their reward potentials, i.e. adopt a probability matching strategy, to create an equilibrated evolutionary stable situation that does not give rise to conditions selecting against it (Gallistel, 1990). Evidence for such behavior has been provided by experiments that studied groups of animals in the wild, e.g. foraging behavior of ducks on a lake (Harper, 1982) and fish in a tank (Godin \& Keenleyside, 1984).

Our aim was to examine the role of competitive pressures for the facilitation of optimal decision making in simple binary human choice contexts. Specifically, we wanted to assess potential benefits of probability matching under the premise that competitive conditions reinforce its superiority. Following the logic of natural foraging situations, we designed a choice environment in which each decision maker competes against a computerized opponent for the exploitation of a monetary resource that an indifferent 'nature' repeatedly places at one of two choice options with stable probabilities. When both agents converge on the same choice, potential rewards are split evenly between them.

In this competitive context, the success of any strategy largely depends on the behavior of the opponent. Under the assumption that the competitor is attentive towards the decision maker's choice behavior and imitates her course of action, probability matching is an optimal strategy. The prevalence of aggregative behavior in a broad range of natural group settings, e.g. flocking behavior of birds, shoaling of fish, swarming of insects and herd behavior of land animals (Allee, 1978), suggests that a strategymirroring opponent creates competitive conditions closely in line with real life ecological pressures. Thus, in one experimental condition each opponent's choice probabilities are close imitations of participant behavior which renders probability matching optimal (see appendix). In a second condition (between-subjects), each participant is paired with a computer opponent who is indifferent towards subjects' choices thereby making exclusive preference for the more profitable resource (i.e. probability maximizing) the optimal strategy. This is the case because sporadic choices by the participant to the lesser option will not tempt this indifferent opponent to replicate deviant behavior but will merely result in relinquished earning potential for the participant.

By manipulating opponent behavior as described, we created two competitive choice environments that differed solely in the extent to which participants had influence on their competitors' behavior. Thus, we can assess the role of the qualitative nature of competition for the facilitation of adaptive decision making. Given the availability of sufficient feedback (Shanks, Tunney, \& McCarthy, 2002), we predicted that choices will converge on the respective optimal strategy in both environments as learning progresses, i.e. probability matching when competing against a mimicking opponent and probability maximizing when encountering an indifferent opponent.

\section*{Models of Learning under Competition}

To shed more light on the nature of underlying learning processes within such competitive environments, we discuss the applicability of reinforcement learning models proposed for similar choice settings, e.g. learning in experimental games (Erev \& Roth, 1998), learning in the Iowa Gambling task (Yechiam \& Busemeyer, 2005) and strategy selection learning (Rieskamp \& Otto, 2006), to our experiments and outline potential adaptions of such models to account for the competitive pressures examined here. Such models typically
include assumptions regarding three main components (see e.g., Sutton, 1998): a utility function that specifies the goal of the learning problem; a learning rule which establishes propensities for each choice option; and a choice rule defining the course of action given current propensities. Here, we examine two learning models postulating different conceptualizations of the utility formation process.

Utility Function In a learning environment where an agent's primary goal is maximization of total payoffs, the utility of a choice is typically directly specified by its associated monetary reward (e.g., Rieskamp \& Otto, 2006):
\[
\begin{equation*}
u_{t}(i)=r_{t}(i) \tag{1}
\end{equation*}
\]
where \(u_{t}(i)\) corresponds to the utility of the monetary gains \(r_{t}(i)\) associated with choice \(i\) on trial \(t\), namely, in our task, 0,2 or 4 cents for no, split and full payoffs (see below). The focus on monetary gains for the evaluation of choice utilities has left systematic investigations of a wider range of factors potentially influencing this important model component largely unexplored (with few notable exceptions, e.g., Janssen \& Gray, 2012; Singh, Lewis, \& Barto, 2009). This is the case even though various additional motivational sources of utility are conceivable: e.g. avoidance of boredom associated with repetitive tasks (Keren \& Wagenaar, 1985) or task completion time (Gray, Sims, Fu, \& Schoelles, 2006). Relating this prevalent negligence to the competitive task employed here, we argue that describing utilities in terms of monetary rewards only confounds two discrete learning goals vital in this context, namely, correctly assessing the profitability of an option and attending to the competitor's choices. In fact, monetary based utilities understate the crucial role differential causes of opponent behavior play when subjects face an imitative vs. an indifferent competitor. That is to say, different opponent strategies necessitate divergent learning goals: if an opponent is identified as attentive, deciding on a course of action requires consideration of ways to influence and outsmart that other agent; if, on the other hand, the competitor is indifferent, the impact of opposing actions on one's own decisions should be strongly discounted.

Incorporating these aspects into the learning model we propose a utility function that disentangles the two learning goals present in our task and allows direct estimation of the importance decision makers attribute to the choice strategies they observe in their competitors compared to the importance they ascribe to making accurate choices:
\[
\begin{equation*}
u_{t}(i)=\left[\beta \cdot g_{t}(i)\right]+\left[(1-\beta) \cdot s_{t}(i)\right] \tag{2}
\end{equation*}
\]

Here, the utility \(u_{t}(i)\) of a choice, is expressed as the weighted sum of its accuracy \(g_{t}(i)\) ( 0 for incorrect and 1 for correct guesses) and the choice of the competitor \(s_{t}(i)\) (-1 for converging choices and 1 for incongruent choices) on any given trial. The additional free parameter \(\beta\) determines the weight a subject assigns to choosing the correct option as compared to outsmarting their competitor in terms of choosing the opposite line of action. For \(\beta=1\) subjects
value the accuracy of their choices only, whereas for \(\beta=.5\) the importance of correct choices and outwitting the competitor are weighted equally. We predict that balancing these two requirements of the task would be more pronounced when facing an imitative competitor, thus \(M_{\beta, \text { indifferent }}>M_{\beta, \text { mimicry }}\), and that learning models considering these differential challenges of the task would account for the data more thoroughly.

Updating and Choice Rule Adjustment of propensities follows a delta learning rule commonly employed in similar decision tasks (e.g., Yechiam \& Busemeyer, 2005):
\[
\begin{equation*}
q_{t}(i)=q_{t-1}(i)+\alpha\left[u_{t}(i)-q_{t-1}(i)\right] . \tag{3}
\end{equation*}
\]

Here, initial propensities towards both options are assumed to equal zero and are then gradually updated in increments of the learning rate \(\alpha\) based on the prediction error in brackets. As outcomes are mutually exclusive in our task, propensities for both options are updated simultaneously regardless of the actual choice on any given trial. An agent's probability of choosing either option is determined by these propensities following an exponential 'softmax' choice rule:
\[
\begin{equation*}
p_{t}(i)=\frac{e^{\theta \cdot q_{t}(i)}}{e^{\theta \cdot q_{t}(j)}+e^{\theta \cdot q_{t}(i)}}, \quad \theta=3^{10 \cdot c}-1 \tag{4}
\end{equation*}
\]
where the sensitivity parameter \(\theta\) governs the precision with which the preferred option is chosen. If \(\theta=0\), decisions are made at random, i.e. \(p_{t}(i)=p_{t}(j)=.5\), whereas large sensitivity parameter values \((\theta \rightarrow \infty)\) correspond to strictly deterministic choices to the option with the higher propensity. Following Yechiam \& Ert (2007), an exponential transformation of \(\theta\) was employed to allow variation of choice sensitivities between random guessing (for \(\theta \approx 0\) ) to fully deterministic (for \(\theta>700\) ) within narrow bounds of \(c\), which denotes the sensitivity constant constrained between 0 and 1 .

\section*{Method}

\section*{Participants}

Fifty (35 female) undergraduate students from the University of New South Wales (mean age 18.9, \(S D=1.2\) years) participated in this experiment in return for course credit and performance based monetary compensation.

\section*{Decision Task}

A standard probability learning paradigm involving repeated binary decisions with mutually exclusive outcomes over 500 choice trials was employed. Choice alternatives were represented by two light bulbs displayed on a computer screen and programmed to illuminate with probabilities of . 7 and .3 , counterbalanced across participants for left and right choice options. Correct predictions were rewarded with 4 cents ( 1 AUD \(=.95\) USD). Choices were made while competing against a computerized opponent and when both agents converged on the correct response, the payoff was evenly split between them, i.e. each agent received 2 cents.

\section*{Design}

We employed a \(2 \times 5\) mixed model design with opponent type (mimicry or indifferent) as between-subjects factor and trial block (five blocks of 100 trials each) as within-subjects factor. The dependent measure was the proportion of choices to the more probable choice option. For the mimicry group, the choice sequence of each opponent was computed one step ahead by equating the opponent's choice probabilities on each trial with the choice proportions the subject had displayed during the past ten trials. For example, when a participant chose the more probable option on 7 out of the past 10 trials, her opponent's probability of choosing the same option on the subsequent trial was .7. \({ }^{1}\) This algorithm creates opponent behavior that probabilistically mimics participants' choices.

By contrast, the choice sequence of each opponent for subjects in the indifferent condition was computed irrespective of participants' choices. Instead, each subject played against an opponent whose set of choice probabilities simply repeated those of an opponent encountered by another subject in the mimicry condition.

\section*{Procedure}

Subjects were asked to predict which of two light bulbs would illuminate over a series of trials while attempting to earn as much money as possible. Instructions indicated that the lighting sequence was random, i.e. no pattern or system existed which made it possible to correctly predict the outcome throughout, and that the outcome probabilities of both choice options remained constant during the entire experiment. Additionally, participants in both conditions were informed that a computerized opponent with learning abilities such as their own and no initial information about the lighting frequencies was monitoring their choices and adapting to their skill level. On each trial, predictions were made simultaneously by both participant and opponent and followed by feedback about the other agent's choice and the outcome, i.e. one light bulb lit up.

Upon completion of every block of 100 trials a self-paced pause interrupted the experiment during which block feedback was provided and a short message reminded participants that the lighting sequence was random. Subjects were told: "In this game you earned X\$. Using an optimal strategy you could have earned at least Y\$.", where X represented the actual earnings of that block and Y was computed by an optimizing algorithm (Shanks et al., 2002). This algorithm was set to probability matching in the mimicry opponent condition and probability maximizing in the indifferent opponent condition while taking both agents' actual predictions during that trial block into account. Additional incentives to improve performance on the following block were provided by informing participants that reaching optimal performance ( \(\pm\) three cents) would

\footnotetext{
\({ }^{1}\) During the first ten trials of the experiment, each opponent randomly adopted one of three possible initial strategies: random response, probability matching, or probability maximizing.
}
double their payoff, whereas suboptimal performance would result in halved earnings on the subsequent trial block.

\section*{Parameter Estimation and Model Evaluation}

We estimated parameters for each individual separately based on the models' accuracy in predicting the observed choice sequence one step ahead for each trial. That is, all models generate trial-by-trial choice probabilities for both response alternatives on the basis of subjects' prior decisions, their associated payoffs and the respective model's parameter values. Employing maximum likelihood estimation we searched for the set of parameters that maximized the summed log-likelihood of the predicted choice probabilities across trials given each participant's observed responses with an iterative particle swarm optimization (Kennedy \& Eberhart, 1995). For each individual, optimization proceeded iteratively with a total of 24 particles, 23 of which started at random positions while the final particle started at the best parameter combination from the previous iteration. Optimization terminated once the model fit did not improve further for at least five successive iterations. The following parameter bounds constrained the optimization process: \(\alpha \in[0,1]\) for the learning parameter, \(c \in[0,1]\) for the transformed sensitivity \(\theta\), and \(\beta \in[0,1]\) for the additional outsmarting parameter.

The final fit of each learning model was compared to a baseline statistical model which assumes constant and statistically independent choice probabilities across trials (see e.g., Yechiam \& Busemeyer, 2005), and hence, accounts for the data without presuming any learning. The stationary probability of choosing the more probable option pooled across all trials \(\left(p_{1}, p_{2}=1-p_{1}\right)\) is the only free parameter in this baseline model and, to account for divergent model complexities, both learning models are evaluated by comparing differences in Bayesian Information Criterion (BIC; Schwarz, 1978) statistics between learning and baseline model (see e.g., Yechiam \& Busemeyer, 2005). If a learning model is superior to the statistical baseline model, i.e. accurately describes how subjects adapt their choice behavior over time, positive \(\triangle B I C\) values result from this model evaluation.

\section*{Results}

\section*{Behavioral Data}

The mean proportion of choices to the more probable choice option for each block of 100 trials averaged across participants in the two experimental conditions is displayed in Figure 1. For inferential statistics, we conducted Bayesian analyses in addition to conventional methods of hypothesis testing to quantify evidence in favor of the null and alternative hypotheses (Wagenmakers, 2007). We assume equal plausibility for the null and alternative hypotheses a priori and report the posterior probability for the null hypothesis, denoted as \(p_{\mathrm{H} 0}^{\text {Bayes }}\), associated with each effect. A mixed model ANOVA revealed a significant main effect of trial block \(\left(F(2.37,113.8)=27.9, \quad p<.001, \quad \eta_{\mathrm{p}}{ }^{2}=.367\right.\),
\(\left.p_{\text {H0 }}^{\text {Bays }}=.00\right)^{2}\), with predictions closer to the respective optimal response strategy in the last compared to the first block of 100 trials for both groups. In the mimicry condition, subjects' choice behavior accurately approached optimal probability matching towards the last trial block ( \(M=.76\) ), whereas an indifferent competitor elicited decisions more in line with a probability maximizing strategy ( \(M=.90\) ). This adaptive divergence of learning processes is emphasized by a significant main effect of competitor type across all trial blocks \((F(1,48)=11.7\), \(\left.p=.001, \eta_{\mathrm{p}}{ }^{2}=.195, p_{\mathrm{H} 0}^{\text {Bayes }}=.03\right)\). The competition type by trial block interaction did not reach statistical significance, although the Bayesian evidence was ambiguous \(\left(F(2.37,113.8)=2.77, p=.058, \eta_{\mathrm{p}}^{2}=.055, p_{\text {H0 }}^{\text {Bayes }}=.66\right)\).

Figure 1: Mean \(\pm\) standard error proportion of choices to the more probable option averaged across trials and subjects.

Similar adaptive differences in choice behavior were also observed at an individual level, with high proportions of subjects in both conditions adopting the respective adequate rather than suboptimal strategy by the final trial block.

In sum, we have demonstrated that subjects are sensitive towards their competitors' decision strategies and modify their choices accordingly. The underlying psychological processes that lead to this adaptive divergence in strategy use, however, remain elusive from the behavioral data. Thus, we now turn to a computational modeling analysis to illuminate the determinants of emergent optimal choice behavior within competitive environments more holistically.

\section*{Modeling Data}

The parameter estimates and \(\triangle B I C\) values for the proposed learning models are compared in Table 1. The first learning model we examined defined decision utilities solely based on their associated monetary payoff and, judging by its

\footnotetext{
\({ }^{2}\) Mauchly's test indicated that the assumption of sphericity had been violated ( \(\chi^{2}(9)=63.0, p<.001\) ), therefore degrees of freedom were corrected for both conventional and Bayesian analyses using Greenhouse-Geisser estimates of sphericity ( \(\varepsilon=.593\) ).
}

\end{tabular}
clearly positive average \(\triangle B I C\) score, accounts considerably better for the observed choice behavior than the stationary baseline model despite greater complexity. However, this basic utility model does not permit differentiation between the learning processes that lead to divergent choice behavior in the examined competitive environments, because estimated individual model parameters did not differ significantly between experimental groups, although the Bayesian evidence was ambiguous \((t(26.0)=1.21, p=.238\), \(p_{\mathrm{H} 0}^{\text {Bayes }}=.71\) for learning rates and \(t(42.6)=-1.87, p=.068\), \(p_{\mathrm{H} 0}^{\text {Bayes }}=.51\) for sensitivity constants).

The second learning model proposed above disentangles the two learning goals of choosing accurately, yet outsmarting the competitor by introducing an additional free parameter, \(\beta\). The differential requirements of the two competitive environments are well represented by this additional outsmarting parameter, which was significantly smaller in the mimicry condition, indicating a tradeoff between betting on the more probable option and deviating from the opposing choice behavior, compared to the indifferent group, where opponent choices were to be disregarded \(\quad\left(t(26.4)=-2.44, \quad p=.022, \quad p_{\mathrm{H} 0}^{\text {Bayes }}=.27\right)\). Parameter estimates for learning rate and sensitivity constant, again, did not differ between conditions, although the Bayesian evidence was ambiguous \((t(48)=.220\), \(p=.827, \quad p_{\text {H0 }}^{\text {Bayes }}=.82\) and \(t(38.6)=1.65, \quad p=.107\), \(p_{\mathrm{H} 0}^{\text {Bayes }}=.59\), respectively). Although the more elaborate utility evaluation model sheds light on the processes underlying the observed divergence in choice behavior, the added complexity results in \(\triangle B I C\) statistics not significantly better than those of the simpler utility model \((t(49)=-.613\), \(p=.543, p_{\mathrm{H} 0}^{\text {Bayes }}=.88\) ). Thus, despite the conceptual promise and excellent parameter fit of the more complex model, overall, the simple monetary utility model is to be preferred for its parsimony.

\section*{Discussion}

Qualitatively different competitive pressures in a binary prediction task result in adaptively divergent choice behavior on aggregate and individual learning levels. Under the influence of an indifferent opponent, resources should and were found to be exploited without consideration for the other agent's preferences, i.e. much like in classic individual
binary prediction tasks, probability matching needed to be dismissed as an inferior strategy. By contrast, the presence of an imitative opponent necessitates response allocations proportional to outcome probabilities in order to maximize payoffs. In this context, we observed an adaptive tendency towards probability matching - i.e. probability maximizing was correctly rejected as an inferior strategy.

What drives this adaptive divergence of strategy adoption in these two competitive contexts? Our evaluation of learning models suggests that the observed adaptiveness of choice behavior largely resulted from differing learning goals with respect to opponent behavior: imitative competitors require consideration for strategies that influence and outsmart these agents, whereas indifferent opponents necessitate disregard for their choices when deciding on one's own course of action. Thus, conceptualizing opponent behavior as a key factor in the evaluation of choice utilities that is traded off against the desire to choose accurately disentangles these divergent requirements while providing a good approximation of observed behavior. Yet, when modeling individual data, the additional outsmarting parameter for each decision maker increased the complexity of the model beyond its explanatory potential as indicated by the \(\triangle B I C\) score comparisons. Omitting the computational representation of opponent behavior from the model, however, resulted in parameter estimates that gave little indication of the underlying learning processes prompting decision makers to respond adaptively to qualitatively different competitive pressures. At best, within this simpler model, divergent environmental requirements were somewhat reflected in marginally decreased sensitivities for evaluated choice propensities in the mimicry competitor condition, i.e. adoption of optimal probability matching is explained in terms of greater randomness in subject's choice behavior. Attributing the observed adaptiveness of strategy use in both contexts to differences in choice rule precision appears, however, conceptually implausible, because under the influence of an imitative competitor, participants are not less sensitive towards monetary rewards per se. On the contrary, we suggest that it is the added requisite to outmaneuver the opposing agent that fuels optimal matching in this context.

Consequently, to account for core learning processes that drive adaptive choice behavior within these competitive environments, an additional representation of opponent
behavior is conceptually essential. To remedy potential disadvantages of added model complexity an interesting avenue for future research is to explore the suitability of hierarchical parameter estimation techniques, which may highlight the benefits of including an outsmarting parameter without introducing the downsides of overly complex models. The take-home message from this study is that learning to choose under uncertainty can indeed be steered by competition and thus proceed adaptively in situations where probability maximizing or matching is optimal.

\section*{Appendix}

Expected reward proportions are defined as the weighted average of all possible outcomes resulting from nature's move and both agents' choices. When two decision makers follow the same course of action, i.e. one imitates the other, the choice probabilities of both agents are identical. Given identical choice probabilities, the agents can either converge or diverge on a choice option, and thus expected rewards can be broken down into split and full payoffs while their sum amounts to the total expected payoff proportion:
\[
\begin{align*}
& r_{S p l i t}=\left(p_{c}(H)^{2} \cdot .7+p_{c}(L)^{2} \cdot .3\right) / 2  \tag{5}\\
& r_{\text {Full }}=\left(p_{c 1}(H) \cdot p_{c 2}(L) \cdot .7\right)+\left(p_{c 1}(L) \cdot p_{c 2}(H) \cdot .3\right)
\end{align*}
\]

For each decision maker, split reward proportions are computed as the joint probability of both agents choosing the same option \(\left(p_{c}(i)^{2}\right)\) weighted by the outcome contingencies (here, .7 and .3 ) and split by two; whereas full reward proportions can be expressed as the joint probability of both players choosing different options \(\left(p_{c l}(i) \cdot p_{c 2}(j)\right)\) weighted by the outcome probabilities. Thus, total expected payoffs are maximized when both players probability match. For outcome probabilities of .7 and .3 , for example, each player's maximal total expected reward proportion equals .395 (compared with .35 for probability maximizing).

\title{
Learning Patterns in Noise: Environmental Statistics Explain the Sequential Effect
}

\begin{abstract}
Effects of trial history, or sequential effects, are typically observed in perceptual, motor, and decision making tasks and explained by subjects' irrational sensitivity to local patterns in stimulus history. We propose that in 2 alternative forced choice reaction time tasks (2AFC), sequential effects are a consequence a rational agent engaging in probability learning but with an inappropriate world model for 2AFC. We manipulate subjects' world model and show expected changes in sequential effects. Sequential effects are at least in part driven by subjects' beliefs about their environment.
\end{abstract}

Keywords: sequential effects; two alternative forced choice reaction time tasks; Bayesian modeling

\section*{Sequential Effects}

Subjects display sensitivity to local patterns in stimulus history in perceptual (Howarth \& Bulmer, 1956; Maloney, Martello, Sahm, \& Spillmann, 2005), motor (Cho et al., 2002; Remington, 1969; Soetens, Boer, \& Hueting, 1985), and decision making tasks (Ayton \& Fischer, 2004; Gilovich, Vallone, \& Tversky, 1985). In two alternative forced choice reaction time tasks (2AFC), for example, subjects' reaction times (RTs) depend not only on the current stimulus but also on the sequence of preceding stimuli (Cho et al., 2002; Remington, 1969), a phenomenon known as sequential effects (SQE). In addition, participants typically respond faster to an alternation of stimuli after a run of alternations compared to a repetition of stimuli after a run of repetitions (Soetens, et al., 1985). We refer to this finding as alternation bias in SQE. While alternation bias seems more common, repetition bias has been observed, too (Cho et al., 2002). We here ask what processes give rise to biased SQE.
SQE are in part determined by the time interval between subsequent stimuli (inter-trial interval). If this interval is short ( \(<500 \mathrm{~ms}\) ), SQE are driven by automatic facilitation (Bertelson, 1961; Soetens et al., 1985). Responses to repeated stimuli benefit from residual activation left by previous stimulus-response cycles and consequently, RTs to repeated stimuli are faster while responses to alternating stimuli are slower (Soetens et al., 1985). If the inter-trial interval is long ( \(>500 \mathrm{~ms}\) ), SQE are driven by subjective expectancy. Subjects use the sequence of preceding stimuli to predict the next, upcoming stimulus and consequently, a run of alternations induces expectancy for more alternations while a run of repetitions induces expectancy for more repetitions (Soetens et al., 1985).
But in typical 2AFC tasks, the sequence of preceding stimuli does not predict the next, upcoming stimulus - a
repetition of stimulus \(X\) does not increase the probability of stimulus X compared to stimulus Y . In other words, stimulus history has no predictive value and should not affect subjects' expectancy (or RTs if the inter-trial interval exceeds 500 ms ). Why do we find persistent SQE (after > 4000 trials) (Soetens et al., 1985) in 2AFC tasks?
Previously, SQE in 2AFC tasks with long inter-trial intervals were cast as instances of irrational sensitivity to local patterns in stimulus history, presumed to give rise to other suboptimal behavior, like the gambler's and hot-hand fallacy in decision making (Ayton \& Fischer, 2004; Gilovich et al., 1985). Instead, we propose that SQE effects are driven by subjects' attempts to learn the probability of occurrence of the two stimuli in 2AFC with a world model that, while ecologically plausible, does not match the true generative model of the task.
In 2AFC tasks, which out of two stimuli is going to appear on each trial is sampled from a Bernoulli distribution. With probability \(p\) one stimulus will appear and its alternative with probability \(1-p\). In common 2 AFC , probability \(p\) is constant throughout the experiment (or at least throughout an experimental block). The true generative model is thus a Bernoulli distribution with constant probability \(p\). Participants could learn probability \(p\) by using stimulus history to update estimated probability \(\hat{p}\) using, for example, Bayesian updating (Gerhard, Wolfe, \& Maloney, under review).
But participants may believe that instead, probability \(p\) changes over time. In other words, instead of a stable world with constant probability \(p\) - the true generative model of 2AFC - participants may believe in a dynamic world with changing probability \(p_{t}\). We propose that such belief could give rise to biased SQE: biased SQE are a consequence of an agent engaged in probability learning with an incorrect world model. As participants cannot possibly know the correct world model of 2 AFC prior to taking part in 2 AFC , a belief in a changing world is, while incorrect, not irrational. Under this account, SQE are a consequence of conditionally rational behavior: given one incorrect assumption - an inappropriate world model - subsequent behavior (SQE) is rational (see Green, Benson, Kersten, \& Schrater (2010) for a similar approach to explain probability matching).
Two previous studies suggested that SQE may be due an inappropriate world model and developed a computational model to explain commonly observed SQE in 2AFC (Wilder, Jones, \& Mozer, 2009; Yu \& Cohen, 2009). We developed a modified 2AFC task to test for effects of an
inappropriate world model on SQE accompanied by a Bayesian model. Participants took part in a 2AFC task before and after a training session (Figure1). Participants were instructed to press a left or right button with their left or right index finger in response to a stimulus, which appeared either left or right to central fixation. On each trial, stimuli were equally likely to appear left or right ( \(p_{L R}=0.5\) ) and were equally likely to repeat or alternate ( \(p_{R A}=0.5\) ). Crucially, \(p_{L R}\) and \(p_{R A}\) did not change over time.

Figure 1: Experimental design. a Participants completed a 2AFC task. The stimulus could appear left or right of fixation and participants were instructed to press a button with their left or right index finger. During pre- and postmeasurement, the probability of left / right and of repetition / alternation was 0.5 . During training, repetition probability was resampled on \(18 \%\) of all trials. Each change was signaled to the subjects. b The probability of repetition was resampled from a Beta-distribution biased towards repetition c (high values, green) or biased towards alternation \(\mathbf{d}\) (low values, orange).

During training, we put participants into an environment with changing \(p_{R A}\). Participants continued responding to stimuli presented to the left or right of central fixation with a left or right index finger button press but \(18 \%\) of all trials, \(p_{R A}\) was (re-)sampled from a Beta-distribution \(\mathrm{B}(a, b)\) ,which was biased either towards repetitions \((a=12, b=6)\) or alternation \((\mathrm{a}=6, \mathrm{~b}=12)\). Each change in \(p_{R A}\) was explicitly signaled to the subject. Belief in change was
induced to produce SQE and belief in a biased world after change (or biased "re-set prior") was induced to produce biased SQE (see Computational Model \& Hypotheses). We expected to find biased SQE before and after training, given the numerous reports of biased SQE in 2AFC. We aimed to change participants' bias in SQE in line with the bias they received during training - towards alternation bias for alternation training and repetition bias for repetition training. Such change would suggest that biased SQE are at least in part - driven by participants' (inappropriate) world model: manipulating their world model during training changes biased SQE in the expected direction in a post- compared to pre-measurement.

\section*{Computational Model and Hypotheses}

If participants believe that probability \(p_{t}\) changes over time, they should estimate current probability \(\hat{p}_{t}\) based on the outcome of all trials since the final change in probability and discard the outcome of all trials prior to this change. The decision which trials to include in estimating \(\hat{p}_{t}\) is easy when participant know when change happened, or alternatively, when they know the run length \(r\) since change. But in most situations, change is not explicitly signaled to participants and participants need to estimate change \(c\) or alternatively run length \(\hat{r}\) (Wilson, Nassar, \& Gold, 2010).
The full Bayesian model of probability updating in changing environments requires maintaining a distribution over all possible \(r\), which grows as participants complete more trials. In addition, participants need to estimate the hazard rate \(h_{t}\) - the probability of change on trial \(t\) - and maintain a distribution across all possible hazard rates (and functions) for optimal Bayesian probability updating in a changing world (Nassar, Wilson, Heasly, \& Gold, 2010). Probability updating can very quickly become computationally expensive if not intractable.
Nassar and colleagues (2010) developed a reduced Bayesian model to make probability-updating algorithms more tractable. They designed their model for probability updating in a changing environment with constant probability of change (or constant hazard rate \(h\) ) and in their model, trial outcomes were supposed to be generated from a normal distribution. We adapted their reduced model to fit our task with an increasing hazard rate \(h_{\hat{r}}\) and a Bernoulli distribution with \(p_{R A}\) (see Appendix for details). We used this model to compute probability estimates \(\hat{p}_{R A}\) of an agent that beliefs in a changing world (incorporated in the model) and completes a 2AFC task (incorporated in the input to the model). Based on the agent's \(\hat{p}_{R A}\) we subsequently computed his expectation \(\gamma_{t}\) (or posterior, see Appendix) for the upcoming trial. We then grouped \(\gamma_{t}\) based on preceding trial history: whether it was preceded by
three alternations AAA, three repetitions RRR, or any of the six other possible combinations: AAR, ARA, ...
In Figure 2 we plot \(1-\gamma_{t}\) grouped by preceding trial history (x-axis). The curves depend on three parameters: the probability of change \(p_{c}\) and \(a_{0}\) and \(b_{0}\) of the Betadistribution \(\mathrm{B}\left(a_{0}, b_{o}\right)\), which incorporates the agents belief in what the world is like after change prior to new, incoming evidence. Simulations show that if \(a_{0}>b_{0}\) and \(p_{c}>0\) SQE are repetition biased and if \(a_{0}<b_{0}\) and \(p_{c}>0\) SQE are alternation biased. During training, we lead participants to believe that \(p_{c}>0\) and either \(a_{0}>b_{0}\) (repetition bias group) or \(a_{0}<b_{0}\) (alternation bias group) and expected to observe a corresponding change in bias from pre- to postmeasurement.

Figure 2: Effects of an agent's belief in frequency of change (solid, dashed, and dashed-dotted lines represent increasing frequency) and bias in its environment after change (green: repetition biased / orange: alternation biased) determined by \(p_{c}, a_{0}\), and \(b_{0}\).

\section*{Methods}

\section*{Participants}

25 participants took part in the experiment ( 12 female, mean age: 22.3 years, age range: \(19-24\) years, 2 left handed) and completed a single session of 60 minutes. They were compensated for time and effort (\$10) and received an additional bonus of \(\$ 4\). Participants were told they would get rewarded for fast responses but we rewarded all participants for their fastest \(25 \%\) of all trials so they all received the same bonus, unbeknownst to them. Informed consent was obtained prior to testing. An internal ethics review board at New York University approved of experimental procedures.

\section*{Procedure and Apparatus}

Participants were randomly allocated to receive either repetition training ( \(\mathrm{N}=12\) ) or alternation training \((\mathrm{N}=13)\). They were seated at approximately 40 cm viewing distance from a \(19^{\prime \prime}\) Dell computer screen in a dimly lit room and
asked to wear BOSE QuietComfort 15 Acoustic Noise Cancelling headphones to reduce background noise and to allow them to listen to incorporated auditory feedback. The experiment was run on a Mac Mini (Mac OS X Version 10.7.5) programmed in MatLab 7.5 (http://www.mathworks.com/) and Psychtoolbox 3 (Brainard, 1997; Pelli, 1997). Participants responded by pressing the c-key with their left index finger or the m-key with their right index finger on a standard QWERTY keyboard.

\section*{Experimental design}

Participants completed a pre-training, training, and posttraining (Figure 1). During the pre- and post-training, participants took part in a 2AFC task based on the arcade game "Whack-a-Mole (elMo)!". At trial onset, participants saw a box with two holes - a gray square with two black circles equidistant from a white, central fixation cross. 250 ms after trial onset, the white fixation cross turned red and then, after an additional 250 ms , blue. Once the fixation cross had turned blue, the stimulus - Sesame Street's Elmo - appeared to the left of right of fixation with probability \(p_{L R}=0.5\) and with repetition probability \(p_{R A}=0.5\) after a time interval chosen from a truncated exponential distribution (mean \(=500 \mathrm{~ms}\), max. 2000 ms ). We chose the exponential to reduce temporal expectancy (Luce, 1991). The initial color change of the fixation cross - or count down - ensured that inter-trial intervals exceeded 500 ms to ensure that we measured subjective expectancy and not automatic facilitation (Soetens et al., 1985).
During training, participants completed the same task with one important modification. The probability of repetition \(p_{R A}\) was resampled on \(18 \%\) of all trials from a Betadistribution with \(\mathrm{a}=12\) and \(\mathrm{b}=6\) in the repetition biased group and \(\mathrm{a}=6\) and \(\mathrm{b}=12\) in the alternation biased group. Each time \(p_{R A}\) changed, this change was signaled explicitly to the subjects. The word 'CHANGE' was displayed on the gray box prior to each trial with a new re-sampled probability. Participants were not told \(p_{R A}\) after change.
We chose to manipulate the probability of repetition versus alternation, instead of the probability of left versus right, for two reasons. First, studies on SQE typically look at effects of trial history coded in as repetition versus alternations instead of left versus right (Cho et al., 2002; Remington, 1969; Soetens et al., 1985; Yu \& Cohen, 2009). Second, by manipulating \(p_{R A}\), we kept \(p_{L R}=0.5\) and therefore, any biases in SQE we find cannot be due to differences in left versus right hand action preparation, for example.

\section*{Data analysis}

We measured RTs, defined as the time interval between stimulus-onset and button press, as a measure of subjective expectancy during pre- and post-training. Trials with incorrect responses (left button press for a stimulus presented to the right of fixation and vice versa) were
removed from the data (5.8\%). We refrained from analyzing error trials, due to their small number. Reaction times were normalized for each participant and the pre- and posttraining separately. We then classified each trial according to its current stimulus and trial history. As we manipulated the probability of alternation and repetition, trials were classified according to whether a trial was a repetition R or alternation A trial and whether a trial was preceded by three alternations AAA, three repetitions RRR, or any of the six other possible combinations: AAR, ARA, ... We computed the mean RTs for each trial group and analyzed mean RTs using a \(2 \times 2 \times 2 \times 8\) mixed design ANOVA with bias as a between subject factor (repetition vs. alternation), and measurement (pre- vs. post), final event (R vs. A) and trial history (AAA, AAR, ARA, ..., RRR) as within subject factors.

\section*{Results}

We found a significant 3-way interaction between group, measurement, and final event \((\mathrm{F}(1,24)=6.39, \mathrm{p}=0.012)\). Prior to training, we found a bias towards alternations A (mean \(=-0.132, \mathrm{SE}=0.022\) ) compared to repetitions R (mean \(=0.124, \mathrm{SE}=0.024\); final event: \(\mathrm{F}(1,24)=24.26, \mathrm{p}<\) 0.001 ; Figure 3). After training, bias was different for each group (final event * training group: \(\mathrm{F}(1,24)=8.89, \mathrm{p}=\) 0.005 ). If repetition trained participants experienced an alternation, then it took them longer to respond (mean \(=\) \(0.076, \mathrm{SE}=0.063\) ), compared to alternation trained participants (mean \(=-0.092, \mathrm{SE}=0.045 ; \mathrm{t}(24)=-2.23, \mathrm{p}=\) 0.036 ). And conversely, repetition trained participants marginally significantly responded faster when they experienced a repetition (mean \(=-0.011, \mathrm{SE}=0.057\) ) compared to alternation trained participants (mean \(=0.118\), \(\mathrm{SE}=0.043 ; \mathrm{t}(24)=1.86, \mathrm{p}=0.076)\). Experiencing a dynamic environment with a bias either towards repetitions or alternations determines the bias in SQE in a subsequent stable environment.

Figure 3: Results. a Prior to training, we find alternation biased SQE. b After training, we find a change in bias from alternation to repetition in repetition trained participants (green lines). Alternation trained participants (orange lines) maintained their alternation bias. \(\mathbf{c}\) bias in SQE prior to training and \(\mathbf{d}\) bias in SQE after training averaged across trial history \(\mathrm{t}-1\) to \(\mathrm{t}-3\).

\section*{Discussion}

SQE are a pervasive phenomenon in 2 AFC and are typically explained by an irrational sensitivity to local patterns in trial history, which is supposed to give rise to other suboptimal behavior, too, such as the gambler's and hot-hand fallacy in decision making. We propose instead that SQE are conditionally rational: they arise because subjects attempt to learn the probability of occurrence of the two stimuli in 2AFC but with an inappropriate world model. Instead of constant stimulus probability, they believe in change. We trained participants in a changing world with a repetition or alternation bias and observed a change in participants' repetition or alternation bias in SQE consistent with the repetition or alternation training they received. Our data support the conclusion that biased SQE are at least in part driven by an inappropriate world model: SQE are conditionally rational.
Two previous studies proposed that participants' belief in a changing world gives rise to SQE. Yu and Cohen (2009) developed a Bayesian model of probability updating. Like our model, probability updating was based on stimulus repetitions and alternations ( \(2^{\text {nd }}\) order) in trial history. Their model produced SQE similar to the one's described in the literature, primarily Cho and colleagues (2002). Crucially, the authors did not explicitly measure the effects of training participants to believe in a particular world model on SQE and their model could account for bias in SQE only through ad hoc choice of a reset-prior (a prior belief in what the world will most likely be like after change) skewed towards, in their case, repetitions. Our results indicate that such biases can be altered by relatively small amounts of training. Wilder and colleagues (Wilder et al., 2009) also developed a Bayesian model of probability updating to explain previously observed SQE based on stimulus repetitions and alternations ( \(2^{\text {nd }}\) order) and stimulus location ( \(1^{\text {st }}\) order). Like Yu and Cohen (2009), Wilder and colleagues (2009) explained bias in SQE through ad hoc choice of a biased reset-prior. They state that bias in SQE changes from experiment to experiment, is difficult to predict, and should not be cast as part of a computational theory of SQE. Instead, it reflects attentional and perceptual mechanism. We assume they hereby mean that bias reflects automatic facilitation and not subjective expectancy, to use Soetens' et al. terminology (Soetens et al., 1985). We observed a predicted chance in bias after a manipulation of participants' world model, which speaks against this interpretation. The bias in SQE should be part of a computational theory of SQE.
Cho and colleagues (2002) conducted a 2 AFC experiment and developed a computational model to explain the repetition biased SQE they observed. Their model explains SQE as the consequence of special pattern detectors. According to the authors, subjects have two detectors: (a) a relatively simple repetition detector, which increases our expectation to observe a stimulus again when it has just occurred and (b) a more complex alternation detector which counts observed alternations and increases the expectation
to another alternation in proportion to the number of already observed alternations. But other than being able to account for their data, the model does not explain why we have certain pattern detectors and not others (Cho et al. (2002) list six possible detectors). Crucially, their model cannot easily explain why the training participants received in our experiment altered bias in SQE.
Green and colleagues took a similar approach to ours to explain a different phenomenon, namely probability matching in sequential binary decision tasks (2010). They proposed that participants' belief in an inappropriate world model for sequential binary decision tasks causes probability matching. In sequential, binary decision tasks, participants have to choose one of two options. One option has a higher probability of winning ( \(70 \%\) versus \(30 \%\) ). The optimal strategy for this task is to determine which option has a higher probability of winning and then choose that option exclusively. Instead, participants tend to choose the option with \(70 \%\) success probability \(70 \%\) of the time and its alternative \(30 \%\) of the time. While this probability matching behavior is suboptimal, Green and colleagues showed that given a particular albeit inappropriate world model for the task, probability matching is optimal. The authors asked participants to complete sequential, binary decision tasks and manipulated them to believe in different world models. This manipulation changed probability matching behavior a strong support for their claim. Probability matching is conditionally rational. We conclude similarly that biased SQE are conditionally rational.
Simpler models, exponential down-weighting of trial history (Anderson \& Carpenter, 2006), for example, can explain SQE but cannot explain the change in bias in SQE that we observed. SQE indicate that subjects are sensitive to recent but not distant trial history. The change in bias in SQE, however, indicates that subjects are sensitive to what they experienced many trials back (during training), too. Exponential down weighting of evidence cannot explain this dependence on temporally distant and at the same time recent information. One could augment a model that explains SQE by exponential down weighting of trial history with a bias but, to compete with our explanation, there would have to be a rational explanation for this bias.

Our findings thus show that an inappropriate world model at least in part gives rise to biased SQE. This shows that in 2AFC, participants try to learn the generative process of the task - the process, which determines how outcomes, in this case repetition versus alternation, are generated. Learning such a generative model is what distinguishes model-based from model-free learning, according to Daw and colleagues (Daw, Niv, \& Dayan, 2005; Doll, Simon, \& Daw, 2013; Otto, Gershman, Markman, \& Daw, 2013) and Green and colleagues (Green, Benson, Kersten, \& Schrater, 2010). We demonstrate that a seemingly simple behavioral phenomenon (SQE) is at least in part driven by model-based learning, which supports the recently proposed ubiquity of model-based learning algorithms (Doll et al., 2013).

In summary, we proposed that biased SQE are a consequence of participants' selection of an inappropriate world model for 2AFC. We manipulated participants' beliefs and observed predicted changes in bias of SQE. Our predictions were based on a Bayesian model of probability updating, which estimates probability of change and estimated run length to derive trial-by-trial estimates of the probability of observing a repetition versus alternation.

\section*{Appendix}

The predictive distribution is computed with respect to expected run length \(\hat{r}_{t}\) (Nassar, Wilson, Heasly, \& Gold, 2010). On each trial, the agent computes the probability that a change \(c\) occurred using Bayes rule:
\[
\begin{equation*}
p\left(c \mid X_{t}\right)=\frac{p\left(X_{t} \mid c\right) p(c)_{t}}{p\left(X_{t} \mid c\right) p(c)_{t}+p\left(X_{t} \mid \hat{p}_{R A, t}\right)\left(1-p(c)_{t}\right)} \tag{1}
\end{equation*}
\]

In the repetition bias group \(p\left(X_{t} \mid c\right)=\max \mathrm{B}\left(a_{0}, b_{0}\right)\) with \(a_{0}>b_{0}\) for a repetition and \(p\left(X_{t} \mid c\right)=1-\max \mathrm{B}\left(a_{0}, b_{0}\right)\) with \(a_{0}>b_{0}\) for an alternation. In the alternation bias group \(p\left(X_{t} \mid c\right)=\max \mathrm{B}\left(a_{0}, b_{0}\right)\) with \(a_{0}<b_{0}\) for an alternation and \(p\left(X_{t} \mid c\right)=1-\max \mathrm{B}\left(a_{0}, b_{0}\right)\) with \(a_{0}<b_{0}\) for a repetition. \(p(c)_{t}\) depends on current, estimated run length \(\hat{r}_{t}\) and increases with increasing \(\hat{r}_{t}\) :
\[
\begin{equation*}
p(c)=1-\left(1-p_{c}\right)^{\hat{t}_{t}} \tag{2}
\end{equation*}
\]

Change becomes more likely as participants complete more trials without intervening change (a uniform distribution has an increasing hazard function). \(p\left(X_{t} \mid \hat{p}_{\text {rep,t }}\right)\) is the predictive distribution if a change point did not occur and depends on \(\hat{r}_{t}\) and the number of alternations A and repetition R in \(\hat{r}_{t}\).
The expected or mean value of the predictive distribution is based on two possibilities: (a) a change point occurred, in which case \(\hat{p}_{R A, t}=\max \mathrm{B}\left(a_{0}, b_{0}\right)\) with \(a_{0}>b_{0}\) for the repetition bias group and \(\hat{p}_{R A, t}=\max \mathrm{B}\left(a_{0}, b_{0}\right)\) with \(a_{0}<b_{0}\) for the alternation bias group, or (b) no change point occurred, in which case the recent outcome \(X_{t}\) is used to update \(\hat{p}_{R A, t}\). If \(X_{t}\) is a repetition, the number of repetitions \(R_{t}\) in estimated run length \(\hat{r}_{t}\) is increased by one: \(R_{t}=R_{t-1}+1\). If \(X_{t}\) is an alternation then \(A_{t}=A_{t-1}+1\) and in the repetition bias group (note that \(R_{t}+A_{t}=\hat{r}_{t}\) ):
\[
\begin{equation*}
\hat{p}_{R A, t}=\max B\left(a_{0}+R_{t}, b_{0}+A_{t}\right) \tag{3}
\end{equation*}
\]
with \(a_{0}>b_{0}\) in the repetition bias group and \(a_{0}<b_{0}\) in the alternation bias group. The posterior distribution is a weighted average of these two possibilities:
\[
\begin{equation*}
\gamma_{t}=p\left(c \mid X_{t}\right) p(c)_{t}+\left(1-p(c)_{t}\right) \hat{p}_{R A, t} \tag{4}
\end{equation*}
\]

Expected run length is updated on each trial based on the probability that change occurred (in which case it is reset to one) and based on the probability that there was no change (in which case it is incremented by one):
\[
\begin{equation*}
\hat{r}_{t+1}=\left(\hat{r}_{t}+1\right)\left(1-p(c)_{t}\right)+p(c)_{t} \tag{5}
\end{equation*}
\]

\begin{abstract}
Joint attention has long been accepted as constituting a privileged circumstance in which word learning prospers. Consequently research has investigated the role that maternal responsiveness to infant attention plays in predicting language outcomes. However there has been a recent expansion in research implicating similar predictive effects from individual differences in infant behaviours. Emerging from the foundations of such work comes an interesting question: do the relative contributions of the mother and infant to joint attention episodes impact upon language learning? In an attempt to address this, two joint attention behaviours were assessed as predictors of vocabulary attainment (as measured by OCDI Production Scores). These predictors were: mothers encouraging attention to an object given their infant was already attending to an object (maternal follow-in); and infants looking to an object given their mothers encouragement of attention to an object (infant follow-in). In a sample of 14month old children \((\mathrm{N}=36)\) we compared the predictive power of these maternal and infant follow-in variables on concurrent and later language performance. Results using Growth Curve Analysis provided evidence that while both maternal follow-in and infant follow-in variables contributed to production scores, infant follow-in was a stronger predictor. Consequently it does appear to matter whose final contribution establishes joint attention episodes. Infants who more often follow-in into their mothers' encouragement of attention have larger, and faster growing vocabularies between 14 and 18-months of age.
\end{abstract}

Keywords: vocabulary, maternal responsiveness, joint attention, growth curve modelling

\section*{Introduction}

An extensive body of research has identified several fundamental influences on word learning during infancy and early childhood. Some influences are broad predictors of language ability, such as maternal education and frequency of story reading in the home (Brooks \&

Meltzoff, 2008; Crain-Thorenson \& Dale, 1992). Other influences on language ability are local and specific, and as a result allow causal hypotheses about specific processes through which words are learned, such as joint attention (eg; Carpenter, Nagell \& Tomasello, 1998;). Joint attention refers to a situation in which two people share a common point of reference, such as when a mother and child both look at a toy and periodically look to one another as well, while at the same time the mother describes the toy (Mundy \& Newell, 2007). In such situations, joint attention is thought to help children identify relations between words and their referents, and in so doing, increase word learning (Baldwin, 1991; 1993; Brooks \& Meltzoff, 2008). Joint attention thus depends on adult and infant behaviours, and the conjunction of the two supports word learning (Smith, Yu \& Pereira, 2011).

Several studies of naturalistic parent-infant interactions have demonstrated that parents differ in how they interact with infants, and these differences influence word learning. These differences include the frequency of utterances, use of prescriptives, and choice of object reference whilst interacting with their infants (Akhtar, Dunham \& Dunham, 1991; Masur, Flynn \& Eichorst, 2005; Tomasello \& Farrar, 1986). Perhaps most importantly, the results of a number of longitudinal studies indicate that caregivers' sensitivity and responsiveness to their infants' focus of attention during parent-infant interactions predicts the timing of early linguistic milestones and vocabulary growth rate (e.g., Carpenter et al., 1998; Tamis-LeMonda, Bornstein \& Baumwell, 2001). This evidence suggests that caregivers are responsible for joint attention episodes: when caregivers notice their infants' focus of attention and join in, joint attention is established, and as a result, word learning is supported.

Other studies have identified robust infant characteristics that influence word learning, such as infant attentional abilities or attention style. For example, Tamis-LeMonda and Bornstein (1989) reported that 5-month-olds who habituated to a visual stimulus more quickly also had larger receptive vocabularies at 13 months. Dixon and Smith replicated this finding and demonstrated that infant temperament moderates the relation between attention and vocabulary size (Dixon \& Smith, 2008). The influence of infant attention on vocabulary size is presumed to function via joint attention, and indeed, individual differences between infants on experimental measures of gaze following predict later language (Brooks \& Meltzoff, 2005; 2008). Until recently, however, the hypothesised relation between infant joint attention and word learning was presumed through global longitudinal relations rather than observations of local, specific relations. Recent work using microanalytic techniques for investigating joint attention and word learning has given insight into both infant and maternal contributions. Infants holding an object named by the adult, the size of the object in the infant's view, and the stability of head movements during naming are predictive of word learning (Yu, Xu \& Zhu, 2011). Additionally parents' holding the object being named is only predictive of word learning when in doing so they attract their infants' attention (Yu et al., 2011). In similar micro-analytic studies of children's eye movements during word learning, systematic, selective and sustained attentional shifts have been labelled the "critical factor" (Smith \& Yu, in press; Yu \& Smith, 2012).

Our aim was to build on the studies of Yu et al., and Yu \& Smith by examining both maternal and infant contributions to joint attention, and to examine the significance of those contributions for word learning at a global, rather than local level. A lot is known about infant and maternal behaviours during constrained learning tasks but much less about their micro-level behaviours in real time such as during free play (Yu et al., 2011). On a general environmental level maternal reponsiveness has been shown to predict language outcomes (TamisLeMonda et al., 2001). Infant joint attention behaviours measured experimentally have also been shown to predict language outcomes (Brooks \& Meltzoff, 2005, 2008). We wished to assess complementary joint attention behaviours of infants and their mothers in a single situation. Our aim was to assess both infants and their mothers in a genuine and sustained learning environment. To do so we implemented a methodology to assess both maternal and infant contributions in the same naturalistic interaction concurrently by using a single micro-level behavioural coding system. Mothers and their 14-monthold infants participated in 10-minute free play interactions in a university laboratory. We coded mother and infant attention independently, using a fine-grained coding system that has been used in a number of studies of
maternal responsiveness and infant attention (Bornstein, Suwalsky, Ludemann, Painter \& Schulthess (1991). We then combined those codes to compute the likelihood that a mother encouraged attention to an object, given that her infant was already attending to it (maternal follow-in) and the likelihood that an infant attended to an object given that the mother encouraged attention to it (infant followin). Both likelihood measures were odds ratios. Maternal follow-in identified situations in which the mother followed an infant's attentional state and as a result, joint attention was established. Infant follow-in identified situations in which the infant followed the mother's attentional state, and as a result, joint attention was established. We then examined the predictive power of each variable (maternal follow-in and infant follow-in) for language development at \(14,16,17\) and 18 months (measured as productive vocabulary size).

In this study three hypotheses were examined. First, in keeping with previous work, we hypothesized that maternal follow-in at 14 months would predict language development from 14 to 18 months. Second, we hypothesized that infant follow-in at 14 months would predict language development from 14 to 18 months. Finally we considered infant follow-in to be an important indicator of the infant's active contribution to establishing joint attention, and therefore hypothesized that infant follow-in would be a better predictor of language development than maternal follow-in.

\section*{Method}

\section*{Participants}

Mothers were recruited in their third trimester of pregnancy to take part in First Steps, a longitudinal study of development from birth to 18 -months, which has since been extended to four-years, (see Ellis-Davies, Sakkalou, Fowler, Hilbrink \& Gattis, 2012). This recruitment took place in community groups. Of the 39 mother/infant dyads initially recruited, 36 infants ( 19 boys, 17 girls) were included in the analyses reported here. Exclusion criteria were failure to complete the interaction (P36 \& P38), and any referral for developmental delays (P18). Infants came from a range of socioeconomic and maternal education backgrounds. Although all infants' data was included in the analysis 4 infants missed vocabulary testing at one of the four time points. The majority ( \(\mathrm{N}=29\) ) were first language English speakers. A further 7 infants were bi-lingual or second language speakers. Monthly testing sessions took place either on campus at Cardiff University or in a local community facility. Parents were given \(£ 25\) in shopping vouchers at each of their monthly visits and a final \(£ 250\) upon completion of the study. For more information on the sample and study see Ellis-Davies, Sakkalou, Fowler, Hilbrink \& Gattis, (2012).

\section*{Procedure}

Infant Vocabulary Growth Measure. Vocabulary acquisition scores were obtained using the Oxford University Babylab U.K adaptation of the MacArthurBates Communicative Development Inventory (OCDI: Hamilton, Plunkett \& Schafer, 2000). Parents completed all sections of the OCDI when their children reached 14, 16,17 and 18 -months of age. Vocabulary production
scores for the infants were the outcome variables of interest for the current study.

Interaction Coding. During the monthly testing session at 14 -months mothers and their infants were left alone with a standard set of age appropriate toys. These "free play" interactions were filmed and the first 10 -mins of uninterrupted interaction were used for coding the variables of interest.

FIGURE 1. Scatterplots and regression lines of vocabulary production and age for all infants who met inclusion criteria.

Interactions were coded using mutually exclusive and exhaustive coding scheme as described in Bornstein, Suwalsky, Ludemann, Painter \& Schulthess (1991). Using Mangold® (2010) INTERACT software infant attention and maternal encouragement of attention behaviours were coded if they met or exceeded one second in duration. Infant codes were limited to: look to object; look to caregiver; or none/not visible. Maternal codes were limited to: physical or verbal encouragement of attention to object; encouragement of attention to caregiver; or none of the above. Interrater reliability was based on \(10 \%\) of interactions. Cohen's Kappa was .64 for infant attention and. 8 for maternal encouragement. This study
was particularly interested in the didactic behaviours of both parties. Once interactions were coded using the two modes a sequential analysis was carried out following the procedures of Bakeman and Quera (1995) and Bakeman and Gnisci (2005). This computed odds ratios, descriptive measures of effect size, for our variables. Odds ratios were computed using episodes where the target follow-in behavior commenced within 3-secs of the preceding behavior beginning. If target behaviours were more likely to be initiated during points when the corresponding behaviour was ongoing (as opposed to any other times) these odds ratios were greater than 1. The Generalized Sequential Querier program (GSEQ version 4.1.2;

Bakeman \& Quera, 1995) was used to compute these values. Infant follow-in was classified as: the infant looks to object given maternal encouragement of attention to object. Maternal follow-in then was classified as: maternal encouragement of attention to object given infant attending to object.

\section*{Results}

\section*{Productive vocabulary scores}

As reported in previous work (eg., Brooks \& Meltzoff, 2008), productive growth increased rapidly across these age ranges in our sample (Figure.1). As expected mean productive vocabulary scores across children at each age correlated strongly and positively. The mean at each data collection point was significantly different from the others with the only exception being between 16-month \((\mathrm{M}=27.58, \quad \mathrm{SD}=31.07), \quad\) and \(\quad 17\)-month \(\quad(\mathrm{M}=46.63\), \(\mathrm{SD}=55.75\) ), values.

\section*{Interaction coding results}

The sequential analysis odds ratios \((\mathrm{N}=36)\), were generated giving a probability of the examined sequence over others. Infant follow-in ( \(\mathrm{M}=1.15, \mathrm{SD}=.33\) ), and maternal follow-in \((\mathrm{M}=1.22, \quad \mathrm{SD}=.52)\), correlated positively ( \(\mathrm{r}=.38, \mathrm{p}=.02\) ). There was no significant difference between these values \(\mathrm{t}(35)=-.78, \mathrm{p}=.44)\). Individual correlations between infant follow-in and vocabulary production at each time step were between \(\mathrm{r}=.34\) and \(\mathrm{r}=.42\), and were all significant, \(\mathrm{p}<.05\). Maternal follow-in correlations were non-signifcant, ranging between \(\mathrm{r}=.07\) and \(\mathrm{r}=.23\). In order to consider the data from all measurement points together in a single overall analysis, we turned to growth curve models (GCMs).

Figures.2a \& 2.b. Line-graphs showing production scores (mean number of words) over time in months based on median split values of subjects on infant follow-in (2a) and maternal follow-in ( 2 b ) variables.

\section*{Models of productive vocabulary growth}

GCMs provide a powerful tool for investigating the impact of predictor variables on both the overall performance and accelerated growth of productive vocabulary (Mirman, Dixon \& Magnuson, 2008). We perfomed a median split on our predictor variables (see Figure. 2a \& 2b), and using the R (version 2.15 .2 [2012-10-26]) package lme4 (Bates, Maechler \& Dai, 2012) both random and fixed effects were input into the model and their predictive strength assessed. The best fitting model was a mixed effects model including random effects of participant on the intercept of a linear growth curve, coupled fixed effects of infant follow-in (median split high-low) on the intercept and on the slope; and fixed effects of other individual differences on the slope. With such models Akaike's Information Criterion (AIC), Bayesian Information Criterion (BIC), and Chi^2 are the most commonly used indices of goodness of fit. For our best fitting model these were: AIC=1311.6, BIC=1335 Chi \(^{\wedge} 2=104.89, \mathrm{p}<.001\) ) (See Table. 1 Model I1). Whereas the addition of maternal follow-in provided a significant improvement in fit over the baseline model of random effects of participant on productive vocabulary growth (see Model M1, Table.1), the addition of maternal followin provided no improvement over and above the inclusion of infant follow in. Infant follow-in is thus a better predictor of both absolute vocabulary values and rate of growth, where maternal follow-in only effects rate of growth and to a lesser extent.

\section*{Follow-up analysis}

In order to eliminate the possibility that our infant followin variable was simply a function of how often an infant looked to objects or how long they looked to objects in total or the average duration of looks to object, a simple independent samples \(t\)-test was carried out to ensure these characteristics of the low and high groups were not significantly different. No differences between high and low groups were found for: number of looks to an object, \(\mathrm{t}=-.54, \mathrm{p}=.59\); total duration of looking at an object, \(\mathrm{t}=.7\), \(\mathrm{p}=.67\); and average duration of looking at an object, \(\mathrm{t}=.48\), \(\mathrm{p}=.64\).

\section*{General Discussion}

In this paper joint attention episodes between mothers and infants were evaluated, in order to examine maternal and infant contributions to joint attention and their relations to language outcomes. The duration of joint attention episodes has previously been correlated with language development (Markus, Mundy, Morales, Delgado \& Yale 2001). It is thought to do so by helping children identify relations between objects and words (Baldwin, 1991; 1993). In this study we sought to elucidate a more specific picture of the components involved. Previous work has demonstrated maternal contributions to joint attention influence vocabulary development (Carpenter et al., 1998; Tamis-LeMonda et
al., 2001). We used naturalistic interactions to evaluate infant and maternal contributions to joint attention in comparable ways. Results from our Growth Curve Analysis models showed that both infant and maternal follow-in behaviours contributed to rate of language growth. Furthermore infant follow-in made the most sizeable contribution to the model: infants' tendency to look at objects after being encouraged to so do was strongly related to productive vocabulary size and growth over the next 4 months. It is not simply infants who look more frequently to objects, or show sustained visual attention whose productive vocabularies are higher. The follow-in variable rests upon the infant's visual attention being temporally contingent on the encouragement of their parent. The current paper provides support for a model in which it is infant and not only maternal offerings to early word learning situations that are substantial (Smith \& Yu, 2010; Yu \& Smith, 2012). For productive vocabulary at 14 months-old it is important that infants respond appropriately to mothers' encouragement of attention by attending to objects, thereby establishing joint attention.

Table 1: Table of growth curve model estimated fixed effects and model fits.

\hline Chi^2 & & 104.89** & 19.35** & 2.36* \\
\hline
\end{tabular}

Such results suggest that those infants who can effectively respond to and engage in shared experience are then able to efficiently attend to the subsequent maternal contributions held within it. That is during play between mother and infant, when a mother is encouraging their infants' attention to an object the infant then responds to this encouragement by sharing their mothers' attentional focus. In such situations, joint attention is achieved by the infant following into their mother's focus of attention. The positive predictive nature of maternal contributions within already established periods of joint
attention, as opposed to outside them, has been previously documented (Tomasello \& Farrar, 1986). Once infants establish a period of joint attention by orienting to a point of shared reference with their parent, given meaningful encouragement to do so, the subsequent information relayed can aid forming new associations (Waxman \& Gelman, 2009).

These findings then add to evidence that global attributes of joint engagement and specific individual differences in the protagonists contributing to it are crucial in guiding language outcome. Our results confirm and extend prior reports that individual differences in infants' abilities to respond to joint attention attempts between 6 and 18-months relate positively to vocabulary development (Morales, Mundy, Delgado, Yale, Messinger, Neal \& Schwartz, 2000). Future studies should investigate this relation further by comparing the contributions of maternal initiation and infant follow-in to joint attention.

By assessing maternal and infant contributions to joint attention in comparable ways within a single naturalistic interaction we have been able to advance beyond previous studies. Such temporally precise micro-analytic analysis of attention has been previously encouraged as a means to elucidate the processes of word learning (eg., Yu \& Smith; 2010, Yu et al., 2011). We aimed to bridge a gap between the micro-analytic measurement-techniques used previously in experimental word learning settings, and a significantly more naturalistic situation. Previous experiments judged word-learning performance on those novel items included in the experimental task. We have moved beyond this to show that global productive vocabulary (as measured by the OCDI) benefits significantly from infants being able to detect and respond successfully to attempts at joint engagement during periods of unconstrained play. Infant follow-in, over and above maternal follow-in, is a novel and valuable predictor of vocabulary development. Future research should address what quality of the episode underlies this result.

\section*{Conclusions}

As early as 14 months the selective visual attention of infants in response to maternal encouragement is predictive of both concurrent and future linguistic success. In this study we demonstrated, as reported previously, responsive caregivers impact infant vocabulary size positively. Moreover, for the first time in this study, the infant's response to joint attention was shown to account for a higher proportion of vocabulary growth.

\title{
Intentionality, Evaluative Judgments, and Causal Structure
}

\begin{abstract}
The results from a number of recent studies suggest that ascriptions of intentionality are based on evaluative considerations: specifically, that the likelihood of viewing a person's actions as intentional is greater when the outcome is bad than good (see Knobe, 2006, 2010). In this research we provide an alternative explanation for these findings, one based on the idea that ascriptions of intentionality depend on causal structure. As predicted by the causal structure view, we observed that actions leading to bad outcomes are associated with negative social pressures (Experiment 1), that these negative pressures give rise to a specific kind of causal structure (Experiment 2), and that when these causal structures are pitted against the badness of the outcome, intentionality judgments track with causal structure and not badness (Experiment 3). While the badness of an outcome may have an indirect effect on judgments of intentionality, our results suggest that the factors that affect judgments of intentionality most directly are non-evaluative and objective.

\section*{Introduction}

Ascriptions of intentionality play a fundamental role in our explanations of behaviors (Malle, Moses, \& Baldwin, 2001). They influence our judgments of character (Rotenberg, 1980), deservedness of blame or praise (Lagando \& Channon, 2008), the impermissibility of actions (Cushman 2008), and the severity of deserved punishment (Horan \& Kaplan, 1983). Standard accounts of intentionality ascription hold that judgments of intentionality are based on objective or descriptive properties of the actors and the situation, such as foreseeability, desire, and belief (Guglielmo, Monroe, \& Malle, 2009; Knobe \& Malle, 1997; Mele \& Sverdlik, 1996; Sripada, 2010). Recent empirical work by Knobe (2003a) and others (Nadelhoffer, 2006; Wright \& Bengson, 2009; Cova \& Naar, 2012) raises an alternative view, that ascriptions of intentionality may be based on evaluative properties of a situation. Specifically, Knobe \((2006,2010)\) has argued that the likelihood of viewing a person's actions as intentional is greater when the outcome is bad than when it is good. In this paper, we offer a critical test of this proposal. We also put forward and test another possibility, that judgments of intentionality are most directly based on the causal structure of a situation, which can be influenced at times by evaluative considerations. In a series of three experiments, we show that the phenomenon originally observed in Knobe (2003a) and others is more
directly explained in terms of causal structure than badness of the outcome.

\section*{The Side-Effect Effect (or Knobe effect)}

A connection between intentionality and badness has been demonstrated in research examining the so-called side-effect effect, or Knobe effect. Experiments investigating this effect have typically included two main conditions. In the harm condition, participants read scenarios like the following:

The vice-president of a company went to the chairman of the board and said, 'We are thinking of starting a new program. It will help us increase profits, but it will also harm the environment.'
The chairman of the board answered, 'I don't care at all about harming the environment. I just want to make as much profit as I can. Let's start the new program.
They started the new program. Sure enough, the environment was harmed.

After reading the scenario, participants are asked "Did the chairman intentionally harm the environment?" For this scenario, Knobe (2003a) found that \(82 \%\) of the participants responded that the chairman intentionally harmed the environment. In help conditions, everything is kept the same except the side-effect is described as good. In the chairman scenario, for example, participants were told that the business plan would not only make a profit but also help the environment. Interestingly, in this alternative condition, only \(23 \%\) of the participants felt that the chairman intentionally helped the environment (Knobe, 2003a). This basic finding has been replicated with other scenarios (Knobe, 2003b; Knobe, 2007; Knobe \& Mendlow, 2004; Mallon, 2008; Nadelhoffer, 2004; Nadelhoffer, 2006; Uttich \& Lombrozo, 2010; Wright \& Bengson, 2009) and in a diverse array of populations, including Hindi speakers when the scenarios are translated into Hindi (Knobe \& Burra, 2006), with four-year old children (Leslie, Knobe, \& Cohen, 2006), with participants who suffer from deficits in emotional processing due to lesions in the ventromedial prefrontal cortex (Young, Cushman, Adolphs, \& Hauser, 2006), and with adults with high functioning autism or Asperger's (Zalla \& Leboyer, 2011). The wide range of situations and populations supports the conclusion that the basic pattern of findings is both reliable and conceptually significant, but do these findings really demonstrate that
intentionality is directly dependent on the badness of the outcome?

\section*{Responses to the Evaluative Accounts}

Though many take the side-effect effect as evidence that ascriptions of intentionality are affected by evaluative considerations (Nadelhoffer, 2004; Nado, 2008; Wright \& Bengson, 2009) such as badness, others have attempted to provide accounts of the side-effect effect that are consistent with standard, descriptive models of intentionality. For example, Adams and Steadman (2004) has argued that the side-effect effect is a result of pragmatic implicature: People assent to the statement that the chairman intentionally harmed the environment not because they genuinely attribute intentionality to the chairman but because they do not want to imply that the chairman is not responsible for harming the environment. Machery (2008) has argued that the effect is the result of calculation of trade-offs, arguing that people are more likely to attribute intentionality whenever there is a trade off and that the higher rates of attributions for outcomes that involve a trade-off occur regardless of the evaluative status of the trade-off. Sripada (2010; 2012; Sripada \& Konrath, 2011) has argued that the side-effect effect can be explained in terms of concordance with deeply held attitudes and values attributed to the actor. For example, in the chairman case, since the chairman states that he doesn't care about the environmental outcome in both the harm and the help case, people take this as evidence that the chairman harbors anti-environmental attitudes. However, only in the harm case does the outcome concord with anti-environmental attitudes. It's this concordance that explains the side-effect effect, not the evaluative status of the outcome (see Hughes \& Trafimow, 2012, for a similar account). However, all these accounts have met explanatory or experimental challenges (e.g., Cova \& Naar, 2012; Knobe, 2003b, Knobe, 2004; Mallon, 2008; Phelan \& Sarkissian, 2009; see Nadelhoffer, 2011 for a review).

Uttich and Lombrozo (2010) have argued that the sideeffect effect results from the fact that behavior that conforms to a norm is less informative about the underlying mental states than is behavior that violates a norm. According to their account it is the fact that a norm was violated, not any particular evaluative judgment, that leads to higher rates of attribution of intentional action. Furthermore, they argued that the higher rates of attribution for norm violations is not specific to violations of evaluatively-laden moral norms but that the phenomenon is a feature of norm violations more generally, including statistical and prudential norms. However, their account does not provide a mechanism that allows us to differentiate why some norm violations (e.g., harming versus helping the environment) lead to larger asymmetries in intentional action attributions than other norm violation (e.g., violating an industry standard versus conforming to an industry standard (see Uttich \& Lombrozo, 2010, Experiment 1)) or why some norm violation do not lead to an asymmetry at all
(e.g., a supervillain who violates supervillain social norms (see Uttich \& Lombrozo, 2010, Experiment 2)). In a slogan, their account can be viewed to being committed to the claim: "A norm is a norm is a norm." But the fact of the matter is when it comes to the side-effect effect, not all norms are equal. Some norm violations are more informative than others. What explains this fact? Furthermore, their evidence is still compatible with the claim that badness (or some other evaluative judgment) best explains the pattern of asymmetries observed in various side-effect effect cases.

\section*{Causal Structure Account}

Though the demonstrations of the side-effect effect suggest that evaluations of the badness of the outcome may enter into our reasoning about intentionality, another possibility is that in Knobe's experiments, more may have been varied than the valence of the outcome. In particular, in varying the badness of the outcome, Knobe may have also varied the causal structure of the scenarios, and it may have been the causal structure, and not the valence of the outcomes per se, that affected people's ascriptions of intentionality. According to this alternative view, the extra something that determines whether actions are judged as being intentional, is whether, in fact, the agent causes himself to produce the action.

The claim here begins with the idea that, in situations such as the harm version of the chairman case, there is normative force that acts on the chairman, and this normative force puts a pressure on the chairman not to pursue behavior that would knowingly violate the norm. In other words, the presence of the norm puts a preventive pressure on the chairman not to harm the environment. This establishes a preventive causal relationship: namely, Norm PREVENTS chairman from harming the environment.

However, in spite of the presence of this PREVENT relationship, the chairman overcomes that pressure and engages in behavior that will knowingly harm the environment. In overcoming the normative pressure, an additional PREVENT relation is formed: The chairman PREVENTS the norm. This string of PREVENT relations establishes what is known as a double prevention (Collins, 2000; Dowe, 2001; Hall, 2004; Schaffer, 2000). In this case, the chairman PREVENTS the norm from PREVENTING him from harming the environment. Prior research has shown that double preventions are interpreted as instantiating CAUSE or ALLOW relationships (McGrath, 2005; Wolff, Barbey, \& Hausknecht, 2010). In this case, the pattern would result in the CAUSE relationship: The chairman causes himself to harm the environment. Interestingly, this "causing of one's self" instantiates a situation in which an actor acts on himself, making it reflexive. This self-causation is particular important for intentionality. To intentionally do something is, if nothing else, to cause oneself to do that something. Importantly, the double prevention, and thus the reflexive relationship, will arise in the harm scenario but not in the help scenario
because there is no preventive pressure against helping the environment, only against harming the environment.

Three experiments were conducted to test this causal structure account against the badness account.

\section*{Experiment 1}

In this experiment we investigated whether the causal structure view could provide an alternative explanation for the results found in previous studies. Just as in previous studies, participants read scenarios in which an actor brought about a good or bad side-effect and then they rated the intentionality of the actor. The scenarios included six scenarios that have been used in other studies in the literature, as well as 10 new scenarios created specifically for this experiment. We were interested in whether we could replicate the intentionality effect observed in other studies. The current experiment also tested one of the main predictions of the causal structure account, that people would infer more preventive pressure in harm scenarios than help scenarios.

\section*{Methods}

Participants Forty-eight Emory University undergraduates participated for course credit.
Materials The materials were 16 scenarios modeled after the chairman scenario described above. For each scenario, there was a HARM version in which the side effect violated a norm and a HELP version in which the side effect did not violate a norm.
Procedure Participants read eight of the 16 scenarios. Each participant received only one version of each scenario they read, either the HARM or HELP version of each scenario. In response to each scenario, participants provided an intentionality rating by indicating their agreement or disagreement with statements of the form "The [primary actor] intentionally [side effect]". Participants also provided preventive pressure ratings by indicating their agreement or disagreement with statements of the form "Knowing that [going forward with the proposed plan of action] would [side effect] put pressure on [primary actor] to not [go forward with the plan]. The two types of ratings were presented in random order. All ratings were made on a scale that ranged from -4 complete disagreement to +4 complete agreement.

\section*{Results and Discussion}

As shown in Figure 1, participants were more willing to say that an actor intentionally brought about the side effect in the HARM condition ( \(M=1.01, S D=1.97\) ) than in the HELP condition ( \(M=-1.71, S D=1.80\) ), \(t(47)=7.91, p<\) . 001 , thus replicating, with a much wider range of materials, the phenomenon originally reported in Knobe (2003a). Of central importance to the causal structure hypothesis, participants rated the preventative pressure on the actor not to act as greater in the HARM condition ( \(M=1.56, \mathrm{SD}=\) 1.85 ) than in the HELP condition ( \(M=-2.28, \mathrm{SD}=1.49\) ), \(t(47)=9.38, p<.001\).

Figure 1: Mean ratings of intentionality and pressure by scenario (HARM vs. HELP) in Experiment 1. \({ }^{* * *} p<.001\)

\section*{Experiment 2}

Experiment 1 established that people infer a greater pressure against bringing about the side effect in HARM than HELP scenarios. With the first link of the double present established, this entails that a double prevention would be established in any case where the first PREVENT relation is overcame. Thus, Experiment 1 establishes that when people knowingly bring about a bad side effect, they infer a sequence of PREVENT relations, or otherwise, a double prevention. Double preventions typically lead to CAUSE or ALLOW relationships (McGrath, 2005). In the context of the scenarios, this implies that people should be more willing to say that the actor either caused or allowed the side effect in the HARM condition than in the HELP condition. In Experiment 2, we tested the prediction that people will be more likely to say that the actor caused the side effect in the HARM scenarios than in the HELP scenarios.

\section*{Methods}

Participants Fifty-two Emory University undergraduates participated for course credit.
Materials and Procedure The materials were the same as in Experiment 1. As in Experiment 1, participants provide ratings of intentionality. Unique to the present experiment, participants also provided ratings of causation by indicating their agreement or disagreement with statements of the form "The [primary actor] caused [side effect]."

\section*{Results and Discussion}

As shown in Figure 2, participants were more likely to say that the actor caused the side effect in the HARM condition ( \(M=1.42, S D=1.97\) ) than in the HELP condition ( \(M=-\) \(.06, S D=1.96), t(51)=5.94, p<.001\). The basic asymmetry in intentional action attributions was replicated in this experiment with participants more likely to attribute intentional action in the HARM condition ( \(M=.40, S D=\) 2.22) than in the HELP condition ( \(M=-1.98, S D=1.84\) ), \(t(51)=6.35, p<.001\).

Figure 2: Mean ratings for cause and intentionality judgments by scenario type (HARM vs. HELP) for Experiment 2. \({ }^{* * *} p<.001\)

\section*{Experiment 3}

The results from Experiments 1 and 2 support the causal structure account but are not conclusive because they remain compatible with the badness account. In order to test between badness and causal structure, the typical alignment between badness and causal structure needs to be reversed. Such a re-alignment was achieved in the current experiment by using scenarios in which an actor either violated or conformed to an unjust rule or law. Such scenarios instantiate situations in which there is a preventive pressure against doing a good thing, and little or no pressure against doing a bad thing.

Take for example the following VIOLATE scenario used in Experiment 3 (brackets indicate changes in wording for the CONFORM condition):

In Midwestern America, there was a church that had explicit rules against interracial couples participating in any church-sponsored activity.

One day a church deacon was considering which of his friends to invite to perform in a concert celebration being sponsored by the church. He decided to invite the Smiths, a husband and wife duet.

Upon hearing the news a fellow church member went to the deacon and said, "By inviting the Smiths, you will be violating [conforming to] the church's rules against interracial couples participating in any church-sponsored activity."

The deacon answered, "Look, I know I will be violating [conforming to] the church's rules against interracial couples participating in any churchsponsored event, but I don't care one bit about that. I just want to invite the most talented people to
perform in the concert. I am going to invite the Smiths to perform."

The deacon invited the Smiths to perform.
In cases like this, it appears the right thing to do would be to violate the rule. Thus, when the deacon violates the rule it is likely that people will judge the violation as good. However, since the rule is in force, it is likely that people will judge that the deacon is under pressure not to violate the rule. In contrast, when the deacon conforms to the rule, it is likely that people will judge the conforming to the rule as being bad, yet it is likely that people will not judge that the deacon is under pressure not to conform. If this is right, then the badness account and the causal structure account make opposite predictions for intentionality judgments in cases like the church case. The badness account predicts that intentionality judgments should be higher for the conform cases than for the violate cases because it is bad to conform but good to violate. The causal structure account predicts that intentionality judgments should be higher for the violate cases than for the conform cases because the actor is under pressure not to violate but is not under pressure not to conform. Additionally, because overcoming a preventive pressure instantiates a double prevention, and since the pattern of double preventions observed in these cases should lead to the inference of a reflexive causal relationship, the causal account also predicts that people will be more likely to say that the actor causes himself to violate the law or rule than to say that the actor causes himself to conform to the law or rule.

\section*{Methods}

Participants Thirty-two Emory University undergraduates participated for course credit.
Materials The materials were 8 scenarios modeled after the church scenario. For each scenario, there was a VIOLATION version in which the decision would violate an unjust rule or law, and a CONFORM version in which the decision would conform to an unjust rule or law.
Procedure Participants were assigned to read one version of each scenario. For each scenario, participants were asked to rate their level of agreement with statements about whether the primary actor acted intentionally and whether the primary actor experienced preventive pressure, as in Experiments 1 and 2 . Unique to the current experiment, participants rated their level of agreement with statements that the primary actor caused himself to bring about an effect by responding to statements of the form "The [primary actor] caused himself to [side effect]." As a manipulation check, participants also rated whether the outcome was good or bad, by responding to statements of the form, "How good or bad is [the occurrence of the side effect]," on a scale from -4 very good to 4 very bad.

\section*{Results and Discussion}

As is shown in Figure 3, Participants were more likely to say that an actor was under pressure not to violate an unjust rule or law ( \(M=1.11, S D=1.89\) ) than to conform to an unjust rule or law ( \(M=-1.31, S D=1.91\) ), \(t(31)=5.24, p<\) .001. Participants were also more likely to say that the outcome was bad when the unjust rule was conformed to ( \(M\) \(=.70, S D=1.70\) ) than when the unjust rule was violated ( \(M\) \(=-1.56, S D=1.31), t(31)=-5.49, p<.001\). These results lead the badness account and the causal structure account to make opposite predictions for intentionality judgments in these cases. The causal structure account predicts that intentionality judgments will be higher in the violate cases, while the badness account predicts that intentionality judgments will be higher in the conform cases. As predicted by the causal structure account, participants were more likely to say that the actor intentionally violated the rule or law ( \(M=1.67, S D=2.35\) ) than conformed to the rule or law ( \(M=-.62, S D=2.01\) ), \(t(31)=5.94, p<.001\). Additionally, as predicted by the causal structure account, participants were more likely to judge that the actor caused himself to violate the rule or law ( \(M=1.98, S D=1.74\) ) than conformed to the rule or law ( \(M=.34, S D=1.82\) ), \(t(31)=\) 4.91, \(p<.001\).

Figure 3: Mean ratings for pressure, badness, intentionality, and reflexive cause judgments by scenario type (HARM vs. HELP) for Experiment 3. \({ }^{* * *}\) p \(<.001\).

To provide converging statistical evidence that causal structure and not badness of outcome was leading to the asymmetrical judgments of intentional action, a regression analysis was conducted with intentionality judgments regressed on pressure judgments, reflexive-causation judgments and badness judgments. After controlling for the other variables in the model, pressure judgments and selfcausation judgments significantly predicted intentionality judgments, \(\beta\) 's \(\geq .349\), \(p\) 's \(<.005\). However, intentionality judgments and badness judgments were unrelated, \(\beta=-\) \(.095, p=.406\).

\section*{General Discussion}

The results from Experiments \(1-3\) support the conclusion that ascriptions of intentionality are driven by the causal structure rather than badness of the outcome. When assessing causal structure, it appears that people may look for reflexive causal relationships, that is, causal relations in which a person causes herself to do something.

Differences in causal structure are descriptive differences, not evaluative differences. Thus, our findings are compatible with the standard, descriptive views concerning the way we reason about mental states. However, it may be objected that the causal structure account is not fully compatible with the standard, descriptive views because, according to our account, causal structure is sensitive to norms. While we acknowledge that prohibitory norms are typically viewed as providing a force against behavior, it is not really any particular evaluative judgment that is providing this force (above and beyond the non-evaluative recognition that a norm is in effect). In Experiment 3, we demonstrated that force against behavior is perceived even in cases in which it is thought to be good to violate the norm. Additionally, even though our experiments focused on norm violations of different kinds, we don't think the effect is particular to norm violations. We would expect there would be higher rates of intentionality attribution for any situation involving a preventive, whether this force is due to norms or physical resistance.

Though we have shown that ascriptions of intentionality depend on causal structure, our results point to the possibility that the concept of intentionality itself may be little more than a kind of causal structure. Such a result might help explicate the curious role that intentionality seems to play in our understanding of causal relationships in general.

\begin{abstract}
Recent research has begun to explore the role of diagrams as cognitive tools. Here I develop new conceptual and methodological tools for exploring the sociality of cognition involving diagrams. First, I distinguish two varieties of groupdependent cognition. Second, extending Nersessian's method of cognitive-historical analysis, I show how a suitablyinformed "literature review" of diagrams published in scientific articles offers a window into the group-dependent cognition of scientists. I end by sketching future avenues of inquiry, and how this approach may inform science education.
\end{abstract}

Keywords: chronobiology; cognitive-historical analysis; group cognition; member cognition; scientific diagrams.

\section*{Introduction}

\section*{Diagrams as Cognitive and Social Tools}

Cognitive scientists have recently adopted a variety of approaches to studying graphical practices ("GPs"). Tversky applies her work on embodiment, spatial cognition and navigation to study spatial graphics and spatial design more generally (2011a; 2011b; Tversky, Heiser, Lee, \& Daniel 2009). Hegarty focuses on the cognitive abilities underlying the "spatial intelligence" which facilitates learning from diagrams by students in the sciences (2004; 2010; 2011). Cheng explores how suitably constrained, innovative GPs support learning the conceptual structure of highly mathematized domains (Cheng 1997; 2002; 2009; 2011).

The focus of such research has tended to be on the consumption of completed diagrams as a cognitive activity of individuals. \({ }^{1}\) A few studies have also addressed the production of diagrams by individuals. However, constructing and reasoning with GPs are also social practices. Some researchers have recently developed ethnographic methods to study group cognition involving completed diagrams (Alač, 2008; 2011; Kirsh, 2009).

Here I take a different approach. First, I highlight social aspects of cognition in diagram production. GPs often integrate ideas from a variety of earlier sources, and diagrams indicate the designer's understanding of her field: GPs inform us about how individuals perceive the social and professional groups of which they are members. Second, I stress the social effects of diagram consumption: creating and disseminating diagrams is a manipulation of the social environment which helps to define boundaries

\footnotetext{
\({ }^{1}\) This is especially true of the experimental literature in which isolated subjects complete tasks involving diagrams.
}
between social-professional groups. To do this I develop a new strategy of inquiry: analyzing published scientific diagrams which document the history of research. My case study concerns research into the mechanisms of circadian rhythmicity in cyanobacteria (blue-green algae). One goal of the paper is to show how such a "literature review" can serve to investigate scientists' group-dependent cognition.

\section*{Extending the Cognitive-Historical Method}

The present paper extends the method of cognitive-historical analysis (Nersessian, 1992; 1995; 2002; 2008). The method is historical in that it takes as data the existing record of investigative practices in the science(s) of interest. In early work, Nersessian focused on the work of notable individuals (e.g., Maxwell), highlighting specific developments in their thinking. Here, I examine a years-long record of published figures depicting multiple authors' conceptions, at various stages of inquiry, of the known and hypothesized mechanisms of circadian rhythmicity in cyanobacteria.

The cognitive aspect of the methodology is rooted in a continuum hypothesis - that "the cognitive practices scientists have invented and developed over the course of the history of science are [...] sophisticated outgrowths of the kinds of cognitive strategies humans employ in coping with their environments and in problem solving of a more ordinary kind" (Nersessian, 2008). Scientists, like other humans, form cooperative groups to tackle large-scale tasks, and freely draw inspiration from peers when it is available. \({ }^{2}\) I shall show that with careful attention to the field-wide context in which diagrams are developed, we can clearly identify aspects of GPs which indicate group-dependent cognition among scientists. In this initial demonstration, I focus on diagrams from review-style articles, penned by (sometimes several) well-known and respected authors in the field. The express purpose of such publications is to offer a window into the social, conceptual, and evidential context constituting the current state of play in the field.

Nersessian has always stressed that a full understanding of cognitive activities must embed them within their social context. Recently, she and her colleagues have directly studied the interplay between social and cognitive factors in scientific practice (Osbeck, Nersessian, Malone, \& Newstetter, 2011). Drawing upon their insights, I hold that the lines between "individual" and "group" cognition are

\footnotetext{
\({ }^{2}\) Scientific research is not fully communal and cooperative; great incentives promote individual achievement as well.
}
not always clear-cut, since properly attending to social context sometimes requires reconceiving an individual's cognitive activities as group-dependent.

\section*{Delineating Group-Dependent Cognition}

Classical cognitive science maintains that individuals exhibit forms of cognition which do not clearly depend upon their membership in a group. Call this individual cognition, or i-cognition. As Hutchins (1995) argued, cognition might also be distributed across a group of cognizers so that the group instantiates a higher-order cognitive architecture. Call this group-level cognition, or \(g\) cognition. I emphasize that individuals exhibit a third, unique variety of cognition when they self-identify as members of a group (whether or not that group exhibits \(g\) cognition). Call this member cognition, or m-cognition. Like \(i\)-cognition (and unlike \(g\)-cognition) \(m\)-cognition is attributable to (first-order) individuals, rather than to groups. However, like \(g\)-cognition (and unlike \(i\)-cognition) \(m\) cognition depends upon an individual's group-membership. Osbeck et al. provide paradigmatic examples of \(m\)-cognition in their analysis of how scientists position themselves and negotiate their identity: "Identity negotiation can be considered a form of sense-making" (what they elsewhere call seeking coherence) "directed to the meanings one applies to oneself within social groups that include but are not limited to the particular research laboratory, one's field of practice... and science as a tradition of inquiry" (2011).

To illustrate how I conceive of \(m\)-cognition, consider the following objections to my proposed method. First, by looking to published diagrams, I am guaranteed to miss many ( \(i-\) ) cognitive activities involved in their production. The creator(s) of a diagram often discard a variety of "failed" versions, deploying expertise in choosing what to represent and how best to do so. Only access to the unpublished, discarded diagrams could really shed light on the process of problem-solving that led to the finished product. Second, publication requirements imposed by journals may add a layer of cognitive opacity, as the designer loses the ability to do just as they like. Published diagrams might be cognitively "whitewashed," so to speak.

While this line of thought is correct as far as it goes, it neglects one important reason for pursuing this inquiry: when authors prepare materials for publication, they knowingly work within the constraints imposed by "outside" powers. Publication is a de facto requirement for active membership in a professional science, and part of one's professionalism consists in navigating the pitfalls of publication. If part of scientists' practice involves "whitewashing" their individual cognitive products, making them ready for public consumption, the whitewashing itself depends upon interesting forms of \(m\)-cognition which reflect an individual's self-identification as a member of a group e.g., awareness of professional-bureaucratic norms, and selfmonitoring with respect to those norms.

More relevant, for my purposes, are the ways scientists self-monitor with respect to the empirical and evidential norms of their field. When a scientist prepares a publication for consumption by her peers, her professional reputation depends upon cognizance of: the empirical support accorded to various hypotheses; which sources of evidence have been deemed reliable; which findings have been replicated or reinterpreted, etc. These are just some of the \(m\)-cognitive activities which an individual engages in to negotiate her specific expertise, self-identifying as an able practitioner of some method(s) or authority on some topic(s).
These norms are especially relevant to the production of my source materials: authoritative review articles presenting the current state of a field. The production of diagrams is an integral part of crafting such articles. Thus, I suggest that cognitive-historical analysis of such published diagrams can plausibly begin with the hypothesis that these GPs, as part of the professional practice of scientists, are guided by \(m\) cognition regarding empirical and evidential norms in the relevant discipline(s). It follows that such diagrams are amenable to analysis as visual traces of \(m\)-cognition. My task in what follows is to demonstrate that this is the case.

\section*{Three Snapshots of Cyanobacterial Chronobiology}

I turn now to canvass three stages of research regarding circadian rhythms in the cyanobacterium Synechococcus elongatus. Here I must be selective in every aspect of my inquiry. \({ }^{3}\) In this section I introduce the details of my casestudy. Cognitive analysis occurs in the section thereafter.

\section*{Stage One: First Steps}

A biological system's circadian rhythmicity ("CR") is its endogenously controlled production, once every \(\sim 24\) hours, of some phenomenon (e.g., waking, onset of metabolic processes, peak transcription of a gene). For decades, while research into the CR of eukaryotes flourished, it was thought that no similar phenomena would be discovered in prokaryotic cells. Prokaryotes lack membrane-bound organelles, exhibit relatively simple metabolic activities, and frequently have lifespans of less than 24 hours. Prevailing wisdom taught that such an organism would have no use for anticipating local day-night cycles.
CR was eventually discovered in S. elongatus (Ishiura, Kutsuna, Aoki, Iwasaki, Andersson, Tanabe, Golden, Johnson, \& Kondo, 1998). Since then this system has become a mainstay of circadian research, owing in part to its high genetic manipulability. In an early review article, Kondo \& Ishiura (1999) made an explicit attempt to shoehorn cyanobacterial rhythmicity into the accepted mechanism for eukaryotic systems. Evidence from a variety of eukaryotic systems had suggested that the CR of single cells was controlled by a Transcription-Translation

\footnotetext{
\({ }^{3}\) For details, cf. Johnson \& Xu (2009) and Huang \& Lin (2009).
}

Feedback Loop (TTFL). A generic eukaryotic TTFL is shown at left in Figure 1. A "clock gene" (dark blue bar) is transcribed, leading to the translation of a corresponding "clock protein" (dark blue oval) outside the nucleus. After undergoing state-changes in the cytoplasm, the clock protein returns to the nucleus, where it interrupts the effect of an "activator" (red oval) at a promoter region (light blue bar). The clock protein(s) thus inhibit further transcription of the clock gene(s). By hypothesis, a TTFL constituted a cell's core circadian "clock" or "pacemaker" and the CR in the expression of other ("clock-controlled") genes was thought to be dependent upon the activity of clock proteins.

The critical functional arrangement of the TTFL is the interplay of positive and negative elements: activation at the promoter increases transcription of clock genes, but clock proteins feedback to inhibit transcription of their own genes. Such systems can instantiate a limit cycle oscillator. With the right time constants, the system could oscillate with a 24-hour period, giving rise to the organism's observed CR.

At right in Figure 1, the authors attempt to fit cyanobacterial CR into the same scheme. Early research (Ishiura et al., 1998) had shown (a) that deletion of any gene in the kai gene cluster (containing genes kaiA, kaiB, and kaiC) abolished CR in S. elongatus, and (b) that a variety of single amino acid mutations to any of the kai genes (resulting in the corresponding production of subtly altered Kai proteins) either disturbed or abolished CR. It was thus concluded that the core clock in S. elongatus involved the kai gene cluster and the Kai proteins working in concert.

The same study also showed that while kaiC overexpression resulted in rapidly decreased activity at the promoter (" \(\mathrm{P}_{\text {kaiBC }}\) " in Figure 1) which controls the transcription of kaiB and kaiC, kaiA overexpression resulted in increased activity of the same promoter. Thus, the Kai proteins appeared capable of participating in a TTFL, with KaiC playing the role of a traditional "negative element" (note the re-use of the dark blue oval) which inhibits its own
gene's transcription, and KaiA playing the role of a traditional "positive element" (note the re-use of the red oval) which promotes KaiC's transcription.

These initial results were consistent with a cyanobacterial TTFL, but left much underdetermined. For example, it was unknown how Kai proteins might influence the transcription of kai genes, since the Kai proteins lacked DNA binding motifs, and were thus incapable of directly influencing promoters (Ishiura et al., 1998). Given the success of the TTFL model in other systems, the authors of Figure 1 posited intervening entities ("x," "y," "z") to mediate between the Kai proteins and transcriptional regulation.

\section*{Stage Two: Troubles with TTFLs}

A few years later, Johnson (2004) published a "minireview" in which he proposed the alternative "Oscilloid" model shown in Figure 2. The interactions between Kai proteins had by now been further determined. As shown top-right KaiC alternates between a highly phosphorylated state (with "P" attached) and an unphosphorylated state (no "P"). KaiA facilitates KaiC's phosphorylation, and inhibits its dephosphorylation. KaiB inhibits those activities of KaiA, biasing KaiC towards dephosphorylation. The result is a \(24-\) hour rhythm in the phosphorylation state of KaiC, which is a determining factor in KaiC's downstream effects.

Meanwhile, the problem of how the Kai proteins might regulate transcription had become more pressing. It had been shown that KaiC expression not only (somehow) repressed transcription of its own gene (and of kaiB), but also globally repressed transcription of virtually every gene in S. elongatus' genome (Nakahira, Katayama, Miyashita, Kutsuna, Iwasaki, Oyama, \& Kondo, 2004). Investigators had also shown that rhythmicity in kaiC expression could be attained in strains in which kaiC transcription was controlled by a promoter taken from another organism's genome (Xu \& Johnson, 2003; Nakahira et al., 2004). These were departures from eukaryotic TTFLs, in which positive

Figure 1: Kondo \& Ishiura's (1999) Figures 3 (left) \& 4 (right). At left is the TTFL model of rhythmicity in eukaryotic cells. At right, available data in S. elongatus are fitted into a similar scheme. See text for discussion.
and negative feedback loops compete for dominance in the activation and inhibition of specific, native promoters.

The same researchers recommended an elegant solution. KaiC had been shown to be part of a large family of DNA recombinases (Leipe, Aravind, Grishin, Koonin, 2000). KaiC was thus hypothesized to be capable of altering the shape and structure of cyanobacterial chromosomes in a rhythmic fashion, thereby globally affecting gene transcription (including, as just one example, the kaiABC cluster). At middle-left in Figure 2, Johnson added this to the hypothetical model of CR in S. elongatus.

\section*{Stage Three: Surviving 2005}

Not long after Johnson's minireview, a pair of momentous reports showed conclusively that cyanobacterial CR was not dependent upon a TTFL. An initial report showed that CR in KaiC's phosphorylation state persists even when both transcription and translation are globally inhibited (Tomita, Nakajima, Kondo, \& Iwasaki, 2005). Shortly thereafter, it was reported that KaiC's phosphorylation rhythm could be reconstituted in vitro, using a mixture containing only the three Kai proteins and ATP (Nakajima, Imai, Ito, Nishiwaki, Murayama, Iwasaki, Oyama, \& Kondo, 2005). The core clock in cyanobacteria, it seemed, was instantiated entirely in post-translational entities and processes, and required no transcriptional regulation whatsoever. Transcriptional and translational regulation were reconceived as effects of clock functioning, not operations constitutive for clock function. \({ }^{4}\)

After 2005, researchers pursued the molecular details of KaiC phosphorylation rhythms. Here I cannot discuss this

Figure 2: Johnson's (2004) Oscilloid model.

\footnotetext{
\({ }^{4}\) Transcriptional regulation was later seen as stabilizing or supporting the Kai-based clock (Johnson, Mori, \& Xu 2008).
}
research in detail. Figure 3, a representative example of the period, displays no details concerning chromosomes, transcriptional regulation, or transcriptional rhythms.

\section*{Analysis}

By attending to the social and evidential contexts surrounding the production of Figures 1-3, we gain insight into the m-cognition of these diagrams' designers. In this way we can provide cognitive answers to questions about scientists' GPs. We simultaneously gain insight into how GPs helped shape the social environment of chronobiology.

Consider Figure 1. A pertinent question to ask regarding this figure is: Why did the authors construct this diagram as they did, drawing an analogy between eukaryotic and prokaryotic CR?

At the time of publication, no data substantively confirmed the presence of a TTFL in S. elongatus. Available data were merely consistent with such a model. What drove Kondo \& Ishiura to produce this diagram was a broader awareness of hypotheses accepted elsewhere in chronobiology. Eukaryotic TTFLs were then considered the sole concrete examples of circadian limit cycle oscillators in living systems. The group of "chronobiologists" was de facto defined by an interest in such mechanisms. By hypothesizing that the newly discovered CR in cyanobacteria fit the same model, the authors explicitly positioned themselves in the broader theoretical community of chronobiologists.

The text of the article supports this interpretation. Kondo\& Ishiura aim to show how cyanobacteria could fit the "basic circadian model" of a limit-cycle oscillator, and explicitly recommend strategies for further-extending this model to CR in plants (1999, p. 171). Kondo \& Ishiura also stress the importance of assimilating cyanobacteria to the TTFL model, forming a theoretically unified chronobiology: "Cyanobacteria could be a model system for molecular approaches to the circadian clock, because it is the simplest organism that has a clock" (1999, p.172). The subsumption of cyanobacterial CR to the TTFL model would lend credence and generality to the working assumptions of chronobiologists at large.

Figure 3: Mackey \& Golden's (2007) visual summary of the stages of the core Kai-based oscillator in S. elongatus.

Figure 1 is the visual depiction of this shared theoretical framework: the authors literally drew the analogy between the models of CR in eukaryotes and prokaryotes which unified the theoretical framework of chronobiology. Kondo \& Ishiura were positioning themselves as (and encouraging other researchers to recognize themselves as) members of a single, theoretically-unified group of "chronobiologists." Their GP is (partly) explained by appeal to this \(m\)-cognition; the graphic itself is a trace of that \(m\)-cognition.

Consider next Figure 2. A pertinent question to ask regarding this diagram is: Why did the author depart from earlier GPs in the field, especially by including a novel depiction of the entire chromosome of cyanobacteria?

New data showed that circadian transcriptional regulation in S. elongatus was not specific to individual promoters, in contrast to eukaryotic TTFLs. Since previous data had been consistent with a cyanobacterial TTFL and had shown that Kai proteins do (somehow) participate in regulating transcription, it was a "surprise" to find these discrepancies with the eukaryotic model (Johnson 2004, p.217.2). It is these data, plus the persisting field-wide theoretical assumption that transcriptional regulation is somehow constitutive for clock function, which "suggests a broadly global mechanism for the cyanobacterial clock system" (Johnson, 2004, p.217.3). It is within these constraints that he appeals to the broader literature regarding chromosome topology in cyanobacteria, and articulates the Oscilloid model to provide a novel hypothesis regarding transcription-translation feedback in cyanobacterial CR.

Thus in Figure 2, Johnson breaks the struct visual analogy with eukaryotic, as was demanded by evidence showing that "the clock system in cyanobacteria is different from that in eukaryotes" (2004, p.217.4). Despite this, the view of transcriptional regulation as a process constitutive for clock function remained part of the shared theoretical framework of a still-unified chronobiology. For this reason, Johnson stresses that the cyanobacterial data might lead us to consider the hypothesis that eukaryotic clocks themselves involve chromosomal topology as a mechanism of transcriptional regulation. He writes that "If this proves to be the case, the investigations of the cyanobacterial clock may lead to fundamental insights that are broadly applicable to all organisms" \((2004,217.4)\). In either case a unified chronobiology would need to refine its theoretical framework to incorporate cyanobacterial data.

Figure 2 is the visual depiction of the new model for cyanobacterial transcription-translation feedback. The graphical disparity from earlier depictions of the cyanobacterial clock reflects the conceptual departure from the TTFL model. Johnson positioned himself as (and encouraged other cyanobacterial researchers to recognize themselves as) a member of a distinct sub-group of chronobiologists which was helping to refine the general theoretical framework of chronobiology. Johnson's GP is (partly) explained by appeal to this m-cognition; the graphic is itself a trace of this \(m\)-cognition.

Finally, consider Figure 3. A pertinent question to ask regarding this diagram is: Why have the authors departed from earlier GPs, especially by excluding all reference to transcriptional regulation?

The core clock in S. elongatus had been identified as a post-translational oscillation in the phosphorylation state of KaiC (involving interactions with other proteins). The data showed that "transcriptional regulation is apparently a dispensable layer of reinforcement on a post-translational clock in the cyanobacterium" (Mackey \& Golden 2007, p.382). Transcriptional regulation (local or global) was no longer considered part of the core clock in S. elongatus.

Figure 3 above is the visual depiction of the new model of the cyanobacterial clock. By excluding any depiction of genes, chromosomes, transcriptional feedback, and the like, Mackey and Golden underscore the distinction between cyanobacterial and eukaryotic clocks. Cyanobacterial chronobiology was no longer theoretically yoked to molecular hypotheses drawn from eukaryotic systems: the hypothesis that some form of transcriptional regulation would be constitutive for the function of every circadian limit-cycle oscillator had been excised from the general theoretical framework of chronobiology. Cyanobacterial chronobiologists had distinguished themselves as a unique subgroup of chronobiologists. Mackey and Golden's GP can be (partly) explained by appeal to this \(m\)-cognition, and the diagram itself is a trace of this m-cognition.

\section*{Concluding Remarks}

In this brief case study, I have demonstrated that the method of cognitive-historical analysis may be fruitfully extended to reveal scientific diagrams as visual traces of groupdependent cognition (m-cognition). In doing so, I have sketched how scientists' GPs help demarcate the boundaries between groups of researchers. It is hoped that with the benefit of future elaboration, this approach can take its place as a compliment to other empirical methods of examining the cognitive activities involved in GPs.

With this initial demonstration completed, I suggest that inquiry into diagrams may be especially well-suited for investigating the \(m\)-cognition of scientists. As in the cases above, published diagrams frequently offer "at a glance" a window into authors' construal of the state of the art in their field. While I have not emphasized it, the examples also hint at the extent to which authors recycle old formats (often citing their original designers), positioning themselves as members of a persisting group and building extended "lineages" of GPs. Further research might fruitfully explore the "cognitive" lineages of which these are visual traces.

Finally, I suggest that such analyses might fruitfully inform science education. The foregoing demonstrates how published figures provide a visual record of the empirical and theoretical developments which fuel scientific fields' growth and subdivision, and how they can serve as a window into researchers' conception of their own field. As I hope to have shown, when such graphics are presented with appropriate context, and when they are queried in a suitable
manner, they can serve as intuitive scaffolds to help novices gain a rich understanding of the course of expert thinking in a field of study.

\section*{Acknowledgments}

This material is based upon work supported by the National Science Foundation under Grant no. 1127640. I learned much from other members of UCSD's Center for Chronobiology while supported by a UCSD Chancellor's Interdisciplinary Collaboratory Grant. Feedback from members of the WORGODS research group (Daniel Burnston, Adele Abrahamsen, and William Bechtel) and from two reviewers strengthened the paper considerably.

\title{
Infants' Early Understanding of Coincidences
}

\begin{abstract}
Coincidences are surprising events that can provide learners with the opportunity to revise their theories about how the world works. In the current research, we investigate whether infants are truly sensitive to coincidences, detecting these events even when they cannot be predicted mere probabilities. In addition, we explore whether this sensitivity is translated into action, encouraging infants to engage in activities that enable them to revise their theories. Results from 2 experiments demonstrate that infants display a sensitivity to coincidence similar to adult intuitions, and they selectively explore objects that produce anomalous data that better supports an alternative theory than their prior theory.
\end{abstract}

Keywords: coincidence; probabilistic reasoning; theory revision.

\section*{Introduction}

As scientists, we are sometimes met with surprising results in our research. At this point, it can be a struggle trying to reconcile the evidence with our theories - do we chalk these results up as experimenter error, or do we discard our theories in favor of an alternative one? Sometimes, such results were a mere coincidence; they go away upon a review of our procedures or an increase in sample size.

Other times, however, unexpected results have led to important scientific discoveries. For example, the discovery that cholera was caused by infected water, rather than the prevailing notion that the disease was transmitted by bad air, was due to a suspicious coincidence observed by John Snow, a physician, in 1854. After a particularly violent outbreak of cholera in the city of London, Snow noticed that the location of the victims were all tightly clustered around a water pump on Broad Street (Snow, 1855). Using this suspicious finding, Snow convinced the local council to remove the handle of the water pump, and this action has since been commonly credited with stopping the further spread of cholera. Such discoveries abound in the history of science, emphasizing the detection of suspicious coincidences as key to causal discovery (Owens, 1992; Nickerson, 2004) and rational inference (Horwich, 1982).

This detection of coincidences is not limited to scientific research, as adults use it to make inferences in daily life as well. They also act on these observations appropriately, taking the nature of these coincidences into consideration. Imagine a situation in which one leaves our apartment in a hurry on the way to work. While waiting for the elevator, we meet three of our neighbors, and each one of them is carrying an umbrella. Do we dismiss this observation as a
mere coincidence? Probably not - we are likely to discard our belief that today is just like any fair weather day in California, rushing back to grab an umbrella too.

According to Griffiths \& Tenenbaum (2007), our reaction at the elevator can be properly understood through a Bayesian framework, in which coincidences are formally defined as events that provide better support for an alternative theory, as compared to a currently favored causal theory. Whether a surprising observation should be taken as compelling evidence or dismissed as a mere coincidence is thus dependent on two factors: the prior probability of the alternative theory, and the strength of coincidence as given by the likelihood ratio. The likelihood ratio quantifies the support that the evidence provides for the alternative theory over the original theory. Griffiths \& Tenenbaum (2007) also show empirically that adults evaluate coincidences in ways that are consistent with this framework - they take into account prior probabilities and likelihood ratios when thinking about unexpected evidence. For example, adults judged the results of a test of psychokinesis (low prior probability) as mere coincidence and that of a test of genetic engineering (high prior probability) as evidence, even when the data provided the same support for the two alternative theories. However, when the strength of the coincidence is manipulated to be sufficiently high in the case of psychokinesis, adults find it increasingly hard to dismiss the observations as just chance results. Therefore, adults act in ways consistent with an ideal Bayesian learner, evaluating and acting on observed coincidences in rational ways.

Our reaction in the elevator situation can thus be easily understood through the Bayesian lens. Given that there are many more fair weather days than rainy days in California, we should favor the null hypothesis due to its higher prior probability: today is a fair weather day, just like most days. However, the surprising observation that our neighbors are all carrying their umbrellas gives a high likelihood ratio, strongly suggesting an unexpected causal structure: today is a rainy day. We have thus detected a coincidence: the observed event provides better support for an alternative theory of rainy weather, as compared to our prior theory of fair weather. In this example, the alternative theory also has a sufficiently high prior probability, pushing us to discard our original theory, and to intervene by retrieving an umbrella from our apartment.

Detecting such coincidences is important for learners, as these events are often great opportunities for us to revise our current theory of how the world works. This opportunity is especially essential for children, whose accounts of the inner
workings of the world are under major construction and revision (Carey, 1985, 2009; Gopnik \& Meltzoff, 1997). Given that many causal relationships in the world are probably novel to young children, coincidences are rich sources of information for how their theories should be revised, and thus one should predict that children should pay great attention to coincidences (Griffiths \& Tenenbaum, 2007). In this paper, we investigate this prediction by asking whether young infants are sensitive to such coincidences, and whether this sensitivity translates into action that can help them update their theories about how the world works.

Recent research exploring the development of probabilistic reasoning has provided ample evidence that 6to 12 -month-old infants are sensitive to differences in probabilities (Denison, Reed \& Xu, 2012; Teglas, Girotto, Gonzalez \& Bonatti, 2007; Xu \& Garcia, 2008). For example, Teglas et al. (2007) showed that in a lottery machine-like setup that consisted of 1 yellow and 3 blue objects bouncing around, 12-month-old infants were more "surprised" to see a yellow object (low probability) exiting the machine, than when a blue object (high probability) did.

However, detecting coincidences is not quite the same as assessing the relative probabilities of different events. In some cases, events can have equal probabilities, but we do not consider them equally surprising. Take the instance of five rolls of a 6 -sided dice. The probability of seeing the sequence " \(2,1,4,3,1\) " is \(\left(\frac{1}{6}\right)^{5}=0.00013\). Although low in probability, this event is unsurprising to most adults. In contrast, the probability of seeing the sequence " \(1,1,1,1\), 1 " is again \(\left(\frac{1}{6}\right)^{5}=0.00013\), but this time we are astonished, becoming suspicious of the dice and the roller of the dice. These intuitions cannot be simply explained by the proposal that learners are actually evaluating and comparing the probabilities of "kinds" of events (e.g. the probability that the sequence consists of different numbers vs. the probability that the sequence consists of the same number), instead of single events (e.g. the probability that the specific sequence is " \(2,1,4,3,1\) "). This proposal is problematic as it is unclear what exactly counts as a "kind" of event, and what a learner should do when there are many possible "kinds" to consider (e.g. running sequences such as " \(1,2,3\), 4,5 " or alternating sequences such as " \(1,2,1,2,1\) " are suspicious too, but do not fit into the two earlier-mentioned "kinds"; see Griffiths \& Tenenbaum, 2007 for a more comprehensive review). Instead, we consider the sequence " \(1,1,1,1,1\) " to be a suspicious coincidence because it provides better support for the alternative theory that the dice is weighted towards " 1, " rather than our original theory that the dice is fair.

As such, there exists a gap in our knowledge of whether infants are truly sensitive to coincidences - we know that they are surprised by the occurrence of low-probability events, but do they detect coincidences even when the mere probabilities of different events are exactly equal? To investigate this question, we designed an experiment analogous to the dice roll example detailed earlier. 8-month-
old infants were familiarized to a box containing 6 different colored balls. An experimenter then tossed out a ball from the box, seemingly with no control over the outcome of the event. The ball was then returned to the box, and this event was repeated 3 more times. Using a violation-of-expectation paradigm, we measured the amount of time infants looked at a trial where the same colored ball fell out each time (e.g. yellow, yellow, yellow, yellow), as well as a trial where a different colored ball fell out each time (e.g. blue, green, red, yellow). Note that each specific sequence shown had the same exact event probabilities: \(\left(\frac{1}{6}\right)^{4}\).

We also designed a second experiment with an exploration measure, examining whether this sensitivity to coincidences translates to action, such that the detection of a suspicious coincidence could potentially have consequences on children's learning. In this experiment, we showed 13-month-old infants two different boxes each containing 6 different colored balls. One of the boxes always generated the same sample each time, and the other always generated a different sample each time. The two boxes were then offered to the infants to play with freely, and we measured the amount of time they played with each box.

\section*{Experiment 1}

In Experiment 1, we investigated whether infants were sensitive to coincidences that cannot be predicted by the computation of the mere probabilities of events. If infants shared adult intuitions, they should look longer at the event in which the same colored ball fell out of the box each time under random sampling, than when a different colored ball fell out each time. We also included a Baseline condition to assess infants' intrinsic preferences for these two events.

\section*{Method}

Participants Forty infants (21 males and 19 females, \(M=8\); 6 [months; days], \(R=7 ; 3\) to \(9 ; 1\) ) were tested. All were recruited from Berkeley, California, and its surrounding communities. An additional 7 infants were tested but excluded due to fussiness \((\mathrm{N}=5)\) or experimenter error ( N \(=2\) ). Infants who participated in the experiment were required to be exposed to English a minimum of 50\% of the time. Infants received a small gift for their participation.

Materials A total of 36 colored balls ( 7 cm in diameter) were used. The balls came in 6 colors: red, purple, blue, green, yellow and orange.

A small white box ( \(28 \mathrm{~cm} \times 10 \mathrm{~cm} \times 7.5 \mathrm{~cm}\) ) constructed from foam core was used in the Free Play phase of the experiment (see Procedure). The box contained 3 different colored balls.

A small, transparent Plexiglas container with an open top ( \(16.5 \mathrm{~cm} \times 7.5 \mathrm{~cm} \times 9 \mathrm{~cm}\) ) was used to display the sampled ball during the test trials.

A large box ( \(30 \mathrm{~cm} \times 26 \mathrm{~cm} \times 21 \mathrm{~cm}\) ) was used to display the population of 6 different colored balls during the familiarization and test phase. The box was rectangular,
with a Plexiglas window to show the population of balls, and two hidden back compartments. One compartment was used to hold the 4 sample balls to be tossed out later during the test trials, while the other compartment was to contain the balls that were being returned to the box after each toss. From the infants' perspectives, the box appeared as one single unit, filled only with 6 different colored balls. The Plexiglas display window was covered with a fabric curtain to ensure that the population would be hidden from sight while each sampled ball was being tossed out.

Apparatus The testing room was divided in half by curtains spanning its width and height. The curtains had a cut-out above a puppet stage that measured \(94 \mathrm{~cm} \times 55 \mathrm{~cm}\) (width x height). The experimenter sat behind the stage with her upper body and head visible to the infant. There was a black back curtain attached to the stage, such that the experimenter is hidden from view when it is dropped. An observer, present to code the infant's looking times, sat in a corner of the room and was not visible to the infant. She watched the infant on a TV monitor and coded the infant's looking behavior online using JHAB (R. Casstevens, 2007). The observer was blind to the order of the test trials.

Infants sat in a high chair about 70 cm from the center of the stage. Each parent sat next to their infant facing the opposite direction, and was instructed to avoid looking at the stage. Two video cameras were used to record each experimental session, one to record the infant's looking behavior, and another to record the experimenter's presentation of the trials.

Design and Procedure Each infant was randomly assigned to a Sampling condition or a Baseline condition. Both conditions consisted of a Calibration phase, a Free Play phase, a Familiarization phase and a Test phase.

Sampling Condition To calibrate each infant's looking window, a squeaky toy and/or keys were used in the Calibration phase to direct the infant's attention to the outside parameters of the stage.

In the Free Play phase, the infant was shown a white box containing three different colored balls. She was encouraged to play with the balls for approximately 30 seconds, and the experimenter ensured that the infant touched every ball. This phase was to allow the infants to become familiar with the balls used in the experiment.

The Familiarization phase that followed consisted of two trials. To begin each trial, the experimenter placed the large box on the stage with its front curtain down. Then, she lifted the curtain to reveal a population of 6 different colored balls, saying "See this?" She proceeded to shake the box side to side 4 times, and then set the box back to the center of the stage. While the infant was looking at the stage, the experimenter said "Look, [baby's name], look!" and dropped the back curtain, hiding herself from view of the infant. The observer began timing upon hearing the second
"look". Trials ended when the infant looked away for 2 consecutive seconds.

The large box was removed from the stage between each familiarization trial, and the back curtain was lowered to conceal the experimenter. These trials were included to familiarize the infants to the population of balls in the large box, as well as to the general procedure of the experiment. The familiarizations lasted about 2 minutes for each trial.

The Test phase consisted of two test trials, a Uniform trial and a Variable trial. On each test trial, the experimenter placed the large box and the small Plexiglas container on the left and right side of the stage (infant's view) respectively. The two objects were placed 8 cm apart. The experimenter then lifted the front curtain of the large box, saying "What's this?" She lowered her head and directed her eye gaze at the box for 1 second, in order to remind the infants of the population of balls in the large box. She then picked up the box and shook it 4 times. After the box was set back down, the experimenter lowered the front curtain to conceal the box's display window. Then, the box was lifted and tilted to its side, allowing one ball to fall out into the small Plexiglas container. Although it appeared that the ball had fallen out from the population of balls at random, the ball actually fell out of the back compartment of the box, which contained balls that had initially been set up by the experimenter. The experimenter then directed her gaze towards the "sampled" ball in Plexiglas container, saying "Look at that!" After 1 second, the ball was returned into the box. This process of revealing the population, shaking the box and tossing a ball out was repeated 3 more times, to make a total of 4 "sampled" balls. When the \(4^{\text {th }}\) ball was tossed out, the experimenter said "Look, [baby's name], look!" and dropped the back curtain of the stage. The observer began timing upon hearing the second "look," and ended the trial after the infant looked away for 2 consecutive seconds. Between trials, the stage was cleared and the back curtain was lowered as well. Each test trial lasted for approximately 2 minutes.

Figure 1: Schematic representation of the two trials.
Each infant participated in a Uniform trial and a Variable trial (See Figure 1). In the Uniform trial, the 4 "sampled" balls were all of the same color (e.g. 4 yellow balls), while
in the Variable trial, the 4 "sampled" balls were all of a different color (e.g. 1 red ball, 1 green ball, 1 blue ball, and 1 yellow ball). The last ball that was tossed out in the Variable trial was always identical in color to the balls used in the Uniform trial, to ensure that any difference in looking time was not due to a preference for balls of a certain color. Trial order and the colors of the sampled balls were appropriately counterbalanced across infants.

Baseline Condition The procedure in the Baseline condition was identical to the Sampling condition, except that instead of having the 4 balls being tossed out from the large box, the balls were individually taken out from and returned to the experimenter's pocket. The Baseline condition provided a measure of the infants' pattern of looking times for 4 balls of the same color vs. 4 balls of different colors.

\section*{Results}

Preliminary analyses found no effects of gender, median age-split (whether the infants were younger or older than the median age of the group), or test trial order (Uniform trial first vs. Variable trial first) on looking times. Subsequent analyses were collapsed over these variables.

Figure 2: Mean looking times in the Sampling condition and the Baseline condition. Error bars represent SE.

Looking times for the test trials were analyzed using a 2 x 2 repeated-measures ANOVA with Condition (Sampling vs. Baseline) as the between-subjects factor and Trial Type (Uniform vs. Variable) as the within-subjects factor. There was a significant interaction between Condition and Trial Type, \(F(1,38)=11.58, p=.002, \eta_{p}^{2}=.23\). There were no main effects found.

To break down the interaction, we conducted follow-up ttests exploring the effect of Trial Type (Uniform vs. Variable) for each Condition separately (See Figure 2 for mean looking times). In the Sampling condition, infants looked significantly longer in the Uniform trial ( \(M=13.68 \mathrm{~s}\), \(S D=9.87\) ) than the Variable trial ( \(M=10.22 \mathrm{~s}, S D=6.35\) ), \(t(19)=2.49, p=.02, d=.42\). Thirteen out of 20 infants in
this condition looked longer in the Uniform trial, Wilcoxon signed-ranked test: \(z=1.93, p=.05\). In contrast, infants in the Baseline condition looked significantly longer in the Variable trial ( \(M=15.96 \mathrm{~s}, S D=9.02\) ) than the Uniform trial \((M=10.14 \mathrm{~s}, S D=6.01), t(19)=2.48, p=.02, d=.76\). Fifteen out of 20 infants in this condition looked longer in the Variable trial, Wilcoxon signed-ranked test: \(z=2.35, p\) \(=.02\).

\section*{Discussion}

In the Sampling condition, infants looked reliably longer when 4 balls that were tossed out at random were all of the same color, than when 4 balls were all of different colors, even though the sequences had equal event probabilities. Hence, infants found it surprising when samples that were being generated from a uniform distribution over the long run were identical, i.e. when 4 randomly generated balls (with replacement) all shared the same color, even though they came from a population of 6 different colored balls. This pattern of looking time was reversed in the Baseline condition, where infants looked longer when 4 balls of different colors were produced from the experimenter's pocket instead. Thus, our findings cannot be attributed to a preference for sequences of identical events. These results support the claim that infants are sensitive to coincidences, even when such suspicious coincidences cannot be predicted by evaluating the mere probabilities of particular events.

\section*{Experiment 2}

In Experiment 2, we used an exploration measure to examine whether the infants' sensitivity to coincidences translates into action with consequences on their learning. We predicted that infants should play longer with the box that generated the same colored ball each time under random sampling as compared to a box that generated a different colored ball each time.

\section*{Method}

Participants Fifteen infants (10 males and 5 females, \(M=\) 13; 3 [months; days], \(R=12\); 18 to 13; 29) were tested. All were recruited from Berkeley, California, and its surrounding communities. An additional 3 infants were tested but excluded for not playing with any of the boxes during the test trial. Infants who participated in the experiment were required to be exposed to English a minimum of \(50 \%\) of the time. Infants received a small gift for their participation.

Materials The materials used in Experiment 2 were identical to those used in Experiment 1, except that the large box containing the population of balls was replaced with two new boxes. Similar to the large box, these two boxes ( \(29 \mathrm{~cm} \times 23 \mathrm{~cm} \times 22 \mathrm{~cm}\) ) each had a Plexiglas window to display a population of 6 different colored balls, as well as two hidden back compartments. One of the boxes had its surface painted white, with a black fabric curtain covering the display window, while the other box had its surface
painted black, with a white fabric curtain covering its window. This design was to enhance infant's discrimination of the two boxes, without biasing the infant towards any of the boxes.

Design and Procedure Infants were tested individually in a forced-choice paradigm. Each infant sat on her parent's lap on the floor approximately 1.2 meters from a puppet stage. Parents were instructed to hold on to their infant, and to avoid influencing their child in any way. They were also told that they would be asked to set their infant on the floor directly in front of their lap when the experimenter gives the instruction, "Do you want to come and play?" towards the end of the experiment. Each experimental session consisted of a Free Play phase, a Demonstration phase, and a Test phase. Two video cameras recorded the infants' and experimenter's behavior during the session.

Free Play Phase This phase was identical to that of Experiment 1.

Demonstration Phase To begin the Demonstration phase, the experimenter placed the two large boxes on the stage about 20 cm apart, with their front curtains down. One of the boxes was a Uniform box, containing 4 balls of the same color hidden in its back compartment. The other box was a Variable box, containing 4 hidden balls of different colors instead. The experimenter also placed a transparent container in the space in front of the center of the two boxes. She then drew the infant's attention to the box on the left, saying "What's in this box?" The front curtain of this box was subsequently lifted, revealing a population of 6 different colored balls. The procedure that followed was identical to an individual test trial in Experiment 1, in which the experimenter seemingly tosses out 4 colored balls from the box at random, one after another with replacement. The only exception was that the \(4^{\text {th }}\) ball was returned to the box after 1 second, as looking behaviors were not of interest in Experiment 2. After this \(4^{\text {th }}\) ball was returned to the box, the experimenter said "All done!" She then pointed to the box on the right, and said "Let's see what's in this box!" The experimenter then repeated the steps performed on the previous box. This phase lasted approximately 3 minutes.

The boxes that were assigned as the Uniform or Variable box, as well as the colors of the sampled balls, were appropriately counterbalanced across infants.

Test Phase Each infant completed one test trial. The experimenter brought the two large boxes forward and set them down on the ground about 1 m from the infant, saying "Do you want to come and play?" Parents were instructed to let go of their infant if they had not done so at this point. When the infant touched one of the boxes, the experimenter started a timer and the test trial ended after 60 seconds.

Coding Infants were coded for the amount of time in which they were in contact with each of the boxes.

\section*{Results}

All of the infants' behaviors were coded offline. Preliminary analyses found no effects of gender or demonstration order (Uniform box first vs. Variable box first) on infants' exploration of the boxes. Subsequent analyses were collapsed over these variables.

Preliminary results show that infants played significantly longer with the Uniform box ( \(M=25.02 \mathrm{~s}, S D=26.06\) ) than the Variable box ( \(M=7.02 \mathrm{~s}, S D=11.78\) ), \(t(14)=2.08, p=\) \(.05, d=0.95\).

\section*{Discussion}

As predicted, infants played reliably longer with the Uniform box than the Variable box. These results replicate the findings in Experiment 1, demonstrating the infants are sensitive to coincidences that cannot be predicted by mere probabilities. In addition, our preliminary results indicate that infants do translate this sensitivity into action, selectively exploring the box that generated data which was indicative of a suspicious coincidence.

\section*{General Discussion}

We provide some suggestive evidence that infants are sensitive to coincidences, detecting these anomalous events even when they cannot be predicted by their mere event probabilities. In Experiment 1, infants were presented with a box that ostensibly generated balls under random sampling, creating an expectation that a sequence of tosses should result in a sampling distribution that is even across the 6 colors present in the box. Infants were surprised when the box consistently produced samples that were identical instead. This finding is impressive, considering that the two different sequences that infants saw in Experiment 1 had equal probabilities of occurring. Experiment 2 replicated this novel finding with an older age group through an action measure, and extended the finding by demonstrating that the sensitivity that infants show for coincidences translates into action, as infants preferentially explored a box that produced a sequence of four of the same colored balls, as compared to a box that produced a sequence of four different colored balls.

We speculate that the obtained differences in looking exploration times arise because infants are evaluating the data that they receive according to how well it supports different underlying causal models. For example, a sequence of four yellow balls is surprising because the event provides better support for the alternative theory that the box is rigged, rather than the original theory of random sampling. However, another interpretation of our results is possible, namely that infants (and adults) may consider the uniform sequence "yellow, yellow, yellow, yellow" to be lower in probability than the variable sequence "blue, green, red, yellow." Therefore, the results obtained may be due to a misunderstanding of event probabilities, rather than a consideration of alternative theories. More empirical work is thus necessary to parse these interpretations apart. That
being said, our results continue to provide evidence that young infants are sensitive to anomalous data, and will selectively explore the source of these anomalies.

One might also raise the representativeness heuristic as an alternative account of these results (Kahneman \& Tversky, 1972). By this account, infants preferred the box that generated the same sample each time because the samples (e.g. 4 yellow balls) were very dissimilar to the population from which they were drawn (i.e. 6 different colored balls). However, recent research examining infants' probabilistic reasoning has rendered this interpretation unlikely, as looking patterns were predicted by probabilistic reasoning and not by the representativeness heuristic when these two interpretations were pitted against each other (Denison \& Xu, 2010).

Besides understanding how infants’ representation of the presented events led to differences in their looking and exploration times, of interest in these studies is also why such differences arose. We believe that the ideas advanced by Griffiths \& Tenenabaum (2007) may shed light on this issue: infants pay attention to the coincidences that they encounter in the world, as these surprising events are likely to be rich sources of information for theory revision. By selectively investigating these events, children provide themselves with an opportunity to make a discovery that can enable them to revise their theories.

The present results thus provide tentative support for a growing set of findings demonstrating that infants and young children attend to the generative process of the data they observe and effectively consider between different models for the inputs that they receive (e.g. Gerken, 2010). Our results also bring additional insight to recent research demonstrating a Goldilocks effect in infant's allocation of attention, which found preferential attention to visual sequences that are neither too simple, nor too complex (Kidd, Piantadosi \& Aslin, 2012). In this research, experimenters found that 7-month-old infants are likely to look away earlier for events that are highly predictable. However, predictability is probably not the only determinant of how infants allocate their attention - although a sequence of 4 yellow balls in our experiments was highly predictable, infants paid greater attention to this event because it was inconsistent with their prior expectations about random sampling. Thus, we suggest that infants' consideration of the generative process for the observed data may also play an important role in their allocation of visual attention.

In summary, our experiments provide some suggestive evidence that infants may be sensitive to coincidences. Furthermore, this sensitivity translates into action, as infants preferentially explored the source of such anomalous data. However, many open questions remain: How did infants represent the events presented in our experiments? Why did infants show the obtained differences in looking and exploration time? What is the relationship between infants' looking times and their exploration? Future research examining these questions will provide us with a better grasp of infants' understanding of coincidence, and how
children eventually come to have an accurate idea of how the world works by adulthood.

\section*{Acknowledgments}

We thank Anjelica Benitez and the Berkeley Early Learning Lab (BELL) for their help in recruitment and stimuli building, and the parents and infants for their participation. We also thank Tom Griffiths and Noah Goodman for insightful discussions.

\begin{abstract}
Early word learning may be supported by a developmental feedback loop: the kind of words a child learns early on support the development of attentional biases, which in turn facilitate further word learning. In neural network simulations and a longitudinal study of toddlers we investigated how the emergence of an attentional bias to shape in word learning impacts vocabulary growth with respect to different kinds of words. If this relationship is causal, we should see that the emergence of a shape bias leads to an increase in the rate of learning of shape-based words relative to other kinds of words. The networks supported this prediction, showing an acceleration of shape- compared to material-based word learning. However, in toddlers, shape- and material-based words were learned similarly around the shape bias emergence. Implications are discussed for the developmental feedback loop account and causal relationships between attentional bias development and vocabulary growth.
\end{abstract}

Keywords: Word learning; shape bias; neural networks; longitudinal study.

\section*{Introduction}

Children are skilled word learners, in part because of constraints on the range of things they consider when inferring the referent of a new word. These constraints, sometimes referred to as biases, operate by helping children direct attention, resulting in sensitivity to what information matters most in the context of learning different kinds of words. Although there is debate on the origin of these attentional biases (e.g., Samuelson \& Bloom, 2008), evidence from children and from networks suggest that children can learn biases based on the kinds of nouns they acquire early on in their vocabularies (e.g., Colunga \& Smith, 2005; Gerhshkoff-Stowe \& Smith, 2004). This account entails a developmental feedback loop: the early nouns that children learn give rise to attentional biases, and those biases in turn guide further word learning and impact the structure of children's growing vocabularies. In the current paper we use data from neural networks and toddlers to investigate the latter part of this loop, focusing on how different types of words are learned right around the pivotal moment of word learning bias development.

\section*{Children's Early Vocabularies}

Words are an important building block in language and cognitive development. Children make the process of word learning look deceptively simple, typically acquiring their first word around the age of 1 year and experiencing a spike in vocabulary development around 18 months of age (Goldfield \& Reznick, 1990). Some researchers have observed that this vocabulary spike does not tend to occur until a child has at least 50 words in his or her vocabulary (Lucariello, 1987). Other work shows that the vocabulary spike is not only a function of the number of words a child knows, but also depends on the kinds of words that children learn. For example, Goldfield and Reznick (1990) observed that children exhibiting a vocabulary spike tended to add many words for objects (i.e., nouns) to their vocabularies. Children who did not show this dramatic increase in vocabulary size were steadily adding various types of words instead. This result suggests that while vocabulary size may be one key factor in children's language development, the specific kinds of words that children learn also play a role.

More recent research has investigated the question of why learning nouns may help accelerate subsequent vocabulary growth. One reason is that many different nouns have a basic property in common: they tend to refer to categories of things that are alike in shape. For example, a child will hear the word "ball" used to label a variety of spherical objects. Over time, children may pick up on the general pattern that shape is an important feature when talking about things in the world, and this insight in turn facilitates further word learning. Support for this account comes from a longitudinal study of young children's vocabularies (Gershkoff-Stowe and Smith, 2004). Over a three month period, 17-month-old children had a greater increase in object label nouns compared to other types of words. Over this same time period, children attended more to shape, over and above other features, when generalizing a newly learned word to novel objects. This result suggests that as children learn certain kinds of words, they also learn reliable patterns or constraints about how those words are used in the world. In
this paper we focus on one word learning constraint in particular: the shape bias.

\section*{The Shape Bias in Early Word Learning}

The shape bias is the tendency for children to generalize newly learned nouns to other objects based on similarity in shape. This is typically tested in novel noun generalization (NNG) tasks (Landau, Smith, \& Jones, 1988). In this type of task a child may be taught a novel name for a novel solid object. A shape bias is shown when the child extends that name to other objects matching the original in shape, even if the shape match differs from the original in texture, color, or size. Children show a reliable shape bias by 2 years of age (Samuelson \& Smith, 1999).

There is evidence that the emergence of the shape bias can guide children in learning new words. For instance, in one study 17 -month-olds were trained on shape-based categories of words, effectively teaching them the shape bias (Smith et. al, 2002). Not only did these children develop a shape bias earlier than the control group, they also showed accelerated growth in overall vocabulary. This suggests that there is an interaction between the development of word learning biases, particularly the shape bias, and vocabulary growth. This finding is one piece of evidence for a developmental feedback loop between vocabulary development and word learning constraints.

\section*{A Developmental Feedback Loop}

Smith and colleagues (2002) showed that teaching children the shape bias can promote vocabulary growth, but what about the other way around? Many of the previously mentioned studies show a correlation between these two factors. However, rather than word learning biases simply causing vocabulary growth, perhaps these are coupled phenomena that reciprocally influence each other. Previous modeling research suggests this. For instance, Colunga and Sims (2012) trained neural networks with early- and latetalker vocabulary structures as input and then tested for the development of word learning biases. Results showed that networks given late-talker vocabulary input produced different biases than networks with early-talker input. This shows that given only the structure of a child's vocabulary, the network can develop quantitatively different biases, suggesting that vocabulary growth affects bias development. These findings, combined with the experiments of Smith and colleagues (2002), indicate that vocabulary structure and word learning biases may be part of a development feedback loop in which both processes affect one another. Here we investigate the dynamics of this loop in both neural networks and in children.

In prior work, we explored dynamics of and interactions between the shape bias and other word learning biases over time. Neural networks were trained on a typical 30 -monthold child's vocabulary structure, then the bias dynamics were observed. We found that as the shape bias emerged, the development of other word learning biases diminished, suggesting a shift in attention as the shape bias is learned
(Schilling, Sims \& Colunga, 2012). These results were replicated in behavioral data from a longitudinal study of 18- to 30-month-old children (Sims, Schilling, \& Colunga, 2012).

In this paper, we look at the same emergence window, but this time concentrate on how different kinds of words are learned before, during and after shape bias emergence. That is, we focus on the other piece of the developmental feedback loop: how vocabulary structure changes as word learning biases develop. What kinds of words do networks and children learn right around the pivotal point of shape bias emergence? To test this, we used network models and vocabulary data from a longitudinal behavioral study.

\section*{Approach and Overview}

Our approach is to train a network on a typical early child vocabulary in order to observe learning over time that is similar to children's vocabulary development. We use a neural network to model the process of word learning, which differs from some other approaches to modeling word learning. For example, Bayesian networks extract generalities in order to produce a structured system representative of the real world (e.g., a mapping of a child's word representations; see \(\mathrm{Xu} \&\) Tenebaum, 2007). Our networks instead begin with structured representations as input and produce attentional biases. In order to investigate the developmental feedback loop, we are interested in the process: how the network forms these attentional biases from vocabulary structure input. We tested both networks and children on novel word generalization (using a virtual NNG task with the networks and a lab NNG task with children; see Sims et al., 2012 for details) over multiple points of vocabulary development. From this data, we identified the point in word learning at which the shape bias emerged for each individual network and child. Finally, we looked at the kinds of words that networks and children learned around their respective emergence points.

\section*{Network Simulations}

\section*{Method}

Our network was implemented in the Emergent software package (O’Reilly, Munakata, Frank, \& Hazy, 2012), to model word learning. The network was given input structured like that of a typical 30 -month-old's vocabulary. Throughout learning, we tracked what kinds of words the network successfully learned and tested for attentional biases. By analyzing the word learning biases the network developed and how they affected vocabulary structure, we were able to focus on the developmental feedback loop between attentional biases and vocabulary growth over time.

\section*{Network Dynamics}

Our models use the Leabra algorithm (Local, Error-driven and Associative, Biologically Realistic Algorithm), which combines Hebbian and error-driven learning (O'Reilly et al., 2012). The Hebbian, self-organizing learning uses longer time-scale statistics about the environment and is useful for
extracting generalities. However, this type of learning is not as good at compensating for specific, complicated patterns. Therefore, we use error-driven learning, which actively utilizes differences between expectations and outcomes. The total weight change in the network is the sum of that of the error-driven learning and that of the Hebbian learning.

The network uses a function called the eXtended Contrastive Attractor Learning (XCAL) rule. This function uses sending and receiving activity input and has a floating threshold that regulates changes in weights over learning. This function is used for both the Hebbian and error-driven learning with different inputs to the function. Inputs affect threshold changes and therefore different inputs elicit different weight change dynamics.

The error-driven weight changes are updated based on the short-term average connection activity ( \(\langle x y\rangle_{\mathrm{s}}\) ) and the medium-time scale average connection activity \(\left(\langle x y\rangle_{m}\right)\).
\[
\Delta w_{\text {error }}=f_{x c a l}\left(<x y>_{s},<x y>_{m}\right)=f_{x c a l}\left(x_{s} y_{s}, x_{m} y_{m}\right)
\]

Where \(\langle x y\rangle_{m}\) represents the emerging expectation about a current situation and \(\langle x y\rangle_{\text {s }}\) reflects the actual outcome and therefore the result of the received error information.

The Hebbian weight changes are based on the short-term connection activity ( \(\mathrm{xy}_{\mathrm{s}}\) ) and long-term average activity of the receiving unit ( \(\langle\mathrm{y}\rangle_{1}\) ).
\[
\Delta w_{\text {Hebbian }}=f_{x c a l}\left(x y_{s}, x<y>_{l}\right)=f_{x c a l}\left(x y_{s}, x y_{l}\right)
\]

Based on \(\langle\mathrm{y}\rangle_{1}\), the threshold for weight change is adjusted, making the weights more likely to change in the direction given by \(\mathrm{xy}_{\mathrm{s}}\). This creates the structure of generalization for the Hebbian learning mechanism. The combination of these two types of learning mechanisms allows for a balance of feed forward information to form categories and back propagation to allow adjustments based on errors. For more details on network dynamics, see O'Reilly et al. (2012).

\section*{Network Architecture}

The architecture is adapted from Colunga \& Smith (2005) and is implemented as shown in Figure 1. Words are represented discretely and are input on the Word Layer. Features are represented as distributed patterns over several dimensions on the Perceptual Layer. For example, the shape and material of an object (e.g., the roundness of a particular ball and its yellow rubbery material) are represented by an activation pattern along the Perceptual Layer, with 12 units for shape and 12 units for material. Solidity is represented locally; one unit stands for Solid and another for Non-Solid. Finally, there is a 25 unit Hidden Layer that is connected to all the other layers and to itself. The Hidden Layer serves as the bridge between the Word Layer (the sending units) and the Perceptual Layer (the receiving units) and it is where learning occurs. Learning progresses as internal representations, or weights, update and form representations which connect the other two layers.

Figure 1. Network architecture and example input patterns.

\section*{Vocabulary Structure: Network Input Patterns}

The input patterns used to train the network capture the structure of a child's vocabulary and are based on those used in Colunga and Smith (2005). They consisted of 100 noun representations, divided into 6 categories, with a structure analogous to the vocabulary of a typical 30 -monthold child (Fenson et. al, 1993). Categories were divided by both solidity (solid or non-solid) and characteristic feature (shape, material, or both), based on adult judgments. From these, the structure of a typical early vocabulary can be expressed as proportions of each category. Therefore, the network learning the entire set of training patterns represents a child learning a typical vocabulary. See Table 1 for the 6 categories and proportions used in the study.

These input patterns have a correlational structure such that a network learning them should produce a shape bias for solids (and indeed this was first shown by Colunga \& Smith, 2005). This means that learning in the network arises from the structure of the input patterns themselves. The purpose of the network, then, is not to help us discover structure in the input, but to observe the process of leveraging this structure over the course of word learning.

Table 1: Noun category percentages and example words.
\begin{tabular}{|r|c|c|c|}
\hline & Shape & Material & Both \\
\hline & \(52 \%\) & \(10 \%\) & \(12 \%\) \\
Solid & & \begin{tabular}{c}
1 \\
\\
\end{tabular} & ball
\end{tabular}

\section*{Network Training and Testing}

Over the course of training, the network formed biases based on the structure of the vocabulary input. On each trial of training, a word was paired with a pattern of features representing the features of the noun category. For example,
a word for a solid item characterized by shape (like a ball) should be used to label things that are like each other in shape but differ from each other in material. To simulate this pattern, we randomly selected an input vector to represent, for example, ball shape. On individual training trials, we paired that shape pattern with the label ball and a randomly selected material pattern. Therefore over multiple training trials, a word for a solid item characterized by shape would be represented by the same shape but different material patterns (see Figure 1). We did this for each of the 100 nouns in the training set.

We tested 10 runs of the network at multiple points throughout word learning. Weights and words learned from each of the 6 categories of interest were recorded at thirteen discrete checkpoints during the course of each training run. For example, the network was tested at 5 words learned, 10 words learned, and so on. The endpoint of learning was at 500 epochs of training, which was around when the network learned 75 words. For more information on network testing procedures, see Schilling et al. (2012).

\section*{Rationale and Predictions}

We focused our analyses of early child vocabulary composition, particularly shape-based and material-based words, on the period of time during which each network developed a shape bias in the context of solid objects. This approach may offer further insights into the relationship between attentional shifts in word learning and the course of vocabulary acquisition. As skilled attention to shape in the context of solid objects emerges, the networks should more easily learn shape-based words. Also, increased attention to shape may facilitate the learning of shape-based words over and above the learning of material-based words. This would be seen in a relatively lower rate of learning for materialbased compared to shape-based words.

\section*{Results}

The first question is how the networks learned shape-based words over the time window in which the shape bias emerged. The dependent measure was proportion of shapebased words learned at a given time point relative to the total number of shape-based words in the input vocabulary. Proportions of shape-based words learned were submitted to a linear regression with time point (before, at, or after shape bias emergence) as the predictor variable. Shape-based word learning increased significantly over time, \(b=0.06, t(28)=\) \(7.70, p<.001\). The networks showed significant increases in proportions of shape-based words learned from before shape bias emergence \((M=.01, S D=.02)\) to the point of emergence ( \(M=.06, S D=.03\) ), and from emergence to the following time point \((M=.14, S D=.06 ; t(9)>4.60, p \leq\) .001 , Cohen's \(d>1.45\) for both paired comparisons). That is, the networks' learning of shape-based words increased over time, and showed a particularly large increase following the emergence of the shape bias.

The next question is whether the networks' learning of shape-based words differed from learning of material-based
words over the same time period. Proportions of materialbased words learned were similarly computed relative to the total number of material-based words in the input vocabulary. Proportions of words learned were submitted to a multiple regression including time, word type, and the interaction between the two. Overall, these variables explained a significant proportion of the variance in the networks' word learning, \(R^{2}=.69, F(3,56)=40.90, p<\) .001. Consistent with the result above and the fact that the networks continually learned new words over time, time was a significant predictor of word learning overall, \(b=.03\), \(t(56)=4.80, p<.001\). The networks showed increases in learning both shape- and material-based words over the time window of interest (see Figure 2). Word type was also a significant predictor of learning, in that the networks on average learned a greater proportion of shape-based than material-based words, \(b=.03, t(56)=4.03, p<.001\). Additionally, the interaction between time point and word type predicted learning, \(b=.03, t(56)=3.07, p<.01\). As can be seen in Figure 2, there was a steeper increase in the trajectory of learning for shape- compared to material-based words over the time window of interest.

Figure 2. Shape- and material-based word learning in the network simulations over time.

\section*{Discussion}

The results of the network simulations show that the emergence of the shape bias coincided with changes in vocabulary acquisition for different kinds of words. Before the emergence of the shape bias, the networks steadily increased the amount of both shape- and material-based words in their vocabularies to an equal extent. However, after the emergence of the shape bias, learning of shapebased words outpaced learning of material-based words. This result adds support to a developmental feedback loop account of word learning. Adding to previous work showing that networks can learn attentional biases from the vocabulary input of a typical toddler (Colunga \& Smith, 2005; Schilling et al., 2012), the current study shows that in these same kinds of networks, attentional biases in turn influence the trajectories of subsequent vocabulary learning. Next we tested our network predictions in a behavioral study of toddlers.

\section*{Behavioral Study}

\section*{Rationale and Predictions}

To test the predictions of the network simulation we conducted a similar analysis on a longitudinal sample of toddlers. To explore vocabulary learning over time we looked at a parent-filled, standardized vocabulary inventory (the MacArthur-Bates Communicative Development Inventory [MCDI]; Fenson et al., 2007) that had been collected every month for a year for each child in the sample. As in the networks, we centered our analyses of child vocabulary development on the time at which each child first showed a shape bias for solid objects.

The network simulations predict that the emergence of the shape bias for solids leads to a change in the course of subsequent vocabulary learning. Specifically, this change was seen in the trajectory of shape-based relative to material-based word learning. If this prediction bears out in children, we should see a similar pattern in the toddler data.

\section*{Method}

\section*{Participants}

Nineteen children were recruited from the Boulder, CO area. Two children were excluded from the current analyses because they knew greater than \(80 \%\) of the nouns in the MCDI at the beginning of the time window of interest. The final sample analyzed here included 17 children ( \(M_{\text {age }}=\) 22.09 mo., \(S D=2.69\) mo., 9 girls).

\section*{Progression of Word Learning}

Children participated in 12 monthly visits over the course of one year. At each visit children were tested for attentional biases in novel word learning. There were three different stimuli sets, each consisting of an exemplar, and five test items matching the exemplar in shape, material and/or color. The children saw a single set in each visit and thus rotated through the three sets every three months. We calculated the point of emergence of the shape bias as in Sims et al. (2012), for each individual child, as defined by the child having shown a persistent shape bias during three consecutive visits, that is, for all three stimuli sets.

Vocabulary development was measured longitudinally through parent-completed, monthly MCDI checklists of words their child knew at the time of each visit to the lab. We focused our analyses on children's noun learning over the time period of interest. At the beginning of the analysis windows, children had on average 108 nouns ( \(S D=84\) nouns) from the MCDI in their vocabularies. To explore shape- and material-based word learning separately, we used the vocabulary structure classifications collected by Colunga and Smith (2005; see Table 1), combining solid and non-solid shape-based nouns, and solid and non-solid material-based nouns to get our two categories of interest.

\section*{Results}

As in the network simulation analyses, the first question we investigated in the behavioral data was whether children's learning of shape-based words increased over the window
during which each child developed a shape bias. The dependent measure was children's proportions of shapebased words learned at a given time point relative to each child's total number of shape-based words attained at the end of the study. These proportions were submitted to a linear regression with time point as the predictor. Shapebased word learning increased significantly over the time window of interest, \(\mathrm{b}=0.13, t(43)=2.26, p=.03\). Post-hoc paired comparisons showed increases in words learned from before shape bias emergence \((M=.50, S D=.34)\) to the point of emergence ( \(M=.64, S D=.32\) ), and to the time point after emergence \((M=.76, S D=.23 ; t(14)>3, p<.01\), \(d>.90\) for both).

Next we compared children's learning of shape-based words to their learning of material-based words over the same time window. Proportions of words learned were submitted to a multiple regression including time, word type, and the interaction between the two. Overall, these predictors explained a significant proportion of the variance in children's word learning, \(R^{2}=.13, F(3,86)=4.32, p<\) .01. Time point was a significant predictor, showing that the proportions of both shape- and material-based words increased over the time window of interest, \(b=.13, t(86)=\) \(2.18, p=.03\). Word type was a marginally significant predictor of learning, \(b=.12, t(86)=1.86, p=.07\). As can be seen in Figure 3, the proportion of shape-based words learned ( \(M=.63, S D=.32\) ) tended to be higher than the proportion of material-based words learned \((M=.51, S D=\) .34) across all time points. The interaction between time point and word type was not a significant predictor of learning. That is, children's learning of shape- and materialbased words followed the same trajectory.

Figure 3. Shape- and material-based word learning in the behavioral study of toddlers over time.

\section*{Discussion}

These results show that there is an increase in the number of shape based words that children learn as the shape bias emerges. This result is consistent with the networks and supports one piece of the developmental feedback loop in children. However, unlike the network simulations, the increases in children's word learning did not show a marked acceleration for shape-based words. Although proportionally more shape-based words were learned
compared to material-based words, the trajectory of learning for these two types of words did not differ significantly within this time window.

\section*{General Discussion}

In the current studies we found that vocabulary learning around the emergence of the shape bias supported the developmental feedback loop account in our network simulations, but toddlers showed a different pattern. Adding to our previous work with these word learning networks, the current simulations contribute evidence for the effects of attentional biases on subsequent vocabulary learning. The behavioral data show ambiguous results in relation to the developmental feedback loop. There are several possible reasons for this pattern that will inform future research.

Methodological constraints could have contributed to these intriguing results. For example, the networks' performance in the generalization task is much more consistent than the children's performance. Even though individual networks do vary on the epoch at which they show a shape bias, once it emerges, it stays. This is not the case for children. To deal with this, we used a stringent criterion to define the time of emergence for the children by making sure that the preference for shape was present during three consecutive visits, for three different stimuli sets. Probably because of this criterion, the points of bias emergence that we identified tended to occur when children had on average over 100 nouns, with high variation between individuals. This suggests that we may have identified shape bias emergence relatively late in vocabulary development for some of the children in the sample, at least when compared with the criterion used in Gershkoff-Stowe \& Smith (2004). A related possibility is that our network shows bias emergence and subsequent vocabulary changes at a relatively earlier (or "younger") point than the toddlers in our sample. If this is the case, vocabulary changes in the network may be easier to detect because it has progressed less far in the proportion of words learned and thus can statistically show greater growth compared to the toddlers. On the other hand, when the shape bias emerges in toddlers, they already know over half of the words in the MCDI, and thus have relatively less room for growth. Nonetheless, we would still expect to see differences in how toddlers learn shape- and material-based words, yet these interactions are either not present or not being captured by our current measures. In future analyses we plan to explore other measures such as rate of vocabulary growth that may better equate learning in the network and in toddlers. We also plan to look at dynamic attention to shape as a continuous measure over the entire trajectory of learning. Perhaps the emergence of the shape bias puts into motion long-term, rather than immediate, changes in the trajectory of vocabulary growth.

More interesting than methodological explanations are the theoretical implications of this finding. The behavioral results, along with our previous work (Sims et al., 2012), suggest that vocabulary growth precedes bias development,
but the causality of this relationship may not go the other way. Perhaps once children have a consistent shape bias for solids, and those words come easy, they begin to focus on other kinds of words that do not conform to their expectations of naming categories organized by shape. Further work is necessary to see if that is the case. Overall, our novel approach using neural networks allows us to explore not just a causal effect of biases on vocabulary, but the dynamic feedback relationship between the two, the very relationship that builds the developmental trajectory.

\begin{abstract}
The relationship between structural (or syntactic) processing in music and in language is not yet clear. Evidence indicating that these two processes are shared conflicts with other results suggesting that they are largely distinct. These conflicting findings suggest that musical and linguistic processing may share some, but not all, underlying processes, raising the question of what exactly those shared processes might be. Two experiments tested the idea that one shared process is cognitive control by pairing manipulations of musical structure with the Stroop task, a standard test of cognitive control. Manipulations of harmonic expectancy, but not of timbral expectancy, interacted with Stroop interference effects, suggesting that cognitive control is at least one specific process underlying shared syntactic processing in music and language.
\end{abstract}

Keywords: cognitive control; music and language; musical syntax

\section*{Introduction}

Interest in the relationship between music and language has a long history, dating back at least to Darwin (1871). Over the last several years, a more specific focus on the relationship between structural (or syntactic) processing in music and language has received increasing attention (for recent reviews, see Patel, 2008; Slevc, 2012; Tillmann, 2012). This likely is due, at least in part, to an influential proposal about the relationship between structural processing in language and music: Patel's (2003) shared syntactic integration resource hypothesis (SSIRH; see also Patel, 2008). The SSIRH proposes that music and language involve separate representations (e.g., nouns and verbs in language, tonal functions in music), but recruit a shared set of cognitive resources that are required to integrate these separate representations into evolving sequences.

There is a growing body of evidence supporting the SSIRH. Much of this evidence comes from experiments using interference paradigms, where participants are simultaneously presented with both musical and linguistic stimuli. In these paradigms, syntactic manipulations in both domains are crossed to look for interactive effects that indicate shared processing (vs. additive effects, which would indicate independent processes). For example, an
electrophysiological response characteristic of a violation of linguistic syntax (the left anterior negativity, or LAN) is reduced when linguistic syntactic violations are paired with a concurrent music-syntactic irregularity (Koelsch, Gunter, Wittfoth, \& Sammler, 2005). Similarly, sung complex sentences are especially difficult to understand when critical regions are sung out-of-key (Fedorenko, Patel, Casasanto, Winawer, \& Gibson, 2009).

Other behavioral evidence comes from on-line sentence processing paradigms, where readers' slowed processing of temporary syntactic ambiguities is especially pronounced when the disambiguating word is paired with a harmonically unexpected chord (Slevc, Rosenberg, \& Patel, 2009; also see Hoch, Poulin-Charronnat, \& Tillmann, 2011, for related findings). More specifically, Slevc et al. (2009) relied on garden path effects, where readers are slower to comprehend the disambiguating word was in a sentence like "The scientist proved the hypothesis was false" compared to an unambiguous context like "The scientist proved that the hypothesis was false." This slowed processing presumably reflects the need to revise an initial syntactic interpretation where the hypothesis was interpreted as the direct object of the verb proved rather than as the subject of an embedded sentence complement. This garden path effect was more pronounced when the disambiguating word (was) was accompanied by a harmonically unexpected chord (but not when accompanied by a chord of unexpected timbre).

Importantly, such an interaction did not emerge for semantically unexpected words (e.g., pigs as a continuation of "The mailman was afraid of...") suggesting that the interactive processes are specific to syntax. However, a more recent finding casts doubt on this last conclusion: the same harmonic manipulations did lead to interactive effects when paired with sentences containing "semantic garden paths" such as "The old man went to the bank to withdraw his net which was empty" (Perruchet \& Poulin-Charronnat, 2013). Thus it seems that these interactive effects (and the shared integration resource of the SSIRH) may not be specific to syntactic processing per se.

In addition, some recent neuroimaging studies have not found substantial overlap between neural regions implicated in the processing of language and music (Fedorenko, Behr,
\& Kanwisher, 2011; Rogalsky, Rong, Saberi, \& Hickok, 2011). These studies compared a linguistic contrast (activation to intact sentences versus non-words or versus jabberwocky sentences) to a musical contrast (activation to intact music versus scrambled music or versus silence), and found little evidence for shared regions implicated in both contrasts.

These conflicting findings raise the question: what kind of shared process links musical structural processing to some aspects of linguistic processing (including syntactic errors, syntactic complexity, and both syntactic and semantic garden paths), but not to other aspects such as the processing of semantically surprising words and the difference between intact and scrambled sentences? One way to characterize this distinction is that the aspects of language processing that are related to musical structure require not only the processing of an unexpected element, but also the resolution of conflict between this unexpected information and a current representation of an incrementally constructed (and/or predicted) structure. The unrelated aspects of language, in contrast, may not place demands on conflict resolution per se as there is no obvious way to resolve a semantic anomaly or a scrambled sentence.

This sort of conflict detection and resolution process is termed cognitive control, referring broadly to the cognitive processes that allow for the regulation of mental activity required to resolve competing representations (see, e.g., Miller \& Cohen, 2001). Cognitive control processes have been implicated in various aspects of language processing, including parsing of garden path sentences and semantic plausibility effects (see Novick, Trueswell, \& ThompsonSchill, 2010, for a recent review), and it is possible that the types of linguistic manipulations that interact with musical structure are of this general type. By this account, studies finding interactive effects between musical structure and language (be it linguistic syntax or non-syntactic situations that require resolution between conflicting representations like semantic garden paths) might reveal simultaneous use of cognitive control resources.

This account implies that musical syntactic processing-at least as measured in the studies cited above-also relies on cognitive control mechanisms. Indeed, this is likely to be the case. Listening to music involves building up complex cognitive representations of musical structure. This not only involves processing and integrating musical elements as they occur, but also incrementally generating and evaluating predictions based on implicit knowledge of musical structure (see Rohrmeier \& Koelsch, 2012, for discussion). One hazard of this predictive processing is that new information can be inconsistent with one's prediction, thus harmonic processing requires the ability to both detect conflict between predicted and observed precepts and the ability to resolve this conflict by overriding and updating an evolving representation of musical structure. Conflict between musical precepts and predictions likely arises in many situations, not the least of which are cases of musical ambiguity (e.g., musical garden paths; Temperley, 2001).

One form of indirect evidence for a role of cognitive control in musical syntax comes from neuroimaging findings. Regions in the inferior frontal gyrus (including Broca's area) that are linked to cognitive control processes (both generally and in language processing; e.g., Miller \& Cohen, 2001; Novick et al., 2010) have also been implicated in neuroimaging studies of musical syntactic processing (albeit more bilaterally or even right lateralized; e.g., Maess, Koelsch, Gunter, \& Friederici, 2001; Tillman, et al., 2006).

A second form of indirect evidence for a role of cognitive control in musical syntactic processing comes from evidence that musical training is associated with advantages in cognitive control ability (Bialystok \& DePape, 2009; Pallesen et al., 2010) among other types of cognitive advantages (e.g., Schellenberg, 2006). A musician advantage in cognitive control could plausibly result from the additional demands placed on cognitive control mechanisms from extensive musical training and practice, but only if those demands tax (and thus potentially strengthen) cognitive control processes.

\section*{Current experiments}

The aim of the experiments reported here was to provide a direct test of whether cognitive control mechanisms are involved in musical syntactic processing (as has been argued to be the case for linguistic syntactic processing). If cognitive control processes are, in fact, an important part of musical syntactic processing, less expected chords should impose relatively greater demands on cognitive control. Assuming cognitive control is a limited-capacity resource, this should lead to a temporary reduction in the ability to exercise cognitive control in other tasks.

In order to measure demands on cognitive control, we turned to a prototypical cognitive control task: the Stroop task (Stroop, 1935; see McLeod, 1991, for a review). In the standard Stroop task, participants must name the ink (or font) color of printed stimuli. These stimuli can be of three types: congruent, where the printed word is the same as the to-be-named ink color (e.g., the word "GREEN" printed in green font), incongruent, where the printed word is a different color name than the two-be-named ink color (e.g., the word "BLUE" printed in green font), and neutral (e.g., the string "\#\#\#\#" printed in green font). Cognitive control demands are reflected in Stroop interference, where responses are slower to incongruent than to neutral trials. The Stroop task can also yield Stroop facilitation, reflected in faster responses to congruent than neutral trials, however these facilitative effects are not generally assumed to result from demands on cognitive control.

Because Stroop interference is a prototypical measure of cognitive control, it can be used as an index of cognitive control demands at a given moment. The experiments presented below do just this by investigating if, and how, Stroop interference is affected by a concurrent musical syntactic manipulation.

\section*{Experiment 1}

In Experiment 1, participants performed a standard Stroop task while hearing musical chorales. The primary question was whether the harmonic expectancy of a chord occurring during a trial of the Stroop task would influence Stroop interference effects.

\section*{Method}

Participants Twenty-five undergraduate students from the University of Maryland participated in exchange for course credit. Participants were unselected with regard to musical training.

Materials Stimuli for the Stroop task were the strings "RED", "GREEN", "BLUE", or "XXXX". The word stimuli appeared half of the time in a congruent color (e.g., the word "BLUE" in blue font) and half of the time in an incongruent color (e.g., "BLUE" in green or red font); the neutral ("XXXX") stimuli appeared equally often in each of the three font colors. Because the primary effect of interest here is in Stroop interference (vs. facilitation), congruent trials were treated as fillers and excluded from analysis.

Musical stimuli were twelve six-chord chorales based on Western musical structure, half in major and half in minor keys. Each chorale ended either on a tonic chord (the tonal center of the chorale's key) or ended on a chord belonging to another key, and thus was either harmonically expected or unexpected (see Figure 1 for an example). In addition, each chorale occurred once more as a filler item; these fillers ended on a variety of chords. While these fillers were generally harmonically unexpected, they were not constructed in a theoretically constrained way and so were excluded from analyses. (Note, however, that treating these fillers as harmonically unexpected trials does not substantially alter the main pattern of results.)

Figure 1: Example stimuli in Experiment 1. The top panel shows an example musical chorale ending in a harmonically expected tonic chord (A) or a harmonically unexpected chord from a different key (B). The bottom panel represents the incongruent (i) or neutral (ii) visual target for the primary color response task.

Procedure Participants were tested individually on iMac computers using PsychoPy software (Pierce, 2007). The primary task was to respond to the color of the visual stimuli (red, green, or blue) by pressing a corresponding button (the left, down, or right arrow, respectively). These color/button mappings were presented on the screen during the entire task. Participants first performed a practice block of twenty-one color-naming trials (without concurrent musical stimuli) to learn the color/key mappings, then a second practice block of ten trials where the target stimulus appeared at the onset of the final chord of a six-chord chorale (all practice chorales ended on the tonic). Finally, participants performed the experimental block consisting of 72 chord sequences ending on the tonic, 36 chord sequences ending on a harmonically unexpected chord, and 36 filler sequences. Within each musical condition, one third of the trials were neutral, one third were incongruent, and one third were congruent (filler) trials.

A schematic of the four conditions for an individual experimental trial is shown in Figure 1.

Design and analysis Response times were log-transformed and analyzed using linear mixed-effects models in the statistical software R (version 2.15.2; R Development Core Team, 2012). Stroop trial type (text condition: incongruent or neutral) and the harmonic role of the final chord (harmonic condition: expected or unexpected) were entered as fixed effects using orthogonal contrast coding. The fully specified random effect structure was included for both participants and items (see Barr, Levy, Scheepers, \& Tily, 2013), but random effects are not reported as only fixed effects were of theoretical interest. The current implementation of lme4 does not compute \(p\) values for models that include random slopes, therefore we follow Gelman and Hill (2007) by assuming that any absolute \(t\) value greater than 2 indicates a significant effect.

\section*{Results}

A significant main effect of text condition \((b=-0.24, S E=\) \(0.029, t=-8.23\) ) revealed (unsurprisingly) that responses were slower for incongruent than neutral strings. There was not a significant main effect of harmonic condition ( \(b=\) \(0.0048, S E=0.022, t=-0.22\) ), however a significant interaction between harmonic condition and text condition ( \(b=-0.10, S E=0.042, t=-2.39\) ), revealed that the Stroop interference effect was significantly larger when accompanied by an unexpected final chord. The Stroop interference effects in the harmonically expected and unexpected conditions are plotted in Figure 2.

\section*{Discussion}

Experiment 1 found larger Stroop interference effects when Stroop trials occurred during structurally unexpected chords, suggesting that the processing of harmonically unexpected chords involves an underlying process that is shared with Stroop interference. This bolsters theoretical reasons to expect cognitive control processes to play a role in musical
syntactic processing and adds to previous indirect evidence for such a relationship, such as (bilateral) inferior frontal activation associated with musical syntax (e.g., Tillmann et al., 2006) and cognitive control advantages associated with musical training (e.g., Bialystok \& DePape, 2009).

Figure 2: Stroop interference (incongruent minus neutral) by the harmonic condition of the final chord (the tonic chord or an unexpected chord from another key) in Experiment 1.

Data are plotted as untransformed means of participant means and dots indicate individuals' scores. \({ }^{1}\)

A counter explanation for these results might be that the harmonically unexpected chord drew attention away from the primary task of responding to font colors, thus leading to an exaggerated effect of incongruent trials due not to shared mechanisms, but simply to surprise or distraction. It is not obvious that simple distraction would enhance the Stroop effect as this distraction would presumably affect neutral as well as incongruent trials. However it is nevertheless possible that some aspect of the musical manipulation besides its harmonic unexpectedness is responsible for the observed interaction. Experiment 2 aimed to address this possibility by using a noticeable, but not music-syntactically relevant, manipulation of timbre, or sound quality.

\section*{Experiment 2}

If the interaction between Stroop interference and harmonic expectancy found in Experiment 1 results from surprise or distraction, then similar results should emerge when another type of unexpected auditory event occurs, even if that event

\footnotetext{
\({ }^{1}\) For ease of interpretation, Figures 2 and 3 display means of participants' mean untransformed RTs; note, however, that analyses were conducted over non-averaged, log-transformed RTs.
}
does not require conflict resolution. If, on the other hand, the interaction observed in Experiment 1 reflects the role of conflict resolution processes, then such interactions should not arise unless the unexpected stimuli induces some degree of resolvable conflict with an incremental and predictive cognitive representation of musical structure.

To examine these possibilities, Experiment 2 employed the same design as Experiment 1, but instead of manipulating musical syntactic expectancy, manipulated musical timbre (cf. Slevc et al., 2009). In contrast to the harmonic manipulation in Experiment 1, where an unexpected chord could reflect some kind of resolvable modulation or other harmonic "twist," there is no obvious way to resolve an unexpected timbre. Thus, a chord of unexpected timbre (that plays an expected harmonic role) should not lead to conflict resolution processes, and should not interact with the Stroop interference effect.

A chord of unexpected timbre should, however, be at least as surprising and attention demanding as an out-of-key chord, so if the interaction observed in Experiment 1 results from surprise or distraction, the same pattern of results should emerge in Experiment 2.

\section*{Method}

Participants Thirty undergraduate students from the University of Maryland participated in exchange for course credit or for a small (\$5) payment. As in Experiment 1, participants were unselected with regard to musical training.

Materials and Procedure The visual stimuli in Experiment 2 were identical to those in Experiment 1. The musical chorales were also identical except for the final chords in the unexpected conditions, which were always the tonic chord (thus always harmonically expected) but varied in terms of their timbre. Specifically, the final chord was either of the expected piano timbre, i.e., the same timbre as the rest of the chorale, or was played in a distinct timbre (the sitar timbre, as implemented in MuseScore version 1.2). An additional set of trials ended with a timbre only slightly different from the rest of the chorale (MuseScore's ukulele timbre, which sounds remarkably similar to a piano); as in Experiment 1, these intermediate trials were treated as fillers and not included in the analysis.

Design and Analysis Response times were analyzed just as in Experiment 1. Experiment 2 crossed the fixed-effects factors of text condition with timbral condition (expected or unexpected timbre) with the maximal random effects structure supported by the data. \({ }^{2}\)

\section*{Results}

As in Experiment 1, participants were reliably slower to respond to the color during incongruent trials than

\footnotetext{
2 The by-item random slopes for timbral condition and the timbral condition by text condition interaction had to be removed for the statistical model to converge.
}
congruent trials (i.e., a significant effect of text condition; \(b\) \(=-0.17, S E=0.023, t=-7.14)\). There was no significant effect of the timbre of the final chord \((b=0.20, S E=0.14, t\) \(=1.42\) ) and, unlike in Experiment 1, no interaction between these factors \((b=-0.16, S E=0.029, t=-0.55)\). The Stroop interference effects in the timbrally expected and unexpected conditions are plotted in Figure 3.

Figure 3: Stroop interference (incongruent minus neutral) by the timbral expectancy of the final chord (same vs. different timbre) in Experiment 2. Data are plotted as untransformed means of participant means and dots indicate individuals' scores.

\section*{Discussion}

Experiment 2 showed a standard effect of Stroop interference, but this effect did not interact with the timbre of a concurrent (tonic) chord. If anything, the average magnitude of the Stroop interference effect was numerically smaller in the unexpected timbre condition. This suggests that the interactive effects found in Experiment 1 did not result simply from the attention capturing nature of the unexpected stimuli, but were rather a function of the need to resolve conflict between the final chord and its expected harmonic role.

\section*{General Discussion}

The experiments reported here tested the idea that the processing of musical structure relies on general cognitive processes of cognitive control, which are also thought to underlie aspects of language processing. Experiment 1 crossed a standard cognitive control task-the Stroop taskwith a manipulation of harmonic expectancy, and found interactive effects: Stroop interference was exacerbated when accompanied by a structurally unexpected chord.

Experiment 2 showed that this interaction between harmonic expectancy and Stroop interference was not simply due to distraction or divided attention as such an effect did not emerge when Stroop trials were paired with chords of an unexpected timbre.

The interactive effects in Experiment 1 are perhaps especially notable as there was no musical task requiring participants to pay attention to the musical chorales, and participants were an unselected group of undergraduate students, not a group of musicians. These observations suggest that these effects do not depend on any particularly effortful type of musical processing, but instead reflect the broad knowledge of musical syntax that arises simply through a lifetime of exposure to a specific musical tradition (cf. Bigand \& Poulin-Charronnat, 2006).

These findings support the theory that cognitive control does, in fact, underlie at least some of the shared processing resources implicated in linguistic and musical syntax. A further implication is that the processing of both music and language should overlap to some extent with a variety of other domains that also rely on these general mechanisms of cognitive control (not just simple cognitive tasks like the Stroop task). There is already evidence for some such relationships; for example, interactive effects have been demonstrated during simultaneous processing of music and arithmetic (Hoch \& Tillmann, 2012). In addition, "action syntax" or "scripts" (i.e., meaningful structured representations of action sequences) may be related to both linguistic syntax (e.g., Farag et al., 2010) and to musical syntactic processing (Harding et al., 2011).

These relationships between different types of structural processing - be those structures musical, linguistic, mathematical, or action schemas - are not likely to reflect a syntax-specific shared underlying process. Instead, these processes likely draw on the same cognitive mechanisms to deal with similar demands, and these data suggest that one such mechanism is cognitive control. Of course, it is unlikely that the relationship between structural processing in language and music reflects only cognitive control mechanisms. Musical and linguistic structure are rich and complex systems that surely draw on a variety of cognitive mechanisms. Nevertheless, these data take a step towards a more specific account of exactly what sort of shared integration resources might underlie linguistic and musical syntax by implicating the well-studied cognitive construct of cognitive control.

\begin{abstract}
Recent empirical evidence suggests that language-mediated eye gaze is partly determined by level of formal literacy training. Huettig, Singh and Mishra (2011) showed that highliterate individuals' eye gaze was closely time locked to phonological overlap between a spoken target word and items presented in a visual display. In contrast, low-literate individuals' eye gaze was not related to phonological overlap, but was instead strongly influenced by semantic relationships between items. Our present study tests the hypothesis that this behavior is an emergent property of an increased ability to extract phonological structure from the speech signal, as in the case of high-literates, with low-literates more reliant on more coarse grained structure. This hypothesis was tested using a neural network model, that integrates linguistic information extracted from the speech signal with visual and semantic information within a central resource. We demonstrate that contrasts in fixation behavior similar to those observed between high and low literates emerge when models are trained on speech signals of contrasting granularity.

Keywords: The Visual World Paradigm, Connectionist Modeling, Visual Attention, Literacy.

\section*{Introduction}

Eye-tracking studies in which participants are presented simultaneously with spoken language and visual input (i.e. the visual world paradigm, Tanenhaus et al., 1995) have shown that information retrieved via both modalities is mapped at multiple levels of representation. Allopenna et al. (1998), for instance, presented participants with spoken words such as beaker and objects whose names contained word-initial or word-final overlapping phonological information (e.g., beetle, speaker) together with phonologically unrelated objects (e.g., carriage). They found that eye-movements were more likely to be directed to the phonologically related objects than to unrelated objects, indicating that during speech processing, phonologically related representations were co-activated and mapped onto phonological representations retrieved from viewing the copresent visual objects (see Huettig \& McQueen, 2007, for further discussion). Related paradigms have demonstrated that semantic competitors are also co-activated during
listening to speech and attract increased overt attention (Yee \& Sedivy, 2006; Huettig \& Altmann, 2005)

These types of studies leave open one important question: What particular aspects of these representations affect participants' performance? Computational models have been proposed to reproduce the individual phonological and semantic effects on word processing. Allopenna et al. (1998), demonstrated that fixation probabilities during spoken word processing can be predicted by lexical activations in the TRACE model of spoken word recognition. Mayberry, Crocker and Knoeferle (2009) and Kukona and Tabor (2011) extended this work to predict fixation behavior during sentence processing from the integration of visual and linguistic information. Until recently, such models that simulate the interaction between visual and linguistic information did so with representations that were unable to capture fine-grained semantic, phonological or visual feature relationships and were therefore limited in their ability to examine effects of multimodal interactions in language processing. A recent model by Smith, Monaghan and Huettig (in press) based on the hub-and-spoke models of semantic processing which integrates visual, phonological and functional information within a central resource, replicated the intricate time course dynamics of eye fixation behavior reported in Huettig and McQueen (2007). The model highlights the role of differences in the computational properties of each modality's representational structure, demonstrating that such differences are sufficient to produce behavior consistent with multimodal effects reported in the Visual World Paradigm.

The question of how differential representational qualities of phonological and semantic properties affect word processing can also be approached by studying individual differences. Specifically studying participant populations that differ in the form of representation of each modality that they bring to the task. People with different levels of literacy are a critically important population in this regard. There is a well-established link between fidelity of phonological representations of words and development of
literacy (Hulme et al., 2012). Participants who are literate perform better at phonological segmentation or phoneme awareness tasks (Bowey, 2005), and there have been proposals both that literacy causes such improvements in phonological processing (Castles \& Coltheart, 2004; Morais, Cary, Alegria, \& Bertelson, 1979), as well as converse views that effective phonological processing results in improved reading (Muter, Hulme, Snowling, \& Stevenson, 2004). An influential processing model in this literature is that experience of written forms of words results in a change in the granularity of the phonological processing of a word (Ziegler \& Goswami, 2005), such that exposure to written words results in greater awareness of the individual phonemes of words, and without such exposure, listeners are more likely to process the sound of a word without a componential, phonological decoding.

In contrast, effects of literacy on semantic processing have been shown to be minimal and appear to be only quantitatively rather than qualitatively different (Da Silva et al., 2004; Reis \& Castro-Caldas, 1997). Thus, literacy appears to affect lexical processing in a modality-specific manner.

In a recent study, Huettig, Singh and Mishra (2011) compared phonological and semantic competitor effects for Indian participants who had high and low levels of literacy due to poverty or other socioeconomic factors (but no known neurological or cognitive deficits), enabling a direct test of the extent to which the granularity of the phonological form of a word affects performance. In their study (Experiment 1), participants viewed a scene comprising objects representing a phonological onset competitor, a semantic competitor, and two unrelated distractors, and heard the target word spoken in a sentence context. They found that participants with low levels of literacy demonstrated no effects of phonological competitors, but substantial effects of semantic competitors when hearing words. In contrast, the participants with high levels of literacy were similar to the participants in a similar study with Dutch high literates (Huettig and McQueen, 2007) - demonstrating early looks towards objects named by phonological competitors and later looks toward semantic competitors.

We note that looks to the semantic competitors in the Huettig et al. (2011) study were reduced for the low literacy group, which is consistent with accounts of a general processing deficit (cf. Salthouse, 1996), and we return to this issue in the Discussion section.

We adapted our previous multi-modal model of fixation behavior in the visual world paradigm (Smith, Monaghan, \& Huettig, in press) to test the explanatory adequacy of the hypothesis regarding granularity of phonological processing relating to different levels of literacy. We simulated the conditions of the experimental study by presenting visual object representations of phonological and semantic competitors, and two unrelated words and tracking the model's fixation of each of these objects as presentation of a target word unfolded. We adjusted the level of granularity
of the auditory presentation of the word to the model, predicting that a segmented phonological representation would result in early phonological competitor effects, but that less individuated phonological representations, consistent with accounts of phoneme awareness impairment in low-literacy groups, would result in reduced, or absent phonological effects. We also predicted that, consistent with the behavioural data, the later semantic competitor effects would be observed for the model regardless of the granularity of the auditory input to the model.
In order to isolate the effect of the granularity of auditory processing of the spoken word, we controlled for the overall similarity between words in terms of their auditory form, but varied whether the similarity was compositional and at the phoneme level within the model, whether it was sublexical but not at the phonological level, or whether it was not sublexical and represented only at the word level.

\section*{Method}

\section*{Model}

The models described in this paper are based on the model of language mediated eye-gaze presented in Smith, Monaghan and Huettig (in press). The general architecture of the model is shown in Figure 1.

Figure 1: Network Architecture.
Architecture The network consists of four modalityspecific layers which were fully connected to a central resource consisting of 400 units (see Figure 1). The model implements a hub-and-spokes model of multimodal integration, with input visual, auditory and semantic information about words, and output behavior of an "eye" layer which indicates the direction of the attentional focus of the model as a consequence of the combination of the modal inputs.
The vision layer ( 80 units) simulated the extraction of visual information from the surrounding environment, providing visual input to the system. It was divided into four slots, each defined by 20 processing units. Each slot corresponded to the visual information available at each of four possible locations within the visual field. The vision
layer was fully connected in a forward direction to the integrative layer.

Similarly the auditory layer provided input from the auditory modality, simulating the extraction of spoken information from the speech signal over time. The auditory layer was also fully connected to the central integrative layer in a forward direction.

The semantic layer consisted of 160 units, allowing the network to represent semantic features associated with a given object or spoken word. The semantic layer was fully connected to the integrative layer with activation flowing both from integrative units to semantic units and also back from semantic to integrative units.

The eye layer, to reflect the viewing behavior of the system, was also fully connected in both a forward and back direction to the central integrative layer. It consisted of four units, a unit for each location in the visual field represented in the vision layer. Activation of an eye unit was taken as representing the probability of fixating the location in the visual field associated with the given eye unit.

Representations An artificial corpus consisting of visual, auditory, and semantic representations for 200 items was constructed to train and test the network on multiple crossmodal tasks mapping between each of the modalities. A fundamentalist approach (Plaut, 2002) was taken in the construction of representations to ensure all aspects of the representations were controlled within the simulations.

Visual representations of named objects were implemented as 20 unit binary vectors, with each unit representing the presence or absence of a given visual feature for the object. Each object had approximately 10 units activated, which were selected at random, and balanced for their distribution across the set of all 200 items.

For the semantic representations, each item was represented in terms of 8 units active from a set of 160 semantic features, such that the overall set of semantic representations were fairly sparse, simulating semantically
distinct words. Semantically similar pairs of words each shared 4 of the 8 active units representing each item.

To simulate different grain-sizes of speech representation, three forms of auditory input were constructed, but with the overall similarity between representations controlled.

For the fine grained auditory processing, representing phonological segmentation of the spoken word by the listener, words were encoded as six phonemes, with phonemes implemented as sets of 10 units, from which five units were active. All words within the corpus were composed of phonemes taken from an inventory of 20 possible phonemes. To present the word an additional phoneme from the target word sequence was presented to the auditory layer at each time step.

To simulate sublexical representations of a coarser grain size (moderate), two 30 unit binary feature vectors were created for each word from which 15 units were active. Coarse grained representations were formed by 60 unit binary feature vectors of which 30 units were active.

Table 1: Mean cosine similarity of speech signal representations calculated between targets and distractors.
\begin{tabular}{llccc}
\hline Grain Size & Distractor & \multicolumn{3}{c}{ Signal Overlap \((\bar{x}, \sigma)\)} \\
& Type & Onset & Rhyme & Word \\
\hline Fine & Competitor & \(.18(.07)\) & \(.50(.13)\) & \(.34(.07)\) \\
& Unrelated & \(.50(.12)\) & \(.50(.12)\) & \(.50(.09)\) \\
Moderate & Competitor & \(.17(.08)\) & \(.50(.11)\) & \(.34(.07)\) \\
& Unrelated & \(.51(.10)\) & \(.51(.10)\) & \(.50(.07)\) \\
Coarse & Competitor & \(.34(.10)\) & \(.34(.10)\) & \(.34(.07)\) \\
& Unrelated & \(.51(.10)\) & \(.51(.10)\) & \(.50(.07)\) \\
\hline
\end{tabular}

Visual, semantic and auditory competitors were also embedded within the corpora for 40 target items. For visual competitors 10 of 20 visual features were shared with target items with \(\mathrm{p}=1\), with the remaining features shared with p \(=0.5\). Semantic competitors shared 4 of 8 semantic features with target representations, while unrelated items shared a maximum of 1 semantic property with any other item.

Table 2: Temporal organization of events in training. Describes input and target representations provided in training trials.
\begin{tabular}{|c|c|c|c|c|c|c|c|c|}
\hline \multirow[t]{2}{*}{Task} & \multicolumn{2}{|l|}{Visual Input} & \multicolumn{2}{|l|}{Auditory Input} & \multicolumn{2}{|l|}{Semantic Layer} & \multicolumn{2}{|l|}{Eye Layer} \\
\hline & Activity & ts & Activity & ts & Activity & ts & Activity & ts \\
\hline Form to Semantics & 4 items selected at random from corpus & 0-14 & Time invariant noise provided as input & 0-14 & Target: Target's Semantic representation & 3-14 & Input: Only location of target active & 0-14 \\
\hline Speech to Semantics & Time invariant noise provided as input & 0-14 & Phonology of target as staggered input & 0-14 & Target: Target's Semantic representation & 5-14 & No constraints on activation & - \\
\hline Speech to Location & 4 items selected at random from corpus & 0-14 & Phonology of target as staggered input & 0-14 & No constraints on activation & - & Target: Only location of target active & 5-14 \\
\hline Semantics to Location & 4 items selected at random from corpus & 0-14 & Time invariant noise provided as input & 0-14 & Input: Target's Semantic representation & 0-14 & Target: Only location of target active & 2-14 \\
\hline
\end{tabular}

Fine grained spoken word competitors were defined by an overlap in the initial two components of their speech signal. For the unrelated items, we ensured that this set of words did not share more than the first component of the word and that no items shared their initial nor final three components. For moderate grain size representations \(2 / 3\) of the initial 30 features of a competitor were shared with a target with \(\mathrm{p}=\) 1 , with remaining features overlapping with \(\mathrm{p}=0.5\). Controls ensured all initial and final moderate grain vectors were unique. For coarse grain competitors \(1 / 3\) of all features were shared with the corresponding target with \(\mathrm{p}=1\), with remaining features overlapping with \(\mathrm{p}=0.5\). Defining competitors in this way lead to the contrasts in levels of similarity between representations across corpora as described in Table 1. Although the level of similarity between competitor-target and unrelated distractor-target is consistent across corpora at the word level, the distribution of overlap varies between implementations as a function of grain size.

Model Training The model was trained on four tasks (see table 2). Tasks were designed to simulate those performed by participants prior to testing through which associations between representations are acquired. The tasks were to map from visual representation to semantic representation, from auditory representation to the semantic representation, to activate the eye unit corresponding to the location of the item whose semantic representation is presented, and to activate the location of the item whose auditory representation is presented. Tasks were presented on a pseudo random basis with the task of mapping speech to location occurring four times less than other tasks. Items were selected from the corpus and assigned roles (target or distractor) and locations randomly. Initial connection weights were randomized and adjusted during training using recurrent back-propagation (learning rate \(=0.05\) ). Training was terminated after 850000 trials.

\section*{Results}

In the following sections we report the performance of three categories of model 1) Fine, models trained and tested on representations that simulate extraction of fine grained structure within the speech signal; 2) Moderate, models trained and tested on representations that simulate extraction of moderate structure within the speech signal; 3) Coarse, models trained and tested on representations that simulate coarse grained structure within the speech signal. The following results represent performance averaged across five instantiations of each model. For each instantiation a new corpus was constructed on which it was then trained and tested each initialized with a different random seed.

\section*{Pre-Test}

Once trained all models were tested on their ability to complete each of the four training tasks for all items in the training corpus presented in all possible locations within the
visual field. All three categories of model displayed similar levels of performance across all four tasks. In mapping from speech to semantics, activation of the semantic layer was most similar (cosine similarity) to the target item for \(100 \%\) of items for all models. When mapping from visual to semantic representations, activation in the semantic layer was most similar (cosine similarity) to that of the target for \(98 \%\) of items in the case of coarse and fine grained models and \(97 \%\) of items in the case of moderate models. When challenged to select the location of a target when presented with its corresponding auditory representation, the correct location was activated in both the coarse and fine models for \(96 \%\) of items and \(98 \%\) of items for moderate models. All models displayed equal performance when locating a target indicated by the presence of its semantic representation, selecting the correct location for \(99 \%\) of items.

\section*{Simulating Huettig, Singh and Mishra (2011)}

The following conditions remained consistent across all simulations. Visual input was provided at time step (ts) 0 and remained until the end of each test trial (ts 29). We report the activation of each unit within the eye layer as a proportion of the total activation of all units within this layer. This proportion is taken to represent the probability of fixating p (fix), the associated location within the visual field. Word onset occurred at ts 5 , with an additional component of the speech signal presented at each time step until the entire speech signal had unfolded (ts 10). Auditory input then remains fixed until the end of the test trial.

To simulate the conditions of Huettig, Singh and Mishra (2011) experiment 1 , input to the models visual layer consisted of the visual representations of the target's auditory competitor and semantic competitor along with two unrelated distractors. The target word's auditory representation was presented as a staggered input to the auditory layer from ts 5 . All models (fine, moderate and coarse) were tested on all 40 test sets embedded within the corpus (target, auditory competitor, semantic competitor and two unrelated distractors) in all 24 possible combinations of item and location. Figure 2 displays the change in p (fixation) from ts 0 for each category of item (Aud \(=\) auditory competitor, Sem = semantic competitor, Control = unrelated distractor), averaged across all test trials.

For analysis ratios were calculated between the proportion of fixations to a given competitor and the sum of the proportion of fixations to both the competitor and distractors (see Huettig \& McQueen, 2007). A value of 0.5 would indicate both items were fixated equally, a value greater than 0.5 would indicate increased fixation of the competitor and lower than 0.5 increased fixation of the distractor. Mean ratios were calculated across items and instantiations.

We conducted a 2-way ANOVA on the auditory competitor-distractor ratios with model as between-subject factor and time as within-subject factor for three theoretically-motivated time regions (preview, early and late). No significant differences were predicted during the
preview period which refers to the time between display onset (ts 0 ) until the first time step in which auditory information relating to the target word is able to influence output layers (ts 7). The remainder of test trials was divided equally into two time bins, an early (ts 8-18) and a late (ts 19-29) period as previous research had shown that auditory effects would occur (if at all) during the early but not the late period.

Figure 2: Change in fixation proportions for simulations of Huettig, Singh and Mishra (2011) Experiment 1.

There was a significant main effect of time, \(\mathrm{F}(2,234)=\) \(38.155, \mathrm{p}<.001\), eta- \(2=.246\), with auditory competitordistractor ratios differing between preview and early time windows, \(\mathrm{F}(1,238)=39.387, \mathrm{p}<.001\), and preview and late time windows, \(F(1,238)=29.202\), although there was no difference between early and late time windows. There was also a significant main effect of model, \(F(2,117)=4.467\), \(p\) \(=.014\), eta- \(2=.071\), with the fine and medium models resulting in significantly more fixations to the phonological distractor than the coarse model, means \(=.544, .544\), and .508, respectively. Critically, there was a significant interaction between model and time, \(\mathrm{F}(4,234)=3.582, \mathrm{p}=\) .023 , eta- \(2=.058\). The quadratic contrast effect for time was significant in the interaction, \(\mathrm{F}(2,117)=5.074, \mathrm{p}=.008\), eta-2 \(=.080\), indicating that the models were more differentiated at the early time steps than during the preview or later time steps. Models did not differ significantly within the preview period. There was however a significant difference between fine and coarse models, \(\mathrm{F}(1,78)=\) 14.373, p < .001, and coarse and moderate models, \(\mathrm{F}(1,78)\) \(=9.544, \mathrm{p}=.003\), in the early time window. The coarse model also differed from the fine \(F(1,78)=4.286, \mathrm{p}=.042\), and moderate model \(F(1,78)=7.153, p=0.009\), in the later time window. No difference was found between fine and moderate models in any time period.

A 2-way ANOVA was also conducted on semantic competitor-distractor ratios with model as between subject
factor and time as within-subject factor. Again we observed a main effect of time, \(F(2,234)=230.642, p<.001\), eta-2 \(=\) .663, semantic competitor distractor ratios differed significantly between preview and early, \(\mathrm{F}(1,238)=59.607\), \(\mathrm{p}<0.001\) preview and late, \(\mathrm{F}(1,238)=243.403\), \(\mathrm{p}<.001\) and early and late time windows, \(\mathrm{F}(1,238)=80.562\), \(\mathrm{p}<\) .001. There was no main effect of model nor was there a significant interaction between model and time.

We then compared whether competitor-distractor ratios differed from chance (0.5) for each time step using one sample t-tests. The probability of fixating the auditory competitor first differed ( \(\mathrm{p}<0.001\) ) from that of the distractor from time step 11 in both fine and moderate models and continued to differ for all subsequent time points. In contrast fixation of the auditory competitor by the coarse model only differed marginally ( \(p<0.1\) ) from the distractor item in time steps \(13-17\). Fixation of semantic competitors first differed significantly ( \(\mathrm{p}<0.05\) ) from distractor levels at ts 12 and continued to differ for all remaining ts, this was the case for all models.

\section*{Discussion}

Our study aimed to examine the explanatory adequacy of the hypothesis that increased granularity of phonological processing, can account for the differences in fixation behavior between low and high literates observed in Huettig, Singh and Mishra (2011) Experiment 1. Our simulations demonstrate that increasing the grain size at which speech is processed can lead to a modulation of phonological effects. A model trained on representations of speech at the word level displayed only a marginal increase in fixation towards competitor items that overlapped in an auditory dimension, whereas models trained on componential, phoneme level representations or moderate grain size, sublexical components did display a significant increase in fixation of auditory competitors. Between model comparisons further demonstrated that the coarse grained implementation differed significantly from both fine and moderate grain models post word onset.

Interestingly, such comparisons did not display a graded effect of grain size, with fine and moderate models not differing in fixation proportions towards auditory competitors at any stage within test trials. There are two possible reasons for our failure to observe a graded effect. On the one hand, qualitative features of the data hint that given a larger corpus and hence test set such effects may be observable. One sample, left tailed t-tests comparing the ratio between the proportion of fixations towards auditory competitors in the moderate model and the sum of the proportion of fixations to the auditory competitor in the moderate and fine model indicate a significant difference at ts \(13-16\), ( \(\mathrm{p}<0.05\) ), this difference can be observed in Figure 2.

On the other hand, it is conceivable that illiterates and low literates rely on very coarse grained structure within the speech signal. Although previous studies have shown that illiterates and low literates perform slightly better on
syllable awareness than on phonemic awareness tasks, they still tend to perform far worse than proficient readers. This may suggest that achieving even moderate granularity of phonological processing may not be rapid. The results of our simulations could be interpreted as reflecting that when a moderate grain size of phonological processing is achieved performance improves rapidly and becomes similar to fine-grained models.

Our results also demonstrate that increased granularity does not necessarily lead to a decrease in semantic effects as observed in Huettig, Singh and Mishra (2011). Although our simulations indicate phonological effects could be modulated by an increase in the grain size, an additional mechanism is needed to create the distinction between semantic effects observed across populations. A reduction in general processing speed in the illiterate population has been offered to account for differences in performance on a large variety of cognitive tasks (Salthouse, 1996). This potentially offers an explanation for a reduction in both auditory and semantic competitor effects. A general processing deficit for low literates, could be implemented by adding noise across sematic representations, representing a reduction in the fidelity of such representations. Adding noise in this manner would result in a general reduction of semantic competitor effects, however it is less clear whether the introduction of noise could also lead to the elimination rather than a general reduction of the phonological effect as observed in illiterate performance. As the authors acknowledge, behavior observed in Huettig et al (2011) suggests that the qualitative changes to the phonological competitor effects and the semantic competitor effects are distinct. Teasing apart the factors underlying observed differences in behaviour between populations is far from trivial, however explicit implementations such as the one described in this paper provide a means of testing the plausibility of proposed explanations.

\begin{abstract}
Research into human models of intuitive physics typically falls into one of two camps, either claiming that intuitive physics is biased and not representative of real physics, or claiming that it consists of a collection of veridical physical laws. Here we investigate the causes of this tension, suggesting that prediction is based on real physics, but explanation is susceptible to biases. We gave participants three tasks based on the same physical principles: two prediction tasks and one task that required drawing the future path of motion. We found distinct biases in all three tasks; however, the two prediction tasks could be explained by consistent application of real physical principles under uncertainty, while the drawing task produced many more idiosyncratic biases. This suggests that different tests of intuitive physics are capturing different types of knowledge about the world.
\end{abstract}

Keywords: intuitive physics; uncertainty; ballistic motion prediction

\section*{Introduction}

Classic studies have suggested that many people base their physical intuitions on incorrect and inconsistent physical theories (Anzai \& Yokoyama, 1984; McCloskey, Caramazza, \& Green, 1980). Others have reported that people are biased by surface-level differences between tasks (Kaiser, Jonides, \& Alexander, 1986), and that their inferences about simple physical situations rely on shallow heuristics and are frequently mistaken (Proffitt \& Gilden, 1989; Todd \& Warren, 1982). However over the past few years, a number of researchers have explained human physical predictions using quantitative cognitive models that assume people have an accurate and consistent understanding of the laws of physics that they apply flexibly across tasks (Hamrick, Battaglia, \& Tenenbaum, 2011; Sanborn, Mansinghka, \& Griffiths, 2013; Smith \& Vul, 2013; Téglás et al., 2011).

We suggest that a core difference between the above studies is the task given to participants. Some have asked participants to make a single judgment about the future state of the world, for instance, the direction a tower of blocks will fall (Hamrick, et al., 2011) or where a ball will cross a line (Smith \& Vul, 2013). In contrast, classic studies tap into explicit explanations of physics, through verbal problems (Anzai \& Yokoyama, 1984) or line drawings of motion (McCloskey, et al., 1980). Here we argue that people can apply correct physical principles consistently to simulate the world forward; however, explicit explanations of how the world will unfold draw upon an idiosyncratic set of background knowledge.

We assessed participants' understanding of the movement of balls after they had fallen off of pendulums in three separate tasks: predicting where a ball would land if cut from a pendulum, deciding when to cut a pendulum string such that the ball would fall into a fixed bucket, and drawing the path of the ball after the string is cut. We picked these tasks because there is evidence that people understand the motion of pendulums (Pittenger, 1985, 1990) and can predict the motion of projectiles under gravity (Saxberg, 1987), both of which must be combined to determine the ultimate trajectory of the balls. But there is also evidence that people show systematic errors when asked to explicitly draw the path of the ball (Caramazza, McCloskey, \& Green, 1981), and that these errors are attenuated with kinematic information (Kaiser, Proffitt, Whelan, \& Hecht, 1992).

The same physical principles apply to each of these tasks, and so in the present experiment we investigated whether the tasks that require implicit prediction (catching the ball and cutting the string) can be explained by veridical physical principles. We find that subjects' performance on the catching and cutting tasks differs between the tasks, but in the tasks that involved perceptually guided movements the differences can be reconciled by considering a single, valid model of physics that incorporates the different sources of perceptual and motor uncertainty from each task. Conversely, the sketches based on explicit conceptualization were inconsistent and idiosyncratic.

\section*{Experiment}

\section*{Methods}

Fifty-seven UC San Diego undergraduates (with normal or corrected vision) participated in this experiment for course credit. All were treated in accordance with UCSD's IRB protocols.

\section*{Procedure}

Participants viewed a computer monitor from a distance of approximately 60 cm , which initially depicted a ball swinging from a string, consistent with pendulum motion. At some point in time the string would be cut and the ball would be released, thus entering ballistic motion. Beneath the pendulum there was always a bucket, and in every trial the participant's goal was to cause the ball to drop into the bucket after being released. How they were allowed to interact with the scene differed between two tasks, which were organized into blocks that were randomized across participants. With the exception of one initial practice trial per task that familiarized participants with the task, the path of the falling ball was occluded in order to prevent
participants from learning a simple relationship between the ball's release position and its landing position. At the end of each trial, participants were given binary feedback that indicated whether or not the ball successfully landed in the bucket. After the two tasks on the computer, participants were asked to draw the ball's motion in a diagram task.

Catching task. Participants were instructed to adjust the bucket's horizontal position using the mouse so that the ball would land in the bucket after being released. The release time was pre-determined and varied across trials. To relieve time pressure placed on participants, at the moment the string was cut, all ball and string movement was paused. Once the participant chose a bucket position, they could unpause the motion by clicking the mouse. The center of the bucket was recorded as the participant's judgment about where the ball would land.

Cutting task. The bucket was held fixed at a predetermined position and participants were instructed to cut the pendulum string by clicking the mouse at a time that would cause the ball to drop into the bucket. The time at which the string was cut was recorded for each trial.

Figure 1: Diagram of the two tasks: catching on top, cutting on the bottom. (A) The pendulum swings freely to start; this ends at a predetermined time (catching) or when the participant clicks the mouse (cutting). (B) An occluder is placed over the string. In the catching task, the action is paused until participants click the mouse, during which time they can move the bucket. In the cutting task, there was no pause, but the falling motion of the ball was occluded. (C)

Participants are given feedback on success or failure.
Trials. For each task, participants repeated 48 distinct trials five times each. Trials were matched across tasks such that where the ball landed in a catching trial was the bucket position in the matched cutting trial. In the catching task, there were 16 distinct release times, crossed with three vertical distances between the nadir of the pendulum and position of the bucket - either 20,35 or \(50 \%\) of the total screen height. No participant indicated they were aware that
the trials were repeated or matched across task in an informal post-experiment survey. \({ }^{1}\)

Simulating pendulum motion. Both tasks and all trials used the same pendulum. This pendulum had a length of half of the screen, and reached a maximum angle of \(35^{\circ}\) from vertical of the nadir. The period of the pendulum was 2.46s. The string was assumed to be massless, and therefore the position of the pendulum at any time could be calculated according to the laws of physics. \({ }^{2}\)

Both the pendulum motion and the falling ball obeyed Newtonian mechanics as if the pendulum was positioned at a depth of 6 m from the participants. This value was selected through pilot tests to conform to participants' general expectations about the natural period of the pendulum.

Diagram task. After participants completed both tasks, they were given diagrams of pendulums and asked to draw the path of the ball if the string was cut at four positions indicated in those diagrams (a replication of Caramazza, et al., 1981). One participant did not perform this task due to a logistical error.

Figure 2: The four problems in the diagram task.
Participants were asked to draw the expected path of the ball if the pendulum string were cut at each of the four points.

\section*{Results}

Accuracy in the catching and cutting tasks was measured as the proportion of trials in which the ball successfully landed in the bucket. Participants' mean accuracies were \(30.7 \%\) (s.d. \(14.1 \%\) ) on the catching task, and \(47.4 \%\) (s.d. \(15.6 \%\) ) on the cutting task. Participants' individual accuracies were (Pearson) correlated across tasks, \(r=0.68\). There was no evidence that participants improved over trials on the cutting task ( \(z=1.23, p=0.22\) ), but they did improve on the catching task ( \(\mathrm{z}=3.04, p=0.0024\) ), from \(28.8 \%\) accuracy on the first half to \(32.8 \%\) on the second half.

The remaining analyses quantified participants' performance as the displacement between the ball's landing position and the bucket's position; in the catching task the bucket position was under participants' control and the landing position was under experimental control, and vice versa for the cutting task. We aggregated performance by

\footnotetext{
\({ }^{1}\) One participant noted that they solved trials by "remembering where the ball should go" but it was not clear whether this was memory for the trials or prior knowledge of pendulum motion.
\({ }^{2}\) For computational reasons, this was calculated using the small angle approximation to pendulum motion, which should be correct to within \(2.4 \%\) of actual pendulum timing.
}
trial across participants in each task to determine how trial factors influenced participants' decisions.

Catching task. Participants' mean bucket positions were correlated with the ball's actual landing positions ( \(r=0.95\), SumSq \(=880^{*} 10^{3}\) ), and were highly consistent with each other (split-half correlation: \(r=0.993\) ). Participants also demonstrated a systematic bias: on average their judgments were slightly shifted away from the actual landing position, toward the center of the pendulum (see Fig. 3). The consistency across participants suggests that the position bias is shared, capturing a commonality in physical models.

Figure 3: Catching task. Actual landing positions (x-axis) versus participants' mean bucket positions ( y -axis) for each trial (individual trials, error bars are \(95 \%\) CIs).

Cutting task. We calculated the projected landing positions of the ball as a function of each release time chosen by participants, per trial. Participants' mean landing positions were highly correlated with the actual bucket positions ( \(r=0.98\), SumSq \(=187 * 10^{3}\) ), and were again highly consistent with each other (split-half correlation: \(r=0.998\) ). Participants also demonstrated a distinct bias, which differed from that in the catching task: when the bucket was near the horizontal position of the pendulum's nadir, participants' mean landing positions were shifted away from it, but when the bucket was far from the nadir, their mean landing positions were shifted toward it (note the sigmoid curvature in Fig. 4). This high inter-participant correlation again suggests a common bias across people.

Figure 4: Cutting task. Actual bucket positions (x-axis) versus mean ball landing positions (y-axis) for each trial (individual trials, error bars are \(95 \%\) CIs).

Comparison. Both tasks required using the same physical principles to determine where the bucket should be placed or when the rope should be cut, yet showed divergent biases. Moreover, the correlation between the mean bucket position and mean landing position for matched trials was high ( \(r=0.93\) ), but this demonstrates only that participants were in general accurate at this task - the inter-task correlation was less than each task's correlation with the ideal response, suggesting that the sources of deviation from the ideal response are distinct.

Diagram task. Two research assistants naïve to the purpose of this experiment sorted participants' diagram trajectories into one of eight types (see Figure 5). Inter-rater reliability was high (Cohen's kappa \(=0.826\) ) - the raters agreed for 47 of the 56 of the participants; where they disagreed, the first author acted as a tie-breaker. Twenty-one percent of the participants' figures were idiosyncratic and could not be categorized. Only 4 (7\%) of participants drew the correct path for all diagrams.

Figure 5: Diagram patterns drawn by more than one participant. Excludes 12 participants who drew idiosyncratic paths. The top pattern represents correct physics.

We reviewed subjects' beliefs about trajectories under gravity: whether they demonstrated that balls would fall in a curved pattern: only \(18 \%\) of our participants did (less than the \(55 \%\) reported by Caramazza, et al., 1981). If participants were learning principles about pendulums from the catching or cutting task, we would have expected a higher proportion of curved paths.

Thus participants display high inter-subject reliability on the catching and cutting tasks (despite large differences between the two) but when explicitly drawing pendulum
trajectories they show much less agreement and consistency with any kind of physical or non-physical principles. We believe this discrepancy arises because the diagram task taps into idiosyncratic, strategic explanations of physics, but the cutting and catching task behaviors arise from a single consistent application of physical principles under different task demands. We designed a model to test the latter claim.

\section*{Physics-based model observer}

We designed a model observer that used a single system of physical mechanics rules to predict participants' behavior on both the catching and cutting tasks. These model predictions used real-world physics, just as was used in the experiment to determine the trajectory of the ball both on and off of the pendulum string. The model adapted to each task by adjusting how its physical predictions were applied to the judgment. In the catching task it computed the expected landing position of the ball and selected that as its bucket position, but biased its estimates of the ball's pre-release velocity toward a slower speed based on "misremembering" the velocity through a pause. In the cutting task it computed which release time would cause the ball to land in the bucket and selected that as its judgment, but this timing was subject to errors that reflected realistic constraints on people's timing precision.

\section*{Catching task}

Description. Because the ball was motionless while participants placed the bucket, participants were required to remember the velocity of the ball and form their judgment based on that memory. This could introduce biases that would cause participants to recall the velocity as slightly different than it had actually been before the pause (Brouwer \& Knill, 2009), especially favoring slower speeds (Stocker \& Simoncelli, 2006; Weiss, Simoncelli, \& Adelson, 2002). This bias was treated as a single parameter ( \(\mathrm{v}_{\mathrm{adj}}\) ) that determined the proportion of the original velocity the ball would have upon being released. This proportion was constant across all trials.

Based on this (mis)remembered velocity, the model calculated the expected landing position of the ball when it would hit the paddle, and assumed all deviation from that position was Gaussian noise. This placement noise could arise from noise in either the motor system during placement, uncertainty in estimation of the velocity of the ball, or simulation uncertainty that accumulates symmetrically around the position over time (e.g., Smith \& Vul, 2013). \({ }^{3}\)

Model fit. The model explained participants' average bucket positions well ( \(r=0.994\), \(\operatorname{SumSq}=41 * 10^{3}\), see Fig. 6 ), and accounted for participants' center-shift bias. The model predicted participants' responses as well as

\footnotetext{
\({ }^{3}\) Simulations indicated that noise in the initial velocity (speed and direction) would give rise to roughly Gaussian error, suggesting that this is a reasonable assumption.
}
participants predicted each other, which suggests that the model captures nearly all of the systematicity in people's underlying judgments.

The best fitting parameters assumed that participants recalled the ball as having \(51.7 \%\) of its pre-pause velocity magnitude, which caused their judgments of its predicted final horizontal distance to be shifted nearer to the center when it reached the ground. Although this is directionally consistent with our assumption that people remember velocity as slower than it was, the magnitude was larger than expected. Individual errors were predicted to be distributed around that point with a standard deviation equal to \(14.5 \%\) of the screen width.

Although accuracy increased across trials in the catching task, this had relatively little impact on the model parameters (first half \(\mathrm{v}_{\mathrm{adj}}: 47 \%\), second half \(\mathrm{v}_{\mathrm{adj}}\) : \(55 \%\) ). Therefore we do not believe that this pattern of errors was driven by feedback during the task.

Figure 6: Catching task. Model's bucket positions (x-axis) versus participants' mean bucket positions ( y -axis) for each trial (individual points, error bars are \(95 \% \mathrm{CIs}\) ).

Uncertainty The model assumed that the error in the catching task arose from Gaussian noise in the bucket position around the expected location. This implies a constant error in paddle position regardless of where the ball lands. Thus error should be constant across trials.

Figure 7: Catching task. Actual landing position (x-axis) versus participants' bucket positions' SD (y-axis) for each trial (individual points).

As can be seen in Figure 7, there is no evidence for a linear \((F(1,46)=0.27, p=0.61)\) or quadratic \((F(2,45)=1.31\), \(p=0.28\) ) relationship between the landing position of the ball on each trial and the standard deviation of participants' bucket positions on that trial. \({ }^{4}\) This suggests that error does not vary as a function of bucket position, which agrees with our prediction that this is only a combination of motor error and unbiased prediction noise.

\section*{Cutting task}

Description Participants' release time choices were variable, likely due to imprecise visual estimates of the ball's position and velocity as well as noise inherent to fine motor behaviors. As a result, if the participant intended to release the ball at time \(t\), they may have instead released it at time \(t+\varepsilon\). Because the physical dynamics induce a nonlinear relationship between \(\varepsilon\) and the error in landing position, a rational participant should select a time for which the probability of the ball landing in the bucket is highest rather than when it would land closest to the bucket center. If people understand their own timing imprecision (as reported in Hudson, Maloney, \& Landy, 2008), then they should marginalize over \(\varepsilon\) in order to maximize their chance of success. If \(R^{*}\) is the intended release time, \(R\) is the actual release time, and \(t_{\text {err }}\) is the variability in timing, the probability of hitting the bucket given \(R^{*}\) is:
\[
P\left(h i t \mid R^{*}, t_{e r r}\right)=\int P(h i t \mid R) * P\left(R \mid R^{*}, t_{e r r}\right)
\]

Here \(P(h i t \mid R)\) is either 1 or 0 , because hit depends deterministically on \(R\). The distribution of \(R\) given \(R^{*}\), \(P\left(R \mid R^{*}, t_{\text {err }}\right)\), was assumed to be Gaussian distribution with mean and \(\mathrm{SD}, R^{*}\) and \(t_{e r r}\) respectively. The model assumed that people selected \(R^{*}\) such that \(P\left(h i t \mid R^{*}\right)\) was at a local maximum. The cutting task contained an important additional feature: for most trials ( \(58 \%\) ) there were two time spans in the pendulum period during which the string could be cut to get the ball into the bucket - usually one time while the pendulum is swinging left, and once while swinging right. In these cases, there were two locally maximum modes of \(P\left(h i t \mid R^{*}\right)\). Puzzlingly, people did not always choose the optimal (higher probability) mode given the model assumptions, but instead often favored the suboptimal mode. This suboptimality may have been due to participants' desire to accumulate more information by waiting for the later time (Battaglia \& Schrater, 2007; Faisal \& Wolpert, 2009), or minimize trial duration by selecting the earlier time. Since our model did not capture such factors, we simply set the model's choice of modes to match the participants' proportion.

Timing errors were represented by two parameters in this model, describing the bias ( \(\mathrm{t}_{\text {bias }}\) ) and the noise ( \(\mathrm{t}_{\text {err }}\) ). These

\footnotetext{
\({ }^{4}\) We attempted to fit polynomial regressions up to fifth-order to this data but found no significant relationships (all ps \(>0.1\) ).
}
parameters were fit to the observed cut timings, though for consistency, results are presented as the average landing position based on these cuts.

Model fit. The model assumed that people tended to release the ball 38 ms after the optimal time, and the variability in responses had a standard deviation of 165 ms . This timing variability is similar in magnitude to that reported in another task that required physical prediction \((130 \mathrm{~ms}\); Faisal \& Wolpert, 2009). The correlation between people's mean projected landing position given their choice of release time and that of the model was high ( \(r=0.993, \operatorname{SumSq}=87 * 10^{3}\), see Fig. 8).

Figure 8: Cutting task. Model's landing position (x-axis) versus participants' mean projected landing positions ( y axis) for each trial (individual points, error bars are \(95 \%\) CIs).

Uncertainty. The model assumed that the source of error in landing positions was in the cutting time, but a constant error in time does not imply a constant error in landing position: if the ball is released near the apex when moving slowly, a small time error will lead to a small difference in landing position, while if the ball is released at the nadir when moving fastest, the same timing error will lead to a larger difference in landing position.

Figure 9: (Left) Variability in empirical ball landings by where the ball will land. (Right) Model predictions of trial variability in the cutting task versus empirical observations. Each point represents a separate trial.

Unlike the catching task, there is a quadratic relationship between the landing position of the bucket on each trial and
the SD of the ball landing positions on that trial \((F(2,45)=13.8, p<0.001\), see Fig. 9, left). Furthermore, the model predicts this variability. We calculated the SD of landing position that the model expected for each trial and found that it was correlated with participants' projected landing position SD with \(r=0.67\) (see Fig. 9, right), although the model's predicted SD was slightly lower on some trials. This suggests that the physics-based model captures differences in trial variance.

\section*{Discussion}

In this experiment, we found that people show very different behaviors on three tasks that use the same underlying model of physics: predicting the trajectory of a ball on a pendulum after the string has been cut. Two of the tasks required people to make a judgment about the future state of the world: where the ball will land or when to cut the string to control the ball's landing. While people responded in different ways on each of these two tasks, both sets of responses were consistent with veridical physical principles once task uncertainties were accounted for. On the other hand, participants were much more variable on the diagram task: they often drew trajectories that were physically impossible.

These differences imply that the catching and cutting tasks are tapping a different sort of knowledge than the diagram task. Perhaps people can simulate the world forward in a way consistent with Newtonian physics, but the workings of these simulations are opaque, making description difficult and more reliant on conceptual understandings. This would suggest a need for both types of intuitive physics: research into how people make predictions informs how we use physics to plan our actions or make judgments about the world (e.g., Gerstenberg, Goodman, Lagnado, \& Tenenbaum, 2012; Hamrick, et al., 2011), while research into how people describe physical events informs how we form concepts about the workings of the world (e.g., diSessa, 1993).

It has been suggested before that "a person may possess a perceptual appreciation of... natural dynamics... yet be unable to draw upon this knowledge... in a representational context." (Kaiser, Proffitt, \& McCloskey, 1985, p. 539). Here we provide evidence that even when people cannot explain how the world will unfold, their predictions and actions are reflective of a veridical physical model of the world.

\title{
Hear No Evil: Can Music Attenuate the Irrelevant Speech Effect?
}

\author{

\begin{abstract}
This study aims to replicate the irrelevant speech effect (ISE) in a local context and, more important, is the first to directly investigate if musical information can reduce impairments imposed by the ISE on a serial word recall task. Thirty-five undergraduates from the National University of Singapore performed serial recall on 10 word lists. The lists were presented under 5 auditory conditions, namely: Music-Only, Combined (music with background speech), Scrambled music with background speech, Background Speech-Only and White Noise conditions. The Scrambled condition contained the same piece of music as the Combined condition except that it was re-arranged in a random fashion; the mission of this condition was to specifically provide a comparison basis to test if "musical structure" per se actually attenuates the ISE. A significant main effect of music conditions emerged. ISE was successfully replicated, where a significantly lower percentage of correct words was recalled in the Background Speech-Only condition compared to all other conditions. ISE was also successfully attenuated, but the present data suggest that musical structure per se was not (at least not entirely) responsible for the attenuation, since the Scrambled condition had superior performance than both the Combined and Background Speech-Only conditions. Here, we propose and discuss several novel theoretical models involving changing acoustical features, selective attention, and arousal to account for the present findings.
\end{abstract}

Keywords: Irrelevant speech effect; music; recall performance.

\section*{Introduction}

The irrelevant speech effect (ISE) is the finding that background speech significantly impairs serial recall performance, even when the background speech is irrelevant to the task (Farley, Neath, Allbritton \& Surprenant, 2007). First demonstrated by Colle and Walsh (1976), the researchers presented subjects with lists of eight consonantitems visually together with a passage read out in German. The background speech was considered irrelevant as participants were told to ignore the passage and that no subsequent recall of the background speech was required. Serial recall was significantly impaired in the irrelevant speech condition compared to the quiet (control) condition. The ISE is found to be robust and independent of speech intensity, within the range of 40 to 76 dB (Ellermeier \& Hellbrück, 1998). The effect is also significant regardless of whether the irrelevant speech is presented together with or after the word list (Miles, Jones \& Madden, 1991), and evident over repeated trials or sessions (Tremblay \& Jones, 1998).

The question of greater interest (and importance) is whether one could ever circumvent the ISE, given the potential costs on cognitive performance that are associated with the negative impacts of ISE under a variety of situations. A possible candidate to abate irrelevant speech is instrumental music, due to the fact that music has been found to modulate work performance. Lesiuk (2010), for instance, found that listening to preferred music led to improvements in performance within the context of highly cognitive demanding jobs.

This study had two goals. The first was to (first) replicate the ISE in a local context (among undergraduates at the National University of Singapore). The background speech, accordingly, comprised of contents related to undergraduates, ranging from modules, bid points, gossip and current news ensuring that the contents were distracting enough while trying to concentrate on learning a word list. Second, and more important, this study aimed to discover whether instrumental music, with all its purported positive effects and benefits on cognitive performance (e.g., Nantais \& Schellenberg, 1999; Schellenberg \& Hallam, 2005), can reduce the detriments of ISE during a serial word recall task. Accordingly, this study has been designed to contain five auditory conditions: (1) Instrumental Music-Only, (2) Combined (music with background speech), (3) Background Speech-Only, (4) Scrambled Music with background speech, and (5) White Noise.

Two specific hypotheses follow. First, under the Background Speech-Only condition, participants will have the worst recall performance compared to all other conditions, while Instrumental Music-Only and White Noise conditions will produce the best performances. This hypothesis, if supported, would mean that ISE effects are replicated in a local context, which further qualifies that instrumental music and white noise have less detriments on serial word recall than irrelevant speech does. Second, the Combined condition is predicted to yield superior performance in the recall task compared to the Background Speech-Only and Scrambled conditions would.

Hypothesis 2 addresses the possibility that the instrumental music - with its musical harmony and internal musical structure - may result in a more stable auditory scene for selective processing than the changing-state features of background speech. The Scrambled condition consists of the same piece of instrumental music, only rearranged to disrupt its internal musical structure. Hence, the Combined condition is predicted to enhance task performance compared to the Scrambled condition and Background Speech-Only conditions.

\section*{Method}

\section*{Participants}

Thirty-five undergraduates from psychology classes in National University of Singapore took part in the study and were awarded course credits for their participation. All participants reported normal hearing.

\section*{Design}

A 5 [Music Conditions: (1) Music-Only, (2) Background Speech-Only, (3) music with background speech (Combined) versus (4) Scrambled music with background speech, and (5) White Noise] \(\times 2\) [Word frequency: high versus low] within-subjects design was used.

\section*{Serial Word Recall List}

Eighty 4-letter English words were chosen for the 10 word lists (Lim \& Yap, 2010); orthographic neighborhood density (held constant at 3.33) and word frequency (high versus low; see Table 1) effects per se were not expected to emerge in this study (i.e., music condition effects, if any, ought to persist across high and low frequency words).

Table 1: Means and Standard Deviations of Logfrequency for Low and High Frequency Words.
\begin{tabular}{lcc} 
& \multicolumn{2}{c}{ Log-frequency } \\
\cline { 2 - 3 } Conditions & \(M\) & \(S D\) \\
\hline Low-frequency & 6.61 & 0.544 \\
High-frequency & 11.8 & 1.230 \\
\hline
\end{tabular}

\section*{Stimuli}

A total of five auditory conditions were created: MusicOnly, Background Speech-Only, music with background speech (Combined condition), Scrambled music with background speech, and White Noise. The backgroundspeech auditory track was superimposed at the same volume on Bach's Italian Concerto (First Movement) and Haydn's Piano Sonata in E-Flat Major, No. 52. The superimposed tracks were split into sets of 42 seconds each, in order to match the duration of each word list's presentation. This procedure is illustrated in Figure 1.

The same musical track was randomly split and rearranged to create the Scrambled condition, therefore maintaining the exact same number of musical notes while disrupting the musical structure. This prevented differences in number of musical notes from producing any differential (unintended) effects in recall performance

Intact Instrumental Music Track

Figure 1: Arrangement of auditory tracks and assignment of word lists.

\section*{Manipulation Check}

The manipulation check, which asked participants to recall the segments of conversations, was instituted to rule out the possibility that the complete or scrambled music (in the Combined and Scrambled conditions) was (merely) masking off the background speech track.

\section*{Procedure}

Participants were presented with the word lists paired with each of the five auditory conditions and were instructed to ignore the background auditory stimuli. Once the list stops, the auditory stimuli paused and the participants were given one minute to recall the words presented. Immediate recall was required after every list using a booklet provided. It was emphasized that only words recalled in the correct position would be scored as correct responses. Exposing participants to different segments specifically controlled for habituation and familiarity effects. In addition, the order of the five different auditory conditions was counterbalanced across the two test sessions.

\section*{Results}

\section*{Analysis of Manipulation Check}

The manipulation check was instituted in order to critically rule out the possibility that the music or scrambled music could merely be masking the speech information. Importantly, approximately \(73 \%\) of the participants recalled more than 2 categories of contents in the background speech. This high recall performance of speech contents constituted important evidence in suggesting that the music tracks did not (merely) mask the background speech.

\section*{Analysis of Word Recall Performance}

A \(5 \times 2\) repeated-measures ANOVA was conducted on the percentage of words recalled correctly. The two-way interaction was not significant as earlier predicted, \(F(4,136)\) \(=.653, M S E=.31, p=.626\), and data were subsequently collapsed across word frequency. The main effect of word frequency did not reach significance as well, \(F(1,34)=1.57\) , \(M S E=.031, p=.219\).

A significant main effect for music conditions emerged, \(F(4,136)=5.25, M S E=.71, p=.001\). The irrelevant speech effect was successfully replicated: Post hoc comparisons revealed that percentage of correct recall in the Background Speech-Only condition ( \(M=.554, S D=.280\) ) was significantly lower than recall in Music-Only ( \(M=.713\), \(S D\) \(=.274\) ), Combined ( \(M=.664, S D=.241\) ), Scrambled ( \(M=\) \(.741, S D=.259)\) and White Noise \((M=.698, S D=.275)\) conditions. This means that the Background Speech-Only condition yielded the worst recall performance compared to all other sound types.

While instrumental music appears to be influential in attenuating the ISE, an intriguing finding was that instrumental music per se - specifically its musical structure (or music-ness) - did not appear to attenuate ISE, due to the fact that the Scrambled condition produced significantly higher recall performance than both the Combined condition and Background Speech-Only condition did. The critical interpretation is that instrumental music attenuated ISE, but musical structure per se is not (at least not entirely) responsible for this effect. Figure 2 presents recall performance across conditions.

Figure 2: Plots and error bars of mean percentage recall across music conditions. Background Speech Only produced the lowest recall, while Combined and Scrambled yielded significantly higher recall than Background Speech-Only.

\section*{Discussion}

The present results show that the ISE was replicated in a local context. Recall performance in Background SpeechOnly was the worst compared to that in all other auditory conditions. However, the intriguing finding was the
apparent lack of evidence to support the hypothesis that musical structure per se can attenuate the ISE (in the Combined condition), given the observation that the Scrambled condition actually produced better recall scores than both the Combined and Background Speech-Only conditions did. Auditory masking, albeit a convenient explanation, clearly cannot account for the present data, because of the high percentage of speech contents recalled (73\%). Clearly, participants did process the background speech.

\section*{Towards a Hybrid Model of Changing States and Attention}

Here, we propose a novel hybrid model that combines the attention component from the feature model by Neath (2000) with the changing-state accounts from the O-OER model (Jones, Madden \& Miles, 1992) to account for the present data (i.e., improvements in recall performance under both the Combined and Scrambled conditions compared to Background Speech-Only condition).

According to the O-OER model, these changing state features give rise to multiple objects, which interfere with serial processing of the word list compared to a repeated, steady auditory stream. In this study, music did not impose additional processing because it may have less changing features than the irrelevant speech. Therefore, the music tracks are preferred over the irrelevant speech whereby in the Combined and Scrambled conditions, attention was diverted away from the damaging irrelevant speech. Additional cognitive resources can then be allocated towards the serial word recall task. Ahveninen et al. (2011), using multimodal techniques (PET, fMRI, MEG and EEG), found that auditory cortices can selectively deploy attention to segregate relevant sounds from noise, thereby mitigating the detrimental influence of irrelevant speech. In this study, the music track, with less changing-features, makes processing easier, delegating more cognitive resources for the serial word recall task, thereby explaining superior performances in Combined and Scrambled conditions.

An alternative explanation is that the cumulative presence of the additional auditory stimuli and irrelevant speech in this study led to an increase in distraction levels, resulting in a compensatory increase in attention to the serial recall task. Weissman, Warner and Woldorff (2004) found in their experiment that as the irrelevant stimulus increases in their distraction levels, a compensatory increase in selective attention follows. Therefore, an overall increase in distractibility of auditory stimuli can lead to a compensatory increase in attention, thereby explaining why performances are better in the present Combined or Scrambled condition.

Summarizing, these findings represent active processing by participants where changing acoustical features of the irrelevant speech and music tracks were compared and the latter (steadier) stream is preferred. Attention is either selectively deployed to the less distracting stream or increased via compensatory mechanisms, allocating more
attentional resources towards the serial recall task. Task performance is consequently enhanced.

However, it must be noted that the hybrid model makes the implicit assumption that music has less changingfeatures than irrelevant speech does, and this model would not particularly aim to differentiate between intact and scrambled music. Therefore, there is a possibility that the present results, where scrambled music yielded better recall performance than did the Combined and Background Speech-Only conditions, are not (yet) thoroughly accounted for by this model. We next briefly describe (for future work purposes) another property of music that might explain the attenuation of ISE.

\section*{Arousal-mood Hypothesis}

One particular property of music - arousal - may be promising to explain why scrambled music produced such superior recall performance. The arousal-mood hypothesis by Thompson, Schellenberg, and Husain (2001) argues that the tempo of music is related to arousal while its mode is linked to mood. Music in a major mode corresponds to a happy mood whereas minor mode to a sad mood (Husain, Thompson \& Schellenberg, 2001). The re-arrangement of the original Bach and Haydn sonatas music could, in fact, augment the perceived tempo in the scrambled track given its now more "staccato-like" (and therefore "rapid") quality (compared to its original unscrambled (and "unrushed") counterparts). The perceived faster tempo in the Scrambled condition could possibly have produced higher arousal states than did the perceived tempo in the Combined condition, which might directly predict recall performance. The view, in a sense, is that the Scrambled music then offered listeners with greater cognitive resources (due to heightened states of arousal) to engage in their recall task, than did unscrambled music.

\section*{Future Directions}

The intriguing finding was that the Scrambled condition in fact enhanced recall more than the Combined condition did. Since the musical structure (i.e., music-ness) of the present auditory stimuli did not appear to be (solely) responsible for this attenuation, future research, as recommended above, could explore effects of alternative (e.g., arousal) properties to understand the workings beneath ISE more directly.

\section*{Conclusion}

This study reports novel data that suggest that ISE can be attenuated (even in a local context) but how that the reason for this attenuation is not (solely) musical structure per se. Changing acoustical properties and arousal capabilities of the auditory stimuli may unveil how we might exactly attenuate the ISE. For scrambled music, its arousing properties may potentially attenuate ISE. Therefore, beyond changing-states and selective attention, music's arousing capabilities should be directly investigated in a future study. It is likely that both changing acoustical features and arousal
capacities found in music may collectively help attenuate the ISE. These are exciting predictions which would have brought us closer to answering the long-standing question of just why "music" is so capable of offering inoculation against a harsh auditory environment that comprises a host of distractions (e.g., why thousands of students around the world continue to listen to music whenever they study).

\title{
Priming randomness increases the evaluation of ritual efficacy
}

\begin{abstract}
Reestablishing feelings of control in the face of uncertainty is a fundamental motive for human behavior. We propose that rituals (i.e., socially stipulated, causally opaque practices) provide a means for coping with the aversive feelings associated with randomness due to the perception of a connection between ritual action and a desired outcome. Two experiments were conducted (one in Brazil [ \(N=40\) ] and another in the U.S. [ \(N=94]\) ) to evaluate how the perceived efficacy of rituals is affected by feelings of randomness. In a between-subjects design, the Scramble Sentence Task was used as a priming procedure in three conditions (i.e., randomness, negativity, and neutral) and participants were then asked to rate the efficacy of rituals used for problem-solving purposes. The results demonstrate that priming randomness increased participants' perception of ritual efficacy relative to negativity and neutral conditions. Implications for increasing our understanding of the relationship between perceived control and ritualistic behavior are discussed
\end{abstract}

Keywords: Randomness; Ritual; Perception of Control; Supernatural Cognition.

\section*{Introduction}

Anthropologists have long noted that the use of rituals for instrumental purposes is linked to conditions of risk and uncertainty (Malinowski, 2004). When Malinowski visited the Trobriand Islands of New Guinea, for example, he noted that at times the Trobrianders would base their behavior on practices with clear causal rationales while at other times they would rely on causally opaque practices such as ritual. The Trobrianders rarely relied on ritual when fishing in a reliable and safe setting such as the lagoon; they described their successes and failures in terms of skill. In contrast, extensive ritual preceded the uncertain and dangerous conditions of deepsea fishing.

The Trobriand fishermen are not alone in their use of ritual to restore feelings of control when confronted with uncertainty (Souza \& Legare, 2011). On college campuses, for instance, up to \(70 \%\) of students employ such strategies to assist with performance on exams (Gallagher \& Lewis, 2001) or athletic competitions (Bleak \& Frederick, 1998; Ciborowski, 1997; Todd \& Brown, 2003; Van Raalte, Brewer, Nemeroff, \& Linder, 1991; Vyse, 2000; Womack, 1992).

To the extent that the rituals have little or no actual bearing on the success of instrumental outcomes (Lobmeyer \& Wasserman, 1986) through a process of physical causation (Legare \& Herrmann, 2013; Legare \& Souza, 2012;

Humphrey \& Laidlaw, 1994), we propose that one of the functions of rituals is to maintain an illusion of control, a phrase coined by Langer (1975). An illusion of control is inferred when participants believe or respond as if contingencies between their behavior and the outcome exist, even if the outcomes are random (Alloy, Abramson, \& Viscusi, 1981; Matute, 1994). Regardless of how the illusion of control is manipulated, all dependent measures reflect a belief that one's actions can influence an outcome that is, in fact, outside of their control.

There is considerable empirical evidence demonstrating that lack of perceived control - an individual's belief that he or she cannot predict and affect future events - has applied consequences and is associated with a number of negative outcomes. For example, it contributes to the tendency to demonstrate depressive and pessimistic behavior and avoid facing challenging situations (Fast, Gruenfeld, Sivanathan, \& Galinsky, 2009). Conversely, feelings of control promote increased self-esteem, optimism and greater sense of agency (Scheier, Carver, \& Bridges, 1994). Despite the benefits associated with feelings of control (Kofta, Weary, \& Sedek, 1998), people frequently experience situations in which they lack the capacity to exert the control they desire. Many of the most pervasive ailments that afflict humans such as chronic illness (e.g., cancer), economic insecurity (e.g., unemployment) and interpersonal problems (e.g., infidelity) are often not within our control.

When people are unable to control and predict their environment, attributional biases are activated and strategies are implemented to restore feelings of control (Underwood, 1996; Vaughn \& Weary, 2003; Weary \& Jacobson, 1997; Weary, Jacobson, Edwards, \& Tobin, 2001). For example, people detect correlations among random sets of stimuli that are presumably unrelated when they are primed with feelings of lack of control (Whitson \& Galinsky, 2008). There is also evidence that when desire for a coveted item and uncertainty are high and personal control is lacking, people may be more likely to help others, as if they can encourage fate's favor by doing good deeds proactively.

Seminal work on the illusion of control and magical thinking has examined first-person experiences with superstitious behavior (Keinan, 1994) or procedures that approximate rituals (Rudski, 2001; Rudski \& Edwards, 2007). Keinan (1994)
explains the increase in superstitious behavior under conditions of stress and uncertainty as an attempt to regain control. Rituals, which we define as conventional, causally opaque procedures may provide a means for coping with the aversive feelings associated with randomness by reestablishing feelings of control. We propose that the structure of ritual can be interpreted in light of intuitive causal beliefs (Legare \& Souza, 2012) and predict that intuitive causal reasoning, not familiarity with the content of particular rituals, drives how ritual efficacy is evaluated.

Despite the fact that engaging in causally opaque practices may seem to be a paradoxical means of increasing perceived control, we hypothesize that this is possible because rituals provide a socially stipulated and culturally sanctioned opportunity to exert agency through action, thereby giving the illusion of increased control (Thompson, Armstrong, \& Thomas, 1998). We propose that priming randomness increases the activation of attributional biases to detect a connection between action and outcome as a means of reestablishing feelings of control. The perception of a connection increases the evaluation of ritual efficacy. We predict that this effect occurs not only in first-person experiences with uncertainty (Keinan, 1994,2002 ) but also implicitly when evaluating the experiences of others. Two studies investigated this prediction directly by examining whether priming randomness affects the perception of the efficacy of rituals.

Study 1 was conducted in Brazil, a cultural context in which a particular type of ritual - called simpatia - is used to treat a variety of problems. Simpatias are ritualistic remedial procedures used to solve everyday biological (e.g., sinusitis, asthma), psychological (e.g., depression, anxiety), and interpersonal problems (e.g., attracting a partner, infidelity). They are available to the general population, are relatively low-cost, and do not require any specialized expertise to be performed. Despite the lack of a physical-causal mechanism underlying their efficacy, simpatias are widely endorsed and used for a greater variety of problem-solving purposes. For example, a simpatia to cure depression might require a person to drink coconut water straight from the coconut and then bury the coconut husk in a garden full of flowers (Legare \& Souza, 2012).

Legare and Souza (2012) designed experimental simpatias to match the characteristics and content of existing ones. A selection of these simpatias was used in the current studies to assess perceptions of ritual efficacy. To prime feelings of randomness, we used a previously validated task called The Scrambled Sentence Task - SST (Kay, Moscovitch, \& Laurin, 2010). A more detailed description of the task is provided below.

\section*{Study 1}

\section*{Methods}

Participants Forty Brazilian Portuguese-speaking adults participated in the study. Participants were recruited from the metropolitan area of the city of Belo Horizonte located in
the southeastern region of Brazil. They were recruited from public health centers located in a peripheral neighborhood of Belo Horizonte. The public health centers (known as Posto de Saúde) are centers maintained by the city administration, and serve the population from the community in which the center is located.

According to the Brazilian Institute of Geography and Statistics, Belo Horizonte has a population of over 6,082,776 people. The ethnic composition of the population is \(47 \%\) Black, \(41 \%\) Pardo (mixed-race), and \(12 \%\) White.. In terms of religious composition, over \(68 \%\) of the population selfidentify as Catholic, \(19 \%\) Protestant, and \(8 \%\) of the population reported not having any religious affiliation. Although census data has traditionally failed to capture the range of religious traditions available in Brazil (especially those of AfroBrazilian roots), the endorsement of simpatias exists across all religious groups.

Materials To assess the perceived efficacy of rituals, we used simpatias designed by Legare and Souza (2012). They were designed to match the characteristics of existing simpatias to maximize ecological validity. A previously validated task called The Scrambled Sentence Task - SST was used to prime randomness in one condition and negativity in the other (Kay et al., 2010). A baseline condition containing neutral words was also created. In the SST, each participant is given 20 scrambled sentence strings composed of five words each. Participants were asked to rearrange four of the five words to form a meaningful sentence and then to cross out the one word left out. For half the participants, the word sets contained words related to randomness (e.g., chaotic) and for the other half, these words were replaced with negatively valenced control words (e.g., lazy). This procedure is similar to the one used by Kay et al. (2010).

Procedure Participants were randomly assigned to one of the two conditions (i.e., randomness condition and negativity condition). The second author, a native speaker of Brazilian Portuguese, interviewed each participant individually. Each participant was given a set of words (according to the condition assigned) and was asked to form sentences. Participants were allowed to take as long as they wanted to for the sentences. For the randomness condition, 10 of the 20 lists contained randomness-related words, whereas for the negativity condition, these 10 words were replaced with negatively valenced words.

Following the priming task, participants were presented with six simpatias paired with specific problems. The order of presentation was randomized across participants. Then participants were asked: "In a scale from 1 to 10, 1 being EFFECTIVE and 10 being INEFFECTIVE, how much do you think this simpatia is effective for treating this specific problem?"

\section*{Results and Discussion}

Preliminary analysis revealed that the priming manipulation affected all six simpatias equally, that is, in terms of efficacy ratings, there was no main effect of specific simpatia used and no interaction between specific simpatias and the priming procedures. Thus, the ratings of the six simpatias were averaged to form a single index of ritual efficacy for each participant. Results revealed that participants in the randomness condition rated the simpatias as significantly more effective ( \(M=4.33, S D=.31\) ) than participants in the negativity condition \((M=4.64, S D=.40), t(38)=2.65, p<.05\), (simpatias with lower ratings were judged to be more effective than simpatias with higher ratings).

This finding supports the hypothesis that the evaluation of ritual efficacy increases when the motivation to reestablish control is primed. Rituals may provide a mechanism for accomplishing this goal (Keinan, 2002). Alternatively, however, this pattern of data could potentially be explained by the possibility that negativity reduced perceptions of efficacy, instead of randomness increasing perceptions of efficacy. To address this potential alternative explanation, in Study 2 we included a third condition containing neutral words. In previous research by (Legare \& Souza, 2012), the evaluation of ritual efficacy did not vary between populations familiar with (e.g. in Brazil) and unfamiliar with (e.g. in the U.S.) simpatias. Thus to examine the generalizability of the results from Study 1 in a population unfamiliar with the content of these culturally specific rituals, Study 2 was conducted in the U.S.

\section*{Study 2}

\section*{Methods}

Participants Ninety-four undergraduate students at a large research university located in the southwest of the United States participated in Study 2 for course credit.

Materials The materials used in Study 2 were identical to the materials used in Study 1 except that they were translated from Brazilian Portuguese into American English by the second author.

Procedure The procedure for Study 2 was identical to Study 1 except that the simpatias and efficacy ratings questions were presented using E-Prime rather than being read to participants. Again, participants were asked to rearrange four of the five words to form a meaningful sentence and then to cross out the one word left out. For 33 participants (randomly selected), the word sets contained words related to randomness (e.g., chaotic), for 32 participants, these words were negatively-valenced words (e.g., lazy) and finally for 29 participants, the words were neutral words extracted from the ANEW database (Bradley \& Lang, 1999).

\section*{Results and Discussion}

The objectives of Study 2 were to examine the generalizability of the effect in a cultural context unfamiliar with simpatias and explore the possibility that negative words reduced

Figure 1: Mean Efficacy Ratings per Condition in Study 2
the evaluation of ritual efficacy. As predicted, although the simpatias were rated as less effective in the U.S. sample than in the Brazilian sample (consistent with Legare \& Souza, 2012), a one-way ANOVA revealed a main effect of condition, \(F(2,91)=5.07, p<0.05, \eta^{2}=.10\) on the efficacy ratings. Post-hoc tests (Bonferroni corrected) demonstrated that participants primed with randomness rated the simpatias as significantly more efficacious ( \(M=8.06, S D=1.64\) ) than participants in the neutral condition \((M=9.01, S D=.97), t(60)=\) \(-2.71, p<.002\), and marginally more efficacious than participants in the negativity condition ( \(M=8.84, S D=1.02\) ), \(t(63)\) \(=2.27, p=0.02\). Notably, there was no significant difference between the efficacy ratings of people in the neutral condition and negativity condition (See Figure 1). The results demonstrate that even with unfamiliar content, priming randomness increased ritual efficacy evaluations, consistent with the results of Study 1. Moreover, the lack of difference between the negativity and neutral condition suggest that randomness increases perceptions of ritual efficacy, rather than negativity decreasing ritual efficacy evaluation.

\section*{Discussion}

In the face of randomness, attributional biases are activated and strategies are used to cope with feelings of lack of control (Weary \& Edwards, 1994; Weary \& Jacobson, 1997; Weary et al., 2001; Wichman, Brunner, \& Weary, 2008). We propose that rituals provide a means for coping with the aversive feelings associated with lack of control. The current studies sought to examine this possibility empirically by investigating the extent to which priming feelings of randomness influences perceptions of ritual efficacy.

Our results support the hypothesis that perceptions of the
efficacy of ritualistic behavior are influenced by the drive to regain a sense of control. Participants primed in the randomness condition rated simpatias as significantly more efficacious than participants in the control condition. One potential explanation for this effect is that the experience of randomness triggered by the manipulation activated a need to reestablish perceived control. Rituals may provide a mechanism for accomplishing this by providing an opportunity to posit a connection between action and outcome.

Examining the interplay of perceived control and ritual is of pervasive interdisciplinary interest with longstanding roots in both anthropology and experimental psychology (Keinan, 1994; 2002; Rudski \& Edwards, 2007). Despite this interdisciplinary interest, these studies are the first to examine the relationship between priming randomness and reasoning about the efficacy of ritualistic practices used by others. By examining this relationship experimentally, we have demonstrated that ritual may serve as a mechanism for reestablishing the perception of control and have provided insight into the cognitive underpinnings of the evaluation of ritual efficacy. Studying ritual from this perspective contributes to the body of research (Boyer \& Liénard, 2006; Kay, Gaucher, Napier, Callan, \& Laurin, 2008; Kay et al., 2010; Keinan, 1994, 2002; Rudski, 2001) demonstrating that one of the functions rituals serve is to make the world seem more comprehensible, certain, and predictable.

\section*{APPENDIX - Experimental Simpatias}

Employment In the first day of last quarter phase of the moon, take the milk from a coconut and give it to the unemployed person to drink. After that, ask the person to spit three times in the hole made in the coconut. Following this, light up a brand-new white candle and drop the wax around the hole until the hole is sealed. Take the coconut to a far away beach or river.

Depression For five days, the person with depression should go to a crossroad. While there, the person should say: "Depression, stay here!" The person should not walk through the crossroad for one year.

Infidelity Throw a shoe and a shirt of the unfaithful person into a streaming river unbeknownst to the person. As the river flows away, you say: "I hope the river takes the infidelity away as fast as it can." Take some of the water from the river and keep it somewhere in the house.

Evil-Eye Fill a cup with sand spit inside the cup. Seal the cup and bury it upright before the sunrise.

Lack of Luck Get an orange, peel it, squeeze its juice and bury its flesh. Place the peel on top of the dirt. Drink the juice three times a day (morning, afternoon, and evening).

Lack of Money Collect seven red apples directly from an apple tree. In the morning, before eating anything, peel the apples, eat them and save the peel. Right before going to bed, make a tea with the peel.

\begin{abstract}
Communication systems reliably self-organize in populations of interacting agents under certain conditions. The various fields which model this - game theory, cognitive science and evolutionary linguistics - make different assumptions about the learning and behavioral processes which are responsible. We created an exemplar-based framework to directly compare these approaches by reproducing previously published models. Results show that a number of mechanisms are shared by the systems which can construct optimal communication. Three general factors are then proposed to underlie any selforganizing learned system.
\end{abstract}

Keywords: cultural evolution; communication; selforganization; reinforcement learning; feedback learning; observational learning

\section*{Introduction}

Human communication is a mostly learned behavior, while signaling behavior in the natural world appears to have a major genetic component. While Darwinian natural selection is argued to be the driving force behind the development of such innate capacities (e.g. Scott-Phillips et al., 2012 and Oliphant, 1996), the origin of learned communication is less clear. Effective communication requires consensus within a population; how is this reached given the arbitrary mapping between signal and meaning? In the absence of external or internal guidance, the emergent agreement must be the effect of not just global factors, such as how populations are connected and change over time, but crucially local ones also, for example how individuals learn and interact. Populationlevel behavior can therefore provide insights into aspects of human cognition.

The problem of self-organization of learned communication systems has been investigated by researchers working in game theory, artificial intelligence and evolutionary linguistics. The approaches taken by the different fields have much in common: all investigations focus on how two or more agents can effectively arrive at a mutually agreed set of signaling conventions through repeated interactions (or language games), and they all rely heavily on computational and mathematical modeling. However, the different theoretical perspectives have an understandable impact on how the models are designed and interpreted. In particular, the models of learning, interaction and population dynamics are distinct: game theory concentrates on small populations using varieties of reinforcement learning; feedback in closed groups is central to work in AI; in evolutionary linguistics intergenerational observational learning is the dominant paradigm. Re-
searchers have come to apparently conflicting conclusions regarding exactly which aspects of learning and interaction are crucial for the emergence of signaling. The aim of this paper is to reconcile these views by showing that all proposed solutions have three properties in common, a fact that has been obfuscated by the differing theoretical approaches. Individual bias against homonymy, along with the ability to transmit information about internal representations and a mechanism to discard information are argued to underlie the ability to self-organize successful communication.

\section*{Review}

Lewis (1969) devised his classic signaling game in line with game-theoretic principles. A speaker's signal triggers an action in the hearer: the resulting payoff, and thus reinforcement, depends on the state of the world, which is known only to the speaker. If the number of signals, acts and equiprobable states are all held at two, with equal non-conflicting payoffs, the game is proven to always converge upon an optimal signalling system (Beggs, 2005). Adjusting any of these parameters, however, quickly leads to pooling equilibria, where non-optimal communication strategies become attractors in the system. Barrett (2006) shows that while such sub-optimal situations will unavoidably occur when there are more than two possible states, systems can generally escape the pooling equilibria by enforcing memory limitations or including negative reinforcement (punishment of unsuccessful signals).

Steels' 1998 seminal Talking Heads experiment gave rise to a plethora of naming games which investigate how static populations can converge on functional and efficient naming conventions for a number of objects when agents are able to provide feedback to each other. Instead of observing a world state, speakers are said to randomly pick a topic from a communicative context. Key differences from the signaling game are that agents can indicate their intended referent in the case of communicative failure in some 'extra-linguistic' manner (so-called corrective feedback), and that agents can introduce new signals (or names).

Such systems inevitably develop functional communication, but each object ends up with large number of synonyms, a result of the ability to innovate novel signals. By introducing competition between synonyms for the same object, the systems are driven into an efficient state where each object is known by only one label. De Vylder \& Tuyls (2006) provide a mathematical proof that amplification of the input distribution of names is indeed sufficient to guarantee con-

vergence of the naming game. Agents that implement such amplification are said to employ lateral inhibition to dampen name competitors, the most well-known being Baronchelli et al. (2006)'s minimal strategy. Baronchelli (2010) shows that only the hearer need be modified for effective convergence.

Taking yet another approach, iterated learning is the collective term for a large number of computational and experimental studies which combine varieties of observational learning with intergenerational population turnovers (Kirby et al., 2008). Oliphant \& Batali (1997) is one such example: their obverter strategy is derived from the mathematical result that if agents have perfect information about the internal state of the population, choosing signals by maximizing the chance of correct interpretation always results in the population converging on optimal communication. In simulations where agents use only incomplete information about the population gained through intergenerational learning, the obverter strategy still results in population convergence. In another study, Smith (2002) investigated the role of learning bias using populations of agents represented by Hebbian networks. Results showed that biases against homonymy and synonymy are necessary to produce optimal signaling.

The engine which drives the evolution of optimal signaling is variously stated: for reinforcement learning, it is communicative success; for the feedback models, it is the information gained through mutual alignment. Learning in the above models is horizontal; it takes place in static, closed groups. Intergenerational or vertical learning is employed by observational learners in iterated learning models which focus on individual learning biases, and obverters which stress the importance of explicitly maximizing the chance of being understood. A comparison of the above approaches leads to few clear conclusions regarding which learning and interaction features are responsible for convergence. Table 1 shows how the models contrast over many dimensions. The following section describes how the models were reproduced in a unified framework.

\section*{Replications}

An exemplar-style model was used to replicate the four models described above so that the effect of their different design features could be compared directly. Exemplar models have been employed to solve linguistic problems such as categorization (see e.g. Pierrehumbert, 2001). Learning involves
storing packets of perceptual information with discrete category labels. Our framework represents each exemplar as a simple pairing between a signal and a meaning, where 'signal' can also be read as 'name', and 'meaning' is equivalent to both objects in naming games as well as world-states and actions from signalling games. When an agent maps a signal to a meaning, a single exemplar is stored. As such, the framework does not represent a fundamental departure from network and association weight models, but does suggest the simplification of aspects of these models in ways which are detailed below.

A stored exemplar is atomic, and can not be modified in any way apart from wholesale deletion. Production and interpretation of signals can be deterministic or stochastic. With stochastic methods (excepting obverters) the probabilities of producing or interpreting a signal \(s\) of a total \(S\) signals in association with meaning \(m\) from a total \(M\) meanings are given in Formula 1 below, where \(n_{i j}\) represents an agent's count of exemplars associating meaning \(i\) and signal \(j\). Deterministic methods (also known as winner-take-all or WTA) always select the signal or meaning which yields the highest probability.
\[
\begin{equation*}
P(s \mid m)=\frac{n_{m s}}{\sum_{i=1}^{S} n_{m i}} \text { and } P(m \mid s)=\frac{n_{m s}}{\sum_{j=1}^{M} n_{j s}} \tag{1}
\end{equation*}
\]

Our framework is able to capture deterministic and stochastic behavior, as well as both static and changing populations, and the various manipulations of agents' internal representations employed by each of the models discussed above. For the sake of comparison, some parameters are held constant throughout all simulations presented here: populations consist of 10 agents and there are 5 available signals and meanings, where each meaning is equally likely to be selected. Populations are unstructured, with any two agents equally likely to interact. For models using vertical learning, a single new agent is trained on the data of the existing population at each iteration. The new agent then replaces the oldest member of the population.
In closed groups without population turnover, two agents are picked at random from the group at each time step, with one designated the speaker and the other the hearer. After each interaction, the hearer is updated according to the particular rules of that model, specified below. When lateral inhibition of synonyms and/or homonyms is employed,

Figure 1: (Replication of Barrett 2006) The proportion of 10,000 simulations which had converged to an optimal communication system after a given number of iterations, using negative reinforcement without a memory limit, and basic reinforcement with memory limits of 40 and 50 exemplars.
a newly stored exemplar results in the deletion of one randomly selected exemplar with competing signal/meaning associations. \({ }^{1}\) When a memory limit is included in a model, this is instantiated by enforcing a maximum number of \(n\) stored exemplars per agent. When this is exceeded, one exemplar is selected at random for deletion.

Communicative success was measured analytically by looking at the outcome of all possible communicative interactions over the entire population after each time step. 10,000 individual simulations were run for each configuration of each replication, and the number of iterations taken for each to converge on optimal signaling over the population was recorded. The cumulative distribution of converged populations over time was then plotted, as seen in Figures 1-4.
1. The reinforcement models used by Skyrms and Barrett employ Roth-Erev learning (Roth \& Erev, 1995), which maps exactly onto the exemplar model where behaviour is directly proportional to the relative frequency of memory tokens. When agents produce a signal for a given meaning, they do so by selecting stochastically from all stored exemplars associated with that meaning; interpretation is done similarly. Crucially, however, a new exemplar memory is only stored in the case of communicative success. \({ }^{2}\) Repli-

\footnotetext{
\({ }^{1}\) For the relevant models, lateral inhibition presented an issue: the original models decremented each competing weight equally. This implies that a single added exemplar would be responsible for the deletion of many others. As such, both 'maximal' (many deletions) and 'minimal' (only one deletion) interference were examined. In 10,000 simulations no difference was found between the time taken to converge using either strategy: for the results presented here, the minimal strategy with one random deletion was used.
\({ }^{2}\) For this reason, agents in this game are initialized with an initial copy of every possible exemplar: without this, each agent would be locked in to the first received signal mapping for each meaning.
}

Figure 2: (Replication of Steels \& Loetzsch 2012) The proportion of 10,000 simulations which had converged to an optimal communication system after a given number of iterations, using corrective feedback when either only the hearer or both speaker and hearer were modified.
cations of the basic model (not shown here) confirm Barrett's analysis: only a small proportion of simulations ever converge to even \(95 \%\) communicative accuracy, and even then only after long periods. The model was then modified to include either a memory limit, as described above, or negative reinforcement. With the latter, failed communication would cause the hearer to delete one exemplar of the unsuccesfully interpreted type. As shown in Figure 1, both mechanisms lead to near-certain convergence.
2. The feedback model described in Steels \& Loetzsch (2012) utilizes a complicated system of weighting adjustments. This was implemented in a simpler form: only one exemplar is added at a time, and there is no ability to innovate new signals beyond the five available. As confirmed in Baronchelli (2011), modification of the speaker is not a requirement for convergence, as shown in Figure 2. When lateral inhibition of homonyms was removed, signaling systems failed to develop. A further observation is that when corrective feedback is removed as well (i.e. when a speaker is unable to indicate its intended meaning after a failed communication), the model becomes identical to reinforcement learning, where signaling can only develop via negative reinforcement or memory limitations (see above).
3. Oliphant and Batali's (1997) obverters were replicated in both the original WTA version and a new stochastic one. Obverters produce a signal that maximizes the chances of being correctly understood. As such, the second equation in Formula 1 above defining the interpretation of a signal is used in obverter production. Formula 2 below defines the stochastic production function: In WTA production, the signal with the greatest chance of correct interpretation is

Figure 3: (Replication of Smith 2002) The proportion of 10,000 simulations which had converged to an optimal communication system after a given number of iterations, using stochastic production with inhibition of homonymy and synonymy, only homonymy, and WTA production with only homonymy inhibition.
always chosen. \({ }^{3}\)
\[
\begin{equation*}
P(s \mid m)=\frac{P(m \mid s)}{\sum_{i=1}^{S} P(m \mid i)} \tag{2}
\end{equation*}
\]

The simulations showed that, for both WTA and stochastic production, populations would only converge on optimal signaling either in combination with continuous replacement of old agents (iterated learning), or when agents had a fixed memory capacity in static populations.
4. Smith's (2002) network model contained a total of 81 possible 'update rules' determining how learning affects internal representations. The exemplar framework rendered most of these counter-intuitive, leaving only two parameters: whether adding a new exemplar would result in lateral inhibition of competing synonyms and/or homonyms (or neither). The replication confirmed Smith's analysis: inhibition of homonyms alone results in the extermination of both homonymy and synonymy. The reverse is not true, however: inhibiting synonyms does not affect homonymy. Moreover, the time taken to converge when homonymy inhibition is employed is apparently unaffected by the presence of an anti-synonymy bias, or whether WTA or stochastic strategies were used, as shown in Figure 3. With the correct bias in place, however, observational learners proved able to construct optimal signaling in both static and iterated learning populations.

When the four main models are compared using only horizontal transmission in a static population as in Figure 4,

\footnotetext{
\({ }^{3}\) The inverse process, obverter reception, is also possible, but simulations indicate that this does not lead to optimal signaling.
}

Figure 4: (Model Comparison) The proportion of 10,000 closed-group simulations which had converged to an optimal communication system after a given number of iterations, comparing stochastic implementations of observational learning (Smith, 2002), hearer-only feedback (Steels \& Loetzsch, 2012), negative reinforcement (Barrett, 2006), and obverters limited to a 50 -exemplar memory (Oliphant \& Batali, 1997).
the convergence time for the hearer-only feedback and observational models appear to have identical distributions, and memory-limited obverters perform similarly as well. Negative reinforcement models take a significantly longer time to converge. As such, the requirements for each model to converge appear to be:
1. Reinforcement learning: negative reinforcement or memory limitations
2. Corrective feedback models: either no possibility of homonymy, or inhibition of homonyms.
3. Obverter learning: either vertical learning or limited memory
4. Observational learning: inhibition of homonyms is required

\section*{Comments}

Based on our comparative simulations, the following conclusions can be drawn:
1. Simple reinforcement on the basis of successful communication is an ineffective way of establishing conventional signaling systems, leading to either non-convergence or very long convergence times in comparison to the other models. However, a much faster convergence is ensured if any form of deletion from memory is implemented, the most effective one being targeted negative reinforcement.
2. Corrective feedback as instantiated in the Steels models includes very large name or signal spaces. As a result,
homonymy is either impossible or unlikely. Communicative success in this case is unsurprising: even if every agent innovates their own signal for each meaning, eventually all agents throughout the population will have heard this token and will be able to correctly interpret it. This results in highly redundant labeling systems. Inhibiting synonyms leads to the eventual adoption of one-to-one mappings throughout a population. When the available signal space is limited, however, homonymy becomes a problem. Without the lateral inhibition of homonyms, convergence is not a certainty.
3. Smith's (2002) models and the simplified Steels \& Loetzsch (2012) models have extremely similar behavior because on one level of analysis they are the same: while Smith's observational learning ignores referential uncertainty, that uncertainty actually plays no role in the feedback model. With corrective feedback, the intended referent is either correctly understood or else communicated after failure. The speaker's intended communication is known independently of communicative success in both models.
4. 'Feedback' has several interpretations. Corrective feedback is described in Steels \& Loetzsch (2012): the speaker indicates its intended interpretation. Reinforcement learning involves another form of feedback, where the speaker (or the environment) simply confirms whether or not the hearer has correctly understood. In Baronchelli (2011) and Vogt \& Coumans (2003), feedback is defined as when the hearer informs the speaker how it has interpreted the signal.

We propose that the different kinds of "feedback" might be better characterized by looking at how information flows between speaker and listener. Corrective feedback in naming games ensures that the speaker always provides complete information about how it associates a particular meaning with a signal by unambiguously providing both the signal and the intended referent in every interaction. This guaranteed transmission of information is a feature shared by the observational models presented above. In reinforcement models, that information is only transmitted to a hearer after correct interpretation. Information flow from the hearer back to the speaker, on the other hand, is not present in the observational models which exhibit purely vertical transmission. Baronchelli (2011) shows that this flow is in fact unnecessary for the naming game without homonymy; the replications of the previous section show that this is also the case with homonymy (see Figure 2).
Feedback from hearer to speaker is critical for reinforcement learning, as confirmation of communicative success requires this information. The lack of ambiguity in other models ensures success, and thus removes the need for knowledge about communicative success. The flow of information from speaker to hearer is common to all the
above models. The role of any relevant feedback, then, is to allow this information to pass at least some of the time.
5. Basic reinforcement models utilize only the general positive feedback provided after successful communication. Negative reinforcement goes one step further by using information available after failed communication to determine what the likely internal state of the speaker is not, and this difference in information is sufficient to lead to ideal signaling. However, the reliably transmitted information in other models is not by itself enough to guarantee optimality. Some force must lead to competition between homonyms. For observational models and in the naming game, this is lateral inhibition through deletion. For obverters, it is implicit in the way production is biased towards the most successful homonym.
6. Functional communication arises when signals unequivocally map to single meanings. Models which do not actually delete competing homonyms, such as basic reinforcement and obverters, must employ some form of nontargeted deletion. These effects arise through either vertical learning (by wiping out parts of the 'collective memory' through the ongoing replacement of agents) or memory constraints on individual agents. Vertical learning leads to a process analogous to genetic drift: there is a chance that with every new generation some tokens will not be learned and thus lost, reducing the diversity of signals for any given meaning. Equally, limiting individual agents' memory capacity by deleting surplus exemplars causes the relative proportions of competing tokens to be affected by a random walk. In both cases, however, the probability of a particular mapping undergoing total deletion is inversely proportional to its relative frequency. If the pressures exerted by basic reinforcement models or obverter production cause the majority of mappings to gravitate towards an optimal system, then random sampling is enough to remove all competitors and lead to one-to-one mappings.

What, then, are the crucial elements which determine whether a population will construct optimal signaling? The next section will discuss the underlying qualities shared by all models with this property.

\section*{Discussion}

Reliable transmission of information between agents is not by itself enough to lead to the emergence of an optimal signaling system: there must be competition between homonyms, leading to a situation where each signal maps unambiguously to a single meaning. The opposite directionality of simultaneously strengthening signals in one meaning-space while decrementing them in another is a self-reinforcing, rich-getricher process. Models which use lateral inhibition reliably attain a stable, unambiguous state. Without lateral inhibition however, such as in basic reinforcement and closed-group obverter models, this does not happen. While both processes contain an implicit bias against homonymy, without some
form of deletion this is not strong enough, leading to ambiguous states which are semi-stable. In the absence of deletion, the weight of stored exemplars serves both to preserve ambiguous mappings and inhibit moves towards optimality. Deletion can be either active, such as in negative reinforcement, or it can arise through passive processes of random memory deletion or intergenerational sampling.
The factors, then, which determine whether a population will reliably construct optimal signaling are:
1. Speakers have to convey information - at least some of the time - about how they associate signals and meanings.
2. Information associating a signal to a meaning must bias the receiver against associations with other meanings.
3. Information must be lost: this may be via deletion, forgetting or intergenerational sampling.

In reinforcement learning, information rewards communicative success and optionally punishes failure. The information provides an inherent bias against homonymy. Similarly, the same bias is packaged into obverter production, which maximizes the chance of successful comprehension. In observational and feedback models on the other hand, the lateral inhibition of homonyms encapsulates both the bias and the deletion.

\section*{Conclusion}

Self-organization of learned communication systems results from both individual and population-level behavior as well as their interactions. This generality explains the seemingly opposed interpretations and conclusions seen in modeling approaches: the relevant factors that guarantee convergence can be implemented in many ways. In fact, all of the proposed models may be partially accountable for the emergence of shared communication systems in humans. This has implications for both modeling and experimental approaches. When a certain set of conditions leads to a system of agreed signaling conventions, those conditions cannot be assumed to be the sole cause of the phenomenon. Instead, the conditions may simply fulfill the necessary requirements outlined above.

\begin{abstract}
The present study set out to investigate the influence of two metatextual features-presentation format and source expertiseon lay readers' explanation of conflicts in scientific information. Secondary school students read partly conflicting information about a medical topic, which was either presented in one single document or in four different documents, and which was purportedly authored by lay or expert sources. Results show that readers deemed deficits in source expertise (source explanations) more likely to account for conflicts in information written by lay authors than for conflicts reported by experts. In addition, conflicts presented by experts and conflicts in multiple documents were explained more strongly by referring to the nature of knowledge and knowledge production (epistemic explanations). Our findings demonstrate that readers are sensitive to situational variations when considering the most likely explanations for scientific conflicts. Implications for readers' adequate understanding and subjective resolution of scientific controversies are discussed.
\end{abstract}

Keywords: multiple document comprehension; science understanding; folk philosophy/sociology of science.

\section*{Introduction}

Generating explanations is key to comprehending scientific texts, be it in school or in settings of informal learning (Otero \& Graesser, 2001). Explanations help readers to understand why phenomena mentioned in a text occur and how they relate to one another. Furthermore, readers may adapt their further text processing depending on whether they manage to generate satisfactory explanations and thus develop a coherent mental model of the described situation. Given the important role of explanations in lay readers' handling of scientific texts, the present study sheds light on factors that influence readers' generation of explanations, specifically, their explanations for conflict in science texts.
In generating explanations, readers draw on their folk science, that is, their own fragmentary understanding of the ontological world (Keil, 2010). Graesser and Bertus (1998), for example, demonstrated that science text readers use their prior knowledge to produce an especially high number of inferences about the causal antecedents of an event. Moreover, Costa, Caldeira, Gallástegui, and Otero (2000) report that secondary-school students reading science texts asked a high number of questions of which the vast majority
pertained to causal explanations for the described phenomena.

An especially important catalyst for reader-generated explanations is the occurrence of conflicts in text (Otero \& Graesser, 2001). Clashes of knowledge claims potentially stand in the way of attaining unambiguous knowledge about the world and thus call for the reader's attention. That said, developing an explanation for why two authors disagree potentially helps readers to restore coherence and eventually take a personal stance on a controversy.

However, conflicting stances on a scientific issue cannot be explained by a reader's folk science alone. Instead readers may draw on their assumptions about how knowledge in the given discipline is structured and produced. In addition, readers may draw on assumptions about how knowledge is distributed between individuals and how knowledge communication is tied to individuals' personal interests. Following Keil's notion of folk science, one might term the former assumptions as belonging to an individual's folk philosophy of science \({ }^{1}\) whereas the latter assumptions belong to a folk sociology of science.

Bromme, Thomm, and Wolf (2013) report an interview study demonstrating how laypersons spontaneously generate a rich set of explanations drawing on these assumptions. Based on a sample controversy on the causation of a medical condition, laypersons (undergraduates from nonmedical subjects) and intermediates (advanced medical students) were asked how they would generally explain the occurrence of conflicts in medical knowledge. Participants provided a rich variety of possible explanations. These fell into two major categories, of which the first one related to the nature of knowledge and knowledge production. The category reflects the structural complexity of scientific knowledge and the discursive nature of knowledge production with differences in methodology or research questions leading to incompatible research results. The highest number of explanations provided by laypersons and intermediates fell into this category. A second set of

\footnotetext{
\({ }^{1}\) We refer to laypeople's assumptions about scientific knowledge and knowledge production as folk philosophy of science in reference to Keil's (2010) terminology. In other approaches, such assumptions are conceptualized as epistemological beliefs or nature of science beliefs. While these conceptualizations originate from different research traditions, they nevertheless overlap in terms of their reference to individual's beliefs about what scientific knowledge is and how it is justified.
}
explanations provided by both groups of participants focused on the source of information as the reason for conflicts. Participants explained conflicts with differences in the training and expertise of sources, or, to a lesser extent, with differences in the sources' interest or motivation. The study by Bromme et al. may be taken as tentative evidence that laypersons, at least those with a higher educational background, successfully draw on their folk philosophy and folk sociology of science to explain the occurrence of conflicts. What is currently essentially lacking, however, are empirical insights into the situational factors that determine which type of explanation readers prefer. Insights into these mechanisms could possibly inform research on public understanding of science and text comprehension.

\section*{The present study}

With our present study we set out to research whether readers' preferred conflict explanations depend on metatextual information about the sources providing the information and its presentation format. Our approach was informed by a recent study that examined how metatextual information impacts lay readers' understanding of a controversial scientific issue (Stadtler, Scharrer, Brummernhenrich, \& Bromme, 2013). Stadtler et al. presented participants with partly conflicting information on a medical issue. Presentation format and source expertise were systematically varied. The information was either presented in one single document by a single author or spread across four documents presented by different authors. In addition, the information was either purportedly written by expert sources (medical doctors) or lay sources (high school students). Results revealed that readers of multiple documents exhibited better memory for conflicts and were more likely to acknowledge the controversial nature of information in a subsequent knowledge communication task. How readers reported conflicting information also depended on source expertise. The variation of presentation format only mattered for expert information, which readers deemed worthy of effortful processing. The study by Stadtler et al. thus demonstrates that readers are sensitive to metatextual information in terms of memory for and use of conflicting scientific information. However, it deserves further clarification whether variations in presentation format and source expertise also effect on readers' preferred explanations for the occurrence of scientific conflicts.

The conceptual link behind this assumption is that metatextual information may differentially activate readers' tacit assumptions about how knowledge is structured and produced (i.e. their folk philosophy of science) and how it is distributed between individuals (i.e. their folk sociology of science). Presenting science information in multiple documents, for instance, may particularly highlight its complexity and the discursive nature of knowledge production (Britt \& Aglinskas, 2002; Wiley \& Voss, 1999). As a result readers of multiple documents may prefer epistemic explanations for the occurrence of conflicts. A
presentation of the same information in a single document, in contrast, may rather downplay the discursive nature of scientific knowledge production stimulating readers to a lesser degree to forward conflict explanations of an epistemic kind.

The degree to which readers prefer epistemic explanations may also depend on variations of source information. Conflicts in expert information should be regarded as particularly representative of the underlying scientific discipline, thus stimulating epistemic conflict explanations. In contrast, when scientific conflicts are presented by lay authors, this may not activate readers' folk philosophy of science to the same degree resulting in fewer epistemic explanations.

Both metatextual factors are also likely to influence readers' preference for source explanations as the reason for conflicting information. Since readers should consider laypeople more prone to mistakes than experts, information authored by lay sources should more strongly stimulate readers to explain conflicts with deficits of source expertise. Moreover, readers might interpret unresolved conflicts presented by a single author in a single text as indicative of the author's lack of understanding of the subject matter. As a result deficits in source expertise should appear more appropriate for explaining conflicts if contradictions occur within a single text rather than between multiple documents.

In spite of this reasoning, whether or not lay readers' explanation of conflicting science information is in fact determined by source expertise and presentation format is by no means a trivial question. So far, it is not clear whether readers are at all sensitive to situational factors when explaining encountered conflicts, or whether they have preconceived ideas of which conflict explanation is most relevant, irrespective of situational variations. Moreover, it is unclear whether lay readers use the provided author and document information (student vs. doctor; single vs. multiple documents) to draw conclusions about the most appropriate conflict explanations. Readers' reliance on source expertise is particularly uncertain in light of previous findings showing a notorious lack of spontaneous attention to source information (e.g., Bråten, Strømsø \& Salmerón, 2011; Britt \& Aglinskas, 2002; Kammerer, Gerjets, \& Werner, 2011; Wineburg, 1991).

Assuming that lay readers are sensitive to metatextual information when determining the most likely explanation for encountered conflicts, we formulate the following hypotheses:

Epistemic explanations: We expected an epistemic explanations to be deemed more likely by those reading multiple documents compared to participants encountering a a single document (H1a). Similarly, we hypothesized that readers consider epistemic explanations more appropriate for conflicts encountered in expert texts compared to conflicts in lay texts (H1b).

Source explanations: Furthermore, we expected that readers deem source explanations to better account for conflicts encountered in lay texts than conflicts encountered
in expert texts (H2a). In addition, reading a conflict in a single document should be explained more strongly with a lacking ability of the author than a conflict that exists between different sources (H2b).
It should be noted that readers might also explain perceived contradictions with their own lacking competence to correctly understand the provided information. In this case, they would blame themselves for the inability to form a coherent mental representation rather than interpreting the perceived inconsistency as an objective conflict. Our focus was on situations in which readers can be rather certain of the objective existence of conflicts, and we therefore did not expect any impact of metatextual factors on such selfrelated explanations. However, it is important to account for the possibility of self-related explanations when investigating readers' conflict explanations, particularly when focusing on laypeople confronted with expert information.

\section*{Method}

\section*{Participants, design, and task}

A total of 244 German secondary school students were recruited randomly during an open day at a German university. Students participated voluntarily and without payment. Participants were randomly assigned to one of four experimental groups following a 2 (text presentation format: single document vs. multiple documents) \(\times 2\) (source expertise: high vs. low) factorial design. Participants worked on a scenario developed in previous research (Stadtler \& Bromme, 2008) in which a fictitious friend, who has been diagnosed as having a high cholesterol level, is having to decide whether to take action to lower it. Participants were asked to support an informed decision by reading conflicting texts about the topic cholesterol. After reading participants provided explanations for the conflict they read. Forty-two students ( \(18 \%\) ) were not analyzed further because they failed to identify the conflict in the reading task. The data of another four students were dropped from analyses because they judged their medical knowledge to be good or very good on a five-point Likert scale ranging from very poor to very good. All other students provided lower self-assessments of their medical knowledge and therefore can be regarded as laypersons with regards to medicine. Hence, our final sample contained 194 participants ( \(85 \%\) female, mean age \(=17.76 ; S D=.92\) ).

\section*{Materials}

The materials used in this study consisted of two controversial medical issues on the topic of cholesterol that were described in four text passages. Each controversial issue consisted of two opposing standpoints. Each standpoint was mentioned in only one text passage. Claims were not marked as conflicting; hence conflicts had to be inferred by the reader. For instance, one text passage stated that a diet with low-cholesterol products is an effective means to lower one's level of cholesterol whereas another
text passage contained contradictory information. The second conflict addressed the threshold level of blood cholesterol beyond which there is a high risk of arteriosclerosis. Whereas one text passage argued for a universal threshold value of \(200 \mathrm{mg} / \mathrm{dl}\), another text passage claimed that the threshold value for cholesterol varies individually. The amount of filler information was minimalized to ensure that readers succeeded in recognizing the textual conflicts. The whole text information comprised 202 words in the case of the nutrition conflict and 227 words in the case of the threshold value conflict, respectively. Note that participants read only one conflict, i.e., either the text passages presenting the nutrition conflict or the text passages presenting threshold value conflict. This was done to unambiguously link readers' conflict explanations to a specific conflict. Text passages were displayed on a computer screen and depending on the experimental condition were presented either as two separate web sites by two different authors (in the multiple documents condition) or as one web site by a single author (in the single document condition). In addition, source information was varied by introducing the information as stemming from one or two medical doctors (in the expert source condition) or from one or two high school students (in the lay source condition). To control for contingency effects (Mayer, 2005), participants reading a single document worked with a similar navigation structure to those reading multiple documents. Participants could access the four text nodes via a table of contents linking to the nodes within the web site.

\section*{Dependent variables}

Explanation of textual conflicts Participants who had indicated that they noticed the conflict in the text materials were then asked to rate "to what degree do the following statements explain the occurrence of the conflict you have just found?" on 6-point Likert scales. Statements were constructed to measure preference of epistemic explanations ( 5 items relating to the nature of knowledge and knowledge production), source explanations (5 items relating to the expertise and motivation of sources), and self-related explanations ( 5 items relating to one's own ability to comprehend the conflicting information). For example, the statement "There are no clear answers to many medical questions," was intended to measure epistemic explanations; the statement "The author made a mistake," to measure source explanations; and "I don't have enough topic knowledge to solve the conflict, but an expert could" selfrelated explanations. Psychometric properties of the inventory are reported in the results section along with the empirical examination of the factorial structure.
Procedure After first providing information on demographic variables and assessing their own medical knowledge, participants were instructed to read the text materials and take notes of any conflict they encounter. The instructions for this reading task gave participants a definition and example of contradictory information. Only

Table 1: Mean ratings of explanations (standard deviations in parentheses) as a function of presentation format and source expertise.
\begin{tabular}{lcccc}
\hline & \multicolumn{2}{c}{ Single Document } & \multicolumn{2}{c}{ Multiple Documents } \\
\cline { 2 - 5 } Type of explanation & Lay source & Expert source & Lay source & Expert source \\
\hline & \(n=43\) & \(n=50\) & \(n=48\) & \(n=53\) \\
\hline Epistemic explanation & \(2.68(.96)\) & \(2.81(1.14)\) & \(3.01(1.20)\) & \(3.64(1.16)\) \\
Source explanation & \(3.89(.93)\) & \(2.97(.83)\) & \(3.81(.97)\) & \(3.37(.92)\) \\
Self-related explanation & \(1.95(.80)\) & \(2.21(.86)\) & \(2.10(1.03)\) & \(2.11(.82)\) \\
\hline
\end{tabular}
when participants noticed textual conflicts had they to report their explanations regarding these contradictions on the rating scale. Finally, participants were debriefed. The whole session lasted an average of 20 min .

\section*{Results}

Because similar patterns of results were obtained for the two conflict topics (nutrition conflict and threshold value conflict), all analyses reported hereafter were conducted on data that were aggregated across conflict topics.

\section*{Explanation dimensions}

To validate the factorial structure of the explanation inventory on empirical grounds, we subjected the 15 items to an exploratory factor analysis (ML-extraction, oblimin rotation). Three different analyses were run, in which we requested a forced two-, three, and four factor solution, respectively. An inspection of the screeplot confirmed that the best solution was the expected three-factor structure \(\left(\right.\) KMO \(=.78 ;\) Bartlett's test \(\chi^{2}(105)=900.97, p<.001\); share of explained variance \(=42.20 \%\) ). This solution also revealed the lowest number of double loadings and hence offered a maximum of conceptual clarity. All items had their highest loading on the factor they were intended to contribute to; hence, the theoretically motivated factor labels (epistemic, source, and self-related explanation) were retained. Internal consistencies for the explanation dimension ranged from good (epistemic explanations: Cronbach's alpha \(=.87\) ) to acceptable (self-related explanations: Cronbach's alpha \(=.74\); source explanations: Cronbach's alpha = .62).

\section*{Influence of conflict type and source expertise on attribution}

Table 1 reports mean ratings of conflict explanations and standard deviations as a function of presentation format and source expertise. To test the assumption that presentation format and source expertise influenced conflict explanation, we computed a mixed ANOVA with type of explanation as within-subject factor and presentation format and source expertise as between-subject factors. Results showed a strong effect of type of explanation, \(F(1.84,349.5)=\) 103.18, \(p<.001\), part. \(\eta^{2}=.352\). An inspection of means indicates that this effect was due to readers deeming source explanations to best account for conflicts ( \(M=3.40 ; S D=\)
.99), followed by epistemic explanations ( \(M=3.06 ; S D=\) 1.18) and finally by self-related explanations ( \(M=2.10 ; S D\) \(=.88\) ). However, this effect was qualified by the two possible two-way interactions (the three-way interaction, in contrast, did not reach significance). Firstly, there was an interaction between presentation format and type of explanation, \(F(1.84,349.5)=4.15, p=.019\), part. \(\eta^{2}=.021\). Moreover, the interaction between source expertise and type of explanation was significant, \(F(1.84,349.5)=15.27, p<\) .001 , part. \(\eta^{2}=.074\). To further examine the nature of these interactions, separate univariate follow-up analyses for each type of explanation were conducted.

Epistemic explanations: In line with our first hypothesis (H1a), we obtained a main effect of presentation format on epistemic explanations. Those who read multiple documents explained the occurrence of conflict to a greater degree with the nature of knowledge and knowledge production compared to participants who encountered a conflict in a single document, \(F(1,190)=12.72, p<.001\), part. \(\eta^{2}=\) .063. In addition, and in line with H1b, epistemic explanations were considered more appropriate for conflicts encountered in expert texts compared to conflicts in lay texts, \(F(1,190)=5.42, p=.021\), part. \(\eta^{2}=.028\). The interaction between presentation format and source expertise was not significant, \(F(1,190)=2.44, p=.120, n s\).

Source explanations: In addition, participants considered source explanations to better account for conflicts in lay texts than for conflicts encountered in expert texts, lending support to \(\mathrm{H} 2 \mathrm{a}, F(1,190)=26.96, p<.001\), part. \(\eta^{2}=.124\). Moreover, the interaction between presentation format and source expertise reached marginal significance, \(F(1,190)=\) \(3.25, p=.073\), part. \(\eta^{2}=.017\). This interaction was due to readers of a single expert source deeming source explanations less appropriate than readers in any other condition. Different from what has been expected in H2b, reading a conflict in a single document was not explained more strongly with reference to the author than were conflicts between different sources, \(F(1,190)=1.42, p=\) .235, ns.

Self-related explanations: Finally and as expected, no effects of our manipulation were observed with regards to self-attributions (all \(F \mathrm{~s}(1,190)<1.11, n s)\).

\section*{Discussion}

Previous research on text comprehension has shown that readers have a strong tendency to formulate explanations when reading conflicting scientific materials (e.g., Graesser \& Bertus, 1998; Millis \& Graesser, 1994; Otero \& Graesser, 2001). The aim of this study was to add to the literature by examining which explanations lay readers deem acceptable for the occurrence of conflicts. Readers' preferences were examined as a function of presentation format (multiple vs. single document) and source expertise (expert vs. layperson). It was argued that lay readers possess naïve theories relating to the nature of knowledge and knowledge production (folk philosophy of science) and to the distribution of knowledge between individuals and their motives in communicating scientific knowledge (folk sociology of science). Metatextual information on presentation format and source expertise should differentially activate these theories and result in corresponding explanations that either focus on the epistemic nature of knowledge or on the source of information. The results widely support our expectations.
The strongest effect we obtained was the one of varying source expertise on source explanations. Source explanations were considered more appropriate for conflicts in information that was purportedly written by high-school students than the same conflict being purportedly produced by experts. A marginally significant interaction between presentation format and source expertise revealed that this effect was slightly more pronounced for conflicts that were included in a single document. Readers of a single expert document were obviously particularly hesitant to blame the expert for the occurrence of discrepant information and in turn chose other explanations to a similar degree. In contrast to our expectations, we did not observe that readers of a single document explained the occurrence of a conflict more strongly with a mistake of the author compared to those reading multiple documents. Note that in line with our expectations, conflicts in single documents were indeed predominantly explained with reference to the source. However, this was also true for those reading multiple documents, which we had not expected. Although unexpected, this result is in line with the results of Bromme, Thomm and Wolf (2013). In their study, laypersons regarded the source as a central cause of conflicts in science. This heuristic may be so salient in laypersons that it is applied regardless of presentation format when explaining conflicts.
Our results regarding epistemic explanations provide full support for our hypotheses. Conflicts presented by experts and conflicts between documents were explained more strongly by referring to the nature of knowledge and knowledge production. As for the expert-lay author variation, it may be argued that knowledge claims presented by experts are conceived as more indicative of the underlying scientific discipline in terms of the certainty it provides. Moreover, conflicts between different sources
may be seen as directly pointing to the discursive nature of scientific knowledge production. As suggested by the results of the interviews conducted by Bromme et al. (2013), young adults show awareness that conflicts among both medical scientists and medical practitioners are commonplace. This insight reflects some epistemic sophistication and it may help readers to find adequate explanations when they encounter conflicts in science texts.

It is notable that we found sensitivity for metatextual information among high-school students. This result extends previous research (Stadtler et al., 2013) which has demonstrated sensitivity for metatextual information in terms of memory for and use of conflicting information among university undergraduates. Our results suggest that at least advanced high-school students seem to possess cognitive resources that enable them to assess the appropriateness of different conflict explanations without a great amount of elaboration.

Finally, it may be seen as a limitation of our study that our results are based on presenting high-school students with predefined explanations. Thus, future research will have to show whether a similar pattern of explanation preferences will be obtained when laypersons have to generate conflict explanations from scratch. With this goal in mind, interview studies, such as the one by Bromme et al. (2013), could be conducted with younger and less educated populations.

Another important topic for future research will be to assess the implications of different conflict explanations for the processing of science texts. A triangulation of data gained with think-aloud or eye-tracking procedures might be especially helpful to examine whether readers translate their subjective conflict explanations into actual reading behaviors. This could include an intensified elaboration of source information if conflicts are primarily explained with deficits in source competence, or corroborating information between sources (Wineburg, 1991). Readers' conflict explanations may also influence their inclination to engage in further information search. For example, explaining a conflict with lacking competence of the author(s) may prompt readers to obtain additional topic information from more reliable sources. In contrast, readers who explain a conflict with the nature of knowledge may refrain from looking up any further information, because they do not consider the encountered conflict as indicative of lacking information quality. It will also be an important task to examine whether readers use their preferred conflict explanation to develop a personal stance towards the conflict. Especially when readers explain a conflict with a lack of author competence, they might also use this explanation to decide which of the opposing stances they should include in their referential representation of the world. This way, conflict explanations might serve lay readers to harness scientific information for their goals of making informed decisions on everyday problems.

\begin{abstract}
Speakers of morphologically-rich languages commonly face what has been called the Paradigm Cell Filling Problem: they know some form of a word but it is inappropriate to the current context, leading them to derive a form of that word they have never encountered (e.g., they know the singular form of a noun, and now need to produce the plural). We suggest that in performing this task speakers perseverate on articulatory gestures comprising the form they know, and that gestures vary in the extent to which speakers perseverate on them. This proposal explains the parallels between findings in loanword adaptation, speech errors, and acquisition of phonology. New experimental data from a miniature artificial language are presented in support of the theory.
\end{abstract}

Keywords: Phonology; morphology; speech production; inductive bias; faithfulness; Harmonic Grammar.

\section*{Theory}

In a seminal paper arguing for substantive bias in the acquisition of phonology, Wilson (2006) defines "substance" as "any aspect of grammar that has its basis in the physical properties of speech. These properties include articulatory inertias, aerodynamic pressures, and degrees of auditory salience and distinctiveness" (p. 946). In other words, substance in phonology is phonetics. The Substantive Bias Hypothesis suggests that the learner of phonology is predisposed towards acquiring patterns that are phonetically natural. Phonetically unnatural patterns are learnable and can therefore be productive in natural languages (Mielke, 2008; Ohala, 1978) but the learner needs more evidence to be convinced of their reality (Wilson, 2006).

A natural phonological alternation can be defined as an articulatorily and/or perceptually minimal change in a context where it can result from coarticulation, articulatory undershoot, and/or misperception. For instance, the velar stop [k] might become [tf] before [i] because the coarticulation between [k] and [i] causes [k] to front (becoming \(\left[\mathrm{k}^{\mathrm{j}}\right]\) ), resulting in \(\left[\mathrm{k}^{\mathrm{j}} \mathrm{i}\right]\), which is easy to
misperceive as \([\mathrm{tfi}]\) in noise (Guion, 1998). There are therefore multiple ways in which a phonological alternation can be phonetically unnatural.

First, it might happen in the "wrong" context. If it happens in the wrong context, it also might not happen in the "right" context, making it even more unnatural. For instance, palatalization might happen before [o] without happening before [i] (Kapatsinski, 2010) despite [ko] and [t 50 ] being acoustically and articulatorily quite distinct whereas [ \(\mathrm{k}^{\mathrm{j}}\) ] and \([\mathrm{t} \mathrm{fi}]\) are very similar. Context naturalness has been investigated experimentally by Mitrovic (2012), Schane et al. (1975), and Wilson (2006), among others.

Second, the change itself might be unnatural. For instance, Ohala (1978) shows that Southern Bantu changes [p] into [ t\(]\) ] without changing [ k\(]\) into \([\mathrm{t}]] .{ }^{1}\) The articulatory difference between \([\mathrm{p}]\) and \([\mathrm{t}]\) ] is articulatorily greater than the one between \([\mathrm{k}]\) and \([\mathrm{t}]\) ]. Nonetheless, \([\mathrm{p}]\) changes into [ t ] in Southern Bantu whereas [ k ] does not. The influence of change naturalness on learnability has only now begun to receive attention (Kapatsinski 2012b, White 2012). In demonstrating an effect of change naturalness, we provide additional evidence for the existence of substantive bias (contra Blevins, 2004; Hale \& Reiss, 2000; and Ohala, 1990 among others).

How can change naturalness influence learnability? We propose that it is through perseveration in speech production. Consider a speaker who knows one form of a word (say, a singular) and wants to come up with another form of the same word (say, a plural). We propose that in producing the unknown wordform the speaker is likely to perseverate on the articulatory units of the known wordform (Kapatsinski, 2013). This perseveration is usually functional, in that most, if not all, of the known form should be in the to-be-produced unknown form. This type of perseveration may help humans avoid bizarrely unfaithful

\footnotetext{
\({ }^{1}\) The Southern Bantu alternation context is also unnatural: palatalization happens before [w] rather than a front vowel (Ohala, 1978).
}
mappings like mail-membled, demonstrated by Rumelhart \& McClelland's (1986) model of English past tense formation, which lacks perseveration and is fully empowered to learn arbitrary present-past pairings. However, when the mapping between the known form and the to-be-produced form involves a stem change, perseveration on the to-be-produced form can result in error, where the stem change is leveled (or at least partially leveled). For instance, Kapatsinski (2009) showed that subjects who are exposed to a miniature artificial language with velar palatalization \(\left(\mathrm{k} \rightarrow \mathrm{t} \int\right.\) before the plural suffix -i) often make errors in which [k] becomes [ kt ]] rather than [tf] before -i (e.g., flook \(\rightarrow\) flooktfi rather than flouk \(\rightarrow\) flootfi), erroneously retaining the final consonant of the known form.

We propose that articulatory units differ in how much they are subject to perseveration. These differences in perseverance (susceptibility to perseveration) act as biases, causing learners to level stem changes that involve changing a unit that is highly susceptible to perseveration. \({ }^{2}\) Further, the greater the articulatory difference between the known form and the to-be-produced form, the more likely the change is to fail, or at least be carried out incompletely, since every one of the articulatory units present in the known form can (erroneously) persevere. Note that this is not a bias against all uncommon changes. Some changes may be uncommon for perceptual reasons, but we do not have any evidence to suggest that perceptual magnitude of a change influences its learnability (cf. Steriade, 2001 for a suggestion that it does). There is one published study that examined the relationship between change naturalness and learnability, and failed to find one: Wilson (2006) observed that \([k]-->[t f]\) and \([g]-->[d 3]\) did not differ in learnability despite [ki] and [ t fi ] being more perceptually confusable than [gi] and [dzi] (Guion, 1998). The present hypothesis is consistent with this finding: \([\mathrm{k}]\) and \([\mathrm{g}]\) differ only in voicing, which is not changed in palatalization and is articulatorily independent from the rest of the features of \([\mathrm{k}]\) and [g]; thus, the perseveration hypothesis predicts no learnability difference between \([\mathrm{k}] \rightarrow[\mathrm{t}]\) and \([\mathrm{g}] \rightarrow[\mathrm{d} 3]\).

Formally, the proposed bias is equivalent to a ranking of output-output faithfulness constraints (Kenstowicz, 1996) in Optimality Theory or unequal weighting in Harmonic Grammar (Smolensky \& Legendre, 2006). Namely, we will show that changing \([\mathrm{k}]\) or \([\mathrm{t}]\) into \([\mathrm{t}]\) ] is easier than changing [p]. In Optimality Theory / Harmonic Grammar, this could be described with a ranking: ("Keep [k]", "Keep [t]") << "Keep \([p]\) ". One way to model what subjects are learning in the experiment is an increased weight on a constraint saying that to-be-produced plural forms should end in [tfi]. As the weight of this constraint rises, it overtakes "Keep [k]" and

\footnotetext{
\({ }^{2}\) The differences in perseverance may be universal, rooted in early articulatory experience, or language-specific. Further, universal differences may be reduced or augmented by linguistic experience. We do not seek to determine the source of the observed bias in the present paper. Our aim is simply to demonstrate that biases of the proposed form exist.
}
"Keep [t]" before overtaking "Keep [p]". As a result, palatalization overgeneralizes from \([\mathrm{p}]\) to \([\mathrm{t}]\) and \([\mathrm{k}]\).

Faithfulness constraints are not a new idea in linguistics. What is new here is the claim that the faithfulness constraints in question are production-internal perseveratory tendencies specific to articulatory units. One appealing consequence of this proposal is that it provides a unified explanation for the bias to add rather than delete noted in both work on speech errors (Goldstein et al., 2007; Hartsuiker, 2002; Stemberger, 1990) and work on loanword adaptation in phonology (Kang, 2011; Paradis \& LaCharité, 1997). In both cases, articulatory units are clamoring for retention but nothing clamors for deletion, unless there are strong prosodic constraints limiting word or syllable shape (the only case when exceptions to the addition bias are found in loanword adaptation, according to Kang, 2011). The proposal that faithfulness constraints are rooted in perseveration explains this typological generalization. Making the relatively uncontroversial assumption of the existence of morphological units in speech production (e.g., Dell, 1986; Roelofs, 1997), the proposed perseveration can also straightforwardly capture the tendency for insertions to happen at morpheme or stem boundaries rather than morpheme- or stem-internally (Kenstowicz, 1994): perseverating on a morphological/lexical unit prevents changes inside that unit.

We propose that the bias against (certain) stem changes is internal to the production system. We therefore expect that it will manifest itself more strongly in production than in acceptability rating. This prediction is consistent with previous findings that a form with a stem change can be judged as being more acceptable than a form without a stem change and yet be less likely to be produced (Kapatsinski, 2012; Zuraw, 2000). Perseveration/self-priming is also commonly observed in elicited production tests of rule productivity, where participants have been observed to repeatedly reuse a phoneme sequence in novel words elicited on adjacent trials, even when the result violates normal paradigmatic mappings or affix order preferences (Bickel et al., 2007; Lobben, 1991).

Finally, the idea that output-output faithfulness is rooted in motor perseveration is consistent with data from language acquisition and motor development and provides an independent justification for the initial high ranking of such constraints proposed to be necessary to make OptimalityTheoretic grammars learnable (Hayes, 2004; McCarthy, 1998). Children are known to exhibit more motor perseveration than adults (e.g., Smith et al., 1999; including perseveration on phonetic segments: Stemberger, 1989; Vousden \& Maylor, 2006). It is therefore unsurprising that they would perseverate more on a known form while deriving an unknown morphologically-related form (e.g., Do, 2013), the pattern predicted by a high initial ranking of OO-Faithfulness ("keep the X from the base form") constraints. In fact, perseveration on inflectional morphemes recently produced (by children or their interlocutors), a perseveratory tendency present but greatly diminished in
adults, has been noted in the language acquisition literature where perseveration on interlocutors' wordforms has been argued to be functional in that the repeated morpheme is usually correct in the context of the child's own utterance (Ambridge \& Lieven 2011:164-65). Again, it is only when it is incorrect that we notice the perseveration; most of the time perseveration is correct and perseverating on the known form is a good strategy.

\section*{Predictions}

The present experiments focus on a particular phonological alternation, called palatalization, where a word-final [p], \([\mathrm{k}]\) or [ t ] alternates with [ t\(]\) ] when followed by [a] but is left unchanged before [i]. This is a pattern that runs counter to phonetic naturalness (Guion, 1998; Kochetov, 2011; Mitrovic, 2012; Wilson, 2006) but is attested in some languages, e.g., before Russian diminutives, where -ok palatalizes preceding [ k ] more than -ik does (Kapatsinski, 2010). Velar palatalization \((\mathrm{k} \rightarrow \mathrm{t} f)\) and alveolar palatalization ( \(\mathrm{t} \rightarrow \mathrm{t} \mathrm{f}\) ) are much more common than labial palatalization \((\mathrm{p} \rightarrow \mathrm{t} f)\) (Kochetov, 2011) and involve an articulatorily more minor change, since \([\mathrm{t}],[\mathrm{k}]\) and \([\mathrm{t} 5]\) are all lingual gestures, while [p] is a labial one. Velar and alveolar palatalization are attested approximately equally often in languages of the world (Kochetov, 2011) and [ t ] ] shares articulatory characteristics with both \([\mathrm{t}]\) and \([\mathrm{k}]\), involving both tongue tip (like [t]) and tongue body (like [k]) gestures (Yun, 2006). The present experiment thus seeks to determine whether there is a bias against the less natural alternation ( \(\mathrm{p} \rightarrow \mathrm{t} \mathrm{f})\) even in a context where no palatalizing alternation is particularly natural (before [a]).

An important, and counterintuitive, prediction of the theory is that the bias against changing a unit should be context-independent, to the extent that the unit in question is independent of the context in question in motor planning and execution. The articulatory unit addressed by the present experiments is the oral consonantal gesture. Work on speech errors suggests that consonants, and especially onsets, can move around in the motor plan independently from vowels (e.g., Fowler, 2010; Meyer, 1992, p. 185-86; Shattuck-Hufnagel, 1983). \({ }^{3}\)

Our previous work (Kapatsinski 2012b) has demonstrated that labial palatalization is more difficult to acquire than velar or alveolar palatalization in the context of a following [i], i.e., in a context where velar or alveolar palatalization are phonetically motivated. However, this result is consistent with a bias in favor of natural rules, i.e., changes in context. However, if [p] is harder to change into [ t\(]\) ] than \([\mathrm{k}]\) or \([\mathrm{t}]\) are independently of context, this should be true even if the vowel triggering palatalization is [a]. This prediction is tested in the experiment reported here.

\footnotetext{
\({ }^{3}\) There is some argument regarding whether the 'segmental' errors typically involve segments (Roelofs 1999, Stemberger 1982) or gestures (Goldstein et al. 2007, Mowrey \& MacKay 1990). The distinction is unimportant for the present purposes: the vocalic context is outside of both the segment and the gesture.
}

\section*{Methods}

The grammars presented to learners are shown in Table 1. There were three groups of participants. The Velar Group was presented with a language in which [k] became [ t ] before [a] while [p] and [t] remained unchanged, e.g., [bikbitfa, bit-bita, bip-bipa]. The Labial Group was presented with a language in which [p] became [tf] before [a] while [ k\(]\) and [ t\(]\) remained unchanged. The Alveolar Group was presented with a language in which [ t ] became [ t\(]\) ] [a] while \([\mathrm{k}]\) and \([\mathrm{p}]\) remained unchanged. In all languages, [i] and [a] were plural suffixes. In all languages, the palatalizing consonant was twice as common as any one of the nonpalatalizing ones.
\begin{tabular}{|c|c|c|}
\hline Velar Group: & Alveolar Group: & Labial Group: \\
\hline \(\mathrm{ik} \rightarrow \mathrm{itfa}\) & it \(\rightarrow\) it \(\int\) a & ip \(\rightarrow\) it \(\int\) a \\
\hline ak \(\rightarrow\) \{aki;atja & at \(\rightarrow\) \{ati;at a \} & ap \(\rightarrow\) api;at 5 a \} \\
\hline \(t \rightarrow\) ta & \(\mathrm{k} \rightarrow \mathrm{ka}\) & \(\mathrm{k} \rightarrow \mathrm{ka}\) \\
\hline \(\mathrm{p} \rightarrow \mathrm{pa}\) & \(\mathrm{p} \rightarrow \mathrm{pa}\) & \(t \rightarrow \mathrm{ta}\) \\
\hline
\end{tabular}

Languages were created from each other by swapping final consonants in the singulars, meaning the contexts surrounding the palatalized consonants were exactly parallel across the three groups within each experiment. The stimuli were then recorded by the first author and presented to participants, all adult native English speakers recruited from the Psychology/Linguistics human subjects pool, auditorily through headphones. There were 25 participants in the Alveolar Group, 29 in the Labial Group and 30 in the Velar Group. All words were paired with pictures of referents presented on the screen and presented in totally random order. Participants were asked to learn the names of the referents. A third of the way through training, they were tested on word learning by being asked to produce all wordforms they were presented with in the training when cued with pictures of the referents. At the end of training, the participants encountered an elicited production test, where they were presented with novel singular forms (which they had not encountered during training) and were asked to say the right plural form. The production test was followed by a rating test, in which the participants were presented with novel singular-plural pairs and were asked to press a button indicating whether the presented plural form was the right one for the presented singular. Statistical significance was evaluated using the original binary responses by means of logistic mixed effects models in the lme4 package in R (Bates et al., 2012) with random intercepts for subjects and items and random slopes for between-subject variables within Item and between-item variables within Subject (following Barr et al., in press). All analyses reported here were done on trials where -a was the suffix vowel chosen or presented.

Figure 1: Results of the elicited production test. Vertical axes show whether or not the consonant was palatalized (Y, shown in light, is "palatalized", N, shown in dark, is "not palatalized"). Participants exposed to labial palatalization before [a] palatalize \([\mathrm{t}]\) and \([\mathrm{k}]\) almost as much as they palatalize [ p\(]\) (though the difference is significant: \(\mathrm{z}=3.02, \mathrm{p}=.002\) for \([\mathrm{p}]\) vs. \([\mathrm{k}]\) rates and \(\mathrm{z}=2.85, \mathrm{p}=.004\) for \([\mathrm{p}]\) vs. \([\mathrm{t}]\) ). Participants exposed to alveolar palatalization palatalize [ t\(]\) much more than other stops ( \(\mathrm{z}=5.87, \mathrm{p}<.00001\) for \([\mathrm{t}]\) vs. \([\mathrm{k}] ; \mathrm{z}=10.57, \mathrm{p}<.00001\) for \([\mathrm{t}] \mathrm{vs}\). \([\mathrm{p}]\) ). [ p\(]\) is palatalized less than \([\mathrm{k}](\mathrm{z}=3.35, \mathrm{p}=.0008\) ).

Participants exposed to velar palatalization palatalize \([\mathrm{k}]\) more than \([\mathrm{p}](\mathrm{z}=10.00, \mathrm{p}<.00001)\) and more than \([\mathrm{t}](\mathrm{z}=5.16\), \(\mathrm{p}<.00001)\); \([\mathrm{t}]\) is palatalized more than \([\mathrm{p}](\mathrm{z}=8.55, \mathrm{p}<.00001)\).

Figure 2: Results of acceptability judgments in Experiment 2. Dark parts of bars show the proportion of 'this is the wrong plural form for this singular' responses. Light parts of bars show the proportion of 'this is the right plural form for this singular' responses. Following training on labial palatalization, subjects accept palatalized labials \((\mathrm{p} \rightarrow \mathrm{t} f \mathrm{a})\), alveolars \((\mathrm{t} \rightarrow \mathrm{t} f \mathrm{a})\) and velars \((\mathrm{k} \rightarrow \mathrm{t} \mathrm{fa})\) at roughly equal rates whereas following training on alveolar or velar palatalization, the trained alternation is accepted more often than untrained ones. However, after all kinds of training subjects learn to reject unchanged/non-palatalized stops before the palatalizing vowel [a], and they do it at equal rates.

\section*{Results}

As shown in Figure 1, participants exposed to labial palatalization do not learn the pattern as well as participants exposed to velar or alveolar palatalization do, often learning to palatalize everything or to palatalize nothing. The differences in palatalization rates between the to-bepalatalized consonant and the not-to-be-palatalized consonants is significantly smaller in the group trained on \(\mathrm{p} \rightarrow \mathrm{t} \mathrm{f}\) than in the group trained on \(\mathrm{k} \rightarrow \mathrm{t} \int(\mathrm{z}=8.98, \mathrm{p}<.00001)\) or \(\mathrm{t} \rightarrow \mathrm{t}\) ( \(\mathrm{z}=3.34, \mathrm{p}=.0008)\); the latter two groups do not significantly differ ( \(\mathrm{z}=0.09, \mathrm{p}=.93\) ).

Figure 2 suggests that the same pattern holds for acceptability judgment data: subjects trained on \(\mathrm{p} \rightarrow \mathrm{t} \int \mathrm{a}\) judge \(\mathrm{p} \rightarrow \mathrm{t}\) fa examples ungrammatical almost as often as examples of \(t \rightarrow t \int a\) and \(k \rightarrow t \int a\) (for this group, there is no significant effect of singular-final consonant on acceptability of palatalization, \(\mathrm{z}=0.76, \mathrm{p}=.45\) ). By contrast, subjects trained on \(\mathrm{t} \rightarrow \mathrm{t}\) fa or \(\mathrm{k} \rightarrow \mathrm{t}\) a judge the alternations they were trained on as being grammatical more often than alternations they were not trained on ( \(\mathrm{z}=2.84, \mathrm{p}=.004\) ).

In addition, Figure 2 shows that the bias against labial palatalization (i.e., changing [p] into [tfa] rather than [pa]) is not due to a bias in favor of [pa]: subjects learn that [a] should not be preceded by [ p ] as easily as they learn that it should not be preceded by [k] ot [t]: while \(\mathrm{p} \rightarrow \mathrm{t} \mathrm{f}\) is worse than \(\mathrm{k} \rightarrow \mathrm{t} \oint\) and \(\mathrm{t} \rightarrow \mathrm{t}\), [pa] is as bad as [ka] and [ta] ( \(\mathrm{z}=.83\), \(\mathrm{p}=39\) ). Thus the observed bias against \(\mathrm{p} \rightarrow \mathrm{t} \int\) is not a bias in favor of [pa] or against [ka] and [ta]. \({ }^{4}\)

Finally, stem changes are accepted in acceptability judgment much more than they are produced: the dark bars in Figure 2 are lower than in the top panels of Figure 1 ( \(\mathrm{z}=3.07, \mathrm{p}=.002\) ), indicating that palatalization is usually rated as acceptable, and in fact more acceptable than nonpalatalization, yet is rarely produced. Furthermore, the bias against labial palatalization appears to be stronger in production than in judging acceptability: to-be-palatalized and not-to-be-palatalized consonants differ in acceptability of palatalization across subject groups numerically but not significantly ( \(\mathrm{z}=1.11, \mathrm{p}=.27\) ), but, as described above, these between-group differences are significant in production. The three-way interaction between test modality, whether or not a consonant is to be palatalized, and subject group is also significant ( \(\mathrm{z}=2.37, \mathrm{p}=.018\) ). These data provide direct

\footnotetext{
\({ }^{4}\) Some may wonder whether participants actually learn to palatalize before [a] rather than learning to palatalize before [i] or after [i]. There was no effect of stem vowel on acceptability ( \(\mathrm{z}=1.01, \mathrm{p}=.31\) ) of palatalization, whereas in production stem [i] disfavored palatalization \((\mathrm{z}=3.55, \mathrm{p}=.0003)\) rather than favoring it. The effect of final vowel on palatalization production probability ( \(\mathrm{z}=4.99, \mathrm{p}<.00001\) ) and acceptability \((\mathrm{z}=2.14, \mathrm{p}=.03)\) was in the direction predicted by training, rather than phonetic naturalness, i.e., palatalization occurred/was rated more acceptable than nonpalatalization before [a] more often than before [i]. Thus, the vowel triggering palatalization in the grammars learned by our subjects does appear to be a following [a], making the context for palatalization phonetically unnatural.
}
evidence for a production basis for faithfulness and the observed bias against \(\mathrm{p} \rightarrow \mathrm{t} \mathrm{f}\).

\section*{Discussion and Conclusion}

In this experiment, we have demonstrated that there is a bias against labial palatalization in a context where all kinds of palatalization are phonetically unmotivated. Thus we suggest that the bias is not in favor of phoneticallymotivated rules, or changes in context. We have also shown that the bias is not due to differentially ranked phonotactic constraints on the output forms: the result of alternation is always the same [ t f a ], regardless of the consonant that is changed, and learners acquire a dispreference against [pa], [ta], and [ka], the outputs competing with [ \(\mathrm{t} f \mathrm{a}\) ] equally well. We are therefore left with two options, both of which can be modeled using Faithfulness constraints in Harmonic Grammar (Smolensky \& Legendre, 2006): the learners might be biased against mapping [p] onto [ t\(]\) ] (Steriade, 2001), or against deleting the labial closure gesture associated with [p] (Kapatsinski, 2013; Kenstowicz 1996).

Theories of Faithfulness / avoidance of stem changes differ on whether Faithfulness is grounded in perception (avoiding changes that the listener would easily perceive and would face difficulty undoing to recover the base form of the stem, Steriade, 2001), articulation (perseverating on gestures of the known form while deriving an unknown form, Kapatsinski, 2013), or an offline preference for uniform morphological paradigms (e.g., storage economy or one-to-one form-meaning mappings, Kenstowicz's [1996] uniform exponence; McCarthy's [2005] optimal paradigms). The present data support the gestural account, as it alone seems to account for the differences between production and acceptability judgment. Namely, the biases against stem changes are stronger in production (see also Kapatsinski, 2012; Zuraw, 2000). The gestural account is also the only one that can account for the data described in the introduction, and it alone seems to be an inevitable component of the production process when a novel form is derived from a known one.

The bias we observe may or may not be specific to English speakers. While labials are unlikely to change across languages (e.g., Kochetov, 2011), English does have palatalization of alveolars, as in create/creature or, variably, in would/would you. The fact that we also observe a preference for velar palatalization over labial palatalization suggests that the preference against labial palatalization is not solely a first-language effect. Nonetheless, first language experience undoubtedly changes the weights of faithfulness constraints, hence cross-linguistic and developmental work on this issue would be most informative. Of particular interest here are languages that have labial palatalization, e.g., Southern Bantu (Ohala, 1978).

All we wish to claim at this point is that there are faithfulness constraints militating against stem changes, regardless of context, that they are production-based, and that they vary in weight, making some of these constraints stronger than others at the beginning of our experiment.

\title{
Parsing Sequentially Presented Commands in a Large-Scale Biologically Realistic Brain Model
}

\begin{abstract}
We present a neural mechanism for interpreting and executing visually presented commands. These are simple verb-noun commands (such as WRITE THREE) and can also include conditionals ([if] SEE SEVEN, [then] WRITE THREE). We apply this to a simplified version of our large-scale functional brain model "Spaun", where input is a \(28 \times 28\) pixel visual stimulus, with a different pattern for each word. Output controls a simulated arm, giving hand-written answers. Cortical areas for categorizing, storing, and interpreting information are controlled by the basal ganglia (action selection) and thalamus (routing). The final model has \(\sim 100,000\) LIF spiking neurons. We show that the model is extremely robust to neural damage ( \(40 \%\) of neurons can be destroyed before performance drops significantly). Performance also drops for visual display times less than 250 ms . Importantly, the system also scales to large vocabularies ( \(\sim 100,000\) nouns and verbs) without requiring an exponentially large number of neurons.
\end{abstract}

Keywords: neural engineering; parsing; cognitive control; spiking neurons; whole-brain systems; cognitive architecture

\section*{Large-Scale Functional Brain Modelling}

Our goal is to produce models of human cognition that are specified down to the neural level. That is, we want to know how the low-level neural details (including spikes and various neurotransmitters) give rise to human behaviour via their complex interconnections and interactions. We have previously published our first step in this direction, which is currently the world's largest functional brain model (Eliasmith et al., 2012). This model, "Spaun", has 2.5million spiking neurons, includes twenty different brain areas, and can perform eight different cognitive tasks (including digit recognition, list memory, addition, and pattern completion). Input is through a single eye with a 28 by 28 retina, and the output controls a simulated three-joint six-muscle arm, allowing it to write its answers. Spaun is told what task to perform via its visual input, so it must selectively re-route information between brain areas as appropriate for different tasks. This uses the cortex-basal ganglia-thalamus loop, where the basal ganglia performs action selection by comparing the current brain state to the ideal brain state for each action, and the chosen action activates cortical communication channels via the thalamus.

One limitation with Spaun is that it cannot learn new tasks. The eight tasks it can perform are set by the synaptic connections between cortex and basal ganglia. To address this, the work presented here adds a new general-purpose task for Spaun: one where it can be visually presented with commands for it to follow.

\section*{Parsing Visual Commands}

To provide new instructions to a model that only has a visual input, we need the model to process a sequential set of images and convert that into an internal representation of a command. This is a simplified language comprehension task, within a fairly restricted domain.

Basic commands can be thought of as verb-noun pairs, such as WRITE NINE. However, because the visual system is limited to \(28 \times 28\) pixels, it does not have the visual acuity to interpret full words at a time. Rather than flashing each letter in each word up individually (a fairly non-typical reading strategy), we use a single symbol for each word, and present those symbols sequentially. So, for the command WRITE NINE, we present a "W" followed by a " 9 ".

Valid commands are limited by the set of basic actions that the model knows how to do. While the full Spaun model can perform many operations including mental arithmetic, keeping track of elements in a list, and pattern completion, for simplicity in this paper we only consider the actions WRITE (W), REMEMBER (R), and INCREASE (C). For example, the model could be told to remember a two, increase it, and write the result ("R 2, C \#, W \#", where \# is a general-purpose indexical referring to the number currently being remembered, and a comma is a slight pause between instructions). The correct result from this command would be the written number 3 .

Furthermore, instructions can also include conditional clauses based on what the model can currently SEE ("S"). For example, "S 4, W 9" is interpreted as "if you see a four, then write a nine". To do this, the model must be capable of representing structured relationships.

The goal of this work is to give a spiking neuron implementation of this parsing process, integrated within an existing spiking neuron model of the rest of the brain (including vision, motor, working memory, and cognitive control areas). To argue that this is a plausible model, we show that a) its performance degrades gracefully as neurons die, b) it fails on uninterpretable grammatical structures, and c) it scales to human-sized vocabularies, dealing with the exponential growth of vocabulary combinations.

That said, there are considerable limitations to this work. It does not deal with token separation, since the symbols are shown to it one at a time. It also does not handle ambiguous terms (all symbols have exactly one meaning). We are also not specifying the full developmental and learning process that results in this model (although existing learning rules could be used, given a detailed error signal and large amounts of time).

\section*{The Neural Engineering Framework}

The Neural Engineering Framework (NEF; Eliasmith \& Anderson, 2003) transforms a high-level description of the variables being represented and the operations on those variables into a detailed spiking-neuron model subject to neurobiological constraints.

In the NEF, neurons are organized into groups, and each group forms a distributed representation of a particular variable. Different patterns of activity across the group correspond to different values for that variable. These values are, in general, vectors, so a particular group of 2,000 neurons might represent a 64-dimensional variable. While the NEF supports any neuron type, for this paper we use standard leaky integrate-and-fire (LIF) neurons whose parameters (refractory period, capacitance, neurotransmitter time constant, etc.) are set to be consistent with the details of the particular brain regions being modelled.

Within a population of neurons, each neuron has a particular preferred direction vector. This is the vector for which that neuron will fire most strongly. These vectors \(\boldsymbol{e}\) are randomly chosen along with the neuron gain \(\alpha\) and bias \(J_{b i a s}\) to produce a heterogeneous population of neurons. The current flowing into a neuron when representing a vector \(\boldsymbol{x}\) is given by Equation 1.

Given a pattern of activity, we can estimate the currently represented \(\boldsymbol{x}\) value as \(\sum d_{i} a_{i}\) where \(a_{i}\) is the neuron activity and \(\boldsymbol{d}\) is a decoder given by Equation 2. This is the optimal least-squares linear estimate of \(\boldsymbol{x}\) (the value being represented) given \(a\) (the current activity of the neurons).

The key part of the NEF is that this decoder also allows us to determine the synaptic connection weights between neural groups that will force them to compute a desired function. For example, if we want to connect a neural group representing \(\boldsymbol{x}\) to a neural group representing \(\boldsymbol{y}\) such that \(\boldsymbol{y}=\boldsymbol{M} \boldsymbol{x}\) (where \(\boldsymbol{M}\) is an arbitrary matrix), then the synaptic connection weights between neuron \(i\) in the first population and neuron \(j\) in the second are given by Equation 3.

For connections that compute nonlinear functions, we adjust Equation 2 slightly as given in Equation 4. This finds a decoder that approximates the arbitrary function \(f(x)\).
\[
\begin{align*}
& J=\alpha e \cdot x+J_{\text {bias }}  \tag{1}\\
& d=\Gamma^{-1} Y \quad \Gamma_{i j}=\int a_{i} a_{j} d x \quad Y_{j}=\int a_{j} x d x  \tag{2}\\
& \omega_{i j}=\alpha_{j} e_{j} M d_{i}  \tag{3}\\
& d^{f(x)}=\Gamma^{-1} Y \quad \Gamma_{i j}=\int a_{i} a_{j} d x \quad Y_{j}=\int a_{j} f(x) d x \tag{4}
\end{align*}
\]

It should be noted that the accuracy with which neurons will perform the desired computation using this technique is dependent on many factors. This includes the neuron properties such as overall firing rate and their membrane time constant. Accuracy can be increased arbitrarily by increasing the number of neurons (but, of course, to be realistic we are constrained by the number of neurons in the
brain). In general, discontinuous functions are very difficult for neurons to approximate.

\section*{Symbol-Like Processing with Spiking Neurons}

While the NEF allows us to convert algorithms that use vectors and functions into spiking neuron models, a further technique is needed to handle the symbol manipulation that is the hallmark of cognitive activity. This is especially important for parsing and representing complex commands.

The core idea is to have a particular vector for each atomic symbol that can be represented. For this paper, these vectors are chosen randomly, but they can also be chosen such that semantically related symbols have similar vectors. To combine symbols, we perform computations on these vectors, giving new vectors that represent the combination.

There are a variety of computations that can be used to combine these vectors (Gayler, 2003), but for our model we follow Plate (2003). Here, symbols can be combined by vector addition (+) and circular convolution ( \(\circledast\) ). Both operations are accurately approximated by the NEF method.

To demonstrate how this system works, consider representing the command "If you see a 9, write an 8". A simplistic approach would be to take vectors for all the atomic concepts (SEE, NINE, WRITE, and EIGHT) and add them together to represent the full sentence (SEE+NINE+WRITE+EIGHT). However, this does not work, since the resulting sentence loses all order information. In particular, the command "If you see an 8 , write a 9 " would result in exactly the same vector.

To deal with this, we use circular convolution ( \(\circledast\) ) and introduce new vectors for denoting structural information. The \(\circledast\) operator takes two vectors and produces a new vector that is highly dissimilar to the original two. So instead of WRITE+EIGHT we can do VERB \(\circledast\) WRITE+ NOUN \(\circledast\) EIGHT. Furthermore, we can nest this process to make more complex phrases. The full command can be represented by the vector \(\mathbf{S}=\mathbf{C O N D I T I O N} \circledast(\mathbf{S E E} \circledast\) NINE)+ VERB \(\circledast\) WRITE+NOUN \(\circledast E I G H T\).
Importantly, given this vector \(\mathbf{S}\) that represents a full command, we can extract out the individual components. Plate (2003) showed that a simple re-arranging of the elements of a vector makes an approximate inverse operation. For example, if we want to know the main verb in \(\mathbf{S}\), we compute \(\mathbf{S} \circledast \boldsymbol{i n v ( V E R B )}\). The result will be approximately WRITE. The accuracy of this approximation depends on the number of terms being added and the dimensionality of the vectors. In particular, as the number of dimensions increases, there is an exponential growth in representational capacity.

We refer to these vectors as semantic pointers. They are semantic in that the vector itself has meaning about the whole. Most usefully, the similarity between vectors indicates the similarity of the full structure. WRITE commands will have a higher degree of similarity to each other than to other commands. Furthermore, they are pointers in the computer science sense because they can be dereferenced, recovering (an approximation of) the original
data. Semantic pointers are compressed representations, in the same way that vision models can be thought of as compressing an image into a high-level representation.

\section*{Vision}

For vision, we adapt a Deep Belief Network (Hinton, 2010). The input is a 28 by 28 pixel retinal image, which is then processed by four different cortical layers. Each layer learns to extract and compress the regular patterns in the layer before it. We convert this model to spiking neurons by simulating each neuron in the DBN with ten realistic spiking neurons and using Equations 3 and 4 to solve for the connection weights that approximate the original model.

The output from the DBN (inferior temporal cortex) must then be mapped to a semantic pointer. One way to perform this mapping would be to use an associative cleanup memory (Stewart, Tang, \& Eliasmith, 2011), which scales to hundreds of thousands of items but requires additional neurons to recognize each item. For simplicity, here we use no additional neurons, but rather compute an approximate mapping between the compressed representation of the visual stimulus and the desired semantic pointers (Equation 5), where \(v_{i}\) is the average output of the Deep Belief Network for a particular category (all the 3's, for example), and \(s_{i}\) is the corresponding semantic pointer (THREE). As always, Equations 3 and 4 give the synaptic connections.

Figure 1: Converting visual input into the correct semantic pointer. For example, showing an image of a 7 to the retina will produce the vector SEVEN in the vision population.

\section*{Simple Parsing}

A first step towards parsing commands is to identify and store noun-verb pairs. That is, given a visual input of WRITE followed by THREE, we need one group of neurons to represent the verb (WRITE) and another to represent the noun (THREE). The outputs from these groups then drive a third group of neurons to represent the full phrase VERB \(\circledast\) WRITE+NOUN \(\circledast\) THREE. This is accomplished by connecting the verb population to the phrase population with connection weights optimized to perform the function
\(f(x)=x \circledast\) VERB. Similarly, the noun population's connection is optimized for the function \(f(x)=\boldsymbol{x} \circledast\) NOUN. As with all synaptic connections in this model, this optimization is performed using Equations 3 and 4.

Figure 2: 5760 spiking neurons combining two arbitrary 64dimensional vectors (noun and verb) into a single 64dimensional vector phrase \(=\) verb \(\circledast\) VERB + noun \(\circledast\) NOUN.

In order for this system to work in the context of an overall brain model, we need a mechanism to selectively route information from visual areas to the two populations. When the system sees WRITE it should pass this vector into the verb neurons, and when it sees THREE it should pass that vector to the noun neurons. This sort of selective routing of information is exactly what the cortex-basal ganglia-thalamus loop is believed to perform. We use our existing model for this loop, which is based on our spiking version of a model of action selection in the basal ganglia (Stewart, Choo, \& Eliasmith, 2010).

The basal ganglia selects between two actions. One action is to route information from the vision system to the noun population, and the other is to route that same information to the verb population. To perform these actions the output from the basal ganglia goes to the thalamus, where it releases the inhibition on the desired communication channel. (A communication channel is a connection that computes the function \(f(x)=\boldsymbol{x})\). If this is inhibited, the neurons do not fire, and so no information is passed. Selecting the action releases the inhibition, allowing the information to flow.
